Therapeutic hypothermia is currently part of the standard treatment for neonatal infants with moderate to severe NE aiming for cooling to commence within 6 hours of hypoxic-ischemic insult to a temperature of 32°C to 34°C for 48 to 72 hours, followed by a gradual rewarming over 12 hours.[201] A number of studies have found improved neurodevelopmental scores in NE infants treated with hypothermia with proposed protective mechanisms of hypothermia including reduced cerebral metabolism, suppression of caspase-3 enzyme and microglial activation, prevention of activation of NMDA receptors, reduction of proinflammatory cytokines, and preservation of lipoprotein membranes.[201,203,229,257,258] Published reports of therapeutic hypothermia in neonatal foals with NE are not available. Other medications reported to be used in infants with NE or animal models, alone or in conjunction with hypothermia therapy, include melatonin (antiinflammatory, antiapoptotic, antioxidant properties); erythropoietin (antiinflammatory, antiapoptotic factors, angiogenesis, neurogenesis properties); N-acetylcysteine (clears free radicals, restores glutathione levels, antiinflammatory, reduces NO production); topiramate (glutamate receptor [AMPA and kainite] inhibition, blocks Na^+ channels and activates Ca^+ currents); desferrioxamine (reduction of free radical production by chelating iron); xenon (NMDA receptor antagonist, antiapoptotic factors); edaravone (free radical scavenger); and stem cells and IL-1 receptor antagonists.[201,203,208,209,229] These therapies and medications require further research in infants and have not been currently used for the treatment of NE in neonatal foals.

Prognosis and Pathologic Findings

In general, foals with a primary diagnosis of NE without complicating factors have a good prognosis for both survival and athletic function with reported survival rates ranging from 70% to 80%.[150,197,225–228,230] The prognosis is poorer in foals that demonstrate clinical signs at the time of birth, have evidence of brainstem or spinal cord involvement, have multiple organs affected by hypoxic-ischemic injury, have complicating factors (e.g., sepsis), remain comatose or are difficult to arouse, show no improvement in neurologic function in the first 5 days, or have severe recurrent seizures.[6,225,227] Recumbency was significantly associated with nonsurvival in one retrospective study,[230] and in a different retrospective study of 78 foals with NE, neurologic signs lasted 1 day in 29 foals (29/59 foals that survived; 49%), 2 days in 17 foals (17/59; 29%), 3 days in 8 foals (13.5%), 4 days in 4 foals (6.8%), and 5 days in 1 foal (1/59; 1.7%); 19/78 foals (24%) did not survive.[197] Rare long-term neurologic deficits include inability to suckle from the mare, prolonged visual impairment, residual spasticity, recurrent seizures, and docility as adults.[197,227]

Four major categories of neuropathology are noted in infants with NE: selective neuronal necrosis, parasagittal cerebral injury, periventricular leukomalacia, and focal ischemic brain necrosis.[229] Histopathologic findings reported in foals with NE are likely skewed toward more severe cases of NE as the majority of foals survive and accordingly do not undergo microscopic evaluation of the CNS. In one retrospective study involving 11 available microscopic descriptions of foals with NE, 10 of 11 foals had histologic evidence of neuronal necrosis and degeneration within the CNS consistent with ischemia.[230] In another study involving 18 foals with NE, necrosis of the cerebral cortex and local hemorrhage was noted in 9/18 foals,[259] whereas neuronal necrosis of the gray matter of the cerebral cortex, caudate nuclei, thalamus, hippocampus, cerebellar cortex,

and medulla oblongata was reported in 3 foals with NE in another report.[246]

Other Neurologic Conditions

Guy D. Lester

Bacterial meningitis should be suspected in a foal with neurologic disease and recent or current signs of generalized or localized sepsis. Agents causing meningitis are the same that cause systemic sepsis, most commonly bacteria such as *Escherichia coli*, *Enterobacter* spp., *Salmonella* spp., and Streptococcal spp.[66,100,194,260] Signs can include hyperesthesia, neck rigidity, varying degrees of obtundation, seizure activity, opisthotonus, limb ataxia and paresis, or specific cranial nerve abnormalities.[25] The definitive diagnosis is dependent on CSF analysis, which reveals a pronounced neutrophilic pleocytosis. Hematology and serum biochemistry reflect sepsis, and the serum IgG concentration often reflects failure of passive transfer.

Antibiotic treatment should be guided by culture and sensitivity data. Successful treatment has been reported using courses of broad-spectrum third-generation cephalosporins.[100] These include cefotaxime or ceftriaxone because of their excellent penetration into the central nervous system. Alternatives include ceftiofur, trimethoprim-sulfa combinations, chloramphenicol, or a combination of aminoglycoside with a β-lactam antibiotic. On the basis of data from human infants, one author has recommended the use of dexamethasone sodium phosphate (0.4 mg/kg IV q12h for 2 days).[25] In many cases, once the diagnosis is made, the infectious process is well advanced both in the brain and other tissues, resulting in a poor outcome. The prognosis is fair in foals where signs are limited to hyperesthesia and neck stiffness.[25]

Neonatal morbidity and mortality can be attributed to equine herpesvirus 1 (EHV-1), EHV-4, equine viral arteritis (EVA), and equine influenza (EI) viruses. The respiratory system is most commonly involved. Viral encephalitis is often quoted as an important differential for seizures in neonatal foals, but this appears to be a rare clinical entity in this age group.

Head trauma occurs commonly in neonates. Foals can receive direct blows to the head after kicks from the dam or other horses, as well as from head-on collisions with stationary objects. There is often external evidence of the trauma, such as hair loss, soft tissue swelling, asymmetry of the facial contour, fracture crepitus, or blood from the nares or ear canal. A range of neurologic signs may ensue that include varying degrees of obtundation; disorientation; head pressing; compulsive walking, often in circles; and seizure. Trauma to the poll can result in vestibular and facial nerve dysfunction, ataxia, and paresis, as well as changes in mentation. The diagnosis is based on history and physical and neurologic findings but is supported by imaging. The management of CNS trauma is discussed elsewhere in this text (Chapter 35).

Benign juvenile epilepsy is a well-described neurologic entity of Arabian foals of Egyptian origin.[261] The age of onset of generalized seizures varies between 2 days and 6 months of age, and the reported duration of seizures is between several seconds and 5 minutes, with most lasting less than 60 seconds. Common postictal findings include obtundation and transient blindness. Physical and neurologic examination during the interictal period is normal, but there may be electroencephalographic changes.[261] As the name suggests, the condition does not persist into adulthood, with cessation seizures by 12 months of age in all foals. As described earlier, active seizures can be treated with diazepam or midazolam and prevented using oral phenobarbital (5 to 10 mg/kg PO as loading dose, followed by 2 to 5 mg/kg PO bid) or potassium bromide (100 mg/kg PO as loading dose, followed by 25 mg/kg PO q24h). Investigation of a small number of Egyptian Arabian foals with juvenile idiopathic epilepsy did not identify a link to the lavender foal syndrome (LFS) genetic mutation (see later).[262]

The role of glucose and electrolytes in seizure disorders should not be discounted. Hypoglycemia, hypocalcemia, hyponatremia, or hypernatremia can all produce signs of spontaneous, involuntary muscle activity with varying degrees of consciousness. Hypoglycemia is the most common metabolic derangement in newborn foals. The response of the nervous system to low glucose is categorized as neurogenic or neuroglycopenic.[263] Neurogenic signs are related to sympathetic discharge and include tremor, tachypnea, and irritability, whereas neuroglycopenic signs relate to impaired brain energy metabolism and include reduced level of consciousness, reduced or absent sucking, hypotonia, and seizure.[263] Specific electrolyte disturbances are discussed elsewhere in this text (Chapters 22, 32, and 44).

Hydrocephalus is the most common congenital brain disease in foals. Distention of the cerebral ventricular system produces a loss of normal cerebral structure. It can also occur secondary to inflammatory changes associated with meningitis.[25] Although pronounced doming of the skull is expected, it is relatively uncommon. Furthermore, a domed head is a physical feature of immaturity seen in premature or dysmature foals. Although signs are variable, most foals are slow and somnolent and can have additional cerebral signs of head pressing, aimless and compulsive walking, blindness, and seizure activity. The diagnosis is usually based on persistence of neurologic signs and ruling out other causes of cerebral disease. The diagnosis is confirmed using CT or MRI. Dandy Walker–like syndrome has been reported as a cause of recurrent violent seizures in a newborn foal.[196] The condition involves agenesis of the corpus callosum with cerebellar vermian hypoplasia.

Tetanus is caused by the exotoxins produced by the anaerobe *Clostridium tetani*. Given the incubation period, clinical cases of tetanus are not likely before 7 days of age. Early signs include difficulty in locating and latching onto the teat and dysphagia. Signs then progress to include gait stiffness, elevation of the tail head, an anxious facial expression, prolapse of the third eyelid, tachycardia, and sweating. The foal will eventually become recumbent with recurrent bouts of tonic muscle contractions, which are severe enough to mimic seizure activity. Foals are at risk of disease if the mare has not been adequately protected through vaccination or the foal has untreated failure of passive transfer of immunity. It is recommended that mares receive a booster of tetanus toxoid 28 days before the estimated parturition date. Tetanus is discussed in great detail in Chapter 35.

Ivermectin and moxidectin toxicity have been described in neonatal and older foals after overdosage.[264–266] Reported signs of ivermectin toxicity can include obtundation, blindness, ataxia, head pressing, and seizure and are caused by opening of GABA-gated chloride channels with resultant membrane hyperpolarization and blockade of neuronal impulses. The related antiparasite drug, moxidectin, can also cause profound obtundation and coma when overdosed in juvenile animals.[267,268] Successful management of ivermectin toxicosis has included the use of intravenous lipid emulsions (20% soybean oil in water, 1.5 mL/kg IV bolus followed by 0.25 mL/kg/min for 30 minutes).[264] The benzodiazepine receptor antagonist, sarmazenil (0.04 mg/kg IV q2h), has been effective in managing moxidectin toxicosis.[268]

Kernicterus is a rare but serious neurologic complication of neonatal isoerythrolysis (NI).[269,270] The condition is also known as bilirubin encephalopathy or nuclear jaundice and results from deposition of bilirubin-IX α in the brain, primarily within the basal ganglia, *cornua ammonis* and *substantia nigra*, but also in the cortex, hypothalamus, cerebellum, and medulla.[271] Bilirubin-IX α is lipid soluble and readily crosses the blood-brain barrier. The mucous membranes of affected foals are deeply

VetBooks.ir

icteric, and neurologic signs include altered mentation and seizures. The seizures are difficult to control, often necessitating euthanasia. In a retrospective study of 72 foals with NI, the heart rate at admission and maximum serum bilirubin concentration were significant factors in the development of kernicterus.[270] The authors determined that foals with serum bilirubin concentration greater than or equal to 27.0 mg/dL (≥466.1 µmol/L) were 17 times more likely to develop signs of kernicterus than foals with a peak bilirubin concentration less than 27.0 mg/dL. Tin-mesoporphyrin is an inhibitor of heme oxygenase and is a recommended therapy for severe hyperbilirubinemia in human infants.[272] The intramuscular therapy has been used in foals with NI at risk for kernicterus.[273] The antibiotic minocycline and the hypolipidemic drug clofibrate have had positive effects in certain experimental models and in human neonates with hyperbilirubinemia[271,274] but have not been evaluated for this purpose in foals.

LFS, also referred to as *coat color dilution lethal* (CCDL), is an autosomal recessive gene disorder of Arabian foals of Egyptian bloodlines.[275] The disorder is caused by a frameshift single base mutation in exon 30 of the myosin-Va gene *(MYO5A)*, resulting in premature termination of transcription. Disruption to the myosin-Va protein is thought to affect trafficking of melanosome to the cell periphery in melanocytes and transport of glutamate receptors and secretory granules in neurons.[275–278] Affected foals have a dilute coat color and are unable to achieve sternal recumbency.[278] Severe neurologic signs include frequent episodes of opisthotonus, limb paddling, and rapid eye movements. Spontaneous death or euthanasia typically occurs before 72 hours of age. The carrier frequency of LFS in the United States is 10.3% in Egyptian Arabians and 1.8% in non-Egyptian Arabians.[277] The disease occurs in homozygous foals, although neurologic dysfunction without coat color changes has been suspected in heterozygotes.

Glycogen storage disease IV is an autosomal recessive disease of Quarter Horses and Paint Horse breeds.[279] The defect has been identified as a mutation in the glycogen branching enzyme, encoded by the *GBE1* gene.[280] Clinical signs of foals not stillborn or aborted include profound muscular weakness and hypothermia. Foals may succumb to hypoglycemic seizures or cardiopulmonary failure. All affected foals have reportedly died or been euthanized by 18 weeks of age.[279]

Anemia

Guy D. Lester

Anemia is a common finding in neonatal foals. The normal ranges of hematologic parameters must be considered when determining the significance of any anemia. The packed cell volume (PCV) at birth is 40% to 52% but decreases to 32% to 46% after colostrum and milk intake by 24 hours of age. PCV, red blood cell count (RBC), and the hemoglobin (Hb) concentration are similar to adult values at 24 hours of age, before decreasing over the first 2 weeks of postnatal life to values that are in the lower level of the normal adult ranges. These relatively low levels are sustained for several months.[281] The mean corpuscular volume (MCV) decreases over the first 4 months of life, leading to microcytosis and anisocytosis. The MCV increases after weaning.[281,282] Foals typically have reduced serum ferritin concentrations and increased total iron binding capacity when compared with adults. Serum ferritin increases significantly on day 1 and is attributed to ingestion of colostral iron, before reducing.[283] Data support relative iron deficiency as a cause of common foal anemia, but supplementation with iron does not improve red cell indices.[284] Supplementation of normal foals with a specific iron preparation, ferrous fumarate, resulted in acute hepatic failure and death.[285] There are reports of absolute iron deficiency anemia in foals,[286] including stabled Dutch Warmblood foals fed cut grass.[287] Findings include a low PCV, low serum iron and ferritin concentration, and normal to increased total iron binding capacity. Improvement is seen in those foals with oral iron supplementation.

Clinical signs of anemia are related to the magnitude and timing of the underlying disease process. Rapidly developing hemolytic anemias, such as NI, produce signs of weakness, lethargy and somnolence, mucous membrane pallor and icterus, tachycardia, and possible mild fever. Intravascular hemolysis will typically cause brown-red discoloration of urine. There is accentuation of cardiac murmur. Foals with hemoperitoneum or internal umbilical remnant hemorrhage are often colicky. Hemorrhage at the apex of the bladder can produce stranguria. Bleeding into the respiratory cavity can produce clinical signs of respiratory distress, and blood loss into the gastrointestinal tract will cause melena. Lameness will be seen in foals with spontaneous hemarthrosis.

Causes

Hemolysis is most commonly seen after consumption of colostral antibodies that are directed against foal erythrocytes. The syndrome is known as neonatal isoerythrolysis (NI) and is discussed in detail in Chapter 53. Less common causes of hemolysis include non-NI immune-mediated hemolysis; intracellular RBC parasites; rapid administration of hypotonic or hypertonic solutions, such dimethyl sulfoxide; or equine infectious anemia. Red blood cell hemolysis can be caused by bacterial toxins, most commonly associated with clostridial infections.

Blood loss occurs commonly with separation of the umbilical cord. Hemorrhage most commonly occurs externally but can occur internally into the umbilical remnants, the urinary bladder, or the peritoneal cavity. Most external cord hemorrhage is a small volume and rarely impacts hematologic parameters.[288] Trauma can cause both internal or external blood loss. Rupture of the spleen often leads to uncontrolled internal blood loss, potentially requiring splenectomy.[289] Hemoperitoneum can also occur secondary to rupture of juvenile granulosa cell tumors in foals.[290,291] Rib shaft fractures can cause hemorrhage into the pleural cavity; on rare occasions fatal hemorrhage can occur if a major vessel or myocardium is lacerated.

Blood loss can occur secondary to problems in homeostasis. Affected foals may have spontaneous hemorrhage into joints, muscle or subcutaneous tissues, or the gastrointestinal tract. Disseminated intravascular coagulation (DIC) is an acquired homeostatic problem secondary to severe sepsis. Adult horses with DIC tend to present with signs associated with failure of fibrinolysis, such as widespread thrombosis. In contrast, septic foals often present with spontaneous or trauma-induced hemorrhage. Inherited disorders are discussed elsewhere in this text but include intrinsic platelet disorders, such as Glanzmann thrombasthenia, where the glycoprotein complex IIb-IIIa is reduced or absent on the surface of platelets, and extrinsic disorders including type 2 von Willebrand's disease.[292]

Decreased erythrocyte production is associated with absolute or relative iron deficiency and chronic inflammatory diseases. Anemia of chronic disease (ACD) is a complex disorder that involves altered iron metabolism, bone marrow depression, and reduced production or action of erythropoietin. Increased levels of hepcidin, released in response to inflammation, may be pivotal in the development of anemia by decreasing iron absorption and iron recycling.[293] Classically ACD is reflected by low serum iron, normal or decreased total iron binding capacity, and increased serum ferritin concentration.

A syndrome of bone marrow aplasia or hypoplasia was reported in three foals born to mares that were under therapy for equine protozoal myeloencephalitis. Therapy included

VetBooks.ir

sulfonamides, pyrimethamine, folic acid, and vitamin E.[294] There is a syndrome of anemia and B-cell lymphopenia in Fell pony foals.[295] Affected foals demonstrate initial bone marrow erythroid hyperplasia with concurrent erythroid and myeloid dysplasia, which progresses to severe erythroid hypoplasia by 5 weeks of age.

Determination of the nature of the anemia may allow specific treatment. The treatment of NI is discussed in Chapter 53. Drug-induced or autoimmune anemias may be treated with corticosteroids (0.05 to 0.1 mg/kg dexamethasone twice a day intramuscularly or intravenously). Blood transfusion following crossmatch may be indicated when anemia develops rapidly or PCV drops below 12%. Associated conditions, such as metabolic acidosis and hypoglycemia, should be corrected. Anemia of chronic disease requires correction of the primary disease condition.

Maturity

Guy D. Lester

The terminology associated with birth maturity is difficult in horses due to the variability in normal gestational length. Retrospective studies report wide variability in gestational age but frequently do not report physical characteristics or foal survival. Gestational age ranges of 305 to 365 days, 315 to 387 days, and 286 to 370 days have been described in Thoroughbreds.[296–298] The term *premature* simply refers to the birth of an infant or animal after a gestational period shorter than normal. A premature human infant is defined as one that is delivered at least 21 days before the mean pregnancy duration of 266 days. The use of a gestational age to classify equine prematurity has been described with the most commonly reported definition being a foal born before 320 days of gestation.[299] This is loosely based on significantly lower birth weights and poor outcomes of foals born before 320 days.[300] It could be argued that foals born outside the lower 95% confidence interval of the normal gestational period would best fit the classification of premature; this would be less than 325 days in Thoroughbreds, using data extrapolated from Hintz and coworkers.[296]

Dysmaturity is a term commonly used to describe foals that have experienced some degree of intrauterine growth retardation. These foals typically demonstrate some signs of physical immaturity, such as a low birth weight. Dysmature foals can have shortened, normal, or prolonged gestation lengths. Other terms used to classify foals with incomplete maturation include *viable* and *nonviable*.[300] In a review on terminology, Koterba suggested the terms *viable* and *nonviable* were inappropriate because outcomes of premature foals are heavily influenced by access to facilities and the value of the animal.[300] The concept of *readiness for birth* was used to categorize foal outcomes based primarily on the degree of maturation of the fetal hypothalamus-pituitary-adrenal (HPA) axis. While this plays a critical role in determining postpartum survival, other factors including the degree of physical maturation and the consequences of an adverse intrauterine environment are also relevant in determining the ultimate outcome. Premature maturation of the HPA axis often will take place at an inappropriate developmental stage for some body systems causing asynchrony of organ maturation and postnatal problems.[301] Following on from the concept of *readiness for birth*, Rossdale introduced the term *twilight foals* to describe those foals with accelerated but incomplete maturation of the HPA axis at the time of birth.[299,302]

The physical characteristics associated with prematurity include a low birth weight and small body size, a short and shiny hair coat, a prominent rounded head, periarticular laxity, and droopy ears (Fig. 17.11). Foals will typically have moderate flexor laxity with elevation of the toe, but some will have contracture of the lower limb. Muscle development is usually poor. Most will demonstrate generalized weakness and hypotonia and will have difficulty in standing. Severely premature foals may have lids naturally sutured closed and little hair covering of their body. Many will have difficulty in maintaining body temperature, blood pressure, and blood glucose.

FIG. 17.11 A premature foal demonstrating a low birth weight and small body size, a short and shiny hair coat, and a prominent rounded head.

Dysmature foals commonly experienced some degree of intrauterine growth retardation (IUGR). This is usually reflected by the birth of a foal that is small for its gestational age. The average relative weight of the term foal to its dam is around 10%. Postmature foals usually have an acceptable birth weight with a large frame but poor muscle development. This gives the foal a lanky appearance. In contrast to premature animals, fetlock contracture is common, although laxity can be present. Consistent with their prolonged gestation, post-term or postmature foals will often have erupted incisors and a long hair coat. In term foals the central incisors typically erupt during the first 5 to 7 days of postnatal life.

Causes

The pregnant uterus is highly responsive to contractile agents such as oxytocin and prostaglandins throughout gestation. Consequently, one of the most important causes of premature birth and perinatal morbidity and mortality is the induction of labor with exogenous oxytocin or prostaglandins. The adverse consequences of premature induction of parturition were identified in a study where parturition was induced either before 300 days' gestation or between 300 and 320 days' gestation.[303] The overall survival rate was only 5%, with the youngest surviving animal delivered after 318 days' gestation. Other surviving foals were all delivered after 320 days' gestation. The decision to prematurely terminate a pregnancy may be done deliberately in the "normal" mare or may be forced due to significant maternal disease. The latter frequently involves delivery of a compromised and often premature foal by cesarean section. Chemical induction of parturition has occurred when late-pregnancy intestinal problems are misinterpreted as ineffective labor. Premature birth can occur as a sequel to placental problems, including placental infection, edema, and/or detachment (premature

placental separation). Placental insufficiency due to twinning is another cause of intrauterine growth retardation.

The consumption by pregnant mares of tall fescue pasture infected with the *Neotyphodium coenophialum* leads to range of abnormal signs including prolongation of gestation, perinatal mortality, and agalactia.[304] The large skeletal frame of the postmature foal predisposes mares to dystocia. The delay in parturition may be due to toxin-induced interference with fetal corticotrophin-releasing horses (CRHs) and delay in maturation of the HPA axis. Foals born to mares grazing endophyte-infected fescue pasture have normal thyroxine and reverse T3 but reduced tri-iodothyronine levels compared with control foals.[305] This is also consistent with failure of cortisol-induced maturation of thyroid function. A syndrome of congenital hypothyroidism has been reported in foals in Western Canada.[306] Signs include prolonged gestation, dysmaturity, and a range of musculoskeletal abnormalities, including flexural deformities, delayed ossification, and mandibular prognathism. The specific cause has not been determined, although consumption of diets that contain nitrate or are deficient in iodine is suspected.[307]

Maturation of the Fetal Hypothalamic-Pituitary-Adrenal (HPA) Axis

The maturation of several organ systems coincides with changes in the fetal HPA axis.[301] Fetal cortisol is critical for organ maturation, but if the fetus is exposed too early in gestation or to too large a quantity, intrauterine growth restriction may occur. The fetus is protected from cortisol during much of gestation. The type 2 isoform of the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD) converts excess biologically active cortisol into the inactive cortisone in the placenta, thereby reducing the exposure of the fetus. The postnatal adrenal gland, under influence of ACTH from the pituitary, can readily synthesize cortisol from cholesterol and pregnenolone (P5). Several important enzymes are required for this conversion, including 3β-HSD, P450scc, and P450C17. These enzymes are either inhibited or deficient during most of pregnancy, again protecting the developing fetus from excessive cortisol. Consequently, during the majority of gestation the major products of steroidogenesis are progesterone and the 5α-reduced progestagens and not cortisol.[308] Foals, like other species studied, undergo enhanced adrenal activity prior to birth. This is reflected by high plasma cortisol and ACTH concentrations in term newborn foal plasma in the first hours after birth.[309] There is also a substantial change in the amount and localization within the adrenal gland of 3β-HSD, P450scc, and P450C17 around the time of birth.[310]

The trigger(s) for the process that results in fetal cortisol production, organ maturation, and birth is not known. Data from sheep indicate that upregulation of CRH mRNA in the fetal hypothalamus and proopiomelanocortin in the fetal pituitary is a key initiating event.[301,311] At the same time there is upregulation of ACTH receptors and key steroidogenic enzymes in the fetal adrenal glands. The consequence is a progressive increase in circulating ACTH and cortisol in the fetus. The rise in fetal cortisol has a direct effect on the placenta to increase prostaglandin H synthase 2, leading to secretion of prostaglandins such as PGE_2.[301,311,312] Prostaglandins further stimulate the fetal HPA axis, stimulate placental 11β-HSD-1 (which favors the production of cortisol from cortisone), and also facilitate the conversion of estrogen from pregnenolone. It is not known if these events occur in the pregnant mare but do appear to be consistent across most species studied. An important difference between equids and other species is the timing of these events before parturition. In pregnant ewes maturation of the HPA axis occurs during the final 20 days of a 150-day gestation. In contrast, the production of significant fetal cortisol appears to occur during the final 48 to 72 hours of pregnancy in mares.[313] A number of important maturational events appear to be tightly associated with the prepartum increase in ACTH and cortisol.[308] These include changes in red and white blood cell parameters, most notably a large increase in the neutrophil to lymphocyte ratio.[313,314] Hepatic and renal glucose-6-phosphatase, a key enzyme of gluconeogenesis, also increases sharply around the time of birth coinciding with increases in hepatic and skeletal muscle glycogen stores.[315]

The prepartum rise in plasma cortisol likely induces deiodination of the outer ring of T4 to produce the biologically active tri-iodothyronine (T3).[316] Adequate levels of T3 are required for a number of biological functions including postnatal thermogenesis. Normal term foals have high levels of thyroid hormones, including T3 at the time of birth.[317,318] These levels decline over the initial weeks or months of postnatal life. A relationship between circulating T3 levels and cortisol was reported in premature, dysmature, and mature foals, and the increase in T3 appears to be dependent on maturation of the HPA axis.[302,319] Both cortisol and T3 are critical for lung maturation, particularly the normal postpartum reabsorption of lung liquid.[319]

Accelerated Maturation of the Fetal HPA Axis

Several factors can induce premature maturation of the fetal HPA axis. Hypoxemia is a potent stimulator of the axis in sheep with rises in fetal ACTH and cortisol.[320] The HPA axis can also be manipulated using exogenous glucocorticoids; betamethasone is commonly administered to women in danger of preterm birth in order to hasten HPA maturation and therefore improve the chances of postnatal survival. Poor nutrition before and after conception in sheep produces a shortened gestational period and hastened maturation of the fetal HPA axis.[311] Placental and/or fetal infection also can accelerate maturation of the HPA axis. The cytokines induced by infection increase prostaglandin synthesis and decrease metabolism. Prostaglandins exert a range of actions in addition to promoting cortisol production. These include important actions on the cardiovascular, renal, and respiratory systems.[321] The healthy newborn foal has higher concentrations of 15-ketodihydro-$PGF_{2\alpha}$ (PGM) in the days after birth than values in adult animals.

The stimuli associated with precocious HPA axis maturation in foals are not well described. The exception is infection of fetal membranes where foals are often delivered preterm with laboratory findings consistent with axis maturation. Spatial and nutritional deprivation resulting from a Thoroughbred foal placed in a pony uterus using embryo transfer also leads to premature maturation of the fetal adrenal.[308,322,323] Many late-term maternal diseases do not appear to have a significant effect on foal maturity. Hypoxemia associated with anesthesia and colic surgery in pregnant mares during the final 60 days of pregnancy results in a high rate of preterm delivery of compromised foals that did not survive.[324] It is likely that the insult in these cases was so severe that the interval between surgery and delivery was inadequate for maturation of the axis to occur. Another important consideration in determining outcomes would be the effect of hypoxia and/or ischemia on other fetal organ systems.

Treatment of the at-Risk Late Pregnant Mare

The administration of corticosteroids to the pregnant mare appears to have little effect on maturation of the fetal HPA axis, at least when doses considered safe are used. Direct injection of $ACTH_{1-24}$ to the fetus results in increased fetal

VetBooks.ir

cortisol, but the effect is dependent on gestational age with maximal responses occurring at around day 313 with no measurable benefit when administered before day 295.[313] Direct administration of CRH, ACTH, or betamethasone to the fetus using US-guided IM injection results in increased maternal progestagen levels consistent with maturation of the fetal adrenal gland.[325,326] The procedure itself can lead to abortion in a small number of mares. Exogenous $ACTH_{1-24}$ administered to late-pregnant pony mares had an impact on both gestational length and fetal maturation.[327] Depot $ACTH_{1-24}$ given to mares at 300, 301, and 302 days of gestation produced a shortened gestational length and lower birth weight but evidence of HPA axis maturation. A confounding effect in this study was the time of conception, with the most significant findings observed in mares bred later in the breeding season.

It is preferable to maintain the fetus in utero to ensure not only adequate HPA axis maturation but also effective ossification and maturation of other body systems. Consequently, the primary focus of therapy for a mare with placental infection is to eliminate the pathogenic organisms, reduce inflammation, and maintain the pregnancy. The specific management of placentitis is not the focus of this chapter, but treatment may involve broad-spectrum antibiotics, nonsteroidal antiinflammatory drugs, pentoxifylline, β_2-adrenoreceptor agonists, and altrenogest. The efficacy of altrenogest use in mares with placentitis has been questioned.[328]

The termination of post-term pregnancies is a difficult decision for practitioners, particularly with the angst that is common in many owners. Given the wide variation in gestational range, it is almost always in the best interests of the foal to let the pregnancy continue. If facilities are available, then rectal and transabdominal US assessment of the fetus and chorioallantois should be made, looking carefully for thickening or detachment of the fetal membranes. Ideally, any induction of parturition should be based on appropriate changes in physical characteristics of the mare and in milk electrolytes. Mares grazing endophyte-infected tall fescue can be medicated with dopamine receptor antagonists, such as domperidone.[304]

Laboratory Assessment

The laboratory data will indirectly reflect the degree of HPA axis maturation. Premature or dysmature foals that fail to survive often have minimal cortisol secretion in the face of adequate endogenous ACTH. Furthermore, the change in plasma cortisol in response to exogenous ACTH (Cosyntropin, 0.125 mg IM) is inconsistent and usually inadequate. The foal with incomplete adrenal maturation will have a low total white cell and neutrophil counts, as well as a neutrophil-to-lymphocyte ratio that is characteristically less than 1 : 1.[314] It is important to determine if sepsis is present, as neutropenia is also a common feature of this condition. Evidence of shifting toward immature cell types and neutrophil toxicity should indicate primary sepsis or prematurity/dysmaturity complicated by sepsis. Premature foals that fail to improve their total white blood cell and neutrophil counts over the initial 24 to 48 hours of treatment have an even poorer prognosis for survival. Changes in red cell indices have also been reported in nonstressed preterm foals.[314] Most notably is an elevated MCV in preterm foals. An elevated plasma fibrinogen concentration is considered to be a good prognostic factor in premature foals as it often reflects prepartum exposure to bacterial infection. Induced or spontaneously delivered term foals have a significantly higher plasma glucose concentration than premature foals.[329] Plasma creatinine levels are often elevated in newly born preterm or dysmature foals due to placental dysfunction. This increase is independent of foal renal function. Measurement of low cortisol levels coupled with increased progestagens would provide further evidence that effective maturation of HPA axis has not occurred in the foal before birth.[216] Thyroxine (T4) is lower in premature foals than in normal foals and term, but sick, hospitalized foals.[317] This is consistent with failure of cortisol-induced maturation of thyroid function (see earlier). Premature foals respond to thyrotropin-releasing hormone (TRH; 0.5 mg IV), but the increase in T4 is less than that observed in both healthy and sick term foals.[317]

Establishing a Prognosis

The prognosis for survival of a prematurely delivered foal is dependent on a range of factors including the gestational age, reasons for delivery, complications associated with delivery, available resources (facilities and expertise), and financial limitations of the owner. Survival of very premature foals (280 to 300 days) would typically require a history of chronic in utero stress with resultant precocious maturation of the HPA axis and critical organ systems. The majority of these foals would still require a lengthy and costly period of hospitalization and experience a range of complications, some of which may be life threatening. Foals delivered prematurely as a consequence to chemical induction of parturition without evidence of chronic in utero stress or through cesarean section typically have a high mortality rate even when delivered close to calculated due dates. Foals delivered under these circumstances before 300 days will almost certainly die irrespective of available resources.

A complete blood count and fibrinogen estimation are key factors in determining short-term prognosis. A normal or elevated neutrophil count, neutrophil-to-lymphocyte ratio (N:L), or total white blood cell count are positive indicators of survival, as they typically reflect maturation of the HPA axis. In a survey of 135 neonates admitted to the University of Florida with a gestational age of fewer than or equal to 320 days' short-term survival was in part predicted by total white blood cell count, neutrophil count, lymphocyte count, and the N:L ratio at presentation.[330] The N:L ratio of surviving premature foals (12.5 : 1) was well above that reported for both normal term foals (2.5 : 1) and that of nonsurviving premature foals. Many of the surviving animals were exposed to confirmed or suspected placental infection. In utero stress, with hastened maturation of the HPA axis, is a good prognostic factor for survival in foals that are delivered preterm. In many foals, the greater the neutrophil count, the better the outlook, at least in terms of short-term survival. A high plasma fibrinogen concentration is also considered to be a positive factor. Reevaluation of the white cell indices on day 2 for appropriate increases also support a favorable prognosis.

A history of placental infection appears to be a positive factor when predicting survival in preterm foals. One obvious downside is that many of these foals are born with aspiration pneumonia (due to in utero aspiration of contaminated amniotic fluid) and/or systemic sepsis. This, coupled with the fact that many foals have an impaired immune system, warrants the use of broad-spectrum antimicrobial therapy.

Consideration should also be given to the long-term outcomes of preterm foals. These animals are at risk of significant and permanent musculoskeletal problems due to bone and ligamentous immaturity. Foals that survive the neonatal period are smaller than their peers, and this difference will often remain noticeable as weanlings and as yearlings. The differences may be less obvious at 2 years and older. Other common complications, such as pneumonia, will further reduce the growth rate in the first 6 months of life. There is nothing to indicate that premature fillies will experience fertility problems as adults.

Clinical Progression

The clinical progression will usually reflect the degree of endocrinologic maturity, additional perinatal stresses, and the extent of physical maturity. Typically foals born prematurely,

but chronically exposed to an appropriate chronic in utero stress, such as placental infection, will appear weak and depressed in the immediate postpartum period. Some will require resuscitation. After a longer than normal period of postural adaptation, they will usually manage to stand but will often require assistance. Suckle reflex and appetite may be reduced or absent, and many will need to be fed initially via nasogastric tube. They will frequently have trouble maintaining their body temperature and blood glucose levels. After the initial 24-hour period, many of these foals demonstrate improvement both in physical strength and mentation. Their appetite for milk will often exceed that of a healthy term foal. Foals with inadequate maturation of the HPA axis will frequently require immediate resuscitation. They may mimic the clinical progression of in utero stressed premature foals up until 12 to 18 hours of age. This initial period after delivery can be deceptive, with many foals showing degrees of improvement, which often promote owner optimism. The rise of hormones accompanying delivery may lead to improvement in alertness and strength. However, after this period a range of progressive abnormalities develop. These include systemic weakness, depression, seizures, respiratory failure, and intolerance to feeding. Cardiovascular collapse may ensue, the first sign of which is a reduction in the intensity of peripheral pulses, followed by a reduction in urine flow, development of subcutaneous edema, and deteriorating neurologic function. Poor tissue perfusion leads to lactate accumulation and a mixed metabolic and respiratory acidosis. Death will certainly occur without aggressive support, and even with high-level intensive care, mortality rates are high.

Treatment of the Premature or Dysmature Foal

Successful outcomes are dependent not only on careful management of identified problems but also in predicting the problems that may arise in the hours, days, or weeks to come. Most premature and dysmature foals will experience some degree of pulmonary insufficiency. Factors that predispose these foals to respiratory problems, including structural and functional immaturity, a naïve and potentially immature immune system, altered pulmonary vascular reactivity, a highly compliant rib cage, and a propensity for prolonged or persistent recumbency. Final maturation of the respiratory system appears to be highly dependent on a functional HPA system. Arterial blood gas analysis is an important tool in the assessment of respiratory function, and the lower arterial oxygen concentration in term newborn foals is further decreased in dysmature or premature foals (Table 17.4). Extrapulmonary shunts account for more than 30% of the cardiac output, in contrast to less than 10% in normal full-term foals.[331] Ventilation/perfusion mismatching also occurs due to a poorly reactive pulmonary vasculature and dependent atelectasis. Deficiency of lung surfactant is not likely to play a primary role in the respiratory dysfunction in most premature or dysmature foals, as it is usually fully developed in most foals by 300 days but could be delayed until after 340 days in some foals.[332] The most severe form of respiratory failure is neonatal respiratory distress syndrome (RDS), a disease characterized by progressive respiratory failure, severe hypoxemia and hypercapnia, and death. A diffuse, severe alveolar pattern is a classical radiographic finding. Intervention would ideally involve mechanical ventilation, bovine or synthetic surfactant, and glucocorticoids; however, outcomes are extremely poor irrespective of the level of care. Fortunately, RDS is relatively uncommon; most premature foals will demonstrate a less severe manifestation of lung dysfunction, characterized by reduced ventilation capacity, tachypnea, hypoxemia, and varying levels of hypercapnia. These foals are susceptible to dependent lung atelectasis from recumbency. Most foals will benefit from supplemental intranasal oxygen with initial flow rates of 5 L/min recommended. Adjustment in flow rate is dictated by positive changes in arterial blood gas analyses or improvement in ventilation rate and depth. It is important to avoid prolonged periods of lateral recumbency in order to minimize the impact of atelectasis. If the foal is unable to stand, then placement in sternal recumbency is recommended. This is made easier by use of a specially constructed V-pad.

Failure of the cardiovascular system is common in foals with partial or incomplete maturation of the HPA axis. Management is challenging, in part due to inconsistent responses to standard inotrope and vasoreactive therapy (see earlier). Successful treatment is reliant on early detection of reduced perfusion. This is reflected clinically by cool extremities, the presence of limb and ventral edema, and darkening of the mucous membranes with prolongation of the capillary refill time. As failure ensues, peripheral pulses will become difficult to palpate, blood pH will fall, and there will be increases in plasma lactate and

VetBooks.ir

anion gap. Indirect (or direct) measurement of mean blood pressure along with determination of blood lactate will help guide therapy. An initial approach to the treatment of failing perfusion may involve intravenous plasma followed, if necessary, by dopamine and/or dobutamine infusion. Dopamine is widely available and relatively inexpensive, with effects that are dose dependent; (1) low doses (0.5 to 5 μg/kg/min) provide agonism of dopaminergic receptors and possible renotubular effects along with vasodilation of coronary and intestinal vasculature; (2) moderate doses (4 to 10 μg/kg/min) stimulate β_1-adrenergic receptors and result in chronotropy; and (3) high doses (≥10 μg/kg/min) cause agonism of α_1-adrenergic receptors, leading to widespread vasoconstriction. High-dose dopamine infusion is generally not recommended in human preterm infants due to the potential for right-to-left shunting.[333] Dobutamine (3 to 20 μg/kg/min) acts principally on β_1 adrenoreceptors, producing an improvement in myocardial contractility without vasoconstriction. Other potential pressor agents used in foal intensive care facilities include epinephrine, norepinephrine, and vasopressin. Milrinone infusion is used in human preterm infants and has been evaluated in anesthetized adult horses, but it has not been evaluated in premature foals.[333,334] The volume and type of fluids given should be carefully monitored, as fluid overload and hypernatremia are common. Urine output should be appropriate for the volume of fluids administered and anuria or oliguria treated aggressively. This may include low-dose dopamine or fenoldopam infusion, furosemide boluses or infusion, or mannitol infusion. Establishment of urine flow is critical in terms of survival.

Signs of gastrointestinal tract dysfunction are rarely evident on initial assessment of premature or dysmature foals; however, most will not tolerate aggressive force-feeding. These foals commonly develop intestinal stasis with reduced fecal passage, gas accumulation, and gastric distension. The combination of prolonged asphyxia and prematurity is also a risk factor for the development of necrotizing enterocolitis. Feeding should be restricted to small volumes (e.g., 10 to 20 mL hourly) until the foal appears to be systemically stable. Concurrent parenteral nutrition is indicated in order to prevent loss of body weight. Foals should be monitored closely for signs of gastrointestinal dysfunction irrespective of feeding volume or frequency. This includes assessment of fecal passage, changes in abdomen size (assessed using a measuring tape), testing for gastric reflux if a nasogastric tube is in place, and frequent assessment with transabdominal US.

Premature and dysmature foals are susceptible to hypothermia. Thermogenic mechanisms develop late in gestation and are related to circulating T3 levels. As discussed earlier, thyroid hormone generation is closely tied to maturation of the HPA axis. Consequently, problems with thermogenesis are exacerbated in preterm foals with incomplete adrenal function. Body temperature needs careful management as rapid warming may result in peripheral vasodilatation and possible cardiovascular collapse. Initially, the foal should be covered by blankets and removed from any drafts. Intravenous and oral fluids should be warmed before use. Once the foal begins to demonstrate vigor, heat lamps and circulating warm-water blankets can be used. The premature or dysmature foal often has inadequate gluconeogenic enzyme activity and limited glycogen stores at the time of birth. Consequently, most will have difficulty maintaining a normal blood glucose concentration. This is managed acutely by infusion of 10 mL/kg of a 10% dextrose solution over several minutes, followed by a constant infusion at about 6 mg/kg/min (≈200 mL/h of a 5% dextrose solution to a 30-kg foal). Blood glucose should be monitored regularly to avoid hyperglycemia. Some foals with persistent hyperglycemia will benefit from insulin supplementation.

Skeletal maturity is assessed by radiographing a carpus and tarsus for evidence of incomplete ossification. Accelerated ossification does not appear to be a feature of foals born prematurely after exposure to chronic in utero stress. Incomplete ossification coupled with periarticular laxity predisposes the premature or dysmature foal to long-term skeletal problems. Foals with incomplete ossification and more than 30% reduction of the central and/or third tarsal bones with pinching or fragmentation of the dorsal aspects of affected bones commonly develop degenerative joint disease and have a guarded prognosis for future athletic performance. Restriction of exercise is recommended in order to minimize collapse of developing carpal or tarsal bones, but forced recumbency may predispose the foal to or exacerbate pulmonary disease. Furthermore, normal load bearing encourages ossification. Periarticular laxity predisposes the premature foal to angular limb deformities that facilitates abnormal load bearing and increase the risk of cuboidal bone crush injury of the carpus or hock. Splinting and attention to hoof care is recommended if angular limb deviation develops. In most cases, flexural deformities and laxities will improve over time. Dorsal splints are recommended for flexural deformities involving the fetlock, and heel extensions are helpful to foals with flexural laxity.

Colostral transfer of maternal immunoglobulin may not occur in premature foals for several reasons. Mares may have lactated prematurely or not at all, and the foal may not be able to suck. It is crucial to ensure that the premature neonate receive ample amounts of high-quality colostrum (>20 mL/kg) in the first 6 hours after birth, although the intestinal tract may not be capable of efficient colostral uptake or may not tolerate large volumes of liquid. Consequently, plasma transfusion is often used even in foals younger than 18 to 24 hours of age. A serum IgG level should be measured to confirm successful transfer of immunity (>800 mg/dL; >8 g/L).

The use of glucocorticoid therapy in the management of prematurity is controversial. Dexamethasone has been used in human medicine due to its potency, but it is associated with adverse side effects including hypertension, hyperglycemia, and catabolism.[335] Hydrocortisone has a shorter half-life and lower biological activity and is as effective for improving lung function and reducing the risk of bronchopulmonary dysplasia. In addition, hydrocortisone is commonly given to preterm infants in the early postnatal life to treat hypotension.[336] There is a risk of adverse complications, including intestinal perforation, which can be minimized by using a lower dose (1 to 3 mg/kg/day divided).[336]

Respiration

Guy D. Lester

The transition from the fluid-filled lung of the fetus to an organ that is responsible for efficient gas exchange is both rapid and complicated. The process can be complicated by a number of factors, including prematurity or dysmaturity; aspiration of meconium or milk; and bacterial, viral, or fungal infection. A highly compliant chest wall, an inefficient immune system, and failure to derive adequate antibody from colostrum (partial or total failure of passive transfer) are additive factors that predispose the neonate to respiratory problems.

The detection of respiratory disease in the newborn foal can be difficult. Thoracic auscultation can be highly misleading. Minute ventilation (frequency × tidal volume) is increased in the healthy neonate, resulting in easily heard bronchovesicular sounds. There is no need to accentuate breath sounds with rebreathing techniques. During the first few hours after birth, fluid can normally be auscultated throughout both lung fields and within the trachea. End-inspiratory crackles are commonly heard over the dependent lung during and shortly after rising from lateral recumbency. This is presumably due to simple atelectasis. Foals with respiratory disease will frequently have

VetBooks.ir

abnormal lung sounds, such as crackles and wheezes, but neonates with even severe pulmonary disease will occasionally have little detectable abnormality during auscultation. Clinical signs that are often associated with pulmonary tract disease in older foals and adult horses are frequently lacking in the sick neonatal foal. Fetal foals develop and mature in a relatively hypoxic environment within the uterus and therefore are more likely to tolerate postnatal hypoxemia than older foals or adults. Cough is also uncommon, likely due to a postnatal delay in maturation of irritant receptors within airways and delayed onset of the laryngopharyngeal cough reflex. This is clinically relevant in that aspiration of milk into the lower airway associated with force feeding can go undetected for several days. Of additional importance is that the respiratory rate and rhythm frequently do not accurately reflect arterial concentrations of oxygen or carbon dioxide. This is particularly relevant in foals that are showing signs suggestive of asphyxial injury, where rising arterial CO_2 concentrations occur in response to hypoventilation and fail to cause an increase in minute ventilation. In these foals the primary drive for ventilation is arterial O_2 rather than CO_2.

In the absence of arterial blood gas data or radiographic information, the clinician must rely on vague signs, such as restlessness and agitation, increased respiratory rate, or respiratory distress. Historical information may also aid in diagnosis. This should include an estimation of gestational age, recognition of any maternal problems (e.g., fever, dystocia, placentitis, or prepartum vaginal discharge), the presence or absence of meconium staining of amniotic fluid, and an assessment of colostral quality and quantity. Failure to make an early identification of pulmonary disease often results in unfavorable outcome, with chronic pneumonia resulting. Malformations, inflammation, or other abnormalities of the upper respiratory tract can cause clinical signs of respiratory distress, stridor, and dysphagia and result in lower respiratory tract problems as well. A number of nonrespiratory conditions also cause clinical signs that mimic respiratory disease.

The ideal diagnostic tools for investigation of neonatal respiratory disease include arterial blood gas (ABG) analysis and thoracic radiography. ABG analysis is the most sensitive clinical tool used to assess lung function. The sample is usually collected from the dorsal metatarsal artery, easily palpated in most foals on the lateral aspect of the third metatarsal bone. Alternative sites include the brachial artery, located at the level of the medial collateral ligament of the elbow joint, or the carotid artery, but hematoma formation is a common sequel to aspiration from this latter site. The sample will remain useful for up to 90 minutes in a capped plastic syringe at room temperature.

Interpretation of the ABG sample involves consideration of the amount of struggling and position of the foal during sample collection. Normal arterial blood gas values for neonates of different postnatal and gestational ages are presented in Table 17.4. Lateral recumbency can reduce the PaO_2 by as much as 30 mm Hg. The sample needs to be handled appropriately, paying strict attention to avoidance of air contamination, which will artificially increase the PaO_2 and decrease $PaCO_2$. The inspired oxygen concentration must also be considered when analyzing ABG values. With supplemental oxygen, PaO_2 is increased variably, depending on the inspired oxygen concentration (FIO_2), the amount of pathology present (particularly the extent of right-to-left shunting), the respiratory rate and tidal volume of the foal, and if the oxygen is delivered by nasal insufflation. A flow rate of 10 L/min, delivered by nasal insufflation, increased the PaO_2 to 298 ± 69 mm Hg in the normal, term newborn foal,[331] roughly equivalent to an FIO_2 of 1.0.[337] In the induced premature foal, the PaO_2 increased only to 111 ± 35 mm Hg.[331] If the respiratory rate of a foal is rapid and shallow, the supplemental oxygen will be diluted by room air because of the large quantity of room air entering the upper respiratory tract, and the concentration of alveolar oxygen will probably be much less than 100%. The two most common respiratory-derived ABG derangements include hypoxemia with normocapnia or hypocapnia or hypoxemia with hypercapnia. It is important to distinguish acute from chronic hypercapnia. Acute hypercapnia is associated with a more substantial drop in blood pH and may lead to circulatory collapse and coma, particularly if accompanied by acute hypoxemia. Chronic exposure to elevated CO_2 permits adaptation and more subtle clinical effects. The change in pH is less dramatic primarily because of enhanced bicarbonate reabsorption in the proximal tubules of the kidney. This effect begins within 6 to 12 hours of exposure to increased concentrations of CO_2 and is maximal by 3 to 4 days. Hypercapnia can be exacerbated by fever or the administration of carbohydrates or bicarbonate. The latter is often clinically relevant and highlights the danger of giving large amounts of sodium bicarbonate to foals with pulmonary disease.

Interpretation of blood gas values of venous blood (Table 17.4) can be deceptive and should be restricted to evaluation of metabolic conditions (e.g., metabolic acidosis) and not pulmonary gas exchange. To avoid problems associated with regional blood sampling, peripheral venous blood should be taken from a free-flowing jugular vein because the metabolic status of the head is usually stable. To obtain a sample representative of the whole body, mixed venous blood is drawn from the right atrium. Determination of mixed venous blood oxygen saturation is a good test for assessing the overall adequacy of oxygen delivery to tissues because it reflects the balance between oxygen delivery and oxygen use.

Several factors need to be considered when evaluating foal thoracic films. Thoracic radiographs are routinely taken only in the standing or recumbent lateral position in foals, with dorsoventral positioning reserved for the anesthetized or depressed foal. In healthy foals, radiographs taken before 4 hours of age will reveal increased opacity associated with retention of fetal fluids.[338] Thus interpretation can be limited because of positioning limitations. If the neonate has been in lateral recumbency for extended periods of time, atelectasis may result in diffuse or localized interstitial infiltrates that usually resolve once lung reexpansion occurs. It can be difficult to accurately distinguish bacterial pneumonia from atelectasis and pulmonary edema on the basis of radiographic appearance alone. In these cases additional diagnostic aids (cultures, hematology, necropsy) should be used in conjunction with radiology to reach an accurate diagnosis. A false overinterpretation of disease is common due to motion artifact, caused by a combination of long exposure times, poor patient compliance, and high spontaneous ventilation rates. When the radiographic appearance of the lung fields is evaluated, the type of infiltrate (interstitial, nodular, alveolar, mixed); severity; and location (diffuse, perihilar, cranioventral, craniodorsal, caudodorsal, caudoventral) should be noted. Other soft tissue structures (including the heart, vessels, and diaphragm) and bones (ribs, vertebrae, long bones) should also be evaluated.

Serial thoracic radiographs are useful in monitoring the progress of a respiratory condition. Radiographic changes may either follow or precede changes in clinical condition, and major changes can occur surprisingly rapidly (Fig. 17.12). Clinical signs of pneumonia frequently resolve much earlier than chest radiographs, and hemograms return to normal. Unfortunately, both ABG analysis and radiography are difficult to perform in field situations.

A study of healthy, sedated neonatal foals compared plain radiography with computed tomography (CT) concluded that CT studies were less subjective and had superior interobserver agreement than plain radiography.[339]

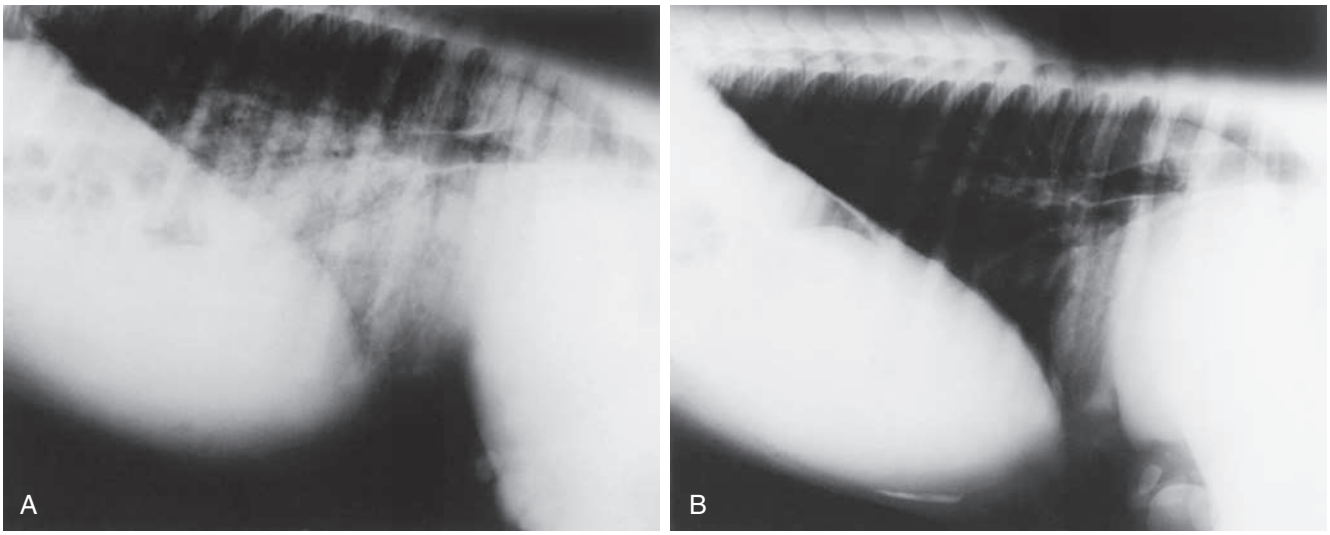

FIG. 17.12 Thoracic radiographs. **A,** Standing lateral thoracic radiograph of a 7-day-old Thoroughbred foal that experienced an acute onset of respiratory distress and cyanosis. Intubation and oxygen administration raised the PaO_2 to only 48 mm Hg. Severe pulmonary interstitial pattern is present in the caudoventral lung fields, and the tentative diagnosis was bacterial pneumonia. With no change in antimicrobial therapy, the foal improved clinically. **B,** Radiographs taken 3 days later revealed marked resolution of the pattern.

Ultrasonographic evaluation of the foal's thorax can yield useful information in a variety of disease processes, including pleural effusion, such as hemothorax or pleuritis, bronchopneumonia, or abscessation. It is also the preferred method for diagnosing rib fracture or dislocation, congenital heart disease, and thus is often a useful technique to differentiate cardiac and pulmonary causes of hypoxemia.

Specific Respiratory Conditions

Upper Respiratory Tract Disorders

Upper respiratory tract disorders are relatively uncommon in neonates. Conditions affecting pharyngeal and laryngeal function are important, as they predispose to aspiration pneumonia. Dyspneic neonates also have difficulty nursing and are subsequently likely to become malnourished. Congenital defects of the upper respiratory tract include collapsed trachea, stenotic nares, choanal atresia, epiglottal cyst, and guttural pouch tympany. There have also been reports of pharyngeal dysfunction as a cause of acute dyspnea, stridor, and dysphagia in neonatal foals.[231,340,341] Endoscopic examination of the upper airways of these foals reveals a variety of abnormalities that include a flaccid, collapsed, and inflamed nasopharynx; intermittent or persistent dorsal displacement of the soft palate; or arytenoid paralysis (Fig. 17.13). Medical management with antiinflammatory drugs, enteral feeding via nasogastric tube, and broad-spectrum antibiotics (for any coexisting aspiration pneumonia) can result in permanent resolution of the problems within 1 to 14 days (mean of 5.5 days).[231] The underlying basis of the condition is not known but may be related to birth asphyxia.

Impaired pharyngeal and laryngeal function may result from physical deformation or neuromuscular disorders. Pharyngeal and laryngeal injuries are often associated with improper application or use of damaged feeding tubes and oral medication equipment. Compression of the larynx by a retropharyngeal abscess or mass tends to cause inspiratory dyspnea, and aspiration pneumonia is a common sequela. Partial occlusion of the upper airway induces turbulent airflow and subsequently mucosal edema. Placement of a tracheostomy tube provides an alternate, sometimes life-saving, airway and rests the inflamed mucosa.

Nutritional myodegeneration, hyperkalemic periodic paralysis, and botulism may induce laryngeal paresis. Dysphagia and subsequent aspiration pneumonia is a common sequela of pharyngeal and laryngeal dysfunction associated with nutritional myodegeneration and botulism. Exercise- and excitement-induced respiratory stridor has been described in foals with hyperkalemic periodic paralysis.[342]

Collapsed trachea is a rare congenital or acquired condition. It is most commonly reported in American Miniature Horses, although those affected typically develop signs as adults.[343] Clinical signs include an intermittent honking cough, stridor, and dyspnea with mild exercise. There is no stenosis of the trachea but rather a dynamic dorsoventral collapse during inspiration. The caudal cervical and cranial thoracic sections of the trachea in the area of the thoracic inlet are most frequently affected. Acquired tracheal collapse is commonly associated with fractured ribs and compression of the trachea at the thoracic inlet by the subsequent bony callus.

Diagnosis of most upper airway disorders can usually be made with a combination of radiography and endoscopy. A 7-mm O.D. endoscope is usually small enough to pass through the ventral meatus of horse and pony foals weighing over 14 kg. An integral part of the diagnostic approach to the neonate with suspected upper airway obstruction is assessment of the lungs for aspiration pneumonia. If the primary upper respiratory problem is not corrected and normal nursing is allowed, the pneumonic process will likely persist and become chronic.

Respiratory Infection

Bacterial infection of the lower respiratory tract most commonly occurs during or shortly after birth, but it can also take place before parturition, through aspiration of contaminated amniotic fluid. This may take place in mares with bacterial placentitis. In the newborn foal pneumonia can result from direct aspiration or inhalation of bacteria or from the hematogenous spread of organisms in foals that are bacteremic. The most common bacterial organisms that have been associated with pulmonary disease in foals are identical to those that cause systemic sepsis. The most common isolates include *Escherichia coli*, *Klebsiella pneumoniae*, *Pasturella* spp., *Actinobacillus* spp., and *Streptococci* spp. Less common isolates include, but are not limited to, *Salmonella* spp., *Enterobacter* spp., *Pseudomonas* spp., *Serratia marcesans*, *Staphylococcus* spp., and *Yersinia pseudotuberculosis.*

The diagnosis of pneumonia involves identification of causative organism. Isolation of bacteria can be attempted from blood

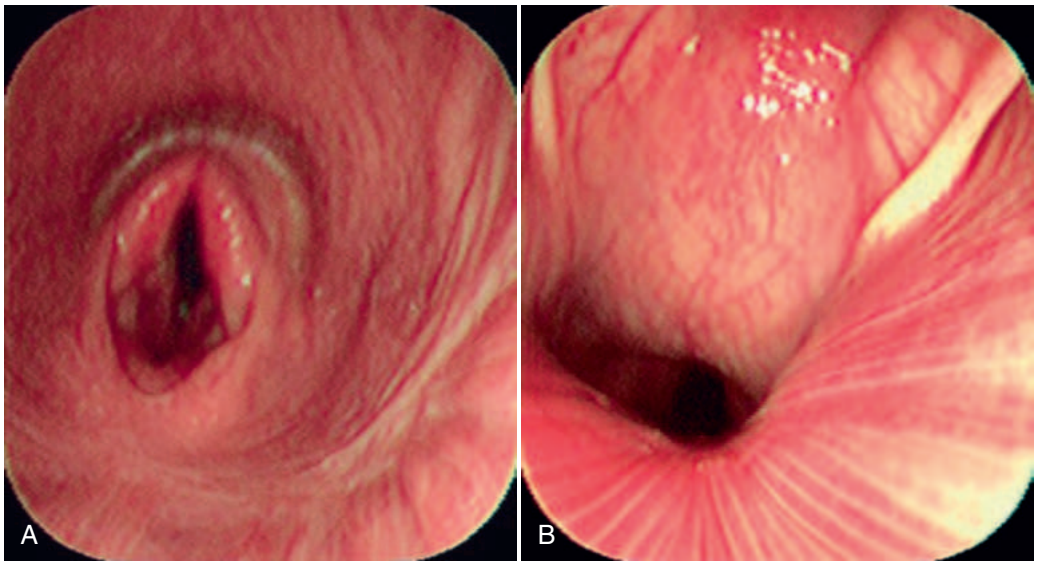

FIG. 17.13 Endoscopic images of a foal with dysphagia and stridor. **A,** Dorsal displacement of the soft palate. **B,** Collapse of nasopharynx associated with pharyngeal weakness.

culture or culture of amniotic fluid or placental tissue if in utero infection is suspected. Lower airway culture can be difficult, as a tracheal aspiration can be dangerous in a compromised neonate. An alternative method involves passage of a guarded swab through a nasotracheal tube into the lower airway. A complete blood count and measurement of an acute-phase protein, such as fibrinogen or serum amyloid A, may support a diagnosis of infection but will not be helpful in localization of infection to the respiratory tract. The treatment of bacterial lung disease involves a combination of respiratory support techniques and antibiotic therapy. The neonatal foal readily develops dependent atelectasis in lateral recumbency. Consequently, positioning in sternal rather than lateral recumbency results in improved ventilatory capacity and higher arterial oxygen tension. Broad-spectrum antibiotic therapy should be commenced as soon as lung disease is suspected. The third-generation cephalosporins, such as ceftiofur, ceftazidime, ceftriaxone, or cefotaxime, have distinct advantages over aminoglycosides in the treatment of bacterial pneumonia. They have superior penetration into the lung and effective tissue concentrations are easily achieved by intravenous or intramuscular routes. Because premature discontinuation of antibiotic therapy has resulted in relapse in a number of cases, repeat radiographs, and hematology (complete blood cell count and plasma fibrinogen) are highly recommended before discontinuation of antibiotic therapy. A minimum course of therapy of 3 to 4 weeks' duration is not unusual in cases of severe pneumonia.

Several viruses can cause pneumonia in neonatal or young foals. These include equine herpesvirus type 1 (EHV-1) and type 4 (EHV-4), equine influenza, equine viral arteritis virus, and adenovirus.[344-347] Neonatal pneumonia due to EHV-1 infection is frequently fatal, even in the face of aggressive supportive therapies such as antiviral medication and mechanical ventilation. Several factors appear common to EHV-1 infected foals, but none should be considered pathognomonic. These include leukopenia with neutropenia and lymphopenia, depletion of the myeloid cell lines on cytologic examination of bone marrow aspirates, and the presence of dilated retinal vessels and a red discoloration to the optic disc on fundic examination. Fatal bronchointerstitial pneumonia occurred in neonatal foals (aged 2 to 12 days) infected with equine influenza virus during the 2007 influenza outbreak in Australia.[345,347] Infection with adenovirus can be a problem in any immunocompromised foal, especially Arabian foals with severe combined immunodeficiency (SCID) syndrome.

In utero infection with *Histoplasma capsulatum* can result in placentitis, abortion, or birth of an infected foal with multiple organ disease, including granulomatous pneumonia.[348] An antemortem diagnosis can be difficult to establish but is aided by airway cytology where characteristic yeastlike organisms (3 to 5 μm in diameter) are seen within macrophages. Infection with *Candida* species (especially *Candida albicans*) is an infrequent complication in foals with chronic bacterial infection. Lengthy antimicrobial use is an apparent risk factor for infection, and many cases begin with oral candidiasis. The diagnosis is based on a history that often includes persistent low-grade fever, worsening respiratory disease or the development of synovitis, and isolation of the organism through blood culture. Successful treatment of neonatal candidiasis has been achieved with ketoconazole, amphotericin B, or fluconazole.

Meconium Aspiration Syndrome

In utero asphyxia or umbilical cord occlusion can result in fetal passage of meconium into amniotic fluid. Hypoxia induces a redistribution of blood flow away from the GIT, resulting in mesenteric vasoconstriction and secondary intestinal ischemia. Transient hyperperistalsis and anal sphincter relaxation occur thereby allowing passage of meconium. Meconium aspiration may occur before, during, or immediately after delivery as a result of fetal breathing or gasping. Meconium can produce a variety of clinical signs including mechanical airway obstruction and regional air trapping, chemical pneumonitis and alveolitis, alveolar edema, and displacement of surfactant.[349] This reduces lung compliance and causes small airway obstruction and focal atelectasis. These events lead to increased pulmonary vascular and airway resistance and ventilation/perfusion mismatching. Meconium may also enhance the growth of bacterial species within the respiratory tract resulting in secondary bacterial pneumonia. It can be difficult to differentiate meconium aspiration from bacterial pneumonia, especially if the birth was unattended.

If meconium has been aspirated into the pharynx, then gentle suctioning of the nasal and oral cavities is recommended. The ideal time to suction the airways is while the animal is still in the birth canal, before it has taken its first breath. If the foal shows signs of meconium aspiration below the vocal

VetBooks.ir

cords, nasotracheal intubation and careful, aseptic suctioning are recommended. Intranasal oxygen should be administered during suctioning. ABG analysis dictates what long-term respiratory and metabolic support is necessary. Mild to moderate hypoxemia can be treated with humidified intranasal oxygen (2 to 10 L/min). Severe hypoxemia with accompanying hypercapnia requires positive pressure ventilation and is associated within increased mortality. If surfactant displacement and secondary atelectasis are contributing to hypoxemia, continuous positive airway pressure (CPAP) alone may improve oxygenation while avoiding any unnecessary increase in peak airway pressure. Exogenous surfactant administration has been advocated to treat the surfactant dysfunction, although efficacy data are lacking. Systemic antibiotic therapy is recommended to prevent secondary bacterial pneumonia. Good airway hygiene and coupage are crucial.

A diagnosis of meconium aspiration is based on a history of meconium-contaminated amniotic fluid and a meconium-stained newborn. Radiographs typically show a ventrocranial distribution of pulmonary infiltrate characteristic of aspiration. Clear, yellow to brown fluid may drip from the nose.

Milk Aspiration

Aspiration of milk into the lower airway may occur as a complication to a wide range of conditions. Most foals that aspirate milk will also demonstrate nasal regurgitation of milk. Unfortunately, the decreased sensitivity of the upper and lower airway to foreign material may make diagnosis of milk aspiration difficult. Aspiration can occur in foals with cleft palate, persistent dorsal displacement of the soft palate (DDSP), botulism, neonatal encephalopathy, or generalized weakness due to sepsis or prematurity. Iatrogenic contamination of the airway can occur when bottle-feeding is forced or if the foal is too weak or sleepy to receive feeding. Substantial and sometimes fatal pneumonia can result from inappropriate placement of nasogastric tube.

The diagnosis of milk aspiration is supported by historical data (nasal regurgitation of milk), physical examination findings (abnormal lung and tracheal sounds), and laboratory data (inflammatory leukogram, elevated fibrinogen and/or serum amyloid A, arterial hypoxemia). Radiographic examination commonly reveals a heavy, perihilar and/or ventrally located interstitial density, with or without air bronchograms.

The treatment of milk aspiration involves long-term, broad-spectrum antimicrobial therapy and prevention of further contamination of the airway. The underlying cause must be pursued diagnostically and treated. This may necessitate the use of further diagnostic tests, including endoscopy and plain and contrast radiography. Enteral feeding through a nasogastric or esophagostomy tube is indicated until the underlying problem has been resolved. Nasopharyngeal weakness will frequently resolve over time but may take weeks.

Pneumothorax, Hemothorax, or Uroperitoneum

Pneumothorax is usually an iatrogenic sequel of positive pressure ventilation of diseased lungs, but it may occur spontaneously as a result of birth trauma and rib fracture or from ruptured bullae within the lung parenchyma.[350,351] During mechanical ventilation, uneven alveolar ventilation leads to alveolar rupture and dissection of air into the interstitium. The air moves along bronchioles and other lung structures to pleural surfaces, forming blebs that can rupture into the pleural space. The condition should be strongly suspected if the respiratory condition suddenly worsens while an animal is being ventilated. Clinical signs may include respiratory distress, cyanosis, hypotension, or subcutaneous emphysema. Although auscultation may reveal decreased breath sounds, it may be misleading because of the wide referral of breath sounds in foals. Radiographs are indicated to confirm the diagnosis, but, if radiology is unavailable or the animal is very distressed, a direct needle aspirate is both diagnostic and therapeutic.

Pneumothorax may be treated conservatively if no distress is associated with the air leak and the condition appears stable. Thoracic tube insertion is indicated with continuing air leak, if underlying pulmonary disease is causing respiratory distress, and in those patients receiving mechanical ventilation. A trocar catheter is sterilely introduced into the chest cavity, and the catheter is secured using a Chinese Finger Trap suture technique.[352] Suction is applied at –15 cm H_2O until the tube has drained no air for 12 hours. The tube may then be placed under water seal for an additional 24 hours, and, if no air accumulates, the tube may be removed.

Hemothorax is occasionally noted in the large animal neonate. It has occurred secondary to unstable fractured ribs, with puncture of the lung parenchyma resulting in hemorrhage into the pleural space. Occasionally, a hemothorax may remain undiagnosed until clinical signs of anemia, hypovolemia, or shock appear in the young animal.

Accumulation of pleural fluid is a relatively common feature of moderate to severe uroperitoneum.[353] The fluid may result from increased hydrostatic pressure from uroperitoneum-induced compression of the caudal vena cava or urine migration from the peritoneal cavity to the pleural cavity through lymphatics.[353,354] In most foals the thoracic fluid is not recognized, but some foals develop tachypnea, tachycardia, hypercapnia, and hypoxemia. This signs can be exacerbated after removal of the abdominal fluid, potentially causing a "reexpansion pulmonary edema."[355]

Transient Tachypnea in the Neonate

A syndrome observed in Clydesdale, Thoroughbred, and Arabian neonatal foals has been the combination of fever and tachypnea. The condition appears to be more frequent during hot, humid weather conditions. The pathogenesis of the condition is unknown, but it is speculated that it results from a transient problem in central or peripheral control of thermoregulation and/or respiratory rate and pattern. There is a syndrome in human infants termed *transient tachypnea of the newborn* (TTN) that is self-limiting and, in contrast to the foal syndrome, is generally attributed to failure to adequately clear the lungs of perinatal fluid after birth.[356]

Affected foals are usually of normal gestation and experience a normal birth. Most display normal activity for a variable period after birth, with a sudden onset of clinical signs. There are usually no signs of pulmonary abnormalities as assessed by thoracic radiographs or ABG analysis. Body temperature is variable between foals, ranging from 102° F to 108° F (39° C to 42.2° C). A poor response to antipyretics has been noted. The respiratory rate and breathing pattern often resemble panting (respiratory rate >80 beats/min). The condition usually resolves spontaneously within a few days to weeks.

Before transient tachypnea is diagnosed, it is important to rule out a pneumonic process or other pulmonary abnormality, other sources of infection, metabolic acidosis, and other causes of an increased respiratory rate. Hematology, lung radiographs, and ABGs should be within normal limits, and bacterial cultures should be negative.

Treatment is directed at controlling the body temperature; body clipping, alcohol baths, and being in a cool environment are the most effective methods. If infection cannot be entirely ruled out, antibiotic therapy should be used.

Treatment of Respiratory Distress

Oxygen therapy is an important component in the management of respiratory distress. The decision to institute oxygen therapy is ideally based on both clinical signs and blood gas analysis. Increased respiratory rate, labored respiration, increased intercostal and abdominal muscle activity, and restlessness are

VetBooks.ir

considered indications for a trial of oxygen therapy. A PaO_2 less than 55 to 60 mm Hg in lateral recumbency is considered an objective indication for oxygen therapy. If blood gas analysis is not available, clinical signs indicating a favorable response to oxygen therapy include a decrease in effort of breathing, decrease in respiratory rate, and a more comfortable appearing foal. An absence of response may indicate a nonrespiratory origin of the clinical signs, severe lung pathology, a cardiac malformation, or inadequate inspired oxygen concentration.

The inspired oxygen concentration is most easily increased by nasal insufflation using a bias flow of humidified oxygen. Depending on the severity of disease and size of the individual, oxygen is initially delivered at a flow rate of about 5 L/min and the response is noted. The oxygen catheter tip should be advanced into the nasopharynx, and the opposite end should be secured to the nostril using tape or sutures. The actual oxygen concentration delivered to the alveoli depends on several factors, including the position of the tube and the depth and rate of breathing. Oxygen therapy should be directed at maintaining a PaO_2 of 80 to 100 mm Hg, and the flow rate should be adjusted according to blood gas results. Oxygen therapy should be on a continuous basis, and weaning from support should be done gradually. Transtracheal oxygen delivery may be beneficial in larger foals; hypoxemic neonatal foals that have a rapid, shallow breathing pattern; or foals with severe pulmonary disease that are unresponsive to nasal insufflation.[357] A percutaneous catheter system is placed using local anesthetic and secured to the skin. The distal location of the catheter bypasses a substantial volume of dead space and results in a higher alveolar oxygen concentration.

Oxygen therapy is not effective in correcting hypoventilation, and, if hypercapnia is progressive and accompanied by signs of increasing respiratory distress, some type of mechanical ventilatory support is usually indicated. This decision to provide mechanical ventilation must take into account several considerations, including the worth of the individual, the commitment of the owners, the facility and availability of personnel, and the type of disease process present. For additional information on mechanical ventilation the reader is directed to other reviews.[358]

Regardless of the level of respiratory support provided, the importance of meticulous respiratory supportive technique cannot be overemphasized. Maintenance in sternal position, frequent turning from side to side, regular coupage, and use of proper suction technique are all important components of respiratory support.

Diarrhea in Neonatal Foals

Guy D. Lester

Diarrhea occurs frequently in foals of all ages and represents one of the most common medical conditions requiring veterinary intervention. The approach to diagnosis can be difficult, and establishment of a definitive diagnosis in a field setting is uncommon. The veterinarian must therefore consider a number of factors in order to construct a list of most likely causes. These factors include the ages of the affected animals, numbers of foals affected, volume and character of the feces, and duration of signs. There are some limited diagnostic tests that can be used to rule in or out many of the common causes of foal diarrhea.

In some foals, diarrheal diseases are associated with signs of colic. The abdominal pain can be severe and can mimic that seen in foals with strangulating intestinal lesions making case management difficult. Colicky signs frequently precede the onset of diarrhea. Passage of a nasogastric tube is equally important in colicky foals as it is in adults. Foals with intestinal ileus or inflammatory diseases of the small intestine will commonly produce large volumes of gastric fluid on reflux. The control of pain is required in order to reduce the chances of injury and to facilitate evaluation. Intramuscular butorphanol can be helpful in providing pain relief in foals with colitis. α_2-Adrenergic agonists should be used with caution in neonates due to their depressive effect on the cardiopulmonary system. If they are to be used, then start with lower doses or consider combining with butorphanol. Nonsteroidal antiinflammatory drugs should be avoided until a diagnosis is established. Neonatal foals generally tolerate flunixin well but require a slightly larger dose rate but reduced frequency when compared with older animals.

There are many causes of diarrhea in young foals including bacteria and bacterial toxins, viruses, nutrition, parasites, and antibiotic usage.[142] Normal physiologic adaptive processes can also produce diarrhea in most foals. The intestinal microbiota of newborn foals is described as "complex" as early as 24 hours of age.[359] The flora develops over the first weeks of life such that by 60 days of age it resembles that of an adult.

Bacteria

Escherichia coli is the most important mediator of systemic sepsis in newborn foals but is not a common primary cause of diarrhea in this age group. The organism is common in normal horse feces and is frequently isolated from animals with diarrhea,[360] but in the absence of typing the role of *E. coli* is highly questionable. There are rare reports implicating an association between *E. coli* and diarrhea in foals. Enterotoxigenic *E. coli* was isolated from a 3-day-old diarrheic foal.[361] The isolate was of the 0101 serotype, was LT-like toxin positive, but negative for STa. Earlier inoculation studies indicated that F4 (formerly K88)–positive *E. coli* was not likely to cause diarrhea in foals, although may have a synergistic role in foals infected with other potential pathogens, such as rotavirus.[362]

Intestinal disease mediated by Clostridial toxins occurs in foals worldwide. The toxins are most commonly derived from biotypes A and C of *Clostridium perfringens* or from *Clostridium difficile*. Classical intestinal clostridiosis of foals is caused by *C. perfringens* biotype C and is characterized by colic, rapid dehydration, cardiovascular collapse, and hemorrhagic diarrhea. The disease occurs most commonly in foals younger than 10 days of age; often younger than 36 hours of age. It is associated with a high mortality, and outcomes are rarely influenced by treatment.[363] Death may occur rapidly and occasionally before any diarrhea has been passed. Biotype C produces both α and β toxins along with variable amounts of enterotoxin. Cases can occur sporadically or as outbreaks and, on some farms, occur annually presumably associated with carriage in specific mares. Biotype A of *C. perfringens* has become well recognized as a specific cause of foal diarrhea over the past decade. Biotype A produces α toxin and enterotoxin and is associated with a slightly lower mortality rate than biotype C. Affected foals are more likely to respond to directed or supportive care. The development of clinical signs is rapid, and diarrhea may or may not contain blood; in the author's experience, passage of bloody diarrhea is common but usually transient. Reported risk factors for *C. perfringens* diarrhea in neonatal foals in Colorado include breed (stock horse type), birth on dirt, sand, or gravel, housing in stalls or on dry lots during the first 3 days of life, and maternal feeding practices. Feeding a low-grain diet prepartum was associated with a decreased risk of neonatal disease.[363] Hematologic findings are consistent with toxemia. This includes hemoconcentration; an initial leucopenia, characterized by a neutropenia with a left shift to immature forms and toxicity; and a lymphopenia. Chronic cases may develop a rebound leucocytosis and hyperfibrinogenemia. Altered coagulation may be evident clinically through prolonged bleeding or spontaneous hemorrhage, or through a propensity to develop thrombosis.

VetBooks.ir

A definitive diagnosis of *C. perfringens* diarrhea is rarely established in practice. The diagnosis is usually based on signalment, clinical features, and outcome, rather than detection of specific clostridial toxins. Positive fecal culture is strongly supportive, noting that healthy foals may shed low numbers of *C. perfringens*. Identification of toxin is ideal but is limited due to availability of appropriate commercial assays. Fecal enterotoxin detection assays are available but lack sensitivity, particularly with biotype C isolates. Biotyping of *C. perfringens* isolates after culture can be achieved using polymerase chain reaction (PCR) analysis for toxin gene sequences. This may be helpful in increasing the accuracy of the diagnosis but again falls short in establishing a definitive cause. Fecal Gram stain is easy to perform and may support an early clinical suspicion of disease if there are abundant numbers of large gram-positive organisms or spores present.

C. difficile can produce an identical clinical syndrome to *C. perfringens*, although it appears to be more variable with respect to fecal blood. The two pathogens were isolated together in several foals with fatal hemorrhagic diarrhea.[364] *C. difficile* also occurs as sporadic cases or as clusters or outbreaks. Identical strains can be recovered in mare-foal pairs, indicating cross-infection.[365] It is important to recognize that clostridial infection can produce a severe inflammatory syndrome that is restricted to the small intestine and may not cause diarrhea. Affected foals can present with signs that mimic strangulating small bowel disease, including severe abdominal pain, gastric reflux, and sanguineous peritoneal fluid. Two principal toxins can be liberated from *C. difficile:* an enterotoxin (toxin A) and a cytotoxin (toxin B). Both nontoxigenic and toxigenic strains exist and can only be differentiated after culture using molecular techniques. Consequently, commercial toxin tests (available for both toxin A and B) are recommended in addition to fecal culture to establish a diagnosis. As with *C. perfringens* cases, a fecal Gram stain can also increase suspicion. Hematologic changes associated with *C. difficile* infection can mimic those associated with *C. perfringens* disease.

Most cases of clostridial enterocolitis require aggressive medical intervention, irrespective of clostridial type. Antimicrobial therapy should be both specific and broad spectrum. Targeted antimicrobial treatment typically includes both metronidazole and penicillin. The majority of affected foals will require, at a minimum, intravenous crystalloid solutions. Some will also benefit from plasma or synthetic colloids and inotrope and vasopressor therapy. Additional therapies include *C. perfringens* biotype C and D antitoxin, di-tri-octahedral smectite clay, and lactase enzyme replacement.[366,367] The use of *C. perfringens* antitoxin and toxoid is off-label and not without some risk. Pretreatment with antihistamines has been suggested before antitoxin.[366] Prevention of clostridial enterocolitis centers on hygienic housing practices and avoidance of overfeeding of late-pregnant mares. Affected foals and their mares should be isolated, and strict protocols instituted to limit cross contamination. Administration of *C. perfringens* type C and D toxoid to pregnant mares has been used with anecdotal success on farms with recurrent problems with *C. perfringens* biotype C. The use of prophylactic metronidazole is highly controversial but understandable on properties with a high disease prevalence. Some isolates of *C. difficile* are reportedly resistant to metronidazole,[366] and although this appears to be dependent on geographic location the widespread prophylactic use could promote resistance. Prophylactic use of probiotic preparations are commonly recommended, but there are conflicting efficacy data.[368–371]

Bacteroides fragilis is a gram-negative anaerobic rod and occurs in both enterotoxigenic and nonenterotoxigenic forms. Enterotoxigenic strains of *B. fragilis* have been incriminated with diarrhea in several species, including lambs, calves, pigs, humans, and foals.[372] Enterotoxigenic *B. fragilis* was isolated from young foals (aged 2 to 60 days) with diarrhea.[373] Half of these foals had other potential pathogens detected, including *Salmonella* or rotavirus. In a study reviewing 20 isolates of *B. fragilis* from hospitalized foals with diarrhea, only 4 had the enterotoxin gene.[372] The most common isolate from foal feces was a nonenterotoxigenic strain casting doubt as to clinical relevance.

Enterococcus (Group D *Streptococcus*) *durans* has also been implicated as a cause of diarrhea in foals.[374] Similarly, *Aeromonas hydrophila* was isolated more commonly from foals with diarrhea than control animals, suggesting a potential role in foal diarrhea.[375] *Rhodococcus equi* is an important cause of pulmonary disease in foals. Although abdominal involvement appears common, the relevance of *R. equi* as a significant primary enteric pathogen, in terms of number of animals affected, is likely small. An intestinal syndrome has been directly attributed to *R. equi* that involves necrosis of the small intestinal Peyer's patches and multifocal thickening and necrosis of the cecum and large intestine.[376] The changes include multiple areas of intestinal ulceration with an associated mesenteric lymphadenopathy. The diagnosis of *R. equi* ulcerative colitis is difficult for a variety of reasons. In contrast to *Salmonella* infection, where recovery of the organism from the feces has significance, the recovery of *R. equi* is common in asymptomatic animals. Up to 100% of foals older than 2 weeks of age may shed large numbers of the bacteria.[35]

Salmonella infection of neonatal foals is also associated with high mortality. As with clostridial infection, cases can occur sporadically or as part of an outbreak. Mares provide the most important source of *Salmonella* to newborn foals, but it is rare that both mare and foal will develop clinical disease. Clinical signs can become apparent by 24 hours of age but are more common in older foals. The severity of signs is related to virulence of the serotype involved, inoculation dose, and level of host immunity. In contrast to adult infections, detectable bacteremia occurs commonly in affected foals. Consequently, foals that may survive the initial intestinal or systemic disease remain at risk for secondary complications that include osteomyelitis, synovitis, meningitis, uveitis, hepatitis, or pyelonephritis. In some foals these complications may not become clinically apparent until days or weeks after resolution of enteric disease. Therefore appropriate and sustained broad-spectrum antibiotic therapy is important in known affected foals. The selection of antibiotic should be based on known sensitivity patterns understanding that in vitro sensitivity may not accurately translate into clinical efficacy due to the intracellular location of *Salmonella*. For example, the limited distribution of aminoglycosides can lead to therapeutic failure despite often promising in vitro sensitivity.

Viruses

Rotavirus is the most common cause of infectious diarrhea in foals. There are seven known groups of rotavirus (A through G) and many different serotypes within each group. Group A is the primary cause of rotaviral diarrhea in foals with G3 the most common serotype.[377] Rotaviruses have the ability to change their surface proteins over time, and this rearrangement of gene segments takes place during coinfections with other strains. This leaves the possibility for many variations of the virus.

Transmission may be direct from animal to animal or indirect through fomites. Disease occurs after a short incubation period. Experimentally, this period may be as brief as 48 hours.[378] Rotavirus replicates within the intestine and invades the lining of the proximal small intestine causing villous cell death and a resultant loss of absorptive area. Diarrhea may result from several mechanisms: (1) a loss of absorptive capacity coupled with a decrease in lactase production can lead to an osmotic load of undigested lactose delivered to an immature hindgut;

VetBooks.ir

(2) a compensatory crypt cell proliferation may cause an increase in intestinal secretion; and (3) the virus produces an enterotoxin that causes or contributes to the development of diarrhea. The putative viral enterotoxin and cytotoxin, NSP4, is a nonstructural glycoprotein of rotavirus that is released from virus-infected enterocytes.[379] NSP4 is a noncompetitive inhibitor of the Na-glucose symporter and also enhances intestinal chloride secretion.

Disease can be seen between 2 and 160 days of age but is most common in foals younger than 60 days. Indeed, most clinical infections probably occur between 5 and 35 days of age. The presence and severity of diarrhea are highly dependent on the degree of hindgut maturation. Consequently, infection in foals younger than 2 weeks of age may result in life-threatening watery diarrhea, whereas infected older foals may have minimal or no diarrhea due to effective colonic compensation of osmotic and fluid loads. Diarrhea when present is often watery but nonfetid in odor.

There is serologic evidence that broodmares may have an important role in propagation of the virus within a herd. Infections can occur as isolated cases or as outbreaks following periods of overcrowding and stress. Shedding after infection is usually complete by 10 days after the cessation of clinical signs but may occur intermittently for up to 9 months.[380] The virus can persist in the environment for up to 9 months, and disinfection usually necessitates the use of substituted phenolic compounds.

The diagnosis of rotaviral diarrhea is based on an appropriate signalment, clinical signs, and detection of the virus in feces. Tests include electron microscopy, commercial immunoassays (enzyme-linked immunosorbent assay [ELISA] or latex agglutination), and PCR. Several diagnostic companies and university laboratories have developed comprehensive equine diarrhea PCR panels that include rotavirus. Virus is shed in large concentration early on during infection. Central to the management of affected foals is maintenance of hydration through enteral and/or intravenous fluid therapy.

Prevention involves good hygiene and reduction in crowding. Vaccination of mares during pregnancy has yielded variable results in terms of efficacy.[381,382] There is some evidence to suggest that vaccination may at a minimum delay the onset of disease, thereby reducing both the severity and duration of diarrhea.

Coronavirus can cause diarrhea in foals during the neonatal period. It was originally thought to be an uncommon but severe cause of diarrhea.[383,384] Survey data using real-time PCR analysis indicated a high rate of carriage in both healthy and diarrheic foals.[385] Antemortem diagnosis can also be made using electron microscopy, serology, or commercial fecal-capture ELISA. As with rotaviral infection, shedding is greatest in the early stages of disease.

Parasites

Strongyloides westerii is a common parasite of foals, with early infection of the foal occurring through mare's milk. Experimental studies have indicated that higher numbers of infective larvae than are found in milk are needed to produce diarrhea.[386] Furthermore, foals with high egg counts are often asymptomatic.

Cryptosporidium parvum is not considered to be an important pathogen of foals in terms of numbers of animals diseased, although it can be a problem in specific locations.[387] On the basis of epidemiologic studies, the parasite appears to be concentrated in some breeding operations.[388] Foals diseased with *Cryptosporidium* shed enormous numbers of infective oocysts into the environment. The parasite is considered to be coccidian-like but differs from coccidia in terms of size (4 to 6 μm diameter compared with 23 to 34 μm for other coccidia), host specificity (not host specific), pathogenesis (only invades epithelium), and drug sensitivity (resistant to many drugs). Infection is by the fecal-oral route. The oocysts can survive in the soil or water for months. They do not require a period of sporulation outside of the host to become infective. In a study of asymptomatic foals, between 15% and 31% of foals were shedding *Cryptosporidium*, and that shedding began between 4 and 19 weeks of age and persisted no more than 14 weeks.[389] All shedding had ceased by weaning and was not identified in adult horses. The diagnosis is usually made through microscopic examination of the feces. Acid fast or Ziehl-Neelsen stains are required to detect oocysts. Immunofluorescence assays and flow cytometry techniques have also been described. *C. parvum* infection may be seen with concurrent enteric or systemic infections. The disease is generally self-limiting in immunocompetent animals. Historically, the pharmacologic control of *Cryptosporidium* has been difficult, but paromomycin, nitazoxanide, or azithromycin may be efficacious. The organism is potentially zoonotic, and transmission from foals to humans is reported.[390]

Giardia may be found in normal foals with infection rates reported from 17% to 35%.[389] *Giardia* is present in all age groups, and it is believed foals acquire infection from nursing mares. Concurrent infection with *Cryptosporidium* and *Giardia* may be observed. Disease should be suspected if large numbers of parasites are seen on fecal analysis. Affected animals should respond within a few days to treatment with metronidazole; failure to respond should alert to other pathogens.

Nutritional Causes

Nutritional causes of diarrhea include overingestion of milk (as might occur when the mare and foal are separated and rejoined) or overfeeding orphaned or sick foals. Overwhelming the ability of the small intestine to digest and absorb results in presentation of milk to the colon, where it is fermented and produces osmotically active sugars and acids. In a controlled study of foals younger than 5 days of age, an elemental isotonic diet produced diarrhea in healthy foals when fed as the sole source of nutrition. Older foals fed a similar diet apparently did not develop diarrhea.[391] Orphan foals and foals fed commercial mare milk replacer may experience diarrhea associated with these diets. Foals that are fed raw cow's milk frequently experience diarrhea and failure to thrive. Cow milk replacer uncommonly causes diarrhea but remains a less than ideal replacement. In contrast, foals fed goat's milk grow well and rarely develop diarrhea, although they may develop a metabolic alkalosis of minimal to no clinical significance.

Transient lactase deficiency has been proposed in foals. An oral lactose tolerance test is conducted after a 4-hour fast. Foals are administered 1 g/kg of body weight of a 20% solution of lactose powder and observing an increase of plasma glucose of 35 mg/dL (1.9 mmol/L) by 90 minutes.[392] Agents such as rotavirus that damage epithelial cells may cause prolongation of the diarrhea because of temporary lactase deficiency.

Foal Heat Diarrhea

Diarrhea developing during days 5 to 14 of life has been termed "foal heat diarrhea" because of the time relationship to the occurrence of postfoaling estrous in the mare. Diarrhea has developed in foals in this age group that have been raised separated from the dam on a consistent diet and isolated from pathogens, so it does not appear to be causally related to estrous. The most likely cause of foal heat diarrhea is the establishment of normal flora in the hindgut. Foal heat diarrhea is typically preceded by coprophagy 2 to 3 days before the onset of diarrhea. Classical foal heat diarrheas are mild and require no specific therapy. Continued diarrhea, fever, or depression with signs of reduced sucking activity on the mare should raise concern

of other etiologic agents with appropriate diagnostic testing and treatment.

Treatment and Prognosis

The three main components of therapy of diarrhea in the neonatal foal consist of (1) fluid therapy (either oral or intravenous), (2) intestinal protectants/adsorbents, and (3) antibiotics if indicated to treat suspected bacteremia or clostridiosis. Sodium-containing isotonic intravenous fluids are an important component of diarrhea therapy in the compromised neonate. Potassium is lost in severe diarrhea and, if hyperkalemia is not present, should be supplemented by adding 15 to 20 mEq/L of KCl to fluids. Foals that are not nursing normally may have hypoglycemia and may need glucose-containing fluids. Acid base correction by volume expansion and replacement of bicarbonate can be lifesaving and should be monitored frequently when significant intestinal fluid losses occur.

Ideally milk should not be withheld from foals with diarrhea. The clear exceptions are foals with colic and those with bloody diarrhea. The foal can be muzzled for 8 to 12 hours while the mare is milked out, and the foal provided oral fluids through stomach tube or a bottle if a suck reflex is present. Although labels of electrolyte replacers do not always specify for use in foals, many preparations used in calves have been used in foals. Most of these preparations provide insufficient energy and should be used for short intervals of no more than 24 to 36 hours unless parenteral nutrition of some type is provided to maintain blood glucose levels.

Intestinal protectants may be all that are required in uncomplicated cases or may be used in conjunction with other therapies. Bismuth subsalicylate, kaolin or pectin, and activated charcoal have been used for this purpose. Suggested advantages of bismuth subsalicylate are its neutralization of bacterial toxins and antisecretory effect through its local antiprostaglandin activity. DTO smectite clay is also commonly used in the management of diarrhea.

Systemic antibiotics should be used in the neonate with diarrhea that may have systemic sepsis or compromised immunity. Blood cultures should be obtained before initiation of antimicrobial therapy. Antibiotics with a spectrum against gram-negative and gram-positive organisms should be used. In general terms, renal toxicity associated with aminoglycoside use is uncommon in clinical practice. The clear exception is the foal that is dehydrated, most commonly due to ongoing losses through diarrhea. Consequently, the monitoring of renal function is indicated when using potentially nephrotoxic drugs.

Plasma therapy for hypoproteinemia associated with failure of passive transfer or protein-losing enteropathy is useful to maintain plasma oncotic pressure and expected protein binding of medications. Diarrheic foals with albumin levels below 20 g/L or total plasma protein levels less than 42 g/L may benefit from plasma therapy.

Prevention and Control

Prevention is best accomplished by minimizing density of populations of horses, separating of age groups, providing appropriate sanitation and hygiene, and obtaining adequate colostrum of good quality (see Chapter 53). The risk of neonates developing diarrhea in a hospital environment is increased with the use of histamine type 2 receptor antagonists or omeprazole.[134]

Distended and/or Painful Abdomen

Evaluation of the colicky newborn or older foal often presents a diagnostic challenge. As with adults, differentiation between surgical and nonsurgical abdominal diseases is often the primary focus in any evaluation of abdominal pain in foals. Rectal palpation, one of the most important diagnostic aids used in the assessment of adult animals with colic, is limited to digital palpation in foals for obvious reasons. This size limitation does, however, allow other diagnostic modalities to be used effectively, such as US and plain and contrast radiography.

The most commonly used analgesics in colicky neonatal foals include flunixin and butorphanol. Xylazine can be used, but care is needed in sick foals as the drug is associated with significant hypotension. Another important procedure is to pass a nasogastric tube and check for gastric fluid accumulation, a critical aspect of examination of the adult horse with colic but often overlooked in neonatal foals.

The decision to select certain diagnostic tests is based on a number of historical and physical examination findings. The duration and severity of signs, together with evaluation of response to chemical analgesia, will often dictate surgical versus nonsurgical management. Severe, unrelenting pain that is poorly or unresponsive to analgesics is often unto itself a valid criterion for surgical exploration. The decision to explore the abdominal cavity in the newborn should not be taken lightly, as this age group appears more susceptible to the consequences of adhesion formation postoperatively.[393] A thorough physical examination is key as many gastrointestinal diseases in young foals can occur either as a secondary manifestation to other diseases (e.g., sepsis or prematurity) or in coexistence with other disorders that could impact adversely on either short- or long-term survival.

The evaluation of a colicky foal can often be guided initially by the presence or absence of gross abdominal distention. In young foals, this can be monitored by repeated use of a measuring tape around the abdomen. The position of the tape can be maintained in a constant site by clipping a small mark over the dorsum. The most frequent cause of an enlarged abdomen is gas accumulation within the intestinal lumen, most commonly the cecum and/or large colon. It may be important to determine if the gas is maintained within the intestinal tract or if it is free within the peritoneal cavity. This is particularly true in foals with clinical and/or hematologic evidence of sepsis or toxemia. Free peritoneal gas can be detected by US examination or, more easily, by plain radiography. This can occur secondarily to abdominal rupture or by inadvertent puncture or laceration of the bowel during attempted abdominal fluid collection.

Newborn foals with uroperitoneum can present with abdominal distention and low-grade pain. Differentiation between gas and fluid can generally be made by careful physical examination and confirmed by US examination. Typically, a large amount of free peritoneal fluid is noted and a free-floating empty bladder is clearly seen caudal to the umbilicus. If maintained on a milk diet, most neonates with uroperitoneum will develop the classical electrolyte derangements: hyponatremia, hypochloremia, and hyperkalemia. Foals that develop uroperitoneum during treatment of other diseases (e.g., necrotic urachus in a foal with systemic sepsis) may not develop the classical changes if maintained principally on replacement solutions intravenously.

An US examination of the foal abdomen is best done with the foal in a standing position. The ventral abdomen is clipped, and a coupling gel is applied in a liberal manner. A linear or sector probe with a frequency range between 5 and 7.5 MHz is the most common probe type used for routine scanning. In older foals and adults, a lower frequency probe is needed to provide deeper penetration into the abdomen. In newborn foals every abdominal US should include examination of all umbilical structures, including both arteries, vein, urachus, and urinary bladder. The intestines should be evaluated for wall thickness (should be <4 mm), the presence of edema or gas within the wall, and echogenicity of contents. Fluid-filled loops of small intestine are often consistent with either primary or secondary ileus or enteritis. Gas echoes within the wall are

VetBooks.ir

a feature of necrotizing enterocolitis, a disease of neonates with a high mortality rate. Gas-filled intestine is seen on US as a bright line caused by reflection and refraction of sound waves when contact is made with the gas. A subjective assessment of intestinal motion can also be made during the examination. Typically, in foals with enteritis or enterocolitis intestines will be fluid and gas filled with frequent motion. In contrast, in foals with a mesenteric volvulus or ileus the intestine is relatively motionless. The diagnosis of small intestinal intussusception is commonly made on US examination alone. A series of concentric circles are seen within each other, the so-called target lesions.

Plain radiography is an important diagnostic tool in foals with abdominal pain. This technique is often useful in diagnosing intraluminal obstructions, caused by things such as meconium, bedding, or sand (Fig. 17.14). A knowledge of normal radiographic findings is important for comparison (Fig. 17.15). It is also helpful in differentiating small and large intestinal disease. Obstructive small intestinal disease, such as a mesenteric volvulus or an intussusception, when advanced, will produce characteristic hairpin or stacked loops. A prominent small intestinal gas pattern is commonly seen with ileus or enteritis. Ileus can occur in prematurity, after birth asphyxia, or as a consequence to systemic sepsis or toxemia, and often can be difficult to differentiate from mechanical obstruction. Meconium impactions usually occur in the most distal segments of the intestinal tract and therefore frequently lead to colonic distention with gas. The condition appears to be more common in colts than fillies, and foals with a prolonged gestational period (>340 days) are at greater risk. Large intestinal volvulus occurs infrequently in newborn and young foals and, as with catastrophic small intestinal lesions, should result in a period of violent abdominal pain. However, signs of severe pain may not be evident in some foals with other concurrent diseases, such as overwhelming sepsis or hypoxic-ischemic encephalomyelopathy. Contrast radiography using barium sulphate is helpful in defining problems related to gastric-emptying, small intestinal obstructive diseases and, when administered as an enema, can be helpful in identifying impactions or congenital abnormalities, such as atresia coli. When given as an enema, up to 20 mL/kg of a 30% wt/vol suspension may be administered through a 24-French Foley catheter with an inflated cuff. Although not reported, rectal or colonic rupture could complicate the technique, particularly if the mucosa is inflamed and friable. For an upper gastrointestinal series, typically 5 mL/kg of barium sulfate is administered via a nasogastric tube and films are taken at times 0, 5, 15, 30, 150, and 270 minutes. An upper gastrointestinal contrast study should be avoided in foals with spontaneous gastric reflux or in foals with known small intestinal distention, as gastric rupture or aspiration of the contrast material could occur.

Congenital anomalies should be considered in all colicky newborn foals. Common abnormalities include atresia coli, atresia recti, and atresia ani. Plain radiography and digital examination of the anus and rectum will identify many of these foals. Contrast radiography may further identify others, hopefully avoiding the expense of exploratory celiotomy. White foals born to overo-overo or overo-tovero matings are at risk for intestinal agangliosis with or without atresia or stricture formation, so-called lethal white foals (Fig. 17.16). A careful digital examination in a young foal can provide key information including assessing patency of the anus and rectum. Fecal consistency can also be evaluated.

Peritoneal fluid evaluation is a useful adjunct to the diagnostic work-up of some foals with abdominal pain. The incidence and severity of complications associated with this procedure in foals are greater than that in adults. Therefore, fluid collection should not be routine but reserved for cases where

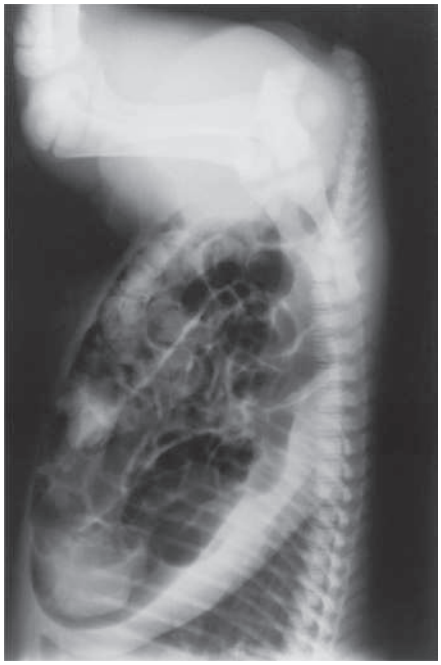

FIG. 17.14 Abdominal radiograph (lateral recumbency) of a 7-hour-old foal with atresia ani, showing meconium retention in a gas-filled large colon.

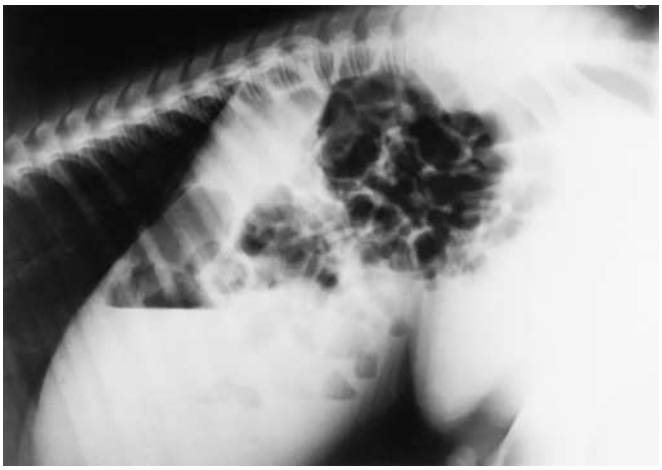

FIG. 17.15 Normal standing radiograph in a neonatal foal. Note the prominent fluid line in the stomach and presence of gas in various portions of the intestinal tract.

VetBooks.ir

the distinction between surgical and medical diseases is not clear. Complications can be minimized by identifying pockets of fluid using US and by using a blunt instrument, such as a bovine teat cannula. Hypodermic needles can cause laceration if the foal moves suddenly during the procedure but are safe and efficient where a large amount of fluid is present. The technique should be avoided, if possible, in conditions with extensive accumulation of large intestinal gas.

Specific Conditions

Meconium Impaction

Meconium impaction is the most common cause of the colic in the newborn foal. This condition is more common in colts due to the narrow pelvic canal. Many foals show some degree of straining and discomfort while passing meconium, but in most instances it is passed uneventfully by 24 to 48 hours of age. The meconium most commonly becomes impacted in the rectum or small colon. The clinical signs associated with meconium impaction in the otherwise normal foal include repeated attempts to defecate, straining with the back arched, swishing of the tail, and restlessness. Nursing stimulates defecation through an oral-rectal reflex, so signs of discomfort may appear shortly after each milk meal. If left untreated, meconium impactions lead to varying degrees of abdominal distention. The foal's abdomen becomes gas distended with tympany detected over the paralumbar fossa. Digital examination often reveals a rectum packed with hard fecal balls. Occasionally, the impaction is located more proximally (large or small colon) and radiography or ultrasonography is required for diagnosis.

Low doses of analgesics such as flunixin meglumine (0.25 to 1.0 mg/kg IV) and butorphanol (0.01 to 0.1 mg/kg IV) may be required to prevent self-trauma during colicky episodes. Xylazine may exacerbate gut stasis and can cause respiratory depression and should be used with caution in newborn foals. A gravity enema with mild soap and warm water or a commercial enema usually results in prompt evacuation of the meconium. Refractory meconium impactions may respond to 4% acetylcysteine retention enemas. The supplies and procedure for a retention enema are as follows: Mix together 150 mL water, 6 g of acetylcysteine powder, and 20 g of sodium bicarbonate (baking soda). Alternatively, commercial acetylcysteine solution (acetylcysteine [Mucomyst] solution, 100 or 200 mg/mL) can be used. Insert a well-lubricated 12- or 14-French, cuffed Foley urinary catheter into the rectum and inflate the cuff. Slowly infuse 120 to 180 mL of the retention enema solution. Plug the end of the catheter. Tape the catheter loosely to the foal's tail. Leave in place a minimum of 15 minutes and then deflate the cuff and remove the catheter. This procedure can be repeated several times. Care must be taken to avoid traumatizing the rectal mucosa by stiff tubing or multiple enemas with harsh detergents. Clinical signs associated with meconium impaction in the compromised foal may be absent. In asphyxiated or premature individuals that are receiving little or no enteral feeding, meconium may remain in the large colon for days, gradually forming into hard concretions that are diagnosed by palpation or radiographs or at postmortem examination. In these cases the routine administration of an enema is often ineffective in mobilizing the impaction because it is high in the large colon. Additional therapy includes IV fluids, oral fluids, and laxatives (60 to 120 mL of mineral oil with 0.5 to 1 oz of psyllium, 60 to 120 mL of Milk of Magnesia). If the gas distention becomes severe, transcutaneous bowel trocarization can be pursued. The author avoids the use of DSS as an oral cathartic because it can cause excessive irritation resulting in diarrhea and colic. Analgesics may also be helpful in controlling the neonate's discomfort and to reduce the risk of self-trauma. Although most meconium impactions can be successfully treated with aggressive medical therapy, those few foals that are refractory to treatment or display uncontrollable pain are candidates for surgical intervention.

Uroperitoneum

Uroperitoneum is a relatively common cause of abdominal distention and depression in the neonatal foal. The condition predominates in males but may occur in females as well. Uroperitoneum may be congenital or acquired. The congenital form occurs due to failure of the dorsal wall of the bladder to close during development. The most common cause of uroperitoneum is a ruptured urinary bladder, but other sites in the urinary tract may also leak, including the ureters, urachus, and urethra. Most cases of ruptured bladders are presumed to occur during parturition because of external pressure on a distended bladder. This form occurs most commonly in colts. Uroperitoneum can also occur secondary to ischemic necrosis or infection of the urinary bladder or urachus in the compromised foal. Critically ill, recumbent foals may rupture their bladders while being lifted and turned with a full bladder or from chronic overdistention associated with their generalized disease state. Foals with botulism may also rupture their bladder secondary to bladder atony and chronic overdistention. Older foals of either sex may experience bladder rupture secondary to focal infection of the umbilical arteries and/or urachus, or ischemic necrosis of the apex of the bladder.

Clinical signs of uroperitoneum are rarely noticed before 48 to 72 hours of age, particularly if the foal is not being watched closely. The first signs may be urinary incontinence or frequent attempts to urinate, with only small amounts voided. Sometimes, particularly in those animals that rupture sometime after birth, there is a history of a period of normal urination, which at some point stopped or became abnormal. Loss of suckle, mild colic, and increasing abdominal distention are usually accompanied by worsening depression and increasing heart and respiratory rate. If the condition is allowed to persist, foals become increasingly weak and dyspneic and may present in cardiovascular collapse. Fillies with ruptured ureters have been reported to have a characteristic protruding perineum, presumably as a result of retroperitoneal accumulation of fluid.[394]

Laboratory findings commonly associated with uroperitoneum are elevated serum creatinine and blood urea nitrogen, hyperkalemia, hyponatremia, hypochloremia, and metabolic acidosis. These changes are probably a result of the normal diet of the foal (milk being relatively high in potassium [25 mEq/L] and low in sodium [12 mEq/L]) and the third spacing of urine in the peritoneal cavity. With urine potassium concentration relatively higher than serum and urine sodium concentration lower than serum levels, the net effect of partial equilibration of serum with peritoneal fluid across a semipermeable membrane is hyponatremia and hyperkalemia, along with an inability to excrete the waste products of metabolism. Hyperkalemia may be severe enough to induce potentially fatal bradyarrhythmias. In hospitalized foals that developed uroperitoneum as a secondary complication, these typical electrolyte abnormalities are not consistently observed. Because most of those foals were receiving replacement intravenous fluids (high in sodium, low in potassium) and very little milk, it was theorized that intake has a great influence on the electrolyte abnormalities associated with uroperitoneum.[395] On the other hand, the electrolyte abnormalities typically associated with uroperitoneum are not pathognomonic for that disorder. Foals with renal failure, blocked urethra, white muscle disease, and enteritis have shown the same electrolyte changes.

A diagnosis of uroperitoneum often can be made quickly using transabdominal US and a 5- or 7.5-MHz transducer to visualize large volumes of free, nonechogenic fluid within the abdomen and a small, irregularly shaped, collapsed bladder. Abdominocentesis usually produces a free flow of peritoneal fluid that contains a low cell count, low specific gravity, and at

VetBooks.ir

least twice the creatinine concentration of peripheral blood. If the creatinine is the same in both serum and peritoneal fluid, other explanations for the clinical signs should be investigated. The WBC count, total protein, and cytology of the fluid should also be determined. Most uncomplicated cases of ruptured bladders have fairly normal values for peritoneal fluid. In some cases, however, an increased WBC count and total protein and the presence of bacteria may suggest peritonitis. This may be a result of the urine in the abdomen, but more commonly there is a primary ongoing infectious problem (necrotic urachus or bladder, enteritis) and the prognosis becomes worse. If laboratory facilities are not available, new methylene blue can be injected into the bladder using a urinary catheter, and a few minutes later a sample of peritoneal fluid should have a blue discoloration if a ruptured bladder is present. However, this technique may not detect other causes of uroperitoneum such as a ruptured ureter or distal urachus. Positive contrast cystography using a 10% solution of water soluble media may be helpful in detecting the location of the urinary tract leakage. The ability to obtain urine on catheterization of the urinary bladder does not rule out uroperitoneum. Hematology and blood cultures should be performed to detect primary or secondary sepsis.

Treatment of uroperitoneum is surgical repair. However, the foal with uroperitoneum should not be rushed to surgery without first carefully stabilizing it. Serum electrolytes and blood gases should be run to determine the extent of hyperkalemia, hyponatremia, and acidosis present. Although the total amount of water in the body is usually grossly increased by the peritoneal accumulation of urine, effective circulating volume may be drastically reduced. If the eyeballs are sunken and pulse quality and capillary refill time are poor, aggressive fluid therapy is indicated to support the circulation. This is best performed by concurrently removing as much fluid as possible from the abdomen with a teat cannula, 14G catheter, or peritoneal dialysis catheter to avoid worsening fluid overload and respiratory distress. The fluids of choice to treat the typical electrolyte alterations associated with uroperitoneum are saline, dextrose, and possibly sodium bicarbonate solutions, depending on the degree of acidosis present. In most instances continuous dextrose infusion is effective in decreasing the serum potassium level to an acceptable level, but values should be rechecked before anesthesia is induced. Insulin and dextrose may also be used to treat hyperkalemia, but the patient must be monitored for hypoglycemia. One suggested regimen is regular insulin at 0.1 to 0.2 U/kg subcutaneously or intravenously accompanied by a continuous IV dextrose infusion (4 to 8 mg/kg/min). Some individuals also have pleural fluid accumulation and atelectasis secondary to the abdominal distention, so oxygenation and ventilation during and after surgery should be closely monitored. Broad-spectrum antibiotics should be started immediately after samples are taken for culture if infection is suspected.

The prognosis for uncomplicated ruptured urinary bladders is usually good (>80% survival), provided the animal is stabilized before anesthesia. The presence of concurrent septicemia carries with it a considerably poorer prognosis.[395] In one retrospective study among foals with uroperitoneum, 100% of those foals with a negative sepsis score lived and only 57% of foals with a positive septic score survived.[396]

Gas or Fluid Accumulation in the Gastrointestinai Tract: Ileus

Abdominal distention and colic secondary to excessive gas and/or fluid accumulation in all or a portion of the gastrointestinal tract are common complications in the compromised neonate undergoing intensive care. The exact mechanisms responsible for the presumably altered GI motility are not well defined. Ileus is associated with the absence of intestinal sounds, abdominal distention, and intolerance of oral feeds characterized by gastric reflux. Auscultation of reduced gastrointestinal borborygmi does not always correlate with the degree of intestinal compromise and decreased motility. Transabdominal ultrasonography helps identify absence of intestinal motility and the location and degree of intestinal distention. Ileus and the attending abdominal distention can cause severe colic and can induce respiratory distress in a weak or premature foal with preexisting pulmonary compromise.

Metabolic and infectious causes of ileus in the foal include hypokalemia, hypocalcemia, hypoxic-ischemic bowel injury, bowel obstruction, peritonitis, enterocolitis, and endotoxemia. Hypokalemia is associated with anorexia, diarrhea, and renal loss. Hypocalcemia is associated with prematurity, decreased dietary intake, excessive bicarbonate administration, diuretic therapy, and those conditions such as asphyxia, toxemia, and sepsis that stimulate release of cortisol and catecholamines. Peripartum hypoxia results in a preferential decrease in blood flow to the gut and kidneys. Poor perfusion of the intestines leads to varying degrees of mucosal damage and decreased motility. Severely damaged bowel requires a period of gut rest to allow healing to occur before restarting oral feeds. Premature resumption of enteral feeding is associated with colic, maldigestion, diarrhea (often bloody), and translocation of intraluminal bacteria across damaged bowel wall into the bloodstream. Some of the more common causes of bowel distention in the neonate include meconium retention, intussusception, ascarid impaction, and small intestinal volvulus. Peritonitis may be associated with intraabdominal abscessation, severe enteritis or gastroduodenal ulcer disease, and generalized septicemia. The most common causes of enteritis in foals include rotavirus, *Clostridia* sp., *Salmonella* sp., and dietary changes. Endotoxemia is usually part of generalized septicemia. Chronic bowel distention, regardless of the cause, further impedes return of normal gut motility. In the foal, aerophagia, particularly in the struggling or hypoxic neonate, often results in gas distention that is not easily removed through a nasogastric tube, since gas tends to move quickly through the GI tract. Abdominal distention is also commonly observed during mechanical ventilation in the foal and as a result of overfeeding in the calf. Foals with botulism are often intolerant of enteral feeding, probably because of altered gastrointestinal motility. Use of certain milk replacers can result in bloat, colic, and diarrhea, even in the apparently healthy orphan neonate. Discontinuation of or a decrease in the amount of enteral feeding and, if possible, increased activity of the patient usually results in resolution of the problem.

Abdominal radiographs reveal gas-distended loops of small or large intestine and may identify bowel obstruction. Sonographic examination permits evaluation of bowel wall thickness, peritoneal fluid volume and echogenicity, gut patency, intramural gas accumulation, location and degree of intestinal distention, and presence or absence of motility. An abdominal sonogram should be performed to rule out the presence of an intussusception or other obstructive lesion before initiating any prokinetic therapy.

Management of ileus includes nasogastric decompression, cessation or reduced volume and frequency of enteral feeds if gastric reflux is present, parenteral alimentation if enteral feeding cannot be maintained at a rate of at least 10% of BW/day, enema administration to relieve distal meconium or fecal retention, correction of any underlying electrolyte abnormalities, exercise for ambulatory foals, and judicious use of prokinetic agents. The gut atrophies without enteral feeding. Prokinetic drugs should not be used when bowel obstruction or compromised bowel integrity is suspected. Prokinetic agents that have been used include metoclopramide, bethanechol, and erythromycin. There have been anecdotal reports of small intestinal intussusception after prokinetic use in neonatal foals.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is a syndrome of acute intestinal necrosis that has been described in human infants

VetBooks.ir

and other species, including equine neonates.[397] The causes of NEC are not well defined, but predisposing factors include ischemic or hypoxic gut injury, the presence of intraluminal bacteria, and enteral feeding. Following gastrointestinal ischemia, mucosal cell metabolism diminishes and the protective mucous layer is lost. This allows enzymes to break down the mucosal barrier, and intraluminal bacteria can then invade and multiply within the bowel wall. Enteral feeding provides substrate for the bacteria. Abdominal signs include progressive abdominal distention, colic, ileus, and ascites. The condition may appear as a fulminant, rapidly progressive disease or progress at a much slower pace.[227]

Clinical signs associated with gut injury include ileus, gastric reflux, colic, lethargy, abdominal distention, and diarrhea. Reflux and feces may be positive for blood. Generalized sepsis often accompanies NEC. NEC should be distinguished from intestinal ileus secondary to other neonatal diseases, other surgical GI lesions, bacterial or viral enterocolitis, and intolerance to a milk diet. Ultrasonography may reveal intramural gas accumulation (Fig. 17.17). If intestinal perforation has occurred, pneumoperitoneum and septic peritonitis may also be noted.[227,397] Intestinal perforation is associated with a hopeless prognosis.

Hemoperitoneum

Hemoperitoneum is a relatively uncommon cause of abdominal distention in the large animal neonate. The most common structures responsible for the hemorrhage are the umbilical vessels and rupture of the liver or spleen secondary to trauma. Occasionally, other structures, such as a ruptured granulosa cell tumor, may bleed.[290] Depending on the cause and severity of the hemorrhage, clinical signs relating to hypovolemia and anemia may be mild or severe and appear shortly after birth or in the older foal. Diagnosis of hemoperitoneum is based on the retrieval of free-flowing blood on peritoneal tap and the detection of free fluid in the abdomen. Ultrasound examination may be of benefit in detecting the source of the bleeding. Of critical importance, regardless of the source of the hemorrhage, is prevention of hypovolemic shock, and intensive patient monitoring and intervention is often indicated. Whole blood replacement may be necessary. If an internally bleeding animal with an unstable cardiovascular system is rushed to surgery without prior stabilization, profound shock may occur and a poor outcome usually results.

FIG. 17.17 An ultrasound image demonstrating gas in the intestinal wall of a foal with necrotizing enterocolitis.

Umbilical Problems

The umbilicus contains a single umbilical vein, two umbilical arteries, the urachus, and vitelline vein remnant.[398] Guidelines for routine care of the umbilicus after birth are discussed in Chapter 16. The most common postnatal problem of the umbilicus is patency of the urachus. The urachus is the anatomic connection between the bladder and allantoic sac. During gestation the predominant flow of urine is through the urachus, but as gestation proceeds some urine will enter amniotic sac via the urethra. The urachus is closed at the time that the cord is broken. Excessive coiling of the umbilical cord during gestation may result in partial obstruction of the urachus with overdistention of the structure, thereby interfering with the normal process of involution when the cord is torn after birth. This is estimated to occur in around 6% of normal foals.[399] The structure may fail to close or reopen for a number of reasons, including cutting of the cord rather than tearing, infection, excessive handling, or weakness of the supporting abdominal musculature. The condition is a common complication in sick neonatal foals, particularly those that are mostly recumbent. Affected foals will typically dribble or stream urine from the umbilicus during urination. There may be excessive straining observed. Physical examination may reveal a moist umbilical stump. In a small number of foals a rent in the urachus occurs as it moves through the subcutaneous tissues, resulting in local swelling, that may be marked. If the tear in the urachus occurs intraabdominally, there will be uroperitoneum and in rare cases omentum may herniate externally through the urachal tear. Ultrasound is recommended, and a fluid-filled urachus is consistent with patency. The umbilical arteries and vein should be assessed for infection as an open urachus is a common finding in foals with umbilical remnant infections.[400]

Therapy for an uncomplicated patent urachus typically consists of conservative management, involving monitoring and frequent disinfection. Cauterization of the urachus using silver nitrate sticks or injection with procaine penicillin was once popular but appears to be used infrequently in recent times. Resection of the structure may be indicated if patency persists beyond 3 weeks of age.

When the umbilicus is enlarged and draining purulent material, infection is easily diagnosed. Many neonates may have a completely normal-appearing external umbilicus but have internal infection of the urachus, umbilical arteries, or vein. Ultrasound is the key tool to diagnose internal abnormalities of the umbilical structures. The umbilical area of neonates younger than 20 days of age with fever of unknown origin should be scanned, as well as any foal with suspected bone or joint infection. A description of normal US findings is described in Chapter 16.

The traditional approach was to surgically remove abnormal umbilical remnants if there were abnormalities detected on US or if the external umbilicus was enlarged and/or draining purulent material. The basis for this was to remove the potential for bacteremia with seeding of other structures, such as bone or joints. There is morbidity and cost associated with simple surgical removal, and there is little evidence that surgical excision is superior to long-term therapy with antimicrobial drugs. More recently, many clinicians favor long-term antimicrobial treatment with oral therapy, such as trimethoprim-sulfa combinations or minocycline. In this approach it is important to monitor responses to therapy using frequent US examinations. Surgical removal would be indicated if the internal appearance worsens in the face of medical treatment.

The Peripartum Ruminant

JOHN K. HOUSE, *Consulting Editor*

Peripartum mortality is a common cause of loss across livestock industries.[1] The peripartum period is high risk for both fetus and dam. Approximately 5% to 10% of the annual calf crop and 15% to 20% of the annual lamb crop in the United States die before weaning.[2-4] Between 50% and 70% of neonatal mortality occurs in the first 3 days of life with dystocia, starvation, and hypothermia responsible for 50% to 60% of these losses.[3,5] The incidence of dystocia is particularly high in Holsteins with reports of 50% of heifers and 30% of cows requiring calving assistance.[6] The risk of neonatal morbidity and mortality is largely influenced by sire selection (calving ease), maternal management, and subsequently maternal health during the peripartum period.

Late-Term Complications of Gestation

Uterine torsion, vaginal prolapse, hydrops allantois, hydrops amnii, and metabolic disorders are disorders of pregnancy and the peripartum period that negatively affect the health of the dam and fetus during late gestation. Over the past 15 years, there has also been increasing application of advanced reproductive technologies with the production of in vitro and cloned embryos. The initial application of these methods was associated with a higher incidence of complications during pregnancy and neonatal mortality. Improvements in embryo production techniques haves reduced the incidence of complications.

Uterine Torsion

Uterine torsion is more common in cattle than other domestic species. The exact etiology is unclear with most occurring during late first-stage or early second-stage labor.[7] Proposed risk factors include poor maternal muscle tone, strong fetal movement, and reduced rumen fill. Retrospective studies have reported no significant seasonal effect, a higher incidence in Brown Swiss cows, and a lower risk in Hereford, Angus, and Jersey cows compared with Holstein-Friesians.[8] Calf birth weight is typically above average, and a greater proportion of fetuses are male (63%).[8] The incidence is also significantly higher in cows as compared with heifers.[7]

Clinical signs associated with uterine torsions include fever, tachycardia, tachypnea, straining, anorexia, and vaginal discharge.[8] The diagnosis of uterine torsion is based on a history of advanced pregnancy and the presenting clinical signs. On transrectal palpation, the orientation of the broad ligaments is distinctly altered; depending on whether the torsion is to the left or the right, the respective broad ligament is pulled tightly across the uterus.[9] Approximately 60% of torsions involve the vagina, and spiral folds can be palpated per vagina.[9] Most torsions are to the left (counterclockwise); in general, the uterus rolls toward and over the nongravid horn (≈60% of all pregnancies in the cow are in the right horn).[9] Forty-five to 90-degree torsions are uncommon; 20% are 90 to 180 degrees, 57% are 180 to 270 degrees, and 22% are 270 to 360 degrees.[8] With severe torsion, circulation is compromised. Treatment involves correction of the torsion and delivery of the calf. In a retrospective study of 164 cases, vaginal delivery was possible after manual correction (20%) or rolling of the cow (18%). Cesarean section was performed immediately in 35% of the cases, after failed detorsion attempts in 7% and due to failure of the cervix to dilate following successful correction of the torsion in 20%. When manually manipulating the fetus per vagina, it sometimes helps to have a person assist by pushing on the calf externally. The prognosis for fetal survival rate influenced by duration of parturition before intervention with calf survival is around 35% when the duration is longer than 12 hours and 80% to 90% when parturition has progressed for less than 12 hours.[10] Often the duration of parturition is unknown. The presence of intact fetal membranes has also been associated with a better prognosis for calf survival, with 70% survival when membranes are intact versus 25% survival when fetal membranes are not intact.[11]

Vaginal Prolapse

The primary predisposition to cervicovaginal prolapse in cattle is elevated plasma estrogen concentrations during late gestation.[9] The higher prevalence in certain beef breeds implies a genetic predisposition, with Bos indicus, Herefords, Charolais, Limousin, and Shorthorns affected more frequently than other breeds.[12-14] Other factors that contribute to the risk of vaginal prolapse include increased intraabdominal pressure in late pregnancy, obesity, and poor vaginal conformation. The pathogenesis and development of vaginal prolapse is progressive; it starts with exposure of some of the vaginal mucous membrane. The prolapsed mass moves in and out as the cow gets up and lies down. Exposed mucosa dries out and becomes irritated, leading to straining and further prolapse. The prolapsed tissues become edematous, leading to circulatory impairment and swelling. Ultimately, the cervix and occasionally the bladder may become involved.[9] The objective of treatment in the case of pregnant animals is to replace and retain the vagina within the pelvic canal and to deliver a live calf. Numerous treatment options are described for vaginal and cervical eversions.[14] These methods include suturing the vulva (caslick, Bruhner's), vaginopexy (Minchef procedure), or cervicopexy (Winkler procedure). Close observation of the cow

VetBooks.ir

for signs of impending parturition is required after suture of the vulva. Failure to release the sutures before parturition can lead to severe laceration of the vulva and potentially the death of the calf. If the patient is close to parturition, induction is recommended to expedite the process and prevent recurrence before parturition. As vaginal prolapse is likely to recur during the next pregnancy, it is recommended that the cow be culled when the calf is weaned.

Ring Womb

Ring womb, or incomplete dilation of the cervix, causes sporadic dystocia in sheep and goats. It is most commonly observed in sheep and may be heritable in some instances.[15] Ring womb has no predisposition associated with breed, age, or body condition score but is associated with a significantly higher lambing percentage.[15] Correction with gentle manual stretching can be attempted. The use of prostaglandin E_2, administered as an intracervical gel in the treatment of ring womb in ewes, is not effective at causing dilation of the cervix.[16] Due to the significant risk of tearing, a cesarean delivery is often required.[17] Ewes with diseases that cause abortion due to infectious agents may exhibit signs similar to ring womb, as can pregnancy toxemia, consumption of poisonous plants, consumption of estrogenic plants, and lasalocid toxicity.[17]

Early Dilation Syndrome

Early dilation syndrome is a condition of sheep that is similar to but considered separate from ring womb. In early dilation syndrome, incomplete dilation of the cervix occurs approximately 7 to 14 days before term. The ewe has little or no udder development or a sudden overnight blooming of the udder and placental membranes protruding when presented. The cervix usually can be dilated by hand, but the lambs, although born alive, are not viable. The syndrome occurs most frequently in ewe lambs and first-lambing 2-year-olds, but occasionally in older ewes. Affected flocks can have higher than 30% morbidity. The syndrome occurs in all breeds and flock management situations. No common link has been found from nutritional, physiologic, toxicologic, or infectious disease investigations.[17]

Hydropic Conditions

Fetal loss associated with abnormal placentation occurs sporadically and is reflected by alterations in volume and composition of allantoic and amniotic fluid. In a study of 60 cases of bovine hydrops, 88% were hydrallantois, 5% hydramnios, and 7% a combination of both.[18] Hydrallantois is often associated with disease of the uterus and hydramnios with genetic or congenital defects of the fetus (Dexter cattle with bulldog calves, Angus calves with osteopetrosis, Guernsey calves with pituitary hypoplasia or pituitary aplasia).[19]

Hydrops Allantois (Hydrallantois)

Hydrops allantois is a sporadic condition of cattle in which there is progressive, excessive accumulation of allantoic fluid. Accumulation of allantoic fluid from midgestation is associated with placental dysfunction.[9] Placental dysfunction is characterized by a reduced number of placentomes (normal 75 to 100) and the development of more primitive villous placentation.[20] An increased incidence of hydrops allantois has been reported with pregnancies derived from in vitro–produced embryos. In a comparative study of in vitro fertilization (IVF) and artificial insemination (AI)–derived pregnancies, the percentage of cows with hydroallantois was 1.8% and 0.07%, respectively.[21] A herd outbreak of hydrops allantois has also been associated with severe nutritional deficiency.[9] Allantoic fluid volume may exceed 100 L (normal 8 to 15 L near term), leading to rapid abdominal enlargement. Rectal examination reveals tight distension of the uterus. The fetus and placentomes are not palpable due to the tightness of the uterine wall. Affected cows become anorectic, leading to dehydration, constipation, and eventually recumbency.

The concentration of sodium and chloride in allantoic fluid of cattle during the last 12 weeks of gestation is normally low (Na = 52 ± 20 mmol/L and Cl = 17 ± 11 mEq/L) and the concentration of creatinine is high (1224 μg/mL ± 458).[22] With hydrallantois, allantoic fluid sodium and chloride concentrations rise toward extracellular fluid concentrations (Na = 116 ± 13 and Cl 81 ± 12 mEq/L) and allantoic creatinine concentration decreases (193 ± 73 μg/mL).[22] Normal amniotic fluid has electrolyte concentrations similar to plasma (Na = 132 ± 7 and Cl 115 ± 8 mEq/L) and a lower creatinine concentration than allantoic fluid (70 ± 26 μg/mL).[22] Cows with hydrallantois are also often hyponatremic and hyperglycemic.[18,23]

Due to the poor prognosis, salvage slaughter is generally recommended. Parturition can be induced if the cow is reasonably close to term and is recommended for the salvage of the calf. Attempts at medical management of affected cows include slow decompression and supportive fluid therapy. The grossly distended uterus is slow to involute and prone to severe metritis. The prognosis for future fertility is guarded.

Hydrops Amnii (Hydramnios)

Hydramnios is rare, accounting for 5% to 10% of uterine dropsy cases.[24] It has been associated with a genetic (autosomal recessive) or congenitally defective fetus in which swallowing is impaired and the amount of amniotic fluid gradually increases over several months.[24] It may affect only one of twin fetuses.[9] Normal amniotic fluid volume at parturition is about 4 to 8 L. Cattle with hydrops amnii may accumulate 20 to 100 L of amniotic fluid.[25] The slowly progressive accumulation of fluid during the latter half of gestation means that the abdominal muscles become stretched and the cow develops the typical "pear-shaped" abdomen. In contrast to the situation with hydrallantois, placentomes and often the fetus are palpable per rectum. The prognosis for the life and future fertility of cattle that have hydramnios is good.[25] The fetus itself is invariably defective and will not be viable. If the owner elects to keep the cow, the genetic implications should be considered. Clinical features that distinguish hydrops amnii and hydrops allantois are presented in Table 18.1.

Abnormal Offspring Syndrome

The transfer of bovine embryos produced and manipulated in vitro results in abnormalities in some conceptuses, foetuses,

TABLE 18.1

Differential Diagnosis Between Hydrallantois and Hydramnios in Cattle[9]

Characteristic	Hydrallantois	Hydramnios
Prevalence	85%-95%	5%-15%
Rate of development	Rapid (within 1 month)	Slow over several months
Shape of abdomen	Round and tense	Piriform, not tense
Transrectal detection of placentomes and fetus	Nonpalpable (tight uterus)	Palpable
Gross characteristics of fluid	Watery, clear, amber-colored transudate	Viscid, may contain meconium
Fetus	Small, normal	Malformed
Placenta	Adventitious	Normal
Refilling after trocharization	Rapid	Does not occur

placentas, and offspring.[26,27] The term *abnormal offspring syndrome* is used to describe the range of abnormalities observed.[28] The exact etiology of the syndrome is uncertain, although developmental abnormalities of the fetus, placenta, and offspring have been predominantly attributed to the presence of serum in the culture medium.[29] In utero manifestations include prolonged gestation; abnormal placental development (placentomegaly, hydroallantois, and edematous placentomes in reduced numbers); and suboptimal embryonic and fetal survival.[20,30] Increased birth weight and incidence of dystocia, congenital deformities, and perinatal mortality are neonatal manifestations of this syndrome. The incidence of abnormal offspring syndrome has declined with refinement of IVF culture systems. There is increasing research focused on the epigenetic effects of assisted reproductive technologies, such as sex sorting and IVF on adult health and production phenotypic expression.[31]

Calves derived from somatic cell nuclear transfer, "cloned calves," have a high incidence of respiratory disease during the neonatal period.[32,33] Possible causes of compromised respiratory function include hypoventilation, ventilation perfusion mismatch, right-to-left shunt resulting from persistent fetal circulation, and respiratory distress syndrome resulting from inadequate surfactant production. Nasal insufflation at birth is recommended to support the respiratory function of cloned calves.[32] In vitro–produced calves are also more frequently born with enlarged umbilical structures. Hemorrhage must be controlled at birth and navels monitored to prevent and manage navel infections.[33]

Maternal Nutrition

Maternal nutrition has epigenetic effects on the developing fetus, influencing postnatal growth, productivity, and reproductive performance.[34] Phenotypic effects are exhibited when stimuli occur during critical development periods, such as during ovarian meiosis, folliculogenesis, and hypothalamic-pituitary axis development.[35]

Reduced fetal viability often reflects mismanagement of maternal nutrition during the last trimester of pregnancy and/or during the prepartum and peripartum period. Maintenance of adequate nutrition throughout pregnancy is essential to provide for the growing fetus and to maintain a healthy dam capable of delivering and nursing the fetus. Pregnancy toxemia, hypocalcemia, protein energy malnutrition, micronutrient deficiencies, and obesity may all impair the health of the fetus directly or indirectly by affecting the health or capacity of the dam to deliver the fetus.

Underfeeding of energy (40% to 70% of requirements)[36] or protein (65% of requirements)[37] during late gestation in beef cattle produces calves that are less able to generate heat to maintain body temperature after birth. This effect was observed despite no significant difference in birth weight.[36,37] The fetal response to growth-restrictive environmental conditions is to partition nutrients toward the development of organs essential to life, such as the brain, at the expense of less vital organs and tissues.[38,39] In humans the repartitioning of nutrients to support fetal development has been demonstrated to have long-term effects on postnatal growth and metabolism, apparent as an increased propensity to develop insulin resistance, high blood pressure, more rapid weight gain, and increased adiposity.[40] Similarly, nutrient restriction during gestation has been demonstrated to alter postnatal glucose metabolism in calves.[41] The consequences of overnutrition during gestation on the developing fetus are less clear. A number of overfeeding trials have resulted in increased birth weight, whereas others have not.[42,43] Maternal consequences include deposition of fat in the pelvis, which increases the risk of dystocia and subsequently fetal compromise.[44]

For high-producing dairy cows, good nutritional and cow management during the transition period is pivotal for maintaining cow health. Hypocalcemia and negative energy balance contribute to the risk of dystocia and subsequently the risk of neonatal morbidity and mortality.[45] Recently there has been a paradigm shift in the thinking regarding the nutrition of nonlactating cows before calving. Previously the focus has been on increasing the amount of energy in the ration fed to cows during the last 3 to 4 weeks before calving to meet the increasing energy needs associated with pregnancy in the face of the cows declining dry matter intake.[46] Paradoxically, overfeeding energy during the dry period has been found to contribute to negative energy balance postpartum and an increased incidence of disease in the peripartum period.[47] This phenomena appears to be associated with increased insulin resistance similar to type II diabetes. The current recommendation is to feed cows throughout the nonlactating period a ration that meets but does not exceed caloric needs. Straw is added to the ration to promote rumen health and prevent overeating.[45]

In regards to trace minerals, selenium and copper deficiency may contribute to neonatal morbidity and mortality. Copper deficiency has been associated with impaired fertility, weak calves, and high calf mortality.[48] In a larger Canadian study, myopathy and cardiomyopathy were common findings in stillborn and neonatal mortality, suggesting the possible contribution of nutritional myopathy.[49]

Investigation of perinatal morbidity and mortality should begin with assessment of maternal management. Some of the more common causes of stillbirth and perinatal mortality are listed in Box 18.1.

Environmental Management

Environmental stress before or around the time of parturition may also compromise the fetus or neonate. Heat stress impacts fetal viability by impeding calf growth in the last trimester of pregnancy[50] and by depressing colostral quality[51] and immunoglobulin transfer.[52] Uterine blood flow and placental mass are reduced, and endocrine profiles are altered when cattle are heat stressed during the last trimester of pregnancy. Heat stress during the last 3 weeks of pregnancy lowers dry matter intake, contributing to a negative energy balance at this time, promoting mobilization of body fat and ketogenesis. Transfer of immunoglobulins to colostrum is impaired, and the concentration of protein, casein, lactalbumin, fat, and lactose in colostrum is reduced.[51] Cold, windy, and wet conditions also adversely affect calf survival. The magnitude of the effect of climate on neonatal survival depends on the age of the dam, sex and size of the calf, and on the incidence of dystocia in the herd.[53] Cold stress sufficient to cause hypothermia in calves leads to subcutaneous hemorrhages and delayed absorption of colostral immunoglobulins.[54]

Assessment of Fetal Viability

Fetal viability is rarely evaluated during the prepartum period in production animals but is a serious consideration when the prepartum dam is diseased or debilitated. Assessment of fetal viability is diagnostically challenging, but a number of methods are available to evaluate the fetus and fetal environment. During the physical examination of cattle, uterine blood flow, uterine tone, and presence of a vaginal discharge may be evaluated via rectal palpation and a vaginal speculum examination. Reduced fremitus in the uterine arteries and increased uterine tone may be appreciated by rectal palpation following fetal death. Abdominal ultrasound is useful for examining the uterus, placenta, and fetuses of small ruminants.[55] When the gestational age of the fetus is known, it is possible to detect fetal growth retardation using ultrasound by measuring abdominal circumference and femur and tibial length.[56] Examination of the fetus may detect gross congenital abnormalities, and ultrasound of the fetal chest allows visualization of a beating heart and determination of fetal heart rate. The normal heart rate of full-term lambs is 108 to

126 beats per minute (bpm).[57] Following fetal death, some of the following may be observed: absence of fetal heartbeat, thickening of the uterine wall, increased echogenicity of chorioallantoic and amniotic fluid, altered fetal posture and definition, altered contour of the amnion, and reduced definition and ultimately reduced size of the caruncles.

The uterus and placenta of cattle can be examined by transrectal ultrasound; however, examination of the fetal calf via transrectal or transabdominal ultrasound is often compromised by limited access. Fortnightly ultrasound of the uterus and placenta of recipient cows carrying cloned calves is conducted to detect evidence of hydroallantois and placental edema in these high-risk pregnancies.[58] The absence of fetal heart beat is a specific sign of fetal death. The presence of large quantities of echoic particles in uterine fluids is also a sign of fetal distress or death. Fetal hyperactivity or inactivity over a 30-minute period of examination suggests fetal compromise.[59] Repeated examinations are required since hyperactivity or sleeping periods have been infrequently observed in other species, and the criteria for this classification is based on limited observations in cattle.[60] Measuring the heart rate of fetal calves is more difficult than small ruminants but can be achieved via transabdominal Doppler using a 1.5-Mhz probe. The normal heart rate of full-term calves is 90 to 125 bpm.[61] In human medicine, fetal heart rate is used as a measure of fetal viability. Fetal heart rate accelerations associated with fetal movement are considered a sign of fetal well-being, and persistent bradycardia or tachycardia is a sign of fetal stress.[62] Normal fetal heart rate patterns of ruminants need to be characterized in more detail before fetal heart rate measurements are used for prenatal clinical assessment of ruminant fetal well-being.[60,63]

Estrone sulfate is a marker of a viable fetoplacental unit and has been used to assess fetal viability in cattle.[64] Estrogen synthesized by embryonic tissue is converted to estrone sulfate by the endometrium, which contains the enzyme sulfotransferase. Estrone sulfate assays can be used to diagnose pregnancy in small ruminants after 50 days[65] and in cattle after 100 days.[66] Estrone sulfate may be measured in plasma or milk,[50,66] and baseline values are low after fetal loss, regardless of the stage of pregnancy. Compromise of the fetoplacental unit reduces estrone sulfate production. In a study of the effects of heat stress on pregnant cattle, plasma estrone sulfate concentrations were significantly lower throughout pregnancy in cows that gave birth to low-birth-weight calves.[50] Plasma concentrations of estrone sulfate rise slowly during the second trimester of pregnancy from 0.74 ng/mL to 3.66 ng/mL from day 90 to day 210 of pregnancy. The last trimester of pregnancy is associated with a rapid rise in the concentration of estrone sulphate to 13.36 ng/mL around 10 days before parturition.[67]

In human medicine, diagnosis of surfactant deficiency is based on the ratio of two phospholipids in amniotic fluid, lecithin (L) and sphingomyelin (S). If the L/S ratio is greater than 2.0, the surfactant system is mature and respiratory distress syndrome is rare.[68] The L/S ratio in amniotic fluid collected from cattle may also be used to assess surfactant system maturity,[69] providing a measure of readiness for birth, but is rarely employed in clinical veterinary medicine. Crude surfactant harvested from bovine lungs at a slaughterhouse has been used

intratracheally with calves that appeared to be in respiratory distress shortly after birth.[70]

Induction of Parturition

Manipulation of parturition may be considered for maternal, fetal, or management reasons. Fetal viability following induced parturition is variable between species. The viability of calves induced within 14 days of anticipated calving date is good.[71] Viability of lambs and kids induced greater than 5 days before anticipated parturition date is poor.[19] Absorption of colostral immunoglobulins by premature calves is reduced, so colostral transfer should be monitored closely in induced neonates.[72] Induction of parturition or cesarean section is often necessary to prevent mortality of small ruminants with pregnancy toxemia.[73] Fetal viability is often improved by induction of parturition with dexamethasone, yet delivery of the fetuses via cesarean section is often necessary due to the debilitated state of the dam. Secretion of glucocorticoid hormones from the adrenal cortex increases markedly during the final days of gestation. The prenatal increase in fetal glucocorticoid secretion plays an important role in the cascade of endocrine events leading to parturition and stimulates maturational events in the lungs, liver, kidney, and gastrointestinal tract in preparation for postnatal life.[74]

Steroids stimulate production of surfactant phospholipids by alveolar type II cells, enhance the expression of surfactant-associated proteins, reduce microvascular permeability, and accelerate overall structural maturation of the lungs.[75] Administration of flumethasone (10 mg) or dinoprost (25 mg) to pregnant cows 30 hours before elective cesarean section increases the lecithin–to–sphingomyelin ratio, improving lung function and reducing complications associated with respiratory acidosis in the calf.[76] Induction of parturition has been used to reduce the incidence of dystocia in herds or breeds experiencing a high incidence of dystocia associated with fetomaternal disproportion.[77] Large birth weights are strongly correlated with fetomaternal disproportion.[78,79] Induction of parturition within 14 days of anticipated calving date is associated with good calf viability and a 3.2-kg reduction in birth weight of beef calves.[71]

Exogenous glucocorticoids, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), or a combination may be used to induce parturition in cattle (dexamethasone 20 to 30 mg alone or in combination with 25 mg of $PGF_{2\alpha}$), sheep, and goats (10 to 20 mg dexamethasone and or 15 mg $PGF_{2\alpha}$).[19] Glucocorticoids are more effective than prostaglandins for inducing parturition in sheep.[80] A lower incidence of dystocia and higher viability of calves has been reported in cattle induced with glucocorticoids compared with cows induced with prostaglandins.[81] Cows treated with dexamethasone or prostaglandin within 14 days of anticipated calving date usually calve within 72 hours of treatment.[71] Combination of dexamethasone with prostaglandin increases the efficacy and reduces the interval to parturition (36 hours).[82,83] Retention of fetal membranes is a common complication of induced parturition in cattle.[84] Induction of parturition with dexamethasone causes a failure of immune-assisted detachment of fetal membranes and the accompanying release of chemotactic factors.[85] Retention of fetal membranes may be associated with reduced first service conception and subsequent pregnancy rates.[86] Treatment of cows with prostaglandin at calving was reported to reduce the incidence of retained fetal membranes,[87] but subsequent studies have failed to support this.[82,88] Induction of cattle by administration of 25 mg/cow of triamcinolone (Opticortinol, Scharwoude, The Netherlands) at day 270 followed by treatment with dexamethasone and prostaglandin 6 days later appears to reduce the incidence of retained fetal membranes associated with induction.[84,89] Where calving induction is used to align calving patterns to pasture availability, cows are induced to calve at around 7 months' gestation. Induced cows have increased rates of mastitis, metabolic disease, and retained placenta[90,91] and have reduced milk production in the lactation of treatment.[92,93] Calves born to cows induced at 7 months' gestation are often stillborn, die, or are subject to euthanasia shortly after birth because they are too weak or suffer from other neonatal diseases.[94,95] This management practice was historically used in seasonal pasture–based New Zealand and Australian dairy production systems. It is now banned in New Zealand and is being phased out in Australia.

Perinatal Adaptation

At birth the fetus must successfully make a series of structural and physiologic changes to survive. Perinatal mortality is often attributable to cardiovascular, pulmonary, thermoregulatory, or metabolic physiologic abnormalities. Dystocia and severe birth asphyxia compromises physiologic transitions, increasing the risk of neonatal mortality. Compromised neonates that survive the birth process are less likely to consume adequate colostrum and are subsequently more likely to die of hypothermia and infectious diseases.

The placenta functions as the respiratory organ of the developing fetus, and efficiency of oxygen transfer to the fetus is increased by the high oxygen affinity of fetal versus adult hemoglobin.[96] In utero the potential spaces of alveoli and the tracheobronchial tree are distended with fluid secreted by pulmonary tissue.[97] Oxygenated blood is delivered to the fetus via the umbilical vein, which anastomoses with the portal vein near the liver, and approximately two thirds of the blood flow is shunted via the ductus venosus directly into the caudal vena cava.[98] The caudal vena cava drains into the right atrium, where over 50% of the volume shunts directly into the left atrium via the foramen ovale.[98] The relatively hypoxic in utero environment causes constriction of pulmonary vessels and dilation of the ductus arteriosus.[98] Because pulmonary arterial resistance is higher than systemic arterial resistance, nearly 70% of pulmonary artery flow is shunted via the ductus arteriosus into the aorta, with the remainder perfusing the lung.[99] Left ventricular output is distributed to the systemic circulation via the aorta. Two umbilical arteries arise from the aorta in the region of the last lumbar vertebra to carry predominantly venous blood back to the placenta via the umbilicus.

At birth some of the lung fluid is evacuated through the trachea during spontaneous delivery.[100] When the umbilicus ruptures, asphyxia triggers reflex gasping, respiratory movements, and increased peripheral vascular resistance.[99] The majority of lung fluid is absorbed through alveolar walls in the initial stages of ventilation.[100] This mechanism is prompted by activation of adrenaline-mediated α-adrenergic receptors in the pulmonary epithelium.[101] The rapidity of lung fluid absorption by the body is optimized at thoracic pressures between 35 and 40 cm H_2O.[100] Pulmonary ventilation reduces pulmonary vascular resistance, promoting perfusion of the ventilated alveolar tissue.[98] The increased O_2 saturation of blood stimulates closure of the ductus arteriosus within 4 to 5 minutes of birth.[99] The foramen ovale functionally closes within 5 to 20 minutes of birth when increased pulmonary venous return raises blood pressure in the left atrium, reversing the right to left shunt.[99] The septum secundum, a thin fold of tissue that lies in close apposition to the foramen, acts as a valve closing the opening. Healthy calves have mean pulmonary arterial pressures ranging from 40 to 82 mm Hg immediately after birth, declining to 22 to 25 mm Hg by 2 weeks of age.[102] Systemic arterial pressure is approximately 100 mm Hg, and arterial saturation is greater than 90%.[98] Transient mild metabolic and respiratory acidosis are observed following rupture of the umbilical cord due to anaerobic glycolysis in poorly perfused tissues during the transition between placental oxygen delivery

and establishment of respiratory function. The mild acidosis is normally corrected within 1 to 4 hours of birth.[103] Anatomic closure of the foramen ovale and ductus arteriosus may take several weeks.[99] Normal blood gas values for the calf during the immediate postpartum period are presented in Table 18.2.

Dystocia is commonly associated with prolonged hypoxia and acidosis. Hypoxia and acidosis maintains constriction of pulmonary arterioles, and the subsequent maintenance of high pulmonary vascular resistance favors continuation of in utero right to left vascular shunts, which contributes to systemic hypoxia. Following dystocia, neonates are less active, slow to stand, slow to nurse, and prone to hypothermia and hypogammaglobulinemia. The normal duration of stage 2 labor (from appearance of fetal membranes at the vulva to delivery of the fetus) in ruminants is generally shorter in multiparous animals (≈30 minutes) than primiparous animals (≈60 minutes).[104] Fetal viability is improved with early intervention; multiparous animals should be assisted after 30 to 60 minutes of stage 2 labor and primiparous animals after 60 to 90 minutes.[79]

The range in ambient temperatures over which newborn animals are able to maintain homeothermy is much narrower than growing or adult animals. Neonates are more susceptible to fluctuations in environmental temperature due to their large surface area to mass, evaporation of amniotic fluid, and limited caloric reserves. Starvation and hypothermia is the second leading cause of death of neonatal lambs.[3] Neonatal mortality increases with decreasing ambient temperature and with increasing precipitation on the day of birth.[53] Thermoneutrality is maintained by shivering and metabolism of brown adipose tissue. Normally at birth, blood glucose concentration in calves ranges between 50 and 60 g/dL, rising to 100 mg/dL within the first 24 hours of life.[98] Lambs born in warm weather can survive for up to 4 days without supplemental nutrition. Severe weather stress may increase energy requirements by 500% and deplete the energy reserves of newborn lambs in 6 to 16 hours.[105] Starvation exacerbates the effects of environmental stress by reducing the available substrates for heat production, and energy depletion leads to hypoglycemia. Administration of glucose to hypothermic neonates before and during warming is important to avoid deaths from cerebral hypoglycemia induced by increased utilization of glucose by peripheral tissues.[106] Warming hypothermic lambs by immersion in 38° C water is more efficient than infrared lamps or wrapping the lamb in a cotton cloth.[107]

No intrauterine transfer of immunoglobulin occurs in ruminants; hence, at birth, neonatal ruminants are agammaglobulinemic and immunologically naive. Infectious disease is the leading cause of morbidity and mortality in calves greater than 3 days of age.[108] Failure of passive transfer increases the risk of neonatal mortality.[109] Colostrum provides a concentrate source of energy and immunoglobulins. Immunoglobulins are concentrated in colostrum by an active, receptor-mediated transfer of IgG_1 from the blood of the dam across the mammary gland secretory epithelium beginning several weeks before parturition.[110] Colostral IgG_1 concentrations may be 5 to 10 times the maternal serum concentrations. IgM, IgA, and IgG_2 concentrations in colostrum are much lower.[111] The large numbers of leukocytes also contribute to providing passive immunity to the newborn.[112] Methods of assessing passive transfer and management of failure of passive transfer are discussed in detail in Chapter 19.

Dystocia

Forty to sixty percent of stillbirths are associated with dystocia. Calves that survive dystocia are more likely to have edema of the head and tongue, making suckling difficult. They are also weak and exhausted and likely to be recumbent for a longer period of time and expose themselves to more fecal pathogens.[113] Dystocia affects the uptake of immunoglobulins by the calf, and calves that survive dystocia are more likely to become sick in the first 45 days of life.[114] Maternal variables correlated with dystocia and consequently calf mortality at birth include parity and conformation. Dystocia and stillbirths in heifers is most commonly secondary to fetopelvic incompatibility. Fetopelvic incompatibility accounts for a lower proportion of dystocias in multiparous cows, but weak labor secondary to hypocalcemia, uterine torsion, and incomplete cervical dilation are more common in older cows.[44] The prevalence of stillbirths in dairy herds globally is reported to be increasing.[1] In the U.S. dairy industry the incidence is currently 8% (11.3% in primiparae and 5.3% in pluriparae).[115] Dam pelvic diameter is an important determinant of dystocia for heifers.[116] Pelvic measurements can be used to identify abnormally small or abnormally shaped pelvises. Large frame size of the dam correlates with a reduced risk of dystocia; however, continued selection for large frame size tends to select for larger birth weight and dimensions of calves.[117] Age at first calving for heifers is not correlated with risk of dystocia as long as heifers are fed and managed to achieve appropriate growth and stature before calving.[118-120] The risk of dystocia in heifers is increased by poor nutrition in the last trimester.[121] Appropriate nutrition and management of replacement heifers to achieve appropriate size and stature at parturition reduce maternal and neonatal losses by reducing the incidence of dystocias. Maternal consequences associated with calving difficulty and delivery of a stillborn calf include decreased milk production and reduced reproductive efficiency. Reductions in milk production ranging from 100 to 400 kg have been reported to be associated with the birth of a stillborn calf. If the stillborn calf is delivered by cesarean section, the reduction in milk yield is on the order of 300 to 500 kg.[122] Delivery of a stillborn calf is also associated with depressed conception rates, increased services per conception, and delayed conception.

Use of calving ease bulls over primiparous cows helps to reduce the incidence of dystocia and subsequently mortality during parturition. The heritability of calving ease is relatively low; estimates of maternal calving ease range from 0.03 to 0.24,[44,123,124] and paternal heritability is around 0.147. Despite the relatively low heritability of calving ease, selection for calving ease should not adversely affect other production parameters in dairy cattle as the genetic correlation between calving ease and other dairy production traits is generally close

VetBooks.ir

to 0.[44] Calving ease evaluations are intended to increase the use of AI for heifers. To facilitate sire selection, most breed associations provide guidelines regarding calving ease or expected progeny difference for calf birth weights. An example of such a scheme is the calving ease and reliability values assigned to AI Holstein bulls. In this system the calving ease score is the expected percentage of difficult births predicted for calves delivered by primiparous cows.[125] The reliability score provides an indication as to the number of births that were considered in deriving the calving ease score. The higher the reliability score, the larger the number of observations the calving ease score is based on and the more likely it is that the calving ease prediction will accurately reflect the outcome.

Management variables that influence the risk of dystocia and perinatal mortality include stocking density of preparturient cows, timing of calving, and cow grouping. In a study of 123 beef herds, the dystocia rate was highest for cows housed in a barn and decreased progressively through barn/yard, barn/pasture, and pasture-only calving location categories.[126] The most common cause of dystocia in penned heifers was vulvar constriction, while dystocias in paddocked heifers were most commonly associated with malpresentations.[127] Calving beef heifers 6 weeks before cows has been recommended to allow the heifers longer to recover and conceive after calving than cows.[128] In a herd-level comparative study, this practice was associated with a higher incidence of dystocia and stillborn calves.[126] Heifer dystocia rate is reduced the longer heifers are maintained as a separate group from cows before calving.[126]

Fetal variables that influence the risk of mortality include sex, size, and number. Calves born to primiparous cows, twins, and bull calves are more likely to die at birth than calves born from multiparous cows, single calves, and heifer calves.[53,129] Low- and high-birth-weight calves are at greater risk of mortality than average-birth-weight calves.[53] Small calves experience greatest mortality at parities greater than one.[118] Large-birth-weight calves have greatest risk of mortality when delivered by heifers. Statistical modeling suggests that for every 1 kg increase in body weight, there is a 13% increased probability of dystocia.[130] Compared with other dairy breeds, Holsteins have the highest ratio of calf birth weight to dam body weight, averaging 7.1%.[131] Holstein cows subsequently have the highest incidence of dystocia.[130,131] Fetal viability may be compromised in utero by a number of infectious agents. Common infectious agents associated with abortion and or birth of weak calves are listed in Box 18.1. Manifestations of disease in the newborn are dependent on the time of exposure to the infectious agent.

Peripartum Assessment of Fetal Vitality

During parturition fetal reflexes can be assessed to ascertain appreciable signs of life. The interdigital, bulbar, and swallowing reflexes can be assessed in calves presenting in an anterior presentation. The interdigital and anal reflex and pulse in the umbilical cord can be evaluated in calves presenting in a posterior presentation.[132] Depressed responsiveness is a feature of impaired acid-base status. An increasing proportion of calves fail to respond as the severity of the acidosis increases. Failure to elicit reflexes is not confirmatory of fetal death as an absence of reflexes has been observed in severely acidotic live calves.[133] Six percent of fetuses with no reflexes intrapartum are normal at the time of delivery.[134]

Criteria commonly used to assess the vitality of the newborn calf are presented in Table 18.3. Timely assessment of the newborn calf is indicated as two thirds of perinatal mortality occur within an hour of birth and 95% of this loss occurs within 5 minutes of birth.[135] Abnormal neonatal behavior in the immediate postnatal period is commonly secondary to perinatal hypoxia and a combination of metabolic and respiratory acidosis. Traditional Apgar parameters, heart rate, respiratory rate, and mucous membrane color, are not predictive of acidemia in newborn calves.[136] Depressed tongue withdrawal and weak suck reflex are correlated with perinatal acidemia in calves.[136]

Calves and lambs normally have a head righting reflex almost immediately after birth. Sternal recumbency is usually attained within 2 to 4 minutes followed rapidly by attempts to stand, at 10 to 20 minutes for lambs and 15 to 30 minutes for calves.[137-139] Failure for calves to achieve sternal recumbency within 15 minutes of birth is highly predictive (84%) of compromised vitality and risk of mortality.[139] Hypoxic neonates may struggle and appear bright initially but have difficulty maintaining sternal recumbency, have depressed or absent suck reflex, are slow to stand or remain recumbent, and develop a depressed mentation within hours. Hypoxic calves can also have an impaired response to environmental stressors such as cold temperature.[140] Reduced muscle tonicity prevents shivering,[141] and the metabolic activity of brown adipose tissue may be reduced, compromising nonshivering thermogenesis.[142] Furthermore, calves with low

TABLE 18.3

Assessing the Newborn Calf

Criterion	Good Vitality	Poor Vitality
Respiration	50-75 bpm and thoracic breathing	Gasping; primary apnea; irregular, abdominal breathing; bellowing and secondary apnea
Hair coat appearance	Placental fluid covered	Meconium stained
Peripheral edema	None	Capital, lingual, or limb edema
Mucous membranes	Pink and normal capillary refill time	Cyanotic, pale, and slow capillary refill time
Response to reflex stimulation	Vigorous head shake; strong corneal, suck, or pedal reflex	Weak or no response
Muscle tone	Active with head-righting within minutes	Inactivity and flaccid musculature
Heart rate	100-150 bpm and regular	>150 bpm followed by bradycardia (<80 bpm) and an irregular, decreasing rate
Rectal temperature	102°-103° F (39°-39.5° C) after calving declining to 101°-102° F (38.5°-39° C) by 1 hour and stable	103°-104° F (39.5°-40° C) after calving declining to 101° F (<38.5° C) by 1 hour and decreasing
Sternal recumbence	Achieved within 5 minutes	Prolonged lateral recumbence
Attempts to rise	Attempting to stand within 15 minutes Standing within 1 hour	Delayed or no attempts to rise
Suckling	Commences within 2 hours	Delayed or no attempts to suckle

From Mee JF: Managing the calf at calving time. In Proceedings of the 41st Annual Conference American Association of Bovine Practitioners, Charlotte, NC, 2008, p 46.

VetBooks.ir

vitality have a limited ability to generate heat through natural physical behavior, and delayed colostrum ingestion may limit the energy available to generate heat.[131]

The normal heart rate of calves is between 100 and 150 bpm immediately after birth. Heart rate normally stabilizes within minutes of calving, but in at-risk calves peripartal tachycardia (>150 bpm) is followed by a declining bradycardia.[132] Following experimentally induced hypoxia, nonviable hypoxic calves had similar heart rates (118 ± 36 bpm) and body temperatures (39.6 ± 0.2° C) as viable calves but lower respiratory rates (14 and 18 vs. normal 49 ± 12).[137] The rectal temperature of a normal newborn calf is higher than normal at calving 102° F to 104° F (39° C to 40° C) and gradually drops to normal within 3 to 5 hours. Calves that experience a protracted, difficult calving may experience hyperthermia (>103° F, >39.5° C) at birth, which drops in the hours following birth and is slow to return to normal.[132]

The normal time taken to stand and nurse varies between species and breeds. The average time from birth to standing and nursing for beef calves is 35 and 81 minutes, respectively. Dairy calves are more variable and take approximately twice as long.[143] A high prevalence of delayed first sucklings has been reported among dairy calves. Failure of the newborn to nurse may result from reduced neonatal vigor, poor mothering, poor maternal conformation, or adverse conditions such as slippery flooring.[144] Calves have difficulty locating teats on low slung udders (<45 cm from the ground)[145] and difficulty nursing teats greater than 35 mm in diameter.[146] Small ruminants are generally quicker to stand and nurse than calves, with most lambs standing within 30 minutes[138] and nursing within 90 minutes of birth.

Observation of interaction between the newborn and dam in the immediate postnatal period allows early recognition of the compromised neonate and facilitates timely intervention if maternal conformation or behavior threatens to impede the neonates' efforts to nurse. Failure of maternal bonding is more common with primiparous dams, multiple offspring, and following delivery via caesarean section. Maternal bonding in sheep is mediated by an olfactory mechanism.[147] Parturition alters the release of monoamines, amino acids, and oxytocin within the olfactory bulb, stimulating an attraction to amniotic fluid and acceptance of the lamb.[148] Artificial vaginocervical stimulation with a gloved hand induces similar alterations in the release of monoamines, amino acids, and oxytocin within the olfactory bulb and is useful for triggering formation of maternal bonds to foster lambs for at least 27 hours postpartum.[148]

In utero infections and congenital neurologic abnormalities should also be considered as possible causes of abnormal neonatal behavior. Collection of sera before feeding colostrum is useful for diagnosing in utero infections. Precolostral serum immunoglobulin concentrations in calves are low (IgM 0.126 ± 0.015 mg/mL, IgG 0.044 ± 0.003 mg/mL).[149] Elevated serum concentrations of immunoglobulins before ingestion of colostrum may be observed with in utero infections.[149] Specific serologic tests are available for Cache Valley virus, Akabane virus, bovine viral diarrhea virus, *Neospora* spp., toxoplasma, and Bluetongue virus.[150] Teratogens and inherited diseases that may cause the birth of weak neonates are listed in Box 18.1.

Resuscitation of the Neonate

Two thirds of perinatal calf mortality occur within an hour of birth, and some 95% of this loss occurs within 5 minutes of birth, underpinning the need for rapid assessment.[135] Survival of the compromised fetus is facilitated by prompt initiation of supportive care. Immediately after birth, almost all calves have mild metabolic and respiratory acidosis.[151] In the first 30 to 60 minutes after birth, there is a decrease in both pH and base excess. After this time, the values normalize in healthy calves but not in calves with respiratory distress.[152] Suction is useful for clearing the pharynx and nasal passages and has been shown to improve pulmonary function in newborn calves.[153] Squeezing the trachea gently may also illicit a cough reflex, which assists airway clearance.[154] Suspending the newborn by the hind legs for less than 90 seconds after delivery is an alternative method for clearing the airways.[155] If the newborn breathes spontaneously, it is placed in sternal recumbency to facilitate efficient pulmonary gas exchange and correction of the mixed acidosis.[155] If the calf does not breathe or move spontaneously within a few seconds after birth, tactile stimulations (inserting a finger or a length of straw in the nasal cavity, pinching the nasal septum, rubbing the calf's body with straw or towel,[156] pouring cold water in the ear or over the head or body of the calf[153]) are necessary to initiate a gasping reflex. In dyspneic neonatal calves, the respiratory center can be stimulated with respiratory stimulants such as doxapram (1 to 2 mg/kg intravenously).[157] Doxapram should be used judiciously as the stimulatory action of the drug is nonselective. Convulsions may be observed with repeated dosing, increasing the demand for O_2 in an already hypoxic neonate.[158]

Weak fetuses are often born with strongly beating hearts but have difficulty initiating adequate inspiratory efforts to expand their lungs. Positive pressure ventilation is required to overcome surface tension in alveoli and the elastic recoil of lung tissue. Fluid within alveolar spaces and the lumen of the tracheobronchial tree is absorbed into the pulmonary interstitium most efficiently at thoracic pressures between 35 and 40 cm H_2O.[100] Less pressure is usually needed for succeeding breaths. Observation of chest wall movement is a reliable sign of sufficient inflation pressure. Ventilation with a pulmonary resuscitation bag (Ambu bag, Copenhagen, Denmark) with a pressure relief valve set at 42 cm H_20 avoids inadvertent overinflation.[159] Applying external pressure across the esophagus helps to prevent inadvertent inflation of the abomasum. Direct mouth-to-mouth resuscitation is generally ineffective at delivering air into the abomasum and poses a risk for contracting zoonotic diseases such as Leptospirosis, Brucellosis, or Q fever. While correction of respiratory acidosis is dependent on achieving adequate pulmonary ventilation, correction of metabolic acidosis requires neutralization of hyperlactatemia. This can be achieved by bolus administration of hyperosmotic sodium bicarbonate (50 to 100 mL of 8.4% solution, IV) once effective pulmonary ventilation has been established.[135]

Thermoregulation is important as recovery from acidosis is delayed by hypothermia.[160] Cold stress leads to increased metabolic needs and produces hypoxia, hypercarbia, metabolic acidosis, and potentially hypoglycemia—metabolic sequelae that resuscitation is aimed at correcting.[161]

Resuscitation procedures for more critical neonatal calves and small ruminants is similar to the approach taken with foals as discussed in Chapter 17.

Initial Management and Clinical Investigation of Neonatal Ruminants

JOHN K. HOUSE, *Consulting Editor*
ALISON A. GUNN, GEMMA CHUCK, and MUNASHE CHIGERWE

Environmental Management

Maternal shedding of enteric pathogens increases around the time of parturition. In intensive dairy production systems, calf pathogen exposure and subsequently the risk of morbidity and mortality can be reduced by removing the calf from the dam after birth and placing the calf in a clean, dry, sheltered environment. Conversely, under extensive livestock husbandry systems where pathogen load is sparse and dispersed, the emphasis is on minimal interference to avoid mismothering. Neonatal calves are cold tolerant when dry and sheltered from drafts. Due to their lower body mass, lambs and kids are more susceptible to cold. Wet, drafty conditions lead to depletion of energy reserves and hypothermia. Hypothermia compromises colostral transfer and increases vulnerability of newborns to contagious and opportunistic pathogens. In cold conditions neonates generate heat by shivering and metabolism of brown adipose tissue. Neonates are born with short-lived, stored energy in the form of muscular glycogen.[1] Colostrum is a critical source of concentrated energy to meet the metabolic demands of thermogenesis.

Colostrogenesis and Colostral Components

Colostrogenesis begins 5 weeks before calving under the influence of prolactin and other lactogenic hormones, with peak production occurring 1 to 3 days prior to parturition.[2] Colostrum is nutrient dense and has a higher level of energy and protein than is found in milk. Bovine colostrum contains approximately 45 mg/mL[3] of immunoglobulin and 1×10^6 leukocytes/mL.[4] Immunoglobulin G1 (IgG1) is transported from blood in endosomes through the polarized mammary epithelial cell by a process known as *transcytosis*.[5] IgG1 is bound by the neonatal Fc receptor (FcRn) at the basal side and transferred to the apical side under the control of intracellular proteins termed *small GTPases*.[6] The FcRn consists of two subunits: an integral membrane α-chain (Fc fragment of IgG, receptor, transporter, alpha; FcGRT) and a β light chain (β2 microglobulin; β2M). In vitro the expression of FcGRT and several of the small GTPases controlling the transfer of IgG are upregulated by estrogen and progesterone, and it is thought that this mechanism results in the marked increase in transport of IgG1 observed in the 4 weeks prior to calving.[6,7] Immunoglobulins account for more than 95% of the whey protein at calving, and IgG1 accounts for approximately 80% of this amount.[8] IgG2, IgA, and IgM account for 10%, 7%, and 5%, respectively. The amount of IgA remains constant throughout all lactations, whereas the colostrum of cows in their first lactation contains less IgG1, IgG2, and IgM. Immunoglobulin levels in mature milk are much lower, comprising only 7% of the total whey protein, with an increase in the relative contribution of IgA. Older cows tend to have a higher ratio of IgG1 to IgG2.[9] This is consistent with a lower level of IgG1 in the serum of heifers. The transport of IgG into bovine colostrum has been associated with a transient decrease in serum total protein, globulin, and IgG concentrations during the preparturient period, particularly in dairy cows. Up to 500 g of IgG1 a week are removed from blood during the most active period of colostrum formation.[10]

Colostrum also contains hormones (growth hormone, relaxin, prolactin, insulin, glucagon), essential fatty and amino acids, minerals, trace elements and vitamins (especially betacarotene; vitamins A, B, D, and E) (Table 19.1), as well as cytokines, growth factors (members of the insulin-like growth factor [IGF] system, including IGF binding proteins [IGFBPs]), and nonspecific antimicrobial factors such as lactoferrin. Colostrum is a significant source of copper to the newborn calf but not a source of selenium or zinc.[11]

The Immunological Benefits of Colostrum

Cows, sheep, and goats have an epitheliochorial type of placenta that does not allow passage of immunoglobulin, hence neonates are born virtually agammaglobulinemic, rendering them susceptible to infection. Ingestion of colostrum provides maternal immunoglobulins that enterocytes selectively absorb by pinocytosis during the first 24 hours after birth. The ability of the enterocytes to absorb immunoglobulins decreases rapidly soon after birth, resulting in "closure" of the intestines by 24 to 36 hours postpartum. "Closure" of the intestines is thought to be mediated through growth factors, including IGF-1, transforming growth factor–beta 2 (TGF-β2), and growth hormone (GH), all of which are present in colostrum.[12] Ingestion of these growth factors through colostrum causes hyperplasia of intestinal epithelium and a decrease in crypt-to-villus ratio, indicating a shift toward differentiated mature enterocytes.[12] Passively derived immunoglobulins enhance neonatal immunity by functioning as neutralizers and opsonins.

The immune system of the neonate starts to develop from birth, with endogenous IgG reaching functional levels at 3 to 6 weeks of age.[13] The uptake of maternal leukocytes by the calf also plays a significant role in the development of the neonatal immune system, by enhancing the antigen-presenting capacity of the calf and regulating the immune response.[14-16] Comparison of the immune response of calves fed

Copper (mg/kg)	0.34	0.14
Sulfur (mg/kg)	2595.67	904.97
Manganese (mg/kg)	0.10	0.11

Ig, Immunoglobulin; *SE*, standard error.

leukocyte-replete or leukocyte-depleted colostrum indicates that colostral leukocytes enhance humoral immunity and phagocyte function.[17-21] Following experimental *Escherichia coli* infection, calves fed leukocyte-replete colostrum recovered more quickly and shed fewer bacteria than calves fed leukocyte-depleted colostrum.[4] Transfer of cellular immunity via colostral leukocytes has also been demonstrated in sheep.[22] Colostral leukocytes are destroyed when colostrum is frozen, pasteurized, or fermented.

Ingestion and absorption of colostral immunoglobulins is essential for neonatal ruminants to thrive, and inadequate colostrum consumption increases the risk of disease. The association between failure of passive transfer of immunoglobulins and neonatal infection has been well established in the calf.[23,24] Passive transfer achieving serum IgG concentrations of 10 mg/mL or greater at 24 to 48 hours is associated with reduced risk for morbidity and mortality.[25-27]

The Nonimmunological Benefits of Colostrum

Provision of adequate good-quality colostrum results in improved daily weight gain and feed conversion efficiency both pre and post weaning, although the effect of this on joining dates and age at first calving varies between studies.[27-31] Calves receiving larger volumes of colostrum at birth have been shown to require less veterinary input in the preweaning period.[28] An increased volume of colostrum fed followed by a higher plane of milk nutrition can significantly increase the average daily weight gain during the first 80 days of life compared to calves fed a lower volume of colostrum followed by the same plane of milk nutrition. In addition, postweaning feed intake was increased in calves fed the higher volume of colostrum. This suggests that there are nonnutritive factors present in colostrum that may contribute to appetite regulation and feed conversion efficiency and that extend into the postweaning period.[32]

Both serum IgG at 24 to 48 hours and the provision of adequate good-quality colostrum have been associated with increased milk production in the first and second lactations.[28,33] There may not be a direct cause-and-effect relationship between serum IgG and future milk production but rather an indirect relationship in that calves with adequate IgG can develop more efficient metabolic systems, which in turn could contribute to future milk production.

Growth factors and hormones in colostrum and milk have been shown to enhance the development of tissues in the gastrointestinal tract of other species.[34] The effect of such bioactive factors in colostrum and milk on the development of specific tissues and/or physiologic functions in the neonate is called the "lactocrine hypothesis."[35] This maternal programming is an example of epigenetics in that the dam continues to influence the development of the neonate even after parturition has occurred. This influence is derived from bioactive factors present in colostrum that can direct the development of specific tissues.[36,37]

The factors present in colostrum that are likely to influence long-term outcomes include IGF-1, IGF-2, insulin, GH, epidermal growth factor, leptin, and prolactin.[38] It is unknown whether all of these factors are absorbed by the gastrointestinal tract of the newborn calf, but studies have shown that serum IGF-1 levels are higher in calves fed colostrum compared to those deprived of colostrum.[39] This may be due to increased endogenous production of IGF-1 as a result of increased intake of energy and protein in colostrum, as opposed to direct absorption of IGF-1 itself.

Lactose intake is insufficient to maintain plasma glucose concentrations, and colostrum feeding increases plasma glucose, most likely due to stimulation of gluconeogenesis. Newborn calves are deficient in vitamin A and have a low lactoferrin status. Both are found in elevated quantities in colostrum compared with milk. Lactoferrin is an iron-binding glycoprotein that is a potent antimicrobial factor in the milk cistern and in the alimentary tract of newborn animals. Digestive functions develop during fetal life and undergo the largest morphological and functional changes during the first 48 hours of extrauterine life under the influence of IGF-1, lactoferrin, and other bioactive substances, many of which are present in significantly higher concentration in colostrum than milk. These factors are key regulators in the development of the gastrointestinal tracts of bovine neonates, including stimulation of mucosal and submucosal growth, brush border enzymes, intestinal DNA synthesis, increased duodenal villus size, and apoptosis; protein synthesis and degradation; and digestion and absorption. They also exert systemic effects outside the gastrointestinal tract on metabolism and endocrine systems, vascular tone and hemostasis, activity and behavior, and systemic growth.[40-42]

Provision of Adequate Colostrum

Optimal transfer of immunoglobulin will occur when calves are administered first milking colostrum at 7.5% to 10% of body weight within 2 hours after birth. The initial feed should provide the calf with a minimum of 150 g of IgG within 2 hours after birth. This is required to ensure that 90% of calves have optimal passive transfer.[43] Dairy calves should be administered colostrum by nipple bottle or esophageal tube, as there is increased failure of passive transfer in dairy calves that are left on their dam.[3,44,45] This is due to the reduced volume of colostrum, and therefore mass of IgG, consumed by the calf if left to suckle naturally during the first 24 hours.[27] Conversely, separation of beef calves from the dam is not practical and may result in mismothering. Generally, failure of passive transfer

is less of a problem in beef cattle, as the lower volume of colostrum produced results in elevated concentration of IgG, and supplementation is recommended only following dystocia.

Failure of Passive Transfer of Immunity

Failure of passive transfer (FPT) occurs when calves do not absorb sufficient immunoglobulins. Only small amounts of IgG and IgM to unknown antigens are made by the fetus, and they offer no protection against disease. It has been estimated that approximately 31% of preweaning mortality events occurring in the first 3 weeks of life can be attributed to FPT.[46] The problem in mixed-source calf-rearing properties is significantly worse.[25] A high percentage (19.2% to 38%) of dairy calves are still found with significant FPT.[44,45,47] There is some debate as to the serum IgG concentration that signifies FPT. Calves are generally defined as having FPT if the calf serum IgG concentration is less than 10 mg/mL when sampled between 24 and 48 hours of age.[48] More recently it has been suggested that serum IgG concentration below 13.4 mg/mL constitutes FPT.[43,49] Ensuring that every calf has adequate passive transfer is challenging, and rates of 10% probably indicate good management practices.[43]

In on-farm monitoring programs for effectiveness of passive transfer, IgG levels are often inferred by measuring serum total protein. A serum protein below 5 g/dL (≈9 mg/mL IgG) will result in a 2.4 to 6 times greater risk of mortality up to 6 months of age.[25,26,50,51] There is still an increase in relative risk of mortality when serum protein is between 5 and 5.5 g/dL as compared to greater than 5.5 g/dL (13.4 mg/mL IgG), but it is not as marked, and the cost benefit of ensuring that all calves achieve a serum protein greater than 5.5 g/dL to prevent mortality is questionable. However, the growing body of evidence suggesting that other colostral factors are positively associated with feed conversion efficiency and lactation performance emphasizes the long-term benefits of actively feeding colostrum and not just the short-term immunological provision of IgG.

On any farm the baseline mortality will reflect management, nutrition, and the pathogens present. The risk of mortality associated with varying levels of passive transfer is independent of baseline mortality rate. Hence where the baseline mortality is high, adequate passive transfer will not prevent calves dying, but as serum immunoglobulin levels decrease below 13.4 g/L, the risk of mortality will increase relative to that herd's specific baseline mortality. It is important to recognize that most calves with total FPT will survive, especially where baseline mortality is low.[25,52] The role of the passive transfer of immunity in preventing morbidity per se is well documented, but the effect of immunoglobulin levels on prevalence of specific disease syndromes varies. Epidemiological studies reflect the variation in management, environment and disease pathogens between properties, and the greater impact of other risk factors on disease incidence. Consequently, there are inconsistent results on the impact of adequate passive transfer on both main calfhood diseases—diarrhea and pneumonia—also reflecting study design and varying serum IgG levels used to define FPT.[24,26,27,53-56] Studies on the risk of pneumonia generally demonstrate FPT as a risk factor, but the impact of FPT as a risk factor of diarrhea is less consistent. Often where a significant effect of IgG levels on the incidence of a specific disease has not been demonstrated, increasing the sample size to examine correlation with all calves treated with antibiotics, or all morbid calves within the study, has demonstrated a significant benefit of adequate passive transfer. The benefits of adequate passive transfer on disease incidence are likely to be long lasting, with evidence of ongoing prevention of postweaning disease, particularly feedlot pneumonia, although, again, not all studies demonstrate this effect.[26,29,57]

A better indication of the effect of passive transfer on disease appears to be consistent positive correlation demonstrated between adequate passive transfer and average daily weight gain both pre and post weaning.[27-29,55,56,58] It is likely that much of the variation in weight gain is secondary to changes in the incidence of disease.[26,57,58]

Risk Factors for Inadequate Colostrum Uptake

The major factors influencing the effectiveness of passive transfer of immunoglobulins in calves are (1) the concentration of immunoglobulins in colostrum fed, (2) the volume of colostrum ingested, (3) the age of the calf at first colostral feeding, and (4) the bacterial load of the colostrum ingested.

There is large variation in colostrum immunoglobulin concentrations between individual cows and a variety of influences (genetic, environmental, physical) on the uptake of colostral antibodies by the calf. Although calves born to beef cows with lower colostrum immunoglobulin concentration had an increased risk of mortality,[59] numerous other studies in beef and dairy calves have failed to demonstrate an association between the colostral immunoglobulin levels and the serum immunoglobulin of the calves at 48 hours of age.[60-64] Administration of a known volume and concentration of colostrum to dairy calves via oroesophageal feeder at a specific time after birth has been shown to have more linear correlation with calf serum IgG,[43,65] but administration of sufficient colostrum to provide 150 g IgG within 4 hours of birth can still result in FPT.

Factors Affecting the Immunoglobulin Concentration of Colostrum

The immunoglobulin concentration of colostrum is known as *colostrum quality*. At the herd level colostrum quality is affected by breed, parity, and climate. For individual cows the biggest determinants are colostral volume and time from calving until milking.[66,67] Colostrum concentrations of Holstein Friesian cows varied from 20 g/L of immunoglobulin to more than 110 g/L of IgG1 in cows from a single herd.[66] First milking colostrum samples collected within 4 hours of milking from cows at 11 dairies in Pennsylvania varied from 9 to 166 g/L IgG1.[68] The mean concentration of IgG1 in first milking colostrum in three large studies of dairy cows varied between 37.5 ± 30.2 and 48.2 ± 28.9 g/L.[66,68,69] Colostrum IgG concentration declines with time after calving, even if the cow is not milked.[66,67,70,71] One study showed that colostral IgG concentration decreased by 3.7% in each subsequent hour after calving.[67] However, several studies have demonstrated that this decline is minimal until the cow has been calved 8 to 9 hours.[66,70] There is no increase in colostral volume if postpartum milking is delayed, so it appears that the declining IgG is not due to dilution.[67,71,72] During the colostrum phase mammary cells have leaky tight junctions,[73,74] so it is likely that once parturition occurs, the active transcytosis of IgG1 ceases and it is passively reabsorbed.

Studies of colostrum and calf immunoglobulin levels in specific beef breeds have failed to demonstrate consistent differences between specific breeds, and many studies showed evidence of variations within breed lines. In dairy breeds colostrum from Holstein cows was statistically lower in total IgG than colostrum from Jersey, Ayrshire, and Guernsey cows.[75,76] In other studies, high-producing Holstein Friesians have a tendency to have lower IgG concentrations in their colostrum than lower producing Jersey cows.[66,75,77] Prepartum dairy cows have a significantly greater decline in serum IgG compared with beef cows,[7] but the colostrum of dairy cows has lower concentrations of IgG due to the much larger volume. Some studies have shown very low volumes of colostrum (<2 L) in beef cows.[78,79] The volume of colostrum produced and the concentration of immunoglobulin in the colostrum are markedly affected by differences in the onset of lactogenesis and the resulting dilution of colostral immunoglobulins; hence it is likely that much of the variation observed between breeds, lines, and cows is an effect of colostrum volume.

VetBooks.ir

The weight of first colostrum produced has a direct influence on the colostrum quality, with cows producing large volumes of first colostrum having a significantly lower concentration of IgG.[66,80] The strong negative association between colostral IgG concentration and volume of colostrum produced is likely to result from the dilution of total IgG with other mammary gland secretions.[7] It has been suggested that using colostrum from cows that have produced less than 8.5 kg will increase the percentage of high IgG concentrations from 64% to 77% in second lactation cows.[66] However, other studies reported a very low sensitivity for weight of first milking colostrum in identifying poor-quality colostrum (<50 g/L).[81]

Parity has been shown to significantly affect the immunoglobulin concentration in colostrum.[80] First and second calving beef and dairy cows often have a lower immunoglobulin concentration than cows of third or greater parity.[9,62,66,76,82,83] Similarly, calves born to beef heifers and second parity cows have a significantly lower mean concentration of serum IgG compared with that of calves born to mature cows.[82,84,85] Other studies contradict this, suggesting that there is no difference in IgG concentration in colostrum from first, second, or fourth parity cows.[86-88] Because good-quality colostrum is such a valuable commodity, the practice of discarding first lactation colostrum is discouraged by some authors.[89]

Genetic variance has been found in the genes encoding the FcRn involved in trancytosis of IgG1 into the mammary gland. In Holstein Friesian cows haplotype 5 of the FcGRT subunit has been shown to be significantly associated with a high colostrum IgG, and FcGRT haplotype 2 shows a similar trend.[90] FPT in beef calves from 16 breeds has been associated with FcGRT haplotype 3, and conversely calves with FcGRT haplotype 2 were less likely to have high levels of serum IgG.[91] FPT in these calves is also associated with one of eight haplotypes of the β2M subunit of the FcRn.[92] It is likely that variation in this receptor affects the concentration of IgG1 in colostrum rather than the uptake of IgG1 by the calf, as neonatal uptake does not involve the FcRn. An estimated 10% of Holstein cows are capable of high mass transfer of IgG1, resulting in an IgG mass more than 1 standard deviation above the mean.[68] Variation in the FcRn probably contributes to this variation, along with other genetic or hormonal regulation of transport. Potentially there is opportunity to enhance the concentrations of immunoglobulins in colostrum by genetic manipulation of IgG transport in the mammary gland. However, it should be remembered that serum IgG concentrations in the periparturient cow are already decreased because of IgG transport into colostrum,[7] and further decrease in immunoglobulins may exacerbate the immunosuppression that occurs during the peripartum period.

Numerous studies have failed to demonstrate an effect of often severe protein and/or energy restriction for up to 3 months before calving on colostrum immunoglobulin levels.[93-96] Protein restriction may result in an increase in IgG levels and a concurrent decrease in colostral volume, making the colostrum more viscous and difficult to suckle, especially in heifers, resulting in decreased IgG levels in the calves.[84,97] This is likely to be a direct volume response, as shown in other studies of colostral IgG concentration.[7,66] There was no significant effect of dietary restriction on colostral IgM in any of the studies. Selenium supplementation has been shown to increase IgG levels in the colostrum of selenium-deficient cows[98] but not lambs. IgG uptake by the calf may also be affected by serum copper levels.[99]

Twins have not been demonstrated to affect colostrum IgG concentration in beef cows[59,82]; however, a study of sheep, goats, and dairy cows demonstrated an increase in total protein, whey protein, and IgG concentration.[100]

Short dry periods of 28 to 35 days do not affect colostrum IgG levels, but when the dry period was eliminated completely there was a decrease.[101-103] Elimination of the dry period did not affect colostogenesis in terms of cellular and fluid composition, and it is likely that the reduced quality is due to the lack of a period of secretion and accumulation. The mean colostral IgG of these cows remained close to 50 g/L so that 3 L of colostrum would provide the calf with adequate IgG. Treatment of cows with internal teat sealant at drying off has no effect on transfer of colostral antibodies following calving but will help prevent leaking of colostrum prior to calving and the consequential reduction of the quality of the colostrum harvested.[87,88,104]

Few studies look at the effects of periparturient disease on IgG levels in colostrum. A decrease in colostral IgG has been observed in cows with periparturient infections and clinical mastitis[59]; where colostral IgG was not measured, calves of cows with periparturient mastitis had a lower serum IgG.[82] The reported effect of subclinical mastitis is also inconsistent. At the quarter level, a persistent infection at the time of calving, detected by serial cultures, results in a decrease in total volume of colostrum produced but no variation in IgG1 concentration, compared with a matched quarter on the same cow.[105] At the cow level an increased risk of colostrum with an IgG content of less than 30 g/L is found in cows with a somatic cell count greater than 50,000 cells/mL, measured at the herd recording after calving.[83] At the herd level, cows from farms with an average count less than 200,000 cells/mL in the month prior to sampling produced colostrum with higher levels of IgG2, tocopherol, vitamin A, potassium, and total solid levels, but no significant variation was noted in IgG1.[69]

Environmental temperatures affect colostral IgG concentrations, with several large studies in dairy cattle demonstrating an increase in colostral IgG concentration in the summer[83,106,107]; however, heifers exposed to heat stress had decreased colostral IgG concentration.[108] Photoperiod has no effect on colostral IgG concentration or volume.[67]

Factors Affecting the Mass of Immunoglobulin Absorbed

The key influences on immunoglobulin absorption by the neonatal calf are the concentration of immunoglobulins in the colostrum, volume fed, and time between birth and colostrum feeding. When small volumes are fed, the method of feeding can also affect the final serum IgG level.

VOLUME OF FIRST FEED. The volume of colostrum fed shortly after birth has a direct, linear relationship with the concentration of serum immunoglobulin in the calf up to 40 hours of age.[109] As the mass of IgG consumed increases, there is a significant difference in serum IgG concentrations in calves fed 3 L of colostrum at birth compared to those fed 1.5 L.[48] The exact volume of colostrum, and therefore mass of IgG, required to avoid FPT has been shown to be variable.[3,81,110] There is no difference in the IgG concentration at 48 hours when 40-kg calves are administered either 3 L or 4 L of colostrum with equivalent immunoglobulin levels regardless of IgG concentration.[43,65] Similarly, with lower quality colostrum, higher serum IgG levels will be achieved when two feeds of 2 L are given at 2 and 6 hours postpartum than when 4 L is given in one feed.[110] The pathophysiology underlying these observations is not fully understood, but 22% of the variation in the effective absorption of colostrum is attributed to abomasal emptying rate, and it is likely that the excessive mechanical distention of the abomasum with 4 L of colostrum delays outflow.[65,110,111]

Calves should be fed a minimum of 150 g of IgG within 4 to 6 hours of birth and earlier whenever practical. The exact volume at each feed should be determined after measuring, usually by indirect estimation of colostrum IgG levels, and is more important to optimize where lower quality colostrum is the only source (Table 19.2). Calf serum IgG levels will be

Calculations of total IgG required and apparent efficiency of absorption are based on Chigerwe et al. (2008)[43,198] using blood volume calculations from Quigley et al. (1998).[325] The correlation between the Brix refractometer reading and serum IgG levels was calculated using Quigley et al. (2013).[72] This table was compiled with the assistance of Zoe Vogels from The Vet Group, Timboon, Australia.

It is assumed that the minimum volume fed would be 5% of body weight even where good-quality colostrum is available. It should be noted that below a Brix reading of 22%, it is not possible to achieve adequate passive transfer with a single feed of colostrum.

[a]Calves should be fed 7.5% of body weight or, at a minimum, the volume shown. IgG levels would be enhanced by 5% of body weight 6 to 12 hours later.

[b]Calves should be fed 7.5% of body weight and an equivalent volume 6 to 12 hours later.

[c]It is unlikely that adequate passive transfer will be achieved.

IgG, Immunoglobulin G.

significantly boosted by a further feed of 5% of body weight of colostrum within 12 hours of birth[110]; if less than 150 g of colostrum was fed at the initial feeding due to limitations of quality or volume, a further 7.5% should be fed.[49] Emphasis should be placed on feeding colostrum with the highest concentration of immunoglobulin at the initial feed, when the effectiveness of absorption is higher. Many farmers are currently feeding 10% to 12% of body weight as a single initial feed. Although this will provide good levels of IgG where colostrum quality is adequate, it may result in moderate depression and discomfort in the calf.[112]

TIME OF FIRST FEED. Early ingestion of colostrum is crucial; IgG is absorbed by the intestinal epithelial cells of the newborn ruminant, and the ability of enterocytes to transport immunoglobulin declines linearly from 2 to 20 hours after birth and completely ceases (intestinal closure) between 24 and 36 hours.[113] Serum IgG concentrations peak around 32 hours and then decline until the production of antibodies by the neonate exceeds the decay of passively acquired antibodies. Any delay in first feeding of colostrum results in decreased absorption of immunoglobulin and a lower serum IgG.[43,114] Absorption of immunoglobulins occurs along the whole length of the small intestine in calves, with the amount transported increasing from the duodenum to the ileum,[115] whereas in lambs and kids there is virtually no absorption from the duodenum and most absorption occurs in the jejunum.[116,117] IgG and other macromolecules are mainly absorbed by micropinocytosis, although some receptor-mediated endocytosis has been demonstrated, but this does not involve the FcRn.[115,116,118] Preferential absorption of homologous IgG has been observed in pigs; however, recent studies in kids and lambs have shown that similar IgG transfer can be achieved by feeding bovine colostrum, although in lambs the apparent efficiency of absorption is lower.[119-121]

The age of the calf when it receives its first feeding and the amount of immunoglobulins received will influence the time of closure of the intestinal permeability to colostral immunoglobulins and the final serum immunoglobulin levels of the calf.[122-126] Cessation of absorption occurs by 24 hours in calves that receive a full feed of colostrum within the first 4 hours after birth. When the colostrum volume is less than 2 L, the gut will remain permeable for a longer time and the rate of absorption will increase in response to a subsequent feed. If the calf is older than 12 hours when it receives its first feed, there is a significant increase in the possibility of the calf being agammaglobulinemic. It is likely that the time of closure is related to the immunoglobulin concentration of the colostrum as well as the volume fed. Delay in colostrum feeding will also result in lower plasma insulin and IGF-1 for up to 48 hours after first colostrum intake and reduce plasma concentrations of betacarotene, retinol, and α-tocopherol for nearly a month after birth.[127,128]

METHOD OF FIRST FEED. Method of feeding also has a significant effect on colostrum intake. A high proportion of calves left to suckle their dams show evidence of FPT, compared to those artificially fed by teat or esophageal feeder.[3,129,130] This is due to the reduced volume of colostrum, and therefore

VetBooks.ir

mass of IgG, consumed by the calf if left to suckle naturally during the first 24 hours; hence it is strongly recommended that dairy calves be administered colostrum containing 150 g IgG within 2 hours of birth.[27] Teat-feeding stimulates a reflex closure of the esophageal groove allowing colostrum to pass directly to the abomasum, where it clots before moving to the small intestine for absorption. When an esophageal feeder is used, this reflex does not occur, and the colostrum passes to the reticulorumen.[131,132] Promotion of the advantages of closure of the esophageal groove has resulted in the use of a nipple bottle as the more common method of administering colostrum. Calves fed a small volume of colostrum (1.5 L) via an esophageal feeder have a lower efficiency of absorption than calves fed colostrum via a teat feeder.[133] However, several studies[134] have demonstrated that there is no difference in immunoglobulin concentrations at 48 hours between calves that sucked larger volumes of colostrum from a nipple bottle and those that were administered a similar quantity via an esophageal feeder, although there may be a delay of approximately 3 hours before the serum IgG increases in the tube-fed calves.[112,135,136] This delay is not due to the deposition of colostrum in the reticulorumen, as all except 400 mL will immediately pass into the abomasum due to the pressure gradient resulting from the placement of the reticulorumen dorsal to the abomasum in the neonatal calf.[137] Instead the delay is likely to be due to delayed abomasal emptying resulting from distention and changes in physiologic and neuronal control mechanisms.[111,138]

Calves fed by a nipple bottle will commonly not ingest sufficient colostrum to minimize the risk of FPT and should be encouraged to ingest the maximum volume they will voluntarily ingest within 1 to 4 hours of age.[49] Calves should be fed as soon as they are standing; delaying up to 6 hours after birth or providing a heat lamp will not increase the amount of colostrum suckled.[49,139] Calves that have a high degree of vigor during the first hour of life and during colostrum suckling will consume more colostrum from the bottle, as will larger calves.[139] Bottle-fed calves that do not ingest their full allocation of colostrum at either the first or the second colostrum feed should be targeted for immediate esophageal feeding, and the total remaining should be fed.

To minimize trauma when an esophageal feeder is used, the calf should be standing with its rump against a solid wall or corner. The feeder used should have a total volume of at least 3 L so that intubation has to occur only once. The calf should be encouraged to swallow prior to insertion by sucking a finger to produce saliva or by being fed a few mouthfuls of colostrum. The tube should be introduced without physical exertion, and the head should be positioned slightly downward to allow swallowing as the tube is inserted into the esophagus. Before feeding, the knob at the end of the tube should be palpated on the left-hand side dorsal to the trachea to ensure that positioning is correct. At this point the calf head may be tilted slightly upward as the bottle is elevated to administer the colostrum. It is important that the tube remains fully inserted during colostrum delivery. It is common for calves to chew during administration, causing retrograde movement of the tube that may lead to the bulb of the tube migrating to the level of the pharynx, resulting in aspiration.

On beef properties, routine administration of colostrum to the newborn calf is disruptive and delays the time until first sucking[140] but will decrease the incidence of FPT.[60,141] Feeding colostrum to high-risk calves is likely beneficial, most commonly after dystocia. Beef cows often produce smaller colostrum volumes; where volumes less than 1.5 L are fed, use of a nipple bottle is recommended, as serum IgG at 24 hours of age is higher compared to that of calves administered colostrum with an esophageal feeder.[142] This most likely occurs because a greater percentage of the total colostrum is deposited into reticulorumen. Where dairy colostrum was fed, this was also shown to be a biosecurity risk.

OTHER FACTORS INFLUENCING IMMUNOGLOBULIN ABSORPTION. Calves that have experienced dystocia are more likely to have failure of passive transfer.[27,84,85,143] Decreased vitality of the neonate, potential hypoxia in the small intestine secondary to respiratory acidosis, and in many cases edema of the head and tongue result in a slower time to stand and inadequate colostrum intake as a consequence. Calves born to primiparous cows have been shown to have a higher risk of FPT compared to those born to multiparous cows.[27,75,144] This may be related to primiparous dams having lower IgG concentrations in their colostrum[145] as a result of reduced exposure to antigens[144] or an indirect effect of increased risk of dystocia in primiparous dams.[146] Another study showed that there was no effect of dam parity or dystocia on calf serum IgG concentration.[81,147] Respiratory acidosis did not result in decreased levels of IgG at 37 to 48 hours in studies where blood gases were measured promptly using arterial blood, although delayed absorption was observed in one study.[148,149] The effects of twinning are equivocal, with two large studies, both in beef herds, demonstrating opposite effects of twinning on calf serum IgG. This is likely to be related to management, as the study that showed an increase in IgG with twinning moved all cows with twins to a barn for care and observation.[82,143]

It has been shown that the conformation of the dam's udder and ventral abdomen has a significant effect on the average teat-seeking time prior to first suckling. There was nearly a 30-minute delay in the time to suckle.[150] Overall effect on the calf IgG was not measured, but a separate study demonstrated a significantly lower serum IgG in cows with pendulous udders.[151]

Protein restriction in the last third of gestation may affect uptake of IgG by the calf,[152] although IgM concentration was unaffected. This finding was attributed to the selective absorption of IgM in newborn calves, which is highly efficient when colostrum intake is low. IgM is the primary immunoglobulin that provides protection to the neonatal calf during the first few days of life, and it has been suggested that the efficient absorption of IgM is a compensatory measure that provides immunity to calves even when they are hypogammaglobulinemic.[153,154]

There is a seasonal variation in the IgG levels of calves and efficiency of absorption after colostrum feeding, being lower in the winter in cold climates and lower in the summer in hot climates.[61,144,155-157] Colostral immunoglobulin concentration is reduced in hot and cold weather,[106-108] and this is exacerbated by calves also being less willing to suckle in extreme temperatures. Heat stress results in smaller calves that may be less vigorous,[156,158] with one study demonstrating that calves subjected to a cold and wet environment had a slower rate of colostral absorption,[159] although the serum immunoglobulin at 24 hours was not significantly different from that in the control calves. In that study the calves exposed to cold temperatures were fed colostrum via an esophageal feeder. The effect would be exacerbated in cold-stressed calves, as they are less likely to suckle voluntarily.

There is some evidence that IgG levels in calves at 24 and 36 hours have low to moderate heritability. The breed of the sire and dam has some effect, but there is variation within lines of the same breed.[62,64,85,160] Haplotypes of both the FcGRT and β2M genes coding for the FcRn are associated with FPT in neonatal beef calves, as discussed previously.[91,92] Since this receptor is not involved in the uptake of IgG by the calf, it is likely that the risk factor for FPT is the colostrum quality of the dam.

Calves that are allowed to remain with the dam for longer periods after birth have been shown to have a higher risk of FPT. Calves removed from the dam within 3 hours of birth are less likely to have FPT compared to those allowed to stay with the dam for more than 3 hours.[45,47] The gender of the primary calf carer has also been shown to influence the odds of FPT,[47] with female calf carers having a positive effect on serum protein levels compared to male calf carers.

VetBooks.ir

Management to Ensure Adequate Passive Transfer

The effectiveness of passive transfer achieved at a farm level reflects farm management. Best practice colostrum management strategies for dairy and beef calves are presented in Box 19.1 and 19.2.

ENSURING OPTIMAL IMMUNOGLOBULIN CONCENTRATION

Colostrum Collection, Handling, and Storage. Colostrum collection should occur as close to parturition as possible. Fresh cows should be removed from the calving area and milked out at least twice daily to help ensure optimal colostrum quality. Colostrum collected from cows that have leaked milk prior to calving, have signs of ill health, or have evidence of mastitis should not be fed to neonatal calves.

Colostrum quality is compromised in cows that have leaked milk prior to calving.[87,88] The colostrum from cows exhibiting signs of ill health or mastitis will have increased potential for the presence of infectious pathogens, such as *Mycobacterium avium* subsp. *paratuberculosis*, *Salmonella* spp., *Mycoplasma bovis*, *Staphylococcus aureus*, bovine diarrhea virus, and bovine leukemia virus.[161-163] Neonatal enteric pathogens such as cryptosporidium may also be present.[164,165] Consequently, unpasteurized colostrum is a potential risk factor for calf diarrhea and neonatal septicemia.[166,167] Unpasteurized colostrum is also a biosecurity risk, and the use of colostrum from cows from a different property is not recommended. Pooling of colostrum significantly increases the biosecurity risk, as organisms are disseminated, subsequently infecting a larger number of calves.[167-169] This is exacerbated further if storage is poor, resulting in pathogen proliferation.[166,170] Colostrum with high bacterial levels not only present a significant disease risk, but also affect absorption of IgG by direct blocking of uptake and transport of immunoglobulin molecules across intestinal epithelial cells or by binding free immunoglobulin in the gut lumen.[48,171] Pooling of colostrum will also result in reduced IgG concentrations due to the overrepresentation of high-volume, low-immunoglobulin colostrum and consequently is associated with an increased level of FPT.[44,89] When pooling is necessary for pasteurization, the colostral IgG should be estimated using a Brix refractometer and low-quality colostrum of less than 22% Brix excluded. However, heat treatment of colostrum increases IgG absorption efficiency even in low-quality colostrum.[172]

Microbial contamination of colostrum compromises colostral quality and subsequently calf health. Bacterial contamination may occur during harvest, storage, or administration.[161,166,170,173] Possible sources of contamination include cow skin, milking cup liners, hoses, milking buckets, and storage and feeding utensils. Contamination of colostrum with pathogens during harvest can be avoided by careful and hygienic teat preparation in fresh cows prior to applying cups.[161] This may involve washing and drying teats and applying a pre-milking teat disinfectant.[174,175] Thorough and effective cleaning and disinfection of collection, storage, and feeding equipment is essential. It is important that separate, clearly marked esophageal feeders are used for feeding colostrum and are not used with sick calves, as this may also be a significant disease risk. Milk feeding equipment should not have cracks or scratches that allow for buildup of bacteria. Equipment should be rinsed in lukewarm water and then actively scrubbed in water hotter than 50° C (122° F) containing either detergent and bleach (6% sodium hypochlorite) or dry chlorinated detergent to remove any residue. Bottle brushes should be used to clean esophageal feeders, nipples, and feeding bottles. Finally, they should be rinsed in water containing acid or an acid rinse and allowed to dry completely before stacking them upside down for storage.

When there is concern about hygiene practices, plating 10 µL of colostrum onto a blood plate and incubating at 37° C overnight provides a simple crude assessment of microbial contamination of colostrum being fed to calves and allows identification of the origin of any process failure. Fresh colostrum fed to calves should have a total bacteria count of less than 100,000 colony-forming units/mL and less than 10,000 coliforms/mL.[161,167]

Short-term storage of colostrum is necessary in order to deliver known good-quality colostrum to neonatal calves within hours of birth to reduce the risk of failure of passive transfer. When colostrum is stored at ambient temperatures, bacterial proliferation leads to fermentation, thus reducing total solids, protein, fat, and lactose content. Refrigeration of colostrum delays bacterial growth. The rate of colostrum cooling in a refrigerator is influenced by the volume and surface area of the container in which it is stored. Colostrum should be dispensed into 2-L containers prior to refrigeration. Producers should aim to feed refrigerated colostrum within 2 days of collection.[170] Storage of colostrum in the refrigerator for more than 24 hours will result in a decreased amount of IgG absorbed, and this may lead to FPT if stored for more than 48 hours.[176] Adding 10 mL of 50% potassium sorbate solution per liter of colostrum at the time of collection (0.5% wt/vol), in combination with refrigeration, inhibits bacterial growth for 4 days.[166]

Heat treatment of colostrum is an effective way to control colostrum bacterial load, reducing the risk of infectious disease

BOX 19.1

Best Practice Colostrum Management for Dairy Calves

- Milk cows as soon as possible after calving. Immunoglobulin G (IgG) concentration declines by 3.7% for each hour after calving.
- Remove calves from the calving area at least twice daily.
- Measure quality of colostrum (Brix refractometer). This will determine the quantity of colostrum to be fed. For the first feed, administer colostrum containing 150 g IgG within 4 hours of calving. Feed a maximum of 7.5% of body weight. If calf does not suckle the full amount, top with esophageal feeder.
- Feed an additional 5% to 7.5% of body weight by 12 hours of age. If the calf did not receive 150 g of colostrum in the first feed, it is preferable to supplement 7.5% of body weight at the second feed.
- On farms with a history of Johne's disease, salmonella, mycoplasma, or leukosis, pasteurize colostrum.
- Avoid pooling colostrum where possible. If pooling of colostrum is unavoidable, mix colostrums of similar quality.
- Implement a monitoring program for failure of passive transfer.

BOX 19.2

Best Practice Colostrum Management for Beef Calves

- Avoid severe restriction of dietary intake prior to calving; this will reduce volume and make colostrum more difficult to suckle.
- Minimize disruption of calving cows.
- Ensure that calves receive colostrum within 6 hours of calving (active suckling); intervene when there is dystocia or dumb calf.
- Intervention may involve restraining the dam and encouraging suckling or administering colostrum by a nipple bottle. An esophageal feeder should be used only when volumes greater than 1.5 L are available or if the calf will not suck.

VetBooks.ir

transmission from cow to calf.[177] Degradation of immunoglobulins may be a problem with large-batch colostrum pasteurizers. Calves fed large-batch pasteurized colostrum have significantly lower serum IgG levels than those fed unpasteurized colostrum.[48] However, pasteurization of small batches of colostrum (57 L) at 67° C (152.6° F) or lower for 30 minutes caused a minimal decrease in the immunoglobulin concentration of colostrum compared to pasteurization of large batches (95 L) or batches at higher temperatures (76° C [168.8° F] for 15 seconds) and had little effect on the subsequent serum immunoglobulin in calves at 24 hours of age.[178,179] At this temperature *M. avium* subsp. *paratuberculosis* may survive.[180,181] Heat treatment of colostrum (at 60° C [140° F] for 60 minutes) at a commercial level has been shown to effectively reduce colostrum microbial counts while maintaining IgG concentration.[182] Calves fed such colostrum were also found have reduced morbidity.[183] This critical temperature and time period appears to significantly reduce the bacterial load while not denaturing the IgG or changing the viscosity of colostrum.[184] Calves fed heat-treated colostrum (in either single aliquots or batch treatment) had significantly improved apparent efficiency of absorption and serum IgG compared to calves fed fresh frozen or fresh refrigerated colostrum (Kryzer, 2015).[172,184a]

The use of ultraviolet (UV) light to reduce the pathogen load of colostrum has been described. UV light inactivates microorganisms by disrupting their RNA and DNA structure.[185,186] However, this process depends on exposure of the microorganisms to UV light, which can be problematic in opaque mediums such as colostrum and milk. Although some microbial reduction has been observed using this process, the significant negative effect on colostral immunoglobulin level is deemed unacceptable, with a final mean IgG reduction of 40% to 50%.[187,188]

Longer term preservation of colostrum can be achieved by freezing or lyophilization without change in the immunoglobulin and nutritional content.[189-191] However, the cellular content of colostrum is destroyed by freezing, which may have longer term effects on the development of the immune system.[192] In kids the feeding of lyophilized colostrum resulted in higher IgG levels than the feeding of frozen colostrum.[193] The freeze-thaw cycle is associated with an 8% to 30% loss in IgG1, with the magnitude of the loss dependent on the method of thawing. Thawing at 40°, 50°, 60°, and 70° C is associated with losses of 8%, 14%, 15%, and 26%, respectively. Thawing in a microwave at 200 and 350 watts causes losses of 20% and 31%, respectively.[194] Thawing larger volumes in a microwave may result in uneven heating and clots and is generally not recommended.[134] The speed of thawing colostrum can be facilitated by freezing 1- to 4-L aliquots in flat plastic bags or purpose-designed equivalents. Thawing in a rocking heated water bath at 40° C (104° F) is recommended; alternatively colostrum may be thawed at room temperature or in a fridge.

Monitoring Colostrum Immunoglobulin Quality. The quality of colostrum has traditionally been measured by visual inspection or by using a colostrometer (a hydrometer). The level of IgG in colostrum cannot be accurately predicted based on its appearance,[88,195] hence the need for more objective instruments. The colostrometer (hydrometer) measures the specific gravity of a liquid, which in the case of colostrum is associated with the protein content. Globulins contribute greatly to this protein, so the colostrometer has been used to determine the immunoglobulin content of colostrum.[196] Although they are relatively quick to use on-farm, the sensitivity and specificity of colostrometers are variable depending on the cut-point selected and the instrument used. The sensitivity of colostrometers to detect high-quality colostrums ranges from 0.32 to 0.84, and specificity for detecting low-quality colostrums ranges from 0.77 to 0.97.[197-199] Colostrometer readings are also significantly affected by temperature,[200] and for a known quality of colostrum, the colostrometer can differ by 0.8 g/L for every degree Celsius change in temperature. The specific gravity of colostrum also can differ between breeds and can be influenced by lactation number, month of calving, year of calving, and protein yield in the previous lactation.[107] Field experience has shown that colostrometers are most accurate in diagnosing samples of moderate or inferior quality but may indicate erroneously high readings for samples in the superior range.[63] It should be noted that the markings on a colostrometer are calibrated for Holstein cows. From a practical perspective, colostrometers are very fragile and prone to breakage in the farm environment.

Cow-side immunoassay kits for measuring colostral IgG are available and have been shown to have an acceptable sensitivity and specificity for this purpose.[201] However, their lack of availability on a global scale, along with financial constraints, limit their use.

Optical and digital Brix refractometers can be used to measure the quality of colostrum using fresh and frozen samples.[202] For colostrum from Holstein cows, the optical Brix refractometer demonstrated a specificity of 85% and a sensitivity of 90.5% using a cutoff of 22% Brix. A cutoff of 22% Brix was deemed to equate to 50 g/L of immunoglobulin using radial immunodiffusion (RID), thus samples greater than 22% Brix were considered to be of adequate quality.[202] In another study the results showed that a cut-point of 21% was estimated in samples greater than 50 g/L, as measured by RID.[72] Breed influences colostrum Brix readings. The cut point for 50 g/L for Jersey colostrum is lower with a Brix of 18% providing a sensitivity of 92.3% and a specificity of 94.7%.[203]

The benefits of the Brix refractometer are that they are not affected by ambient temperature and they are robust, easy, and economical to use at an on-farm level.[198] It has been found that high-quality colostrum samples can yield a "fuzziness" through the viewfinder of a Brix refractometer. Generally this happens in samples greater than 22%. A smaller sample size on the prism can help with clarity in these high-quality samples. The poorer the quality of colostrum, the clearer the value is to read.

Brix refractometers are inexpensive, easily available, and robust, and as such should be standard dairy farm equipment. Farmers are advised to purchase a refractometer that only measure degrees Brix with a scale from 0% to 32%, so that they are easy to read. To get an accurate reading it is necessary to press the cover plate firmly over the prism while looking through the viewfinder, as some thick samples will cause the cover plate to lift off the prism. It is also important that each sample is placed on a clean, dry prism.

The Role of Vaccines in Colostrogenesis. A potential approach to achieving an increased level of protective immunity in neonatal calves is by vaccination of the dam during the period of colostrogenesis. This practice has frequently been adopted to aid in the control of diarrhea-causing pathogens such as *E. coli*, rotavirus, coronavirus, and *Salmonella*.[204-209] Calves fed colostrum from vaccinated cows have shown increased serum IgG and reduced morbidity and mortality compared to calves fed colostrum from unvaccinated dams.[206] Herd-level vaccination has led to an increase in the colostrum quality observed as determined by Brix refractometry.[210] The timing of vaccine administration during the dry period is critical, as an increase in dam serum IgG in response to vaccination must coincide with colostrum production in the udder tissue.[211] If a vaccine is administered too close to parturition, there is an inadequate period for a peak IgG response and subsequent transfer of IgG into colostrum. If a vaccine is administered too far away from expected parturition, peak IgG response will not coincide with colostrogenesis. No one generic vaccination protocol fits all vaccines, so the manufacturer's directions should be followed. Producers should be reminded that the

usefulness of vaccines depends on active colostrum feeding and delivery of an adequate mass of IgG to the calf in a timely manner after birth.

Enhancing IgG Uptake. Numerous attempts have been made to artificially augment passive transfer by adding substances to colostrum that aim to increase efficiency of absorption or provide an increased concentration of immunoglobulins. Addition of dried colostrum powder,[110,212] casein, or concentrated whey protein[213,214] had either no benefit or a detrimental effect on colostrum absorption. Feeding colostrum containing 1000 IU vitamin E to calves does not influence uptake of IgG by the calves but did result in higher levels of vitamin E in the calf plasma.[215] Similarly, the addition of 30 g sodium bicarbonate to colostrum had no effect on uptake.[216] However some studies have demonstrated positive benefit. The addition of spray-dried bovine serum to lower quality colostrum to provide the equivalent level of IgG as found in a high-quality colostrum resulted in a higher level of IgG at 12 and 24 hours of age.[217]

The addition of 5 g/L of a mineral adsorbent zeolite (clinoptilolite) up to a total of 0.5 g/kg/day has been shown to increase rate of absorption of colostrum in the first 16 hours and in some cases to increase serum IgG at 24 and 48 hours, especially where lower colostrum volumes were fed.[218-220] The exact reason for this has not been explained, but it is thought that clinoptilolite may bind some degradation products of colostral proteins, such as ammonia, in the gut, thus preventing their negative effects on mucosal epithelial cells designated for immunoglobulin absorption. It may also slow the passage rate of digesta through the intestine, allowing increased time for absorption. The addition of 1 and 2 g/kg/day of clinoptilolite has a negative effect on serum IgG concentration at 24 and 48 hours, but when colostrum from cows vaccinated against K99 and F41 antigens of *E. coli* was fed, calves fed 1 and 2 g/kg/day had increased blood serum levels of specific antibodies against *E. coli* at 12, 24, and 48 hours.[221,222] In all of these studies very high-quality colostrum (80 to 100 g/L) was fed, and no more than 2 L was fed at any one feeding and often 0.75 L was fed to a 35-kg calf. The benefits of clinoptilolite when larger volumes of lower quality colostrum are fed have not been evaluated. When clinoptilolite is added to milk replacer as well as colostrum, an added benefit of increased hematopoiesis is seen, presumably as this mineral is high in iron.[222,223]

The addition of gut-active carbohydrate (mannan-oligosaccharide) to colostrum has been shown to affect IgG uptake with variable results.[224-226] Again, the mechanisms responsible for this effect have yet to be elucidated. Bacteria in colostrum may directly block uptake and transport of immunoglobulin molecules across intestinal epithelial cells or bind free immunoglobulin in the gut lumen.[48,171] Gut-active carbohydrates have been shown to adsorb pathogens expressing type 1 fimbriae, reducing their ability to colonize the gastrointestinal tract.[227] Thus there is a potential role for gut-active carbohydrates to play in the uptake of IgG from the gastrointestinal tract. However, it is still unclear as to whether the addition of gut-active carbohydrates to colostrum enhances or reduces IgG absorption.[224]

These studies demonstrate that it is possible to influence uptake of IgG with specific additives and that further research is required to investigate their potential while accommodating the variation in colostrum IgG concentration and standard management practices within herds.

MONITORING FOR SUCCESSFUL PASSIVE TRANSFER

Calves. Monitoring programs for FPT are an integral step in neonatal calf disease outbreaks and proactive calf health programs. A range of tests have been used to assess passive transfer.[228-230] The RID assay is considered the reference method and is a direct measure of serum IgG. However, its usefulness is compromised by the processing time and expense. There is some variation in the published research as to the level of serum IgG that indicates adequate passive transfer, but most researchers use 10 mg/mL (1000 mg/dL).[149,228,231,232]

Precipitation Tests. The sodium sulfite and zinc sulfate turbidity tests use salts to precipitate serum proteins, in particular the larger molecular weight immunoglobulins. A measured amount of calf serum is added to a standard volume of solution and incubated at room temperature for up to 30 minutes. The test results are quantified according to the degree of cloudiness of the mixture caused by protein precipitation. The sodium sulfite turbidity test has traditionally been described as a three-step semiquantitative test using 14%, 16%, and 18% solutions. The sensitivity, specificity, and degree of association with IgG are similar to measuring serum protein with a refractometer, but the test is more complicated to perform.[228] The sensitivity has been estimated as 85% to 100% and the specificity as 53% to 87% using an 18% solution (1+ end point).[228,232] The zinc sulfate turbidity test can be influenced by hemolysis, making it difficult for routine use.[89] The standard test is carried out by adding 0.1 mL of calf serum to 6 mL of 208 mg/L zinc sulfate and incubating the mixture for 1 hour at 23° C (73.4° F). The test has a sensitivity of 100% and a specificity of 55%, which is lower than serum protein or sodium sulfite turbidity.[228] The specificity of the test can be improved by increasing the strength of the solution to 300 or 350 mg/L.[233] These solutions resulted in an increase of the specificity to 65% and 76%, respectively, with little decrease in sensitivity.

Recently, ammonium sulfate (immunocrit), previously developed for piglets,[234] was evaluated in dairy calves.[235] The reported advantage of the use of ammonium sulfate is that it only precipitates immunoglobulins and is non–species specific. The test is performed by mixing an equal volume of 55% ammonium sulfate and serum to be tested, followed by collecting the mixture in a microhematocrit capillary tube, and then centrifuging. The capillary tubes are then removed from the centrifuge, and immunocrit values are read with a microhematocrit reader card from the top of the capillary tube sealant to the intersection between the precipitated IgG and the remaining serum. Immunocrit values of 11% or greater indicate adequate transfer of immunity.[235]

Enzymatic Activity. Measurement of serum gamma-glutamyltransferase (GGT) in calves aged 24 hours can indicate positive ingestion of colostrum but has poor correlation with actual serum IgG levels.[236] A limitation of this test is that serum GGT declines rapidly during the first week of life.[237] Thus accurate records reflecting the age of the calf are vital for this test to be interpreted accurately. Both colostrum and milk contain GGT, but activities in milk are considerably lower than in colostrum.[238] GGT rises quickly after the ingestion of colostrum and then falls rapidly over the subsequent 24 hours, followed by a slow decline for the next 2 months. Calves that do not ingest colostrum have serum GGT activities similar to adult cattle. GGT is a useful test when assessing the passive transfer status of clinically ill calves younger than 21 days of age where disease confounds interpretation of serum proteins; a GGT cutoff of 50 IU/L classifies 93% of calves correctly (sensitivity 93%, specificity 92%).[239]

Immunoassay. The on-farm lateral flow immunoassay is one method for identifying calves with less than 10 mg/mL serum IgG. It takes approximately 20 minutes to perform and is relatively inexpensive, but it is not commercially available worldwide. The test yields only a positive or negative result as opposed to the actual level of serum IgG. This is considered a limitation of the test.[48] Published results show that sensitivity ranges from 93% to 99% and specificity from 88% to 89%.[232,240]

Refractometry. An optical handheld clinical refractometer may be used to measure serum protein of calves between 24 hours and 7 days of age. Although it is not a direct measurement of IgG concentration, it is considered an accurate indicator of the

[a]It should be recognized that there is variation among refractometers.[326]

IgG, Immunoglobulin G.

immunoglobulin status of the animal (Table 19.3).[241] Studies have compared refractometry to turbidity testing and GGT activity and have shown that it is equivalent or superior to these assays in the proportion of calves classified correctly.[25,228,236,237] This method is easier to standardize between laboratories and operators than many other indirect methods and is cheaper, quicker, and easier than most direct tests for IgG.[25] A minimum of 12 calves need to be sampled; when interpreted on a group level, this method provides a good correlation between serum protein and serum IgG, as measured by RID.[48] Sick (scouring) calves should not be included in the sample set, as dehydration will falsely elevate the serum protein. It has been suggested that the accuracy of serum protein could be improved if packed cell volume (PCV) is also measured as a proxy for hydration status.[239] The benefits of this method are that it is quick and inexpensive and samples do not need centrifugation.[242] This has an added advantage, as this method can be implemented at the farm level on large calf-rearing units to monitor for FPT in groups of calves. A serum protein concentration less than 5.0 g/dL reflects FPT, between 5.0 and 5.5 g/dL reflects marginal passive transfer, and greater than 5.5 g/dL reflects adequate passive transfer. At a herd level the target should be for 80% of calves to have serum protein concentrations greater than 5.5 g/dL.[161] More recently it has been suggested that a serum total protein of 5.8 to 6.3 g/dL should be used to indicate adequate transfer of immunity in dairy calves.[147] Assessment of serum protein using a refractometer is not a reliable estimate of IgG levels in calves that have received colostrum substitutes or replacers.[243] Using the same methodology, a Brix refractometer can also be used to indirectly assess passive transfer using serum protein. A cut-point of 8.3% Brix can be used to estimate FPT (serum IgG <1000 mg/dL) with reasonable sensitivity (85.5%) and specificity (82.85%).[244]

Lambs. Determination of serum GGT activity,[245-247] serum total protein using the biuret method, and γ-globulin concentrations[247] has been recommended for assessing passive immunity in lambs. However, serum total protein determination by refractometry is considered beneficial in making clinical decisions because of the immediate availability of test results.[247] Previous studies that used zinc sulfate turbidity tests to assess passive transfer in lambs indicated that zinc sulfate readings of less than 10[248,249] and less than 12[249] were associated with increased morbidity and mortality. The zinc sulfate readings of less than 10 and less than 12 were equivalent to serum total protein concentrations of 5.2 and 5.4 g/dL, respectively.[247] Serum total proteins of 5.2 and 5.4 g/dL were also determined to be equivalent to serum IgG concentrations of 1332 and 1521 mg/dL.[247] Serum γ-globulin concentrations of 0.5 g/dL or less were associated with higher mortality rates compared to lambs with higher γ-globulin concentrations.[250] γ-Globulin concentrations of 0.5 g/dL were equivalent to serum IgG concentrations of 681 mg/dL. Based on these observational studies, serum IgG concentrations that provide optimal health below which FPT occurs in 1- to 2-day-old lambs were estimated to be between 600 and 1600 mg/dL.[247] However, the risk for morbidity and mortality for various strata in this serum IgG range has not been fully described and will depend on other components of the epidemiologic triad (agent and environmental factors). Algorithms for predicting passive transfer status of various ages using GGT have been developed in lambs.[245,246] In summary, serum GGT activity and serum protein determination by biuret method are currently the most widely used tests for assessing immunity in lambs. Although determination of serum protein concentration by refractometry is cheaper and practical and test results are readily available, it is likely to misclassify FPT status compared to the other methods.[247]

Goat Kids. FPT in goat kids is defined as serum IgG concentrations less than 1200 mg/dL.[251] Practical tests reported as useful in assessing passive transfer status include the 18% sodium sulfite test and serum total protein by refractometry.[251] Serum total protein concentrations of 5.4 g/dL or higher were considered indicative of adequate passive transfer of immunity.[251]

MANAGEMENT OF FPT. Calves may be managed for FPT by the administration of bovine plasma at a dosage of 20 to 40 mL/kg. The initial rate of administration should be 5 mL/kg/h with close observation for adverse effects, which most commonly include trembling, hives, edema, piloerection, stertorous breathing, and increases in heart rate and respiratory rate. If no adverse effects are noted in the first 30 minutes, the rate can be increased to 10 to 20 mL/kg/h with continued monitoring.[252] Whole blood also can be used, but the dosage should be increased to account for the presence of red blood cells.[89] Calves should be monitored as for plasma transfusions; adverse reactions are very uncommon with first-time transfusions, as there are a large number of blood types in cattle. Plasma or whole blood may also be administered via the intraperitoneal route. An area in the center of the left paralumbar fossa is clipped and surgically prepared. A 14- to 16-gauge, 1.5-inch needle is used to penetrate the skin, abdominal musculature, and peritoneum, and the serum is administered through a giving set.[89] The benefits of plasma administration in healthy or sick calves with FPT has been questioned. Plasma administrations to healthy calves attained serum IgG concentrations greater than 1000 mg/dL, but the decay of transfused plasma was significant such that by 12 hours post transfusion, the serum IgG concentrations were less than 1000 mg/dL.[253] The half-life of transfused IgG was 4.4 days compared to 17.1 days for colostral-derived IgG.[253] In addition, calves with FPT transfused with plasma were five times more likely to experience mortality compared to calves with adequate passive transfer of immunity.[253] This increased rate of decay of plasma-derived IgG may necessitate repeat plasma transfusions, which might predispose calves to transfusion reactions. In another study plasma transfusion had no effect on oxidative and phagocytic activity of neutrophils of calves with FPT.[254] Due to high costs associated with plasma transfusions, the procedure should be considered on a case-by-case basis.

Precautions should also be taken to minimize risk factors for infection in calves with FPT, including minimizing potential exposure to pathogens. Colostrum may be fed beyond the period of closure to provide protection at the level of the gut lumen. Where the environment is less than desirable, the prophylactic administration of broad-spectrum parenteral antimicrobials in calves with FPT should be considered.

Navel Treatment

Omphalitis occurs in 1% to 14% of newborn calves.[255,256] It can lead to reduced growth, joint ill, and other adverse sequelae

associated with bacteremia.[257] Prevention of navel ill is based on maintenance of maternity pen hygiene, reducing the residency time of calves in unhygienic maternity pens, ensuring adequate early intake of good-quality colostrum, and navel antisepsis.[258] Literature on the efficacy of navel treatment in reducing calf mortality is divided. In a study of 104 dairy farms, a farm policy of navel treating newborn calves had no significant effect on calf mortality rates. Similarly, spraying the navels of lambs with iodine spray or applying clamps to the navels failed to change the incidence of joint ill in lambs compared to no treatment.[259]

A significant beneficial effect was observed when the navels of calves that had assisted deliveries were dipped with chlorhexidine; other navel treatments such as iodine tended to be associated with increased odds of dying.[260] Chlorhexidine has a wide antimicrobial spectrum, long duration of activity, and high efficacy in the presence of organic matter.[261] In a controlled clinical trial investigating the efficacy of navel dips, a reduction in the incidence of omphalophlebitis was observed in calves when navels were dipped with tincture of iodine (7% iodine), dilute iodine (0.5% or 0.2%), or a commercial product (Navel Guard [NG], Sirius Chemical Group, McDonough, Ga.) as compared to calves with nondipped navels.[255] Conversely, navel treatment with iodine was associated with significantly higher mortality in another study of 48 farms; however, the association of navel treatment with mortality on these farms may have reflected the response of producers to high neonatal mortality rather than indicated that iodine navel treatment is a risk factor for high calf mortality.[262]

It is interesting to note that navel treatment has been associated with both a reduced[263] and an increased[264] risk of respiratory disease. The bases of these associations are unclear.

Nutrition

Although the neonatal calf stomach has four parts, the rumen is not functional at birth. At birth the abomasum is the only truly functional part and has a capacity twice that of the other compartments. Liquid is shunted past the reticulorumen into the abomasum via the esophageal groove. The groove is closed by a reflex that is stimulated by the intake of liquids (milk is best, electrolyte and glucose water is usually effective, but straight water becomes ineffective in closing the groove fairly early in life). The first enzyme to start the process of milk digestion is salivary lipase. When whole milk enters the abomasum, casein is denatured by the acidic (pH 2.0) conditions. Rennin cleaves a specific peptide bond in κ-casein, which in the presence of calcium ions causes coagulation of the casein proteins. Fat is entrapped within the coagulum, but the whey proteins, lactose, and soluble minerals and vitamins are excluded into the liquid portion (whey) as the coagulum contracts. The soluble components enter the small intestine within 2 to 3 hours after a meal, whereas the casein coagulum is digested more slowly.[265] Casein is partially digested by the abomasal protease pepsin. Polypeptides released from caseins enter the small intestine for further digestion. Milk fat trapped in the abomasum undergoes some digestion by the enzyme pregastric lipase, which is secreted in the mouth. The products of its action are diacylglycerols and free fatty acids, which enter the small intestine for further digestion and absorption. Lactose is hydrolyzed to its component sugars, glucose and galactose, by the intestinal brush border enzyme lactase, and the monosaccharides are absorbed into the epithelial cells by specific active transport proteins.[265] The age at which ruminal digestion begins depends on the diet of the calf. Transition to ruminal digestion begins at 3 to 4 weeks of age; the earlier dry feed is provided, the earlier ruminal development starts.

The energy requirements of the calf may be divided into maintenance and growth requirements, with the magnitude of maintenance requirements influenced by environmental conditions. The basal maintenance requirement for neonatal calves is between 44.7 and 52.4 kcal/kg/day.[266,267] Energy requirements for growth are between 268 and 307 kcal/100 g of body weight gain.[267,268] Since whole milk contains about 70 kcal/100 mL, a 40-kg neonatal calf needs about 3 L of whole milk for maintenance and an additional 4 to 5 L to gain 1 kg of body weight. Cold stress significantly increases energy requirements. A 40-kg calf at –20° C requires 3.31 Mcal/day to meet maintenance requirements and maintain body temperature compared to only 1.59 Mcal/day at 20° C.[265] Similarly heat stress increases maintenance energy requirements by 20% to 30%.[265] The energy requirements of calves managed at different temperatures are presented in Table 19.4. The requirements for a sick, stressed calf are not well established.

TABLE 19.4

Maintenance Requirements for Metabolizable Energy as Affected by Body Weight and Environmental Temperature in Calves Less Than 21 Days Old

BW (kg)	Environmental Temperature (° C)				
	20	10	0	–10	–20
	(Maintenance ME, Mcal/day)				
30	1.28	1.63	1.97	2.38	2.67
40	1.59	2.02	2.45	2.96	3.31
50	1.88	2.39	2.90	3.50	3.91
60	2.16	2.74	3.32	4.01	4.48

Data from National Research Council: *Nutrient Requirements of Dairy Cattle*, ed 7, Washington, DC, 2001, National Academy Press.

BW, Body weight; *ME*, metabolizable energy.

Conventional milk replacers contain 20% to 22% crude protein (CP),[269] but calves benefit most from the increased feeding when milk replacers contain higher protein and lower fat (up to 30% CP with 15% to 20% fat).[269] Digestible protein requirement for maintenance is 0.5 g/kg, and the amount required for growth is about 22 g/100 g gain in body weight. Digestibility of the protein is an important concern in evaluating milk replacers. Some milk replacers substitute legume proteins for milk-derived proteins. Legume-derived proteins contain antinutritional factors that include antigenic proteins, lectins, and trypsin inhibitors.[270] Trypsin provides a protective mechanism against clostridial disease by cleaving the clostridial beta toxin.[271] Soybean flour has been used experimentally to induce *Clostridium perfringens* type C enterotoxemia in lambs.[272]

Many calves are raised according to the "calf starter method," which became popular in the early twentieth century.[273] According to this method, calves are fed limited amounts of milk (approximately 10% body weight). Milk intake is limited to encourage intake of calf starter, facilitating weaning at about 7 to 8 weeks of age. Forage feeding is discouraged during the milk feeding phase, as it lowers starter intake. Rumen papillae growth is stimulated by production of volatile fatty acids (VFAs), in particular butyrate, which is highest in calves that are consuming larger volumes of starter.[274] During the last decade several studies have challenged the "calf starter method." Limiting how much calves are fed has been shown to lead to poor weight gains[275] and a higher risk of disease and abnormal behaviors, indicating reduced calf welfare.[276] Providing greater quantities of milk or milk replacer improves growth and feed efficiency.[276] To achieve biologically appropriate growth, milk feeding rates are approximately twice those of the calf starter method. This calf feeding approach is often referred to as the "accelerated feeding" method. A rule of thumb is to provide 1.5% of body weight as milk solids during the first week of life, then 2% of body weight from the second week of life until the week before

VetBooks.ir

weaning, when one feeding is dropped.[277] Intake of starter lags behind that of calves fed on conventional systems, but increases at approximately the same rate once the amount of liquid is cut back.[277] To avoid or minimize growth slumps around weaning, calves should not be weaned until they are consistently eating 1 kg of starter daily.[265] With accelerated feeding programs it is not uncommon to see a postweaning growth slump. This may reflect poor rumen development due to delayed starter intake. Subclinical acidosis may also be a problem when well-grown calves with poor rumen development eat larger volumes of starter. Variable manure quality in a pen of calves is commonly observed in this scenario. Calves may also have a preoccupation with chewing on inanimate objects in the pen and an increased incidence of respiratory disease. The link between subclinical ruminal acidosis and risk of pneumonia is recognized in beef feedlots, but the mechanism is not yet known.[278] Starter intake, nutrient composition, physical form, and palatability along with the age of the calf affect the risk of rumen acidosis. Experimental trials that feed forage to preweaned dairy calves have produced inconsistent results. The fermentation rate of a starter formulation influences the risk of rumen acidosis and the need to include forage in the diet. Grain type, particle size, and processing affect the fermentation rate of starch in the rumen. Trials in which provision of forage increased starter intake tended to be those feeding a pelleted starter. Conversely, trials in which forage had a negative or no effect on starter intake have often involved the feeding of a textured starter where starch fermentation is slow.[279]

A rule of thumb for preweaning growth is for calves to double their birth weight by time of weaning at 7 to 8 weeks of age. Higher rates of growth observed early in life are associated with reduced breeding age[280] and higher milk yield when the calf matures.[281] One study reported that approximately 25% of the variation in first-lactation milk production could be explained by preweaning average daily body weight gain.[281] Subsequent studies have reported variable milk production responses to preweaning growth. A more recent meta-analysis reported a positive yet less dramatic relationship between first lactation performance and preweaning average daily weight gain; however, the magnitude of the relationship was less than the relationship between the postweaning and puberty periods.[282,283]

Clinical Investigation of Neonatal Disease

The principles of clinical investigation of neonatal disease are similar to those for adults; however, the neonate signalment carries with it a higher risk for sepsis, congenital malformations, and a number of specific neonatal diseases, resulting in a shift in the emphasis of history, physical examination, and diagnostic work-up. When a single individual is involved, observation from a distance, recording of vital signs, and a physical examination guide the clinician to the selection of appropriate diagnostic tests to establish a cause, make a diagnosis, and evaluate the prognosis. For conditions that affect a flock or herd of animals, the examination of affected individuals remains an essential component of the diagnostic work-up, but evaluation of records, the environment (housing and other animals), nutrition, colostrum, treatment, and vaccination protocols is also needed.

History

The investigation of neonatal disease problems is facilitated by the defined period of risk and temporal distribution of the more common disease syndromes. For health problems involving individuals or the flock or herd, it is best to start at birth and work forward. For the individual a history of dystocia indicates the likelihood of neonatal compromise and the possibility of failure of passive transfer. The risk of specific diseases may be influenced by pathogen-specific immunity, which may be manipulated through either maternal or neonatal vaccination. Details of the farms vaccination protocol should be collected. The specifics regarding the timing of vaccination are important, as timing influences the likelihood of achieving effective immune specific passive transfer. At a herd level the likelihood of FPT and the efficacy of maternal vaccination are determined by colostrum management. From a herd perspective it is important to determine the farm's protocol for harvesting, storing, and administering colostrum, as these protocols determine immunoglobulin and microbial quality and the likelihood of achieving adequate passive transfer.

Risk of neonatal infectious disease is determined by the balance among host immunity, environment, and pathogen dose and virulence. Management should strive to maximize host immunity through good colostral management and provision of adequate nutrition and by minimizing environmental stress. The risk of pathogen exposure is influenced by environmental conditions at birth, amount of time spent with the dam, facility hygiene, colostrum and milk hygiene, personnel hygiene, and neonate age grouping. Defining the onset and progression of disease is useful, as certain diseases are more likely to occur at different times. Response to treatment or lack thereof may provide clues regarding pathogen involvement, and details of treatment protocols may identity inappropriate, ineffective treatment. Occasionally disease is iatrogenic, so it is important to collect details of all products administered, specifically time, volume, frequency, and route.

Examination From a Distance

The physical examination begins with examination from a distance, with assessment of behavior, body condition, and stance. Drooping of the head and ears is an early sign of illness. Sick calves spend increasing amounts of time recumbent and are less inclined to drink. In beef calves, lambs, and kids this may be reflected by udder distention in the dam. With dairy calves the calf feeder reports that the calf requires stimulation to stand and fails to drink. Abdominal contour should be noted, with consideration of the neonate's reported appetite; an abdominal contour that appears normal may actually be abnormal if the calf has not eaten for a couple of days. Observing the neonate navigate its environment provides a simple assessment of vision. From a distance, mentation, posture, vision, abdominal contour, stance, lameness, respiratory rate, breathing effort, characters of nasal and ocular discharge, and spontaneous coughing can be evaluated. Abnormal postures exhibited by patients with respiratory conditions may be recumbency, open-mouth breathing, abnormal extension of the head and neck, head tilt, or reluctance to lie down. Abnormal breathing characteristics include prolongation of the inspiratory or expiratory phase of respiration, an expiratory abdominal press or snap, marked tachypnea, frequent spontaneous coughing, stridor, or inspiratory or expiratory noises. Abnormal mentation of neonatal ruminants may be the result of meningoencephalitis, hypoglycemia, hypoxic ischemic encephalopathy, calving injury, or severe metabolic acidosis. Abnormal posture of the head and neck are exhibited by neonates with respiratory difficulty, but meningoencephalitis, otitis media, hypernatremia, polioencephalomalacia, congenital defects of the central nervous system, and lasalocid toxicity should be considered.

Examination from a distance on-farm also provides an opportunity to assess the neonate's environment. Environmental and/or management-induced compromise in the form of inappropriate stocking density; mixed age-groups; inadequate ventilation or shade; wet, muddy conditions; moldy bedding; inadequate protection from adverse weather; evidence of poor hygiene; inappropriate feed on offer; and excessive fly challenge may all contribute to the risk of disease.

With the increasing use of robotic calf feeders, a plethora of data is available on farms that use this technology to monitor calf behavior. Reductions in drinking speed, unrewarded visits,

VetBooks.ir

and milk consumed may be observed 3 to 4 days prior to overt clinical signs of disease.[284] The onset of change in these parameters relative to detection of clinical signs is dependent on disease type, with changes observed earlier in association with diarrhea than pneumonia.[284]

Hands-on Examination

PHYSICAL APPEARANCE, BODY WEIGHT, AND BODY CONDITION. It has been increasingly recognized that genetics influences the risk of perinatal mortality, with the heritability for perinatal mortality ranging from 0.03 to 0.13.[285] Congenital disorders may present with subtle changes in physical appearance and behavior. For example, Salers calves with beta-mannosidosis have moderately domed heads, mild superior brachygnathism, and a slight head tremor.[286] Similarly, in utero infections that lead to growth retardation may be reflected by low birth weight and poor body condition. Low birth weight, contracted tendons, and/or abnormal mentation should prompt consideration of testing for persistent infection with bovine viral diarrhea (BVD).

Head. Observation of facial expression provides an opportunity to assess cranial nerve function. Normal eyeball position and movement is consistent with normal function of cranial nerves III, IV, VI, and VIII. Normal facial expression and ear and eyelid position suggest normal functioning of cranial nerve VII. Vision (cranial nerve II) is assessed by watching the neonate navigate its environment. Because the menace response is learned, it is not particularly useful in very young animals. Normal sucking behavior is consistent with normal functioning of cranial nerves V, VII, IX, and XII. Absence of atrophy of the neck is consistent with normal functioning of cranial nerve XI. Functioning of cranial nerves V, VI, and VII are further assessed by the palpebral and corneal reflexes, and cranial nerves II and III are assessed by the pupillary light response. Eyeball position and skin tent duration are used to assess dehydration and estimate base deficit in calves with diarrhea (Table 19.5).

Depressed mentation is a feature of a number of neonatal diseases. Sepsis and diarrhea are both commonly associated with depressed mentation secondary to toxemia and/or metabolic derangements. Bacterial meningitis is common in neonates following bacteremia; diarrhea, septic arthritis, omphalophlebitis, and uveitis are frequent concurrent clinical problems. The clinical signs of meningitis in neonates (lethargy, anorexia, recumbency) are nonspecific. Concurrent metabolic derangements may appear to provide an adequate explanation for the observed depressed mentation. In a retrospective study of 32 cases of bacterial meningitis in calves, concurrent metabolic derangements included hyperkalemia (15 of 25, 60%), respiratory acidosis (11 of 24, 46%), hypernatremia (3 of 20, 15%), and hypoglycemia (3 of 7, 43%).[287] The more classical clinical signs described for bacterial meningitis in older animals (fever, opisthotonus, extension of the head, convulsions, hyperesthesia, signs of neck pain) may not be evident or perceived in neonates. Seizures in calves are often subtle, manifesting as facial twitches or jaw champing. Common causes of cerebral disease in lambs and kids include polioencephalomalacia and focal symmetric encephalomalacia. Affected animals are typically depressed and blind but have normal pupillary light reflexes.

Mouth. Examination of the mouth includes assessment of the mucous membranes, moisture, color, and capillary refill time. Mucous membranes should be moist and pale pink with a capillary refill time of less than 2 seconds. Gray or cyanotic mucous membranes are associated with severe hypoxia, circulatory collapse, hypovolemic shock, cardiovascular anomalies causing a right-to-left shunt, and/or severe pulmonary disease. Absence of cyanosis is not a reliable indicator of adequate oxygenation in the neonate since the partial pressure of oxygen may reach very low levels (<35 to 40 mm Hg) before cyanosis is observed. Cardiac and pulmonary causes of cyanosis must be distinguished. Petechiae on the oral or nasal mucous membranes are consistent with sepsis-induced vasculitis or thrombocytopenia induced by type II BVD (Fig. 19.1). Proliferative lesions may be observed with bovine popular stomatitis in calves or Orf in lambs. Oral erosions are often observed with BVD infections in calves. Common congenital defects include cleft palate and brachygnathism (inferior and superior). The hard and soft palates should be evaluated; animals with cleft palate may have milk run from the nose and are prone to developing aspiration pneumonia. Examination of the mouth should include assessment of breath odor. A malodorous breath may be present with necrotic pharyngeal injuries, necrotic laryngitis, cleft palate, or aspiration pneumonia. Application of slight pressure on the larynx exacerbates inspiratory stridor associated with necrotic laryngitis. Airflow from each nostril should also be assessed. Conditions causing occlusion of the upper airway—such as choanal atresia, necrotic laryngitis, and pharyngeal swelling or edema—often induce pronounced inspiratory dyspnea, stridor, and/or open-mouth breathing.

Eyes. Eyes should be examined for the presence of entropion, ectropion, corneal abrasions or ulcers, uveitis and hyphema, congenital cataracts, microphthalmia, corneal dermoids, scleral injection, and scleral hemorrhage. Entropion is a relatively common cause of corneal edema and ulceration, conjunctivitis, and lacrimation in lambs. It should be corrected promptly before serious corneal ulceration and keratitis develop. Mild cases may respond to subcutaneous injections of procaine penicillin G into the lower eyelid. Alternatively, entropion

TABLE 19.5

Assessment of Hydration and Acid-Base Status of Neonatal Calves With Diarrhea

Clinical Signs	Demeanor	Skin Tent Duration (Seconds)	Eyeball Recession (mm)	Dehydration (%)	Approximate Base Deficit (mmol/L)
Minimal clinical signs, suck reflex present	Normal	<1	None	5	5
	Slightly depressed	1-2	2-4	6-8 (mild)	10
Suckling decreased, cool extremities	Depressed	2-5	4-6	8-10 (moderate)	15
Very weak or absent suck reflex, cold mouth and extremities	Comatose	5-10	6-8	10-12 (severe)	20
Absent suck reflex, hypothermia	Comatose/dead	>10	8-12	>12	>20

may be corrected by placing vertical or horizontal mattress sutures in the affected eyelid. Treatment following correction of entropion includes topical administration of 1% atropine to dilate the pupil and relieve ciliary body spasm and topical antibiotics to prevent bacterial infection.

Examination of the sclera is useful to detect icterus, scleral injection, and scleral hemorrhage. Icterus may be observed secondary to liver or hemolytic diseases; both tend to be uncommon in neonatal milk-fed ruminants. Conversely, scleral injection is a common finding and suggests sepsis. Observation of fibrin in the anterior chamber of the eye of a neonate is highly indicative of sepsis. Ecchymotic hemorrhages may be observed on the sclera with type II BVD infections, bovine neonatal pancytopenia, or disseminated intravascular coagulopathies, or following birth trauma.

Ears. Bilateral drooped ear carriage is a common observation in sick calves and should prompt a closer examination. Unilateral ear droop may be observed with otitis and facial nerve paralysis. *Mycoplasma* spp., *Pasteurella* spp., and *Haemophilus* spp. are reported to cause otitis in calves. Clinical signs may include facial and vestibular nerve deficits and a purulent discharge from the ear. Calves infected with *Mycoplasma* spp. may also present with tenosynovitis and respiratory disease. Poor perfusion is reflected by cold extremities. A high incidence of pinna abscesses usually reflects contamination of equipment used to place ear tags. Ears should be warm and mobile.

Neck and Back. There are a number of congenital anomalies that affect the alignment of the vertebral column. These include atlantoaxial malformations, scoliosis, kyphosis, lordosis, and combined anomalies, such as kyphoscoliosis. Atlantoaxial malformations may occur with or without cervical scoliosis or signs of spinal cord compression. Holstein calves affected by the hereditary condition complex vertebral malformation may present with a range of abnormalities that include retarded growth, malformation of the head (dysplasia or palatoschisis), bilateral symmetric flexion of the carpal and metacarpophalangeal joints, posterior arthrogryposis, and interventricular septal defects. Of these, growth retardation, vertebral malformation, and symmetric arthrogryposis are the most consistent findings.[288]

The neck and brisket should be examined to evaluate jugular fill and to detect brisket edema. Distention of the jugular veins and brisket edema are consistent with right-sided heart failure but may be absent with left-sided heart failure. Examination of the skin on the side of the neck is a good place to detect lice and fleas, and a skin fold test is performed to assess hydration. Parotid and prescapular lymph nodes should also be palpated to assess size and symmetry. Enlargement of all peripheral lymph nodes may be observed with juvenile lymphoma. Enlargement of specific nodes suggests a localized inflammatory response.

Thorax. Heart rate and respiratory rate vary with activity, excitement, and feeding. Tachypnea can be attributed to elevated temperature humidity index, fever, thermoregulation dysfunction, excitement, pain, stress, respiratory disease, hypoxia (cardiac disease, pulmonary disease, shock), dehydration, shock, toxemia, or metabolic acidosis. Periodic apnea and abnormally slow respirations are often the result of metabolic disturbances (hypoglycemia, hypocalcemia), hypothermia, prematurity, or hypoxia-induced suppression of the respiratory center. Tachycardia may be present with excitement, pain, injury, inflammation, toxemia, dehydration, shock, infectious disease, metabolic acidosis, hypokalemia, hypocalcemia, or heart disease. Bradycardia of neonatal ruminants may be associated with hyperkalemia, central nervous system dysfunction, hypothermia, or starvation.

Cardiovascular disease in neonates may be primary or secondary to other disease processes.

Congenital cardiac anomalies may be asymptomatic. Dyspnea and coughing are often the predominant clinical signs of congestive heart failure in calves. Cardiac auscultation should be carried out systematically with the aim of evaluating cardiac rhythm and detecting normal heart sounds and cardiac murmurs. In most calves the first and second heart sounds are easily audible. The third heart sound is not normally heard in calves, and the fourth heart sound is heard infrequently.[289] Cardiac murmurs are not uncommon during the newborn period. Various congenital anomalies of the heart occur in cattle as the result of defective septa and formation of the cardiac chambers.[290] The prevalence of congenital heart disease in cattle has been reported to be approximately 0.7%,[291] with ventricular septal defects representing the most common type.[292] Other frequent defects include noncyanotic anomalies (atrial septal defect, patent ductus arteriosus without pulmonary hypertension) and cyanotic anomalies (tetralogy or pentalogy of Fallot, Eisenmenger's complex associated with reversion of a previously left-to-right shunt secondary to pulmonary hypertension).[290] The prevalence of the different congenital heart diseases in calves is shown in Table 19.6. Serious heart anomalies may not be accompanied by any murmur, whereas a closing ductus arteriosus may cause a murmur that is very loud. This normal ductal murmur is best ausculted on the left

VetBooks.ir

TABLE 19.6

Prevalence of the Most Common Congenital Heart Diseases in Calves, According to Ohwada and Murakami (2000)[a,290,327]

Congenital Heart Diseases	No. of Cases
Ventricular septal defects	198
Atrial septal defects	148
Double outlet right ventricle	66
Aortic stenosis	53
Double cranial vena cava	50
Patent ductus arteriosus	45
Anomaly of the caudal vena cava	42
Tetralogy of Fallot	32
Hypoplastic left ventricle	25
Transposition of the great arteries	24
Abnormal pulmonary vein connection	21
Total	704

[a]A total of 469 cases of congenital heart diseases were studied.

side of the chest at the third intercostal space at the level of the shoulder. In some instances, however, it is described as a continuous machinery-type murmur, but far more commonly a grade II to V/VI holosystolic murmur is ausculted. Cardiac auscultation will determine heart rate, rhythm, and the presence of murmurs. Abnormal radiation of heart sounds caudal to the fifth intercostal space or dorsal to the level of the scapulohumeral joint on either side of the thorax should be noted. Thoracic percussion may be used to identify the presence of thoracic fluid, cranioventral consolidation, or atelectasis in neonatal ruminants.

Cardiac arrhythmias are observed sporadically in neonates, often associated with diarrhea. Metabolic acidosis secondary to losses of electrolytes and water causes a transcellular shift of potassium ions into the extracellular fluid in exchange for hydrogen ions.[293] Hyperkalemia decreases the membrane potential and slows down impulse conduction by inactivating sodium (Na) channels.[294] As serum potassium increases (>5.5 mEq/L), aberrations in cardiac excitability occur and are manifested as progressive atrial standstill, progressing to ventricular fibrillation and asystole.[295] The response of the myocardial cells to catecholamines decreases with the reduction of blood pH.[294] Influxed H^+ ions repress ventricle contraction by competing with Ca^{2+} ions in binding to myocardial troponins.[294] Tachyarrhythmias may be observed in calves with cardiomyopathies, ionophore toxicosis,[296] or hypomagnesemia.

Cardiomyopathy secondary to selenium deficiency, gossypol, monensin, or lasalocid toxicity may present as a syndrome of sudden death during periods of excitement precipitated by feeding or moving calves out of hutches into group pens.[297]

Inspiratory stridor is often a feature of extrathoracic airway obstruction, and increased abdominal effort on expiration is often an indication of pulmonary disease causing reduced lung compliance. Lung disease in the newborn is usually diffuse and is the result of infection acquired in utero or postpartum and/or lung atelectasis associated with immaturity, recumbency, or surfactant dysfunction. Signs of lung disease include increased work of breathing characterized by nostril flare, rib retractions, and increased abdominal effort. It is useful to palpate the ribs carefully to check for rib fractures, as these may also lead to tachypnea and dyspnea. A cough and nasal discharge, salient features of respiratory disease in older neonates, are infrequent findings in newborns with lung disease. Animals with few or no audible thoracic abnormalities may have severe respiratory disease.

Auscultation of the trachea, thorax, and occasionally the nasal passage are essential elements of the respiratory examination. Tracheal compression should not induce multiple coughs. Lung sounds of neonates are typically easier to hear than those of adults, but lung sounds do not always correlate well with the severity of respiratory condition that is present. Interpretation of the intensity of thoracic breath sounds can be validated by comparison to tracheal breath sounds. The intensity of tracheal breath sounds is gradually attenuated as the stethoscope is moved from trachea to the lung hilus, again to the anteroventral thorax, and finally to the caudal thorax in normal animals. Loud tracheal breath sounds that are not attenuated over the thoracic area may be indicative of atelectasis, lung consolidation, or cardiac enlargement. Added breath sounds such as crackles or wheezes should be noted but may not be heard without augmenting the depth and frequency of the breathing effort with the use of a rebreathing bag.

The advent of portable ultrasound machines commonly used on-farm for reproductive work provides a useful tool for assessing the thorax of calves. The pleural cavity and lungs can be examined through the intercostal spaces. The 5.0 to 7.5 MHz rectal linear transducers used for reproductive work are suitable for this task. Thoracic ultrasound has similar sensitivity (76.5%, 60.2% to 88.8%) for diagnosis of bronchopneumonia as auscultation but a higher specificity (92.9%; 86.5% to 97.1%).[298] In young calves, the lung fields extend cranioventrally from the tenth to the first and second intercostal spaces on the right and left sides, respectively.[299] When standing, it is easiest to scan reaching over the dorsum to the opposite side (Fig. 19.2). The transducing agent of choice is 70% isopropyl alcohol, and the hair is not clipped. Bronchopneumonia most commonly localizes to the cranial aspect of the right cranial lung lobe, followed by the right middle lung lobe and the caudal aspect of the left cranial lung lobe. The cranial aspect of the right cranial lung lobe is imaged from the right first and second intercostal spaces. The right middle lung lobe is imaged from the right fifth intercostal space, whereas the caudal aspect of the left cranial lung lobe can be imaged between the left fourth and fifth intercostal spaces.[299] It is important to scan both sides of the thorax because consolidation may occur unilaterally in up to 1 in 3 dairy calves. When imaging normal lungs the sound waves are reflected at the pleural surface, precluding visualization of the lung. Normal scans reveal a thin, white echogenic, moving pleural line. An increase in pleural fluid is reflected by separation of the visceral and parietal pleura; fibrin may be observed moving in the pleural fluid with the respiratory cycle (Fig. 19.3). Ultrasound is useful for identifying the optimal site for thoracentesis. The inundation of fluid in a consolidated lung provides an opportunity to visualize pulmonary architecture. Similarly, thoracic and/or pulmonary abscesses located adjacent to the thoracic wall may be imaged.

Abdomen. Much can be learned about gastrointestinal function by observing abdominal contour, appetite, and fecal consistency and volume. A normal abdominal contour and vigorous appetite associated with the passage of an appropriate volume of pasty stool suggests normal gastrointestinal function. Examination of the neonatal ruminant should include assessment of abdominal size and contour.

Gradual abdominal distention may be observed with congenital atresia of the gastrointestinal tract (Fig. 19.4, *A*). Atresia may be observed in the colon (coli) (Fig. 19.4, *B*), rectum (recti), or anus (ani); the spiral loop of the ascending colon (spiral colon) is the most commonly affected segment of intestine in calves.[300] Neonates presenting with atresia often have a distended abdomen and a history of declining appetite. Astute owners may notice the lack or reduced volume of feces (Fig. 19.4, *C*).

External palpation of the abdomen can be rewarding, depending on the cooperation of the animal and the tenseness of the abdominal musculature. In calves it is usually possible to palpate

VetBooks.ir

FIG. 19.2 Scanning calf lungs.

FIG. 19.3 Pleural effusion containing fibrin in cranial ventral thorax.

enlargement of the umbilical vein and arteries. The inguinal rings and umbilical area should also be palpated for hernias. Abdominal auscultation, while important, is not used for the forestomach and intestinal motility parameters typically evaluated in the adult ruminant; along with simultaneous auscultation and succession; however, ballottement, or percussion may show evidence of gas, fluid, or disordered motility. Abnormal forestomach function in neonatal ruminants is often reflected by altered abdominal contour. Left and right abomasal displacement and abomasal torsion are observed sporadically in calves. Succussion (simultaneous auscultation and percussion) is useful for delimiting the boundaries of distended visci. Passage of a stomach tube helps distinguish rumen and abomasal distention and facilitates collection of a rumen fluid sample. A putrid odor to neonatal rumen fluid is common with putrefactive indigestion when milk is delivered to the rumen in greater quantities than normal by escaping the esophageal groove or via excessive backflow from the abomasum. Reflux of abomasal contents into the reticulum and rumen, independent of feeding, occurs in connection with abomasal inflammation and obstructions.[301] Evaluation of rumen fluid pH and renin activity are useful for distinguishing abomasal reflux from esophageal groove overflow. Rumen fluid pH is usually 7 or higher with rumen putrefaction and low to normal with abomasal reflux.[301] Chymosin (renin) is normally present in abomasal juice, and renin activity in rumen fluid suggests abomasal reflux.[302] Renin activity is measured by adding 2 mL rumen juice to 2 mL whole milk on a California mastitis test (CMT) plate. Presence of renin in the ruminal fluid causes coagulation of the casein in the milk. Chloride ion concentration in rumen fluid from calves is higher than in adults (55 to 102 mmol/L calves[303] vs 25 mmol/L adults[301]), possibly reflecting the high chloride content of milk (45 mmol/L); as such, the chloride concentration of rumen fluid is not useful for identifying abomasal reflux in calves.

Abomasal ulceration may lead to localized or generalized peritonitis. Normal peritoneal fluid from calves has a higher nucleated cell count than that of adult cattle (3350 cells/μL vs 1371 cells/μL). Total protein concentration in the peritoneal fluid of calves is similar to that in adults (2.5 g/dL vs 3.1 g/dL).[304]

Umbilicus. After rupture of the umbilical cord, the two umbilical arteries retract actively, and the urachus is pulled back passively by these vessels into the abdomen. Smooth muscle contraction brings about luminal closure. The umbilical arteries ultimately become the lateral ligaments of the urinary bladder.

The umbilical vein does not retract but rather collapses in association with some minor smooth muscle contraction. The umbilical sheath shrinks and dries within 3 days postpartum. The body wall closes completely around the umbilical structures within days to a few weeks after birth.[305]

During the physical examination the navel is assessed for diameter, discharge, and pain while the neonatal ruminant is standing and again while it is in lateral recumbency. Abdominal palpation, using both hands pressing together, is useful for evaluating the umbilicus of standing calves. Enlargement of the umbilical arteries can be palpated coursing caudally toward the bladder and enlargement of the umbilical vein coursing cranially to the liver. Application of pressure caudal to the xiphoid often elicits a soft grunt from calves with a septic umbilicus and associated peritonitis. Extensive adhesion of bowel to inflamed umbilical structures produces a large, easily palpable intraabdominal mass. The uterine vein and artery may also be traced within the abdomen with the calf in recumbency. Common abnormalities of the calf umbilicus include umbilical hernias, omphalophlebitis, external umbilical abscess, urachal abscess, and omphaloarteritis. Patent urachus is uncommon in calves. Disorders of the urachus or the umbilical arteries are often associated with pollakiuria and a prolonged stance of urination. Umbilical hernias in cattle do not tend to close spontaneously and are believed to be hereditary.[306]

Ultrasound examination of the calf is performed with the calf standing; occasionally the umbilical vein is easier to identify with the patient in left lateral recumbency.[307] The umbilical vein courses from the umbilicus to the liver, which in the calf is located on the right side. The lumen is generally larger near the body wall, with a diameter ranging from 10 to 25 mm. It appears as a round-to-oval anechoic to hypoechogenic structure. Within 3 weeks after birth, ultrasonographic identification of the intraabdominal umbilical vein becomes impossible in up to 50% of healthy calves. If still visible, the vein appears

FIG. 19.4 **A,** Atresia coli progressive abdominal distention. **B,** Atresia coli dilated proximal section of spiral colon and nondistended distal colon. **C,** Atresia coli—mucus with the absence of feces.

hypoechogenic to the surrounding tissue and indistinctly marginated.[305] In cattle the umbilical arteries and urachus retract into the abdominal cavity when the cord ruptures and thus cannot be identified in the external umbilical stalk in normal calves.[307] The umbilical vein of calves is scanned from the umbilical stalk to the liver along the right abdominal wall. The umbilical vein enters the liver caudoventral to the gallbladder. The umbilical arteries are most easily located adjacent to the urinary bladder and cannot normally be identified much beyond the apex of the urinary bladder, unless enlarged and abnormal. Identification of a urachal remnant in calves is abnormal.[307] Umbilical ultrasound is useful for evaluating the need for umbilical surgery and identifying other organs involved that may influence the complexity of the procedure (Fig. 19.5).

MUSCULOSKELETAL SYSTEM. The musculoskeletal system should be examined for evidence of birth trauma, including fractured ribs, long bones, and mandibles; brachial plexus injuries; and soft tissue trauma, which includes an edematous head and tongue from excessive traction or compression in the pelvic canal. The vertebral column, ribs, and limbs should be palpated carefully to elucidate swelling, heat, or painful areas. Strenuous manipulation during dystocia can result in Salter Harris type 1 fractures characterized by disruption of the distal physis in one or more limbs. Femoral nerve paralysis occurs as a sporadic complication of dystocia associated with "hip lock" in calves.[308]

Dwarfism is a relatively common inherited problem in most cattle breeds. Osteopetrosis has been reported in Angus, Hereford, and Simmental breeds of cattle. Syndactyly is considered an inherited disorder in Holstein Friesan cattle, and affected animals are also predisposed to hyperthermia. Growth retardation, vertebral malformation, and bilateral symmetric arthrogryposis affecting the carpal and metacarpophalangeal joints are features of complex vertebral malformation in Holsteins, a genetic condition associated with a mutation in the gene *SLC35A3* coding a uridine diphosphate *N*-acetylglucosamine transporter.[288]

Peripheral pulses in the middle coccygeal, brachial, and auricular arteries should be strong and regular, and the peripheral extremities should be warm. Assessment of pulse quality includes consideration of pulse strength and frequency. Concurrent cardiac auscultation is useful to verify that heart rate and rhythm matches the pulse. With cardiovascular disease the pulse may be weak and/or uneven and may not correlate with the heart rate and rhythm.

The limbs should be examined for laxity, flexural, and angular limb deformities. Flexor tendon laxity occurs more commonly in calves born prematurely and in calves that are small for their gestational age. Unilateral or bilateral hyperextension of the tarsus can be encountered in newborn calves following forced extraction. A rupture of the peroneus tertius causes the hyperextension of the tarsus (Fig. 19.6). The gait is abnormal but does not appear to be painful.[309] Congenital contracted

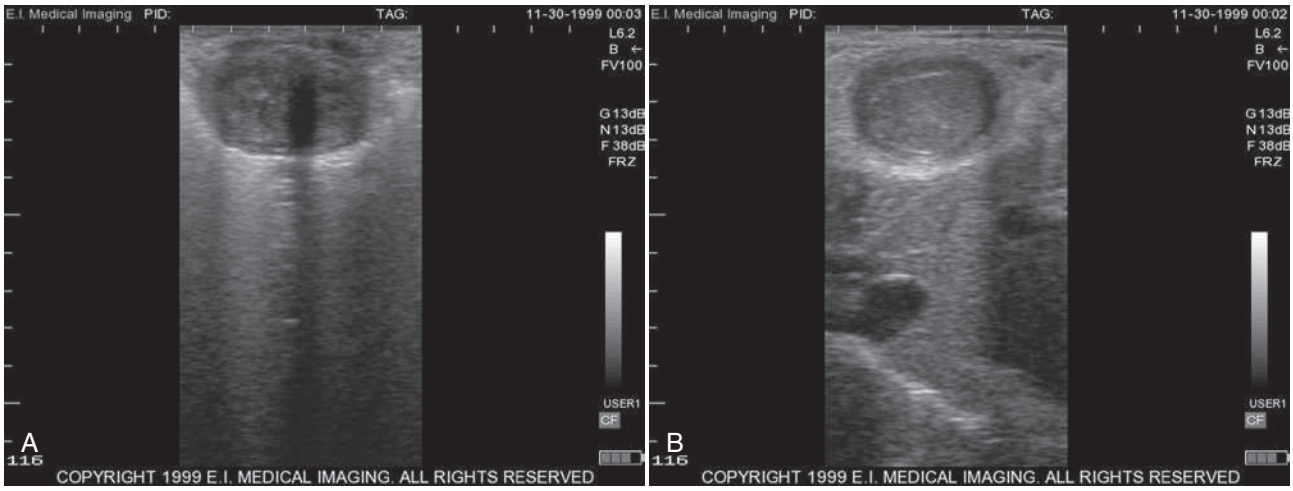

FIG. 19.5 **A,** Enlarged umbilical vein cranial to external umbilical stump. **B,** Enlarged umbilical vein just before entering the liver.

FIG. 19.6 Peroneus tertius rupture. **A,** Standing. **B,** Extended, showing hyperextension of the tarsus with concurrent flexion of the stifle.

flexor tendon is a common defect in cattle; etiologic origins include inherited factors, in utero malpositioning, and overcrowding caused by the size of the fetus relative to the dam. Contracted tendons may occur with other congenital abnormalities, such as cleft palate, dwarfism, and arthrogryposis.[309] Arthrogryposis, abnormal fixation of joints because of damage to or contracture of soft tissues, may be hereditary, secondary to infection in fetal life with teratogenic viruses, or may result from ingestion of teratogenic plants. Following teratogenic viral infections, the clinical presentation is secondary to mild to extensive loss of ventral horn motor neurons in the spinal cord gray matter and Wallerian degeneration of ventral spinal motor nerves.[310] Hereditary congenital deformity in Hereford cattle is characterized by arthrogryposis, kyphosis, torticollis, scoliosis, and cleft palate.[311] Ingestion of lupines by pregnant cows between 40 and 70 days' gestation has also caused various degrees of arthrogryposis with other associated congenital defects.[312]

Skeletal muscle myopathy is an important differential for lame neonatal ruminants. Affected neonates may present with a history of falling behind the mob when mustered and dropping into sternal recumbency. Close examination reveals firmness of the triceps and quadriceps. Deep palpation of affected muscles elicits a pain response. Lambs and kids with selenium and/or vitamin E deficiency are often mentally bright, reluctant to stand, walk with a stiff gait, and cry when forced to move. Evaluation of serum creatinine phosphokinase, blood selenium, and plasma vitamin E concentrations is useful to confirm the diagnosis.

Any heat or cold, swelling, edema, pain around the joints or physes, or lameness should be noted (Fig. 19.7). Due to the propensity of neonates to succumb to sepsis, a swollen joint should be considered infected until proven otherwise. When sepsis is present it is not uncommon to observe enlargement of the corresponding prescapular or prefemoral lymph node in the affected limb. When multiple animals on the same property are affected, this may reflect an infectious etiology such as salmonellosis or mycoplasma; alternatively, poor colostral management may contribute to a high incidence of opportunistic infections of immunologically compromised neonates leading to joint ill. An inflammatory leukogram provides supportive evidence of a septic process, and aseptic collection of joint fluid for cytology and culture provides confirmatory evidence. When interpreting neonatal hematology and biochemistry results, it is important to be aware of age-associated normal values (Table 19.7).

In older neonates metabolic bone disease should be considered as a differential diagnosis for lameness associated with flaring of the physis. Diets high in energy and protein that have low calcium and high phosphorus promote rapid weight gain, increasing the physical load on metabolically compromised growing bones. Damage to the growing physis may result in the subsequent development of angular limb deformities. Calcium deficiency in calves leads to reduced mineralization of bone. The transverse processes of the lumbar vertebrae become soft and bend when palpated. Copper deficiency causes metabolic bone disease that is manifested by physitis and brittle bones, reflected by a propensity to spontaneous fractures.

FIG. 19.7 Calf with cold, swollen hind limbs and serum exuding through the skin on the left hock. The calf was developing gangrenous necrosis secondary to Salmonella *enterica* serotype Dublin infection.

Posterior paresis is common in neonates; causes include border disease, enzootic ataxia, vertebral body abscesses, caprine arthritis encephalomyelitis virus, and vertebral body fractures associated with dietary copper deficiency (or secondary copper deficiency due to molybdenosis) or calcium phosphorous imbalance. These neurologic problems are discussed in Chapter 33.

Perineal Region

The examination from the rear includes assessment of body condition, measurement of rectal temperature, palpation of the coccygeal artery to assess pulse, examination of mucous membranes (female), and collection of urine and feces. Examination of the tail may also reveal evidence of diarrhea. Chronic diarrhea may be reflected by poor body condition and hair loss from the caudal surface of the rear hind limbs.

BODY TEMPERATURE. Rectal temperature in calves ranges between 37.2° and 38.9° C (99° and 102° F) during the first 4 days after birth. Abnormalities of vital signs in neonatal ruminants may be difficult to interpret, as a fever can be transient and patients with septicemia, infection, dehydration, or circulatory shock can be hypothermic or normothermic. Premature calves are prone to hypothermia.[313] Hyperthermia during the first week of life has been reported to be common in cloned calves.[314]

TABLE 19.7

Normal Hematology Reference Values for Neonatal Calves[154,155]

Parameter	Age			
	Birth	24 Hours	48 Hours	3 Weeks
RBCs (1×10^6/μL)	9.35 ± 1.02	8.17 ± 1.34	7.72 ± 1.09	8.86 ± 0.68

FECES. In contrast to the adult, rectal palpation of the abdominal structures of the large animal neonate is of limited value. Small amounts of blood may be observed in the feces of healthy calves. Passage of blood and fibrin is associated with inflammatory bowel disease induced by pathogens such as *Salmonella* and coronavirus that damage the gastrointestinal mucosa. Passage of melena may be associated with infectious enteritis (e.g., clostridiosis, salmonellosis) and necrotizing enterocolitis due to hypoxic-ischemic bowel injury. Infectious diarrhea is the leading cause of mortality in calves between 3 and 21 days of age. Typically more than one pathogen is involved, and the physical examination provides no indication of the etiologic agent. Fecal pH may be used as an indicator to distinguish secretory diarrhea (enterotoxigenic *E. coli*) from diarrhea associated with malabsorption and maldigestion. Secretory diarrhea produces an alkaline pH, whereas malabsorption and maldigestion are associated with an acidic fecal pH.[315] Infectious agents causing diarrhea and ancillary tests available to establish an etiologic diagnosis are discussed in Chapter 20.

URINE. Normal urine osmolarity in the 2- to 3-day-old calf has been reported to be 286 to 391 mOsm/L, and urine volume voided is 34 mL/kg/day.[316] Congenital abnormalities of the urinary system include ruptured urinary bladder, ruptured ureter, ectopic ureter, blocked urethra, renal agenesis, fused kidney, and polycystic kidneys. Rupture of the urinary bladder at parturition is uncommon in ruminants. Hemodynamically mediated renal disease is observed sporadically in calves after chronic enteritis.[317] Prolonged reduced renal perfusion secondary to hypovolemia may lead to ischemia and acute tubular necrosis. Failure to thrive following apparent recovery from diarrhea may reflect compromised renal function.

EXTERNAL GENITALIA. The external genitalia of both sexes should be examined for congenital malformations. In the calf congenital defects described include ovarian aplasia, duplication of the cervix in Hereford cattle, persistence of the hymen (white heifer disease), and rectovaginal constriction in Jersey cattle. Congenital urolithiasis has been described in calves and lambs. Calcium oxalate is the most commonly reported congenital form of urolithiasis and may be associated with other congenital abnormalities.[318] A report of renal oxalosis in a number of Beefmaster calves suggests a possible recessively inherited metabolic defect resulting in primary hyperoxaluria in this breed.[319] Freemartins (XX/XY chimeras) occur in more than 90% of bovine[320] and 1% of ovine[321] female heterosexual twins. Typically freemartins are sterile and have hypoplastic ovaries and internal tubal genitalia; the external genitalia normally are not affected. Males should be examined for cryptorchidism and male pseudohermaphroditism, and both sexes should be assessed for evidence of hermaphroditism (gonads of both sexes).

Problem Solving

The process of diagnostic investigation for neonates is similar to that for adults. A problem list is developed at the conclusion of the physical examination. Differential diagnoses for each problem are considered, and the likelihood of differentials is ranked according to the history, signalment, and physical findings. This process progresses to a tentative diagnosis and development of diagnostic and treatment plans. Details regarding the presentation, diagnosis, and treatment of common neonatal diseases are presented in Chapter 20.

Manifestations and Management of Disease in Neonatal Ruminants

JOHN K. HOUSE, *Consulting Editor*
GEOFFREY W. SMITH, ALISON A. GUNN, SHEILA M. MCGUIRK, and MATHEW IZZO

Weakness and/or Depressed Mentation

Geoffrey W. Smith

If weakness has been present since birth, in utero–acquired bacterial or viral infections, birth asphyxia and trauma, chronic placental problems, and congenital anomalies should be considered on the list of differential diagnoses. A number of congenital, bacterial, fungal, and viral infections that cause abortions and stillbirths may result in the birth of a live but weak calf. In cattle, brucellosis, salmonellosis, leptospirosis, listeriosis, *Escherichia coli*, *Corynebacterium* spp., and *Aspergillus* spp. may cause placentitis and disease in the newborn. In sheep, in utero infection with chlamydia, *Campylobacter*, *Coxiella*, bluetongue virus, and border disease may cause disease in the newborn. Congenital viral infections of neonates are listed in Box 20.1. Clinical manifestations of fetal infections depend on the age of the fetus and the virulence and tropism of the infecting agent (see individual diseases).

Neonatal calves with storage diseases primarily affecting the nervous system may appear reasonably normal for a short period after birth and then show progressive signs of neurologic dysfunction, including tremors, spasms, depression, recumbency, and coma. Differential diagnoses for weakness and depressed mentation after a period of apparently normal strength and mentation include sepsis, electrolyte and acid-base disturbances, hypoglycemia, and hypothermia. A complete history is obtained, including a detailed description of the delivery process, and complete physical and neurologic examinations are performed. Any signs of trauma, infection, or congenital malformations should be noted. Evaluation of hematologic data and immunoglobulin G (IgG) status, combined with historical and physical examination parameters, results in a high suspicion of sepsis. Blood glucose, blood gas, serum electrolyte concentrations, and passive transfer status should be determined promptly. Blood cultures and cerebrospinal fluid (CSF) analysis are useful for verifying central nervous system (CNS) involvement and targeting antimicrobial therapy.

Septicemia

Neonatal septicemia is the third most common cause of calf mortality in the United States (behind diarrhea and respiratory disease) and occurs most commonly in calves associated with failure of passive transfer (FPT). The phagocytic and bacterial killing function of polymorphonuclear neutrophils (PMNs) is a crucial component of the primary immune response against invading pathogens. Despite a larger number of neutrophils in the circulation of normal calves at birth, neutrophils from neonatal calves are functionally less effective than adult cells. Reduced Fc-receptor expression in neonatal PMNs may contribute to impaired phagocytosis and antibody-dependent cellular cytotoxicity.[1-3] Depressed PMN bacterial killing[4] may be related to reduced superoxide anion[5] and myeloperoxidase-hydrogen peroxide-halide antibacterial activity.[3] Adult-level superoxide activity in fetal PMNs suggests that some of the deficits in neonatal PMN function may be a manifestation of perinatal PMN suppression.[6] Calves have elevated cortisol levels for the first 10 days of life, which may contribute to depression of neutrophil function.[7] Dexamethasone depresses neutrophil phagocytosis, antibody-dependent cellular cytotoxicity, and bacterial killing.[8,9] Undefined serum factors also appear to be important for PMN function, as phagocytosis and bacterial killing by neonatal PMNs is similar to that of adult PMNs when bacteria are opsonized with adult serum but is reduced when bacteria are opsonized with neonatal serum.[4] T-helper cells (CD4+) play a central role in humoral and cell-mediated immunologic memory. Lymphokines produced by CD4+ cells, interleukin-2 (IL-2), IL-4, and interferon-γ (IFN-γ) are essential components of antigen-specific immunity. Virtually all IL-4 and most IFN-γ produced by polyclonally activated adult human CD4+ cells is mediated by a subset of "functional memory cells."[10] Leukocyte production of IL-4 and IFN-γ is reduced in human neonates[10] and of IFN-γ is reduced in bovine neonates,[11] possibly reflecting their antigenically naive status. Depressed lymphocyte proliferation and IL-2 activity in the perinatal period correlates with elevated cortisol levels.[7]

Acquisition of humoral immune competence is age and antigen dependent.[12] Neonates are capable of producing humoral immune responses to good immunogens (protein antigens) but may fail to respond to lesser immunogens (sugars and lipids). Calves younger than 3 months of age that are vaccinated with modified live or killed salmonella vaccines produce an adult-type humoral immune response to salmonella protein antigens but do not respond to salmonella lipopolysaccharide.[13] Ingestion of colostrum suppresses the humoral response to some antigens but not others.[12]

Adverse management and environmental conditions further compromise neonatal immunity. Cold stress depresses neutrophil chemotaxis, and vasoconstriction reduces delivery of leukocytes to peripheral tissues.[14] Protein energy malnutrition in calves is associated with depressed lymphocyte IL-2 activity, lymphocyte

VetBooks.ir

BOX 20.1

Differential Diagnoses for the Weak or Depressed Large-Animal Neonate

Bacterial Infection: In Utero or Postnatally Acquired
Septicemia
Joint and bone
Enteritis
Pneumonia
Meningitis
Peritonitis (primary or secondary)

Congenital Viral Infection
Bovine viral diarrhea virus (B)
Bluetongue virus (B, O)
Infectious bovine rhinotracheitis virus (B)
Akabane virus (B)
Parainfluenza (B)
Caprine herpes (C)
Border disease virus (O)
Equine herpesvirus (E)
Equine viral arteritis (E)

Prematurity/Postmaturity
Weak calf syndrome
Bacterial or fungal placentitis
Insufficient fetoplacental matching (twin)

Birth Asphyxia
Placentitis
Dystocia
Cesarean section
Premature placental separation
Induced parturition
Birth trauma
Brachial plexus injuries
Fractured rib, pneumothorax, hemothorax
Ruptured bladder

Congenital Malformations
Cardiac malformations
Central nervous system malformations (e.g., hydrocephalus, hydranencephaly)
Angular limb deformities
Arthrogryposis

Metabolic Derangements
Hypoglycemia
Hyponatremia
Hypokalemia or hyperkalemia
Hypocalcemia
Acidosis (respiratory or metabolic)
Uroperitoneum (with electrolyte abnormalities)
Renal failure

Severe Anemia
Blood loss
Neonatal isoerythrolysis

Brain Disease
Hemorrhage
Ischemia, edema, necrosis
Traumatic injury
Meningitis
Malformations
Narcolepsy-cataplexy syndrome (intermittent weakness)

Spinal Cord Disease
Spinal cord hemorrhage
Vertebral malformation (e.g., atlanto-occipital)
Vertebral abscessation or osteomyelitis
Vertebral fracture or other trauma to spinal cord

Peripheral Nerve and Muscle Disease
White muscle disease
Tetanus
Congenital myopathy, polymyositis
Neuropathy of spinal roots or peripheral nerves
Botulism
Collagen disorder
Aminoglycoside-induced neuromuscular blockade

Liver Disease
Hepatitis
Severe hypoxic insult
Toxin (iron fumarate given to foals)

Storage Disorders
Maple syrup urine disease
Citrullinemia
Shaker calf syndrome (neurofilament accumulation)
GM1 gangliosidosis

Ingestion of Drugs or Toxins
Transplacental transfer of anesthetics and sedatives
Inadvertent oversedation of neonate

Gastrointestinal Disease
Gastrointestinal ulceration
Necrotizing enterocolitis

proliferation, and humoral immune responses.[7] Micronutrient deficiencies also depress immunity. Selenium, zinc, copper, and vitamin E deficiencies depress lymphocyte and phagocyte function.[15,16]

Inherited defects in immune function are sporadically observed in neonates and should be considered when recurrent or atypical infections are observed, such as bovine leukocyte adhesion deficiency in Holsteins.

If invading bacteria are not quickly controlled by the immune system, they can establish focal infections in areas such as the joints, meninges, heart valves, or growth plates. Septicemia refers to a bacterial infection of the blood associated with adverse systemic signs. If not successfully treated, this can lead to multiple organ dysfunction, septic shock, and death. Meningitis is particularly difficult to treat successfully, and therefore prevention of septicemia through good colostrum management is essential.

Blood culture studies of debilitated calves indicate that gram-negative bacteria account for approximately 80% of bacterial isolates; *E. coli* is the most common bacterium isolated.[17-19] In a study of 190 recumbent calves on a large calf-raising facility, 31% were determined to be bacteremic; *E. coli* accounted for 51% of the isolates, other gram-negatives for 25%, gram-negative anaerobes for 5.9%, gram-positive cocci for 11.8%, and gram-positive rods for 5.9%.[17] Other common bacterial isolates include *Salmonella*, *Campylobacter*, *Klebsiella*, and different *Staphylococcus* species. A summary of bacterial pathogens found to be responsible for septicemia is provided in Table 20.1. Polymicrobial infections are common in septicemic calves (28%).[19]

[b]*Pseudomonas aeruginosa*, *Mannheimia haemolytica*

[c]*Clostridia* species, *Bacteroides* species, *Prevotella* species

Calves lack a normal adult intestinal flora, and when born in a heavily contaminated environment, colonization of the gastrointestinal (GI) tract with virulent bacteria may occur prior to the establishment of normal flora. Septicemia may also result from bacterial colonization of another site such as the umbilicus. Bacterial infection and the host inflammatory response should be differentiated. The immune response, in combination with the reticuloendothelial system, prevents the development of sepsis from an opportunistic or pathogenic invasion. However, this initiates an inflammatory cascade involving highly toxic mediators, which, if uncontrolled, will eventually lead to the systemic inflammatory response syndrome (SIRS) and subsequent multiple organ dysfunction syndrome (MODS). There is a balance between an appropriate yet effective immune response and an overzealous response to the bacteria or their toxins.[20,21]

The interaction between endotoxin (lipopolysaccharide) and the immune system triggers a complex inflammatory cascade involving cytokines and other inflammatory mediators. Initiation of the cascade results in the production of arachidonic acid metabolites, release of myocardial depressant factors, activation of the complement system, and production and release of many other mediators of sepsis.[20] The results include dehydration, tachycardia, pyrexia, leukopenia, hypotension, a decrease in systemic oxygen delivery and cardiac output, and generalized weakness. There is a severe and complex pulmonary vasculature response to endotoxin, leading to hypoxemia. Cattle are very sensitive to endotoxin, and even small doses can produce severe lung injury. Severe endotoxemia is frequently associated with death from respiratory failure in both calves and adult cattle. Therefore nonsteroidal antiinflammatory drugs (NSAIDs) are critical in blocking the formation of reactive metabolites (e.g., thromboxanes) and restoring lung function.

Neonatal septicemia should be seriously considered whenever there is multiple organ dysfunction or when severe cardiac and/or respiratory signs are encountered. Classic septicemia is described as a condition affecting newborn calves between 2 and 8 days of age. The progression is rapid and most often fatal. Very early in the disease, the clinical signs are vague, nonspecific, and likely attributed to other disease. An alteration in mental status ranging from a mild depression to coma is commonly observed. Lack of suckling ability or enthusiasm toward nursing are early nonspecific clinical signs.[20] Abnormal rectal temperature (fever or hypothermia) is not consistent; however, sustained tachycardia and eventually tachypnea develop. Hyperemia of the mucous membranes and scleral injection is frequently observed. Capillary fragility may initiate petechiation of the mucous membranes. Eventually, hypotension and clinical signs that are associated with poor cardiac output (slow capillary refill, diminished peripheral pulse, cold extremities, and decreased urine output) become prominent. Dehydration usually develops. Diarrhea is not present in all cases but is common in the terminal stages of septicemia. In a recent study investigating the clinical and laboratory findings of 1400 calves with diarrhea, clinical signs consistent with septicemia, including hypoglycemia, umbilical infection, or predicted sepsis using a scoring model, carried a higher risk for mortality than either clinical findings (poor suckle reflex, comatose) or other blood work abnormalities (severe metabolic acidosis).[22]

Early clinical signs of septicemia can be subtle and nonspecific. Sepsis scoring models have been developed for calves but lack good sensitivity and specificity.[23,24] The most useful parameters for predicting septicemia in calves as determined by these studies include toxic changes in neutrophils, FPT, presence of a focal infection, or elevated serum creatinine concentrations. Ultimately, the presence of clinical signs including lethargy, pyrexia, diarrhea, tachypnea, polyarthritis, uveitis, omphalitis, and meningitis, along with documented presence of FPT, should make the clinician highly suspicious of septicemia. If multiple clinical signs are present, the likelihood of disease is increased. However, the definitive diagnosis of septicemia can be based only on a blood culture. The jugular vein should be clipped and scrubbed prior to sampling. An amount of 10 mL of whole blood is drawn using a sterile syringe and needle, and the blood is placed into a blood culture bottle using a new sterile needle. Taking two samples (from blood collected 1 hour apart) is sometimes recommended to increase the chances of isolating the bacteria and to facilitate the interpretation of results if opportunistic or contaminating bacteria are found in one sample.[20] The bottle is then submitted to the laboratory for culture and susceptibility testing. If the bottle is not submitted immediately, it should be stored at room temperature or at 37° C. A negative blood culture must be interpreted with caution, since many factors may interfere with bacterial isolation from a blood culture. Cultures of other body fluids such as joint, cerebrospinal, peritoneal, or pleural fluids may be helpful for bacteriologic diagnosis whenever the blood culture is negative.

Some laboratory findings may increase the suspicion of septicemia. Hematologic abnormalities of septicemia vary with the severity of the disease. Abnormal neutrophil count (neutrophilia and neutropenia) and increased immature forms (bands) are frequently seen. Fibrinogen concentration is often elevated. Thrombocytopenia may be present in severe cases. One study of suspected septic shock in calves found that 8 of 12 calves had at least three abnormal coagulation parameters, most commonly activated partial thromboplastin time (aPTT) and prothrombin time (PT).[25] Hypoglycemia, or less often hyperglycemia, may be observed. A metabolic acidosis is also frequently present in septic calves. Lactic acidosis occurs as the disease progresses. Some calves will develop respiratory disease (respiratory distress syndrome) or pneumonia and will suffer from hypoxemia and/or hypoventilation.

Neonatal septicemia is a severe disease with high mortality. The primary goals of treatment are to (1) control the infection, (2) modulate the inflammatory response, and (3) support the animal during the disease. Treatment is based on selecting an appropriate antimicrobial drug and dosage, antiinflammatory therapy, and supportive therapy (including fluids). Differences between neonatal and adult animals in drug effects generally can be attributed to differences in drug distribution, metabolism, or excretion. Some general characteristics of the neonatal period include better absorption of drugs from the GI tract,

VetBooks.ir

less drug binding to plasma proteins, increased apparent volume of distribution of drugs that are distributed in the extracellular fluid volume, increased permeability of the blood-brain barrier, and slower elimination (i.e., longer half-life) of many drugs. In general terms, antimicrobials have longer elimination times in neonates (<2 weeks of age) than adults, and as such larger doses are administered with a longer dosage interval to achieve similar peak and trough antimicrobial concentrations. Antimicrobial therapy should begin as soon as possible in order to minimize the bacteremia. The choice and the dosage of antibiotic depend on several factors, and personal preference, along with past experience, is often important. It is generally accepted that the intravenous route is preferable whenever possible and that broad-spectrum drugs are preferred. Appropriate antimicrobial choices include third- or fourth-generation cephalosporins (ceftiofur 5 to 10 mg/kg/day IM or IV have been used, although doses higher than the labeled dose of 2.2 mg/kg are now illegal in the United States), sodium ampicillin (10 to 20 mg/kg tid IV), and florfenicol, although even when given intravenously at the extralabel dosage of 20 mg/kg bid, it only exceeds the MIC_{90} value in plasma for 1 hour.[26] Combinations of drugs can be used to broaden the spectrum of activity (such as ampicillin-ceftiofur or ampicillin-trimethoprim-sulfonamide). Fluoroquinolones can also be effective in countries where their use is permitted. Once the pathogen has been identified and the susceptibility pattern determined (on the individual or on the farm), the most appropriate antibiotic can be chosen.

As just described, the inflammatory response if uncontrolled often causes severe clinical signs. Therefore NSAID therapy should be considered for ancillary treatment. Possible side effects of aggressive NSAID treatment include abomasal ulcers and renal toxicity, particularly in dehydrated animals. The duration of NSAID treatment is often limited to 2 to 3 days because of their potential toxicity. NSAIDs should not be continued for any longer than they are considered essential for survival.

Supportive treatments for septicemic calves include correction of secondary problems, administration of fluids, plasma transfusion, oral or parenteral nutrition, and oxygen administration. Problems that must be addressed include hypovolemia, hypoglobulinemia, hypoglycemia, metabolic acidosis, electrolyte abnormalities, and hypoxia. IV fluids (or oral as a compromise on the farm) should be administered. Dextrose (5%) combined with normal saline (0.9%) should be administered at a rate of at least 50 mL/kg/day. Nutrition is important, and septic calves either nurse reluctantly or are inappetant; as a result, they do not ingest an adequate amount of milk. If the animal refuses to nurse, tube feeding should be used to ensure that the calf ingests at least 10% to 15% of its body weight of milk per 24 hours. The feeding schedule may involve several (three to five) feedings per day and should be gradually increased in amount to prevent abdominal distention. If the GI system does not tolerate the tube feeding regimen, parenteral nutrition should be considered. There is usually no need for total parenteral nutrition, since most animals will continue to nurse or tolerate tube feeding up to 5% of their body weight.

Multiple cases of septicemia occurring on the same farm calls for careful inspection of the environment and management practices. Clusters of septicemia could be related to specific risk factors. As an example, feeding heavily contaminated colostrum could be the origin of the septicemia on some farms.[20,27] Prevention through excellent cleanliness and management practices is the most effective means of controlling and preventing neonatal sepsis.

Meningitis

Meningitis refers to an inflammation of the meninges and potentially brain. It represents an important complication associated with neonatal septicemia in calves. Exactly how bacteria get into the meninges is poorly understood. Multiple mechanisms have been proposed, including the development of a sustained and high-grade bacteremia in the highly perfused dural venous system and choroid plexuses, adherence of fimbriae from some strains of *E. coli*, or the phagocytosis of the pathogens by circulating monocytes and endocytosis through the microvascular endothelial cells.[20] What is apparent is that once they cross into the CNS, bacteria are able to survive and proliferate well in the poorly defended CSF. Complement is essentially nonexistent in CSF, and there are low numbers of antibodies, leading to inadequate clearance of pathogens from the CNS. Gram-negative bacteria also release endotoxin, leading to inflammatory infiltrates that cause thromboses of the arachnoidal or subependymal veins. Congestion or hemorrhagic infarction may follow, with subsequent necrosis of nerve cells. Inflammatory changes in the subarachnoid space may affect the choroid plexus, decreasing the absorption of fluid and potentially creating hypertensive hydrocephalus.[28]

Although bacterial meningitis may occur as a primary entity, it more commonly is a result of generalized septicemia in neonates with FPT. Agents that cause meningitis are the same agents that cause septicemia, most commonly the gram-negative enteric bacteria such as *E. coli*, *Enterobacter* spp., and *Salmonella* spp. In a review of 32 cases of meningitis in calves, the clinical signs of CNS disturbance observed were lethargy, recumbency, anorexia, loss of suckle reflex, coma, opisthotonos, convulsions, tremor, and hyperesthesia.[29] Leukocytosis and a left shift were evident in 11 of 15 calves (73%). Concurrent metabolic problems were common and included hyperkalemia, respiratory acidosis, hypernatremia, hyponatremia, hypomagnesemia, and hypoglycemia. Analysis of CSF revealed pleocytosis, xanthochromia, turbidity, and high total protein concentration. Cytologically, neutrophils predominated in the CSF in calves with acute disease. Mononuclear cells dominated in calves with chronic disease. Microscopically, bacteria were evident in 10 of 22 (45%) of the antemortem CSF samples, and bacteria were isolated from slightly more than half (11 of 19). All of the calves in this review died.[29]

Calves with meningitis are often presented because they have lost their suckle reflex and appear lethargic (Fig. 20.1, *A* and *B*). Previous treatment for diarrhea is common. Fever is often present unless NSAIDs have been given or if the animal is in an extremely cold environment. The calves may have an extended head and neck, and attempts to flex or reposition the neck can result in a tonic extension and thrashing of the limbs. Calves with meningitis almost always have abnormal mentation. As the disease progresses, profound depression develops and eventually the animal becomes comatose and nonresponsive or may develop seizures (Fig. 20.1, *C* and *D*). Presumptive diagnosis of bacterial meningitis is based on demonstration of FPT, presence of a septic focus such as omphalophlebitis or septic arthritis, and the presence of abnormal neurologic signs. However, the definitive diagnosis is based on an abnormal CSF analysis. Collection of CSF from the lumbosacral space is easy and safe in calves. For collection of fluid from the lumbosacral space, a 20-gauge, 1- to 2-inch needle with a clear hub may be used. A change in resistance is felt when the needle penetrates the dural membranes, and CSF appears in the plastic hub as soon as the subarachnoid space is entered. Approximately 5 to 10 mL of fluid may be removed safely.

Urinary reagent strips can be used to rapidly obtain general information about the fluid. If blood is detected, the sample should be spun down after the cytologic examination. Red blood cells contaminating the sample will settle, and the supernatant should be colorless. If hemorrhage occurred before the procedure, the sample remains xanthochromic (yellow). Glucose should be present in "trace" or "positive" (+) amounts in the normal sample. Negative values in the adult suggest severe meningitis, but in the neonate they may also be caused

FIG. 20.1 Calves exhibiting clinical signs of meningitis secondary to septicemia. **A,** The calf is depressed and maintains an extended neck when manipulated. **B,** The presence of fibrin and white blood cells in the anterior chamber of the eye (hypopyon) is suspected. **C and D,** Calves with more advanced meningitis exhibiting profound opisthotonus. *Images reprinted with permission from Dore V, Smith G. White blood cell concentration	<10 cells/µl	4004 cells/µl	2400 cells/µl
Percent lymphocytes	>80%-90%	NR	Range of 1%-17%
Percent neutrophils	<10%-15%	73%	Range of 78%-100%
Culture positive		6 of 9 cases	11 of 19 cases

NR, Not reported.

by profound hypoglycemia. CSF analysis is most useful in determining the presence of septic meningitis. A summary of CSF findings from calves with meningitis is presented in Table 20.2. Generally an elevation in total protein and white blood cell concentration are strongly suggestive of meningitis, combined with a high percentage of the cells being neutrophils. The ratio of CSF to plasma glucose concentration is less than 1 in animals with bacterial meningitis because of bacterial metabolism of glucose in the CSF. Xanthochromia (yellow color) is inconsistent. Free or intracellular bacteria may be observed in some cases. An elevated albumin quotient suggests increased blood-brain permeability and can be seen in both hypoxic-ischemic brain injury and meningitis, but an elevated IgG index indicates increased intrathecal IgG production and is more compatible with a diagnosis of meningitis.

When treating calves with meningitis in a hospital environment, the mortality rate is high; however, aggressive early treatment can be successful. The economics and welfare implications of treating commercial calves in a field setting are questionable. Empiric antimicrobial therapy for meningitis in neonatal calves should include a gram-negative and gram-positive spectrum. Antibiotics enter the CSF predominantly via passive diffusion down a concentration gradient. The major determinant of CSF penetration is lipid solubility. Lipophilic agents diffuse via transcellular pathways; peak concentrations in CSF occur relatively rapidly, and entry into CSF is affected minimally by the presence of inflammation. In contrast, hydrophilic agents enter the CSF through paracellular pathways; their transport depends on the opening of tight junctions, and peak concentrations are relatively delayed.[30]

The ratio of a drug in the CSF to blood generally gives a good indication of the potential for that antimicrobial to penetrate the CNS. Since very few of these studies have been conducted in animals, for the most part we extrapolate data from human medicine. Table 20.3 lists CSF-to-blood concentration ratios (penetration) derived from multiple species for a handful of antimicrobial drugs available for use in cattle.

VetBooks.ir

TABLE 20.3

CSF-to-Blood Concentration Ratios (Penetration) of Antibiotics Available for Treatment of Meningitis in Calves[2,3]

Antimicrobial[a]	Concentration CSF/Concentration Serum (%)	
	Human	Animals
Ampicillin	13-14	8-12
Florfenicol		46 (calves)
Gentamicin	0-30	21-25
Penicillin	5-10	5-6
Trimethoprim-sulfamethoxazole	<41	35-39

[a]The list is not conclusive, reflecting the paucity of available data.

CSF, Cerebrospinal fluid.

It is also important to consider the safety margin of drugs. For example, the β-lactams don't diffuse very efficiently into the CSF, but they have a high safety margin and therapeutic concentrations can be achieved in the brain, since increased doses can be used without toxicity. In contrast, aminoglycosides diffuse relatively easily across the blood-brain barrier but likely represent a poor choice for meningitis, since standard doses are not high enough to achieve therapeutic concentrations in the CSF and higher-than-standard doses carry a high risk for nephrotoxicity.[28] Although broad-spectrum antimicrobials are indicated, *E. coli* is the most common isolate from meningitis cases and so should be the primary target of initial therapy. The choice of antimicrobial for treating meningitis will depend largely on the veterinary drug laws in the country where the calf is being treated. For example, common recommendations for meningitis treatment in calves have included ceftiofur (5 to 10 mg/kg q8h IM or IV) or enrofloxacin (5 mg/kg q12h IV).[20] Either of these would likely represent a reasonable option, but both are prohibited in the United States. Labeled doses of ceftiofur (2.2 mg/kg IM) could be used, or possibly sodium ampicillin (10-20 mg/kg q8h IV) could be tried. Another potential option would be potentiated sulfonamides such as trimethoprim-sulfamethoxazole dosed at 5 mg/kg (trimethoprim component) q8-12h IV. Potentiated sulfonamides could also be given concurrently with sodium ampicillin or ceftiofur to try to broaden the spectrum of activity. Intrathecal therapy (administering antibiotics directly into the CSF) has not been shown to improve outcome in human medicine and is likely too complicated for use in farm animals.[31]

In a CSF pharmacokinetic study of florfenicol in calves, the maximum concentration of florfenicol attained in CSF was 4.67 ± 1.51 μg/mL following a single intravenous dose of 20 mg/kg.[26] The levels remained above the minimum inhibitory concentration (MIC) for *Histophilus somni* over a 20-hour period. This concentration is below the MIC_{90} for *E. coli*. Bactericidal antibiotics are proposed to be more effective for treatment of meningitis in humans, and it is recommended that the concentration of antibiotic in the CSF should be maintained at 10 times the MIC of the target pathogen.[30] Unfortunately, owing to the lack of CSF pharmacokinetic data in cattle, antimicrobial treatment of meningitis is an inexact science. Antiinflammatory therapy and nursing care should be instituted as described previously for neonatal septicemia. Convulsions in calves can be treated with diazepam (0.1 to 0.2 mg/kg IV). This can be repeated every 30 minutes until convulsions are controlled.

Metabolic Acidosis

Profound weakness associated with metabolic acidosis or "strong ion" acidosis is commonly observed in calves with diarrhea and sporadically in kids ("floppy kid syndrome") and calves without other clinical signs of disease.[32,33] This acidosis is often associated with an increased concentration of D-lactate (the anion of D-lactic acid) resulting from bacterial fermentation of carbohydrates in the GI tract of milk-fed calves. Clinical signs of impaired CNS function, including ataxia and coma, in sick calves have been attributed at least partially to the increased D-lactate concentrations.[34,35] Assessment of weak neonatal ruminants for the presence of metabolic acidosis is a critical part of the physical examination. Correction of the acidosis by intravenous administration of bicarbonate produces a rapid recovery. An improvement in mentation and strength should be observed within 12 hours; persistent depression is likely to reflect incomplete correction of acidosis, sepsis, hypoglycemia, hypernatremia, or hyponatremia.

Hypoglycemia

Hypoglycemia is a common sequela to withdrawal of milk for more than 48 hours, especially in cold weather. Affected calves are weak or recumbent but appear to be normally hydrated or minimally dehydrated.[36] They are often emaciated and can occasionally have neurologic signs, including facial twitches, convulsions, opisthotonos, and coma. They will respond to a bolus of 50% dextrose or an infusion of 5% glucose, but often this response is temporary, especially in calves with severe malabsorptive disease. It is important to rapidly restore adequate energy intake to ensure resolution of these cases. Starvation and hypothermia resulting from mismothering are common causes of weakness in neonatal lambs. Similarly, weakness, poor body condition, and increased susceptibility to infectious diseases are observed with protein-calorie malnutrition induced by feeding poor-quality or incorrectly mixed milk replacers.[37] Hypoglycemia is also frequently seen in calves with neonatal septicemia, as discussed previously. In a recent study that reported serum glucose concentrations in more than 10,000 calves 3 weeks of age and younger, the presence of severe hypoglycemia (glucose ≤36 mg/dL or 2 mmol/L) was associated with a poor survival rate, as only 20.6% of these calves survived compared to 74.0% of calves with normal glucose levels.[38]

Hyponatremia

Hyponatremia occurs when loss of isotonic fluid through the GI tract is replaced by free water or hypotonic solutions. The latter often occurs when too much water is added when making up an oral electrolyte solution. Hyponatremia may also occur when isotonic oral electrolyte solutions are administered to calves with compromised sodium absorption capacity. This may be a result of severe pathologic changes or an inadequate level of agents that facilitate sodium cotransport within the oral electrolyte solution. Hyponatremia results in a fluid shift from the extracellular space to the intracellular compartment along the osmotic gradient, and the resultant swelling of the cells can result in neurologic disturbances, depression, disorientation, and even convulsions.[39] Hyponatremia should be considered in calves with serum sodium less than 132 mmol/L; calves with serum sodium less than 120 mmol/L have severe hyponatremia.

The goal of therapy is to restore serum sodium levels to greater than 125 mmol/L over the first 6 hours and then to restore to normal levels over 24 hours.[39] In hypovolemic calves the initial treatment should be achieved using normal saline, and in normovolemic calves hypertonic saline should be used for the initial treatment, since the administration of large fluid

volumes will exacerbate cerebral edema. If the calves are also suspected to be acidotic, this should be corrected with sodium bicarbonate solutions of appropriate tonicity.

The amount of sodium required in the first 6 hours to raise the sodium level to 125 mmol/L can be calculated as follows.[39]

$$\text{mEq Sodium} = (125 - \text{Measured mEq serum sodium}) \times (0.6 \times \text{Body weight in kg})$$

Calves should then be maintained on a sodium-containing isotonic fluid, such as normal saline or lactated Ringer, and treated with oral electrolyte solution as appropriate. The sodium level should be monitored frequently in the first 24 hours because of unknown losses through the GI tract as well as unknown kidney function in a severely dehydrated patient.

Hypernatremia

Hypernatremia (also known as sodium or salt toxicity) is a relatively common problem encountered in young calves. These cases are generally a result of the calf ingesting excessive concentrations of salt without an adequate balance of water to balance the sodium load. The most common clinical scenarios involve calves ingesting milk replacers high in sodium without access to fresh water[40,41] or calves that are being treated for diarrhea and receive oral electrolyte solutions with high sodium concentrations.[42,43] Recently, cases of hypernatremia in calves have been observed associated with the use of high-sodium water on farms. Affected calves are typically younger than 3 weeks of age and often (but not always) exhibit neurologic signs.

The volume of the extracellular fluid (ECF) is determined by the total body sodium content, whereas the osmolality and sodium concentration of the ECF are determined by sodium and water balance. Multiple control mechanisms work in the body to detect and respond to changes in the osmolality and volume of the ECF. These homeostatic mechanisms primarily control retention and excretion of sodium. Examples of regulatory control include the thirst response (water ingestion) and excretion or retention of sodium by the kidneys. Although it sounds simple, these are under complex control by multiple hormonal pathways, including antidiuretic hormone (ADH), atrial natriuretic peptide (ANP), the renin-angiotensin-aldosterone system (RAAS), and the autonomic nervous system. A complete discussion of the physiology of sodium and water homeostasis is beyond the scope of this chapter, but readers are referred to other recent review articles for more detailed information.[44,45] When calves take in too much sodium, this results in expansion of the ECF at the expense of intracellular fluid (ICF) in order to return the osmolality of the blood to normal (relative dehydration). In cases where there is no water intake, fluid loss is associated with reduction in total body water content (absolute dehydration). In cases of hypernatremia, the brain has to adapt to the hyperosmolar state, which typically involves shrinkage of neurons as water follows concentration gradients and moves into the hyperosmolar CSF and plasma. This results in dehydration of neurons and brain shrinkage. As the brain moves away from the calvaria, disruption of the normal blood supply can occur.[44] Neurologic signs often worsen during treatment of calves with hypernatremia, since rapidly lowering the sodium concentration with free water will allow water to flow into neurons, causing the already shrunken cells to swell, resulting in cerebral edema. This edema can lead to seizures and in many cases death.[28] Hypernatremia is defined as a serum or plasma sodium concentration of 160 mEq/L or greater, and neurologic signs of salt toxicity can be seen. Serum sodium concentrations greater than 180 mEq/L generally indicate a guarded to poor prognosis. Sodium concentrations in the CSF of cattle normally range from 130 to 142 mEq/L but are typically above 160 mEq/L in animals with hypernatremia.[46] Ocular fluid represents a good sample to submit to the diagnostic laboratory in dead calves, since it does not change appreciably with advancing postmortem autolysis and provides a stable representation of sodium levels at the time of death. Ocular fluid sodium concentration is reported to be about 95% of the serum sodium value, and levels are significantly elevated in cattle with hypernatremia.[46] In cattle that are dead, the entire brain or cerebral cortex should be submitted to a diagnostic laboratory for sodium analysis and histopathology. Typically no gross lesions of the brain are apparent at necropsy in cases of hypernatremia, and histopathology is nonspecific with cerebral edema present. Therefore submitting fresh brain and/or ocular fluid for sodium analysis in addition to requesting histopathology is critical. Sodium concentrations in brain tissue are generally greater than 2000 μg/g (ppm) in calves with hypernatremia.

Early clinical signs of hypernatremia include lethargy and depression, which, without blood work, cannot be differentiated from many other possible diseases such as acidemia, dehydration, hypoglycemia, or hypothermia. More advanced clinical signs of hypernatremia include twitching of facial muscles, muscle rigidity, tremors, and myoclonus.[28,44,47] Calves will demonstrate seizure and/or coma activity near death. Prognosis in these calves is often guarded to poor even with aggressive treatment.

Treatment of calves with chronic hypernatremia is often very difficult and should be reserved primarily for valuable animals. Classic recommendations call for sodium concentrations to be lowered very slowly, since replacing free water too rapidly could cause neurons to swell, cerebral edema, and a worsening of neurologic signs. The total body free water deficit can be calculated using the following formula:

$$0.6 \times \text{Body weight (kg)} \times ([\text{Current serum sodium concentrations}/\text{Normal serum sodium concentration}] - 1)$$

However, if this fluid is given rapidly, neurologic complications will often arise. In general the recommendation is to formulate fluids that have a sodium concentration approximately equal to that of the calf.[28,44,47] This can be done by adding small volumes of hypertonic saline (1.2 mEq/mL) or 23.4% sodium chloride (4 mEq/mL) to whatever fluid type you have chosen to give the calf. For example, if the calf has an acidemia, additional sodium can be added to isotonic sodium bicarbonate (sodium concentration of 156 mEq/L). However, if the calf has a relatively normal pH, additional sodium could be added to 0.9% saline (sodium concentration of 154 mEq/L). The idea is to decrease the sodium level of the calf very slowly over several days to avoid cerebral edema. A case example below will illustrate the calculation.

A 45-kg Hereford calf had clinical signs of hypernatremia. The calf had a serum sodium concentration of 187 mEq/L. To calculate the free water deficit in this calf we would multiple $0.6 \times 45 \times ([187 - 145) - 1)]$ to get a free water deficit of 7.82 L. In this example we used 145 to represent the "normal" serum sodium concentration for a calf. If we wanted to give 0.9% saline to this calf (154 mEq of sodium per liter), we would need to add 33 mEq of additional sodium to reach the calf's level of 187. The simplest way to do this would be to add a small volume of hypertonic saline (33 mEq/1.2 mEq/mL = 27 mL of hypertonic saline added per liter of fluids). You could also add hypertonic saline to isotonic sodium bicarbonate if the calf had an acidemia. Since isotonic sodium bicarbonate has a sodium concentration of 156 mEq/L, you would need to add 31 mEq of sodium. Be careful about adding large volumes of dextrose to these solutions, as that will lower the sodium concentration.

Although not always successful, a report of treating several hypernatremic calves with 5% dextrose either alone or in combination with sodium bicarbonate has been published.[42] In this study calves were given 2 to 4 L of 5% dextrose at a

VetBooks.ir

slow drip (about 500 mL/h) and had their serum sodium concentrations decreased much faster than is usually recommended. However, the four calves in the case report were treated successfully. Although this approach may not always work and could easily result in cerebral edema, it may be practical for times when the clinician does not have the ability to formulate fluids or monitor serum sodium concentrations frequently. In calves with chronic hypernatremia where "idiogenic osmoles" have formed, it is likely critical to lower sodium levels slowly, whereas the clinician may be able to lower sodium more rapidly in cases of acute hypernatremia.

If the calf's neurologic signs get significantly worse after fluid therapy has started, cerebral edema should be suspected. Treating cerebral edema is difficult but imperative to prevent further brain damage and/or death. Corticosteroids are the easiest choice normally; however, they are only marginally effective in treating moderate to severe cases of cerebral edema. Mannitol (25%) at 1 g/kg given IV over 30 minutes or an oral solution of glycerin diluted 1:1 with water has also been recommended for severe cases of cerebral edema but can be more difficult to obtain.[28]

Hypernatremia is largely avoidable by proper management. Since hypernatremia occurs largely under one of two conditions—(1) calf ingests too much sodium without an adequate volume of water in a short period of time, or (2) sustained water deprivation—the key becomes preventing both of these conditions from occurring. Whole milk is typically fairly low in sodium concentration, so typically calves fed whole milk have little problem with sodium toxicity unless given a large amount of oral electrolytes. Some milk replacer products can have significantly higher sodium concentrations as compared to whole milk (up to 85 to 100 mmol/L). Water quality is another factor that can have a profound effect on the amount of sodium calves ingest. Water that has been through a softening process to remove minerals such as calcium and magnesium can often have very high sodium concentrations and therefore should not be used to dilute commercial milk replacers unless a water analysis has been performed and sodium levels are less than 100 ppm. In one case report of salt poisoning in calves, milk replacer samples diluted with farm water had sodium concentrations ranging from 171 to 185 mmol/L.[40] When cases of hypernatremia are diagnosed on a farm, veterinarians should not forget to consider the drinking water source as a possible source of excess sodium.

In addition to watching how much sodium we feed calves in their normal milk diet, attention must also be given to the feeding of oral electrolyte solutions in calves with diarrhea. When homemade oral electrolyte products are used or when labeled mixing directions are not followed correctly, sometimes the sodium concentration fed to calves can be extremely high. In some cases oral electrolyte products are purchased in bulk containers, and more powder is added to 2 L of water than indicated in the directions. Multiple case reports describing hypernatremia in calves have involved the feeding of unknown amounts of oral electrolyte solution to calves multiple times per day.[42,43] This situation is exacerbated when calves do not have access to fresh water or when the fresh water also contains high sodium concentrations. In one case report, hypernatremia was diagnosed associated with neurologic signs and deaths in a group of 6- to 10-month-old Holstein calves that had access to a salt block without free-choice water available.[48] So ultimately, paying attention to the calf feeding program and the diarrhea treatment (oral electrolyte) feeding protocol for the farm is critical, along with ensuring that calves always have a supply of fresh, good-quality water.

Neuromuscular and Musculoskeletal Disease

Primary neuromuscular or musculoskeletal disease should be considered when weakness is not associated with depressed mentation. Weakness associated with micronutrient deficiencies results from myodegeneration (white muscle disease, selenium, and vitamin E) or demyelination (copper, enzootic ataxia). If weakness is detected in one or more limbs immediately after birth, peripheral nerve and muscle damage associated with birth trauma should be ruled out (see Box 20.1). Femoral nerve paralysis may be observed in calves following a "hip lock" dystocia.[49] A condition resembling congenital myasthenia gravis has also been described in Brahman calves.[50]

Nutritional myodegeneration associated with selenium or vitamin E deficiencies may produce localized (dysphagia) or generalized paresis. Neonatal small ruminants appear to be particularly susceptible. Affected lambs may be unable to rise; others can stand but may be unable to nurse because they are unable to raise their heads. Diagnosis is based on clinical signs, increased serum creatine kinase concentration, and reduced whole blood glutathione peroxidase and/or selenium concentrations (see Chapter 42). Vitamin E deficiency is observed when pregnant ewes are fed stored forage low in vitamin E; the clinical signs in affected lambs are identical to selenium deficiency, but selenium status is adequate. Since vitamin E is labile, serum should be harvested quickly after blood collection, frozen, wrapped in aluminum foil, and sent via express mail on ice.

Paraplegia and tetraplegia are commonly associated with spinal cord compression. Compression of the spinal cord in neonates most commonly results from vertebral body malformations, osteomyelitis, or fractures. Generally vertebral body malformations occur sporadically; genetic, nutritional, and environmental factors have been implicated.[51,52] In older calves, underlying metabolic bone disease (copper, vitamin D, or phosphorous deficiency) may increase the propensity for fractures to occur. Osteomyelitis and vertebral body abscess may be sequelae to bacteremia following neonatal septicemia or pneumonia.[53] The frequent isolation of *Trueperella pyogenes* from vertebral body abscesses in ruminants suggests that chronic respiratory infection is more frequently the source in these species.[54,55] Vertebral body abscesses in lambs are occasionally a sequela to infected docking wounds. Leukocytosis and hyperfibrinogenemia are commonly observed in neonates with vertebral body abscesses. In most instances vertebral abscesses do not infiltrate the pachymeninges, so the CSF either is normal or has a mild elevation of protein and/or a mild pleocytosis.[53,54]

Differential diagnoses for paresis in goat kids include caprine arthritis encephalitis virus (CAEV) and enzootic ataxia. Enzootic ataxia is also common in lambs. Progressive ataxia and paresis or paralysis is a feature of both diseases. There are two forms of enzootic ataxia (swayback): the neonatal and the delayed types. In the neonatal condition, animals are affected at birth; in the delayed type, signs of incoordination appear at 14 to 30 days of age.[56] Most affected kids are afebrile, bright, and alert, and they will continue to eat if it is physically possible. Enzootic ataxia is associated with low liver copper content and occasionally low serum copper concentration. It has been proposed that reduction in the activity of the copper-dependent enzyme cytochrome oxidase impairs phospholipid synthesis and subsequently myelin production. Microcytic anemia and increased fragility of bones may be observed in more chronic cases.[57] The copper, molybdenum, and sulfur content of the maternal diet should be evaluated and adjustments made for copper deficiency or molybdenum or sulfur excess.

Goat kids with the neurologic form of CAEV will have mild to moderate fevers and evidence of cerebral involvement. Cerebral signs commonly identified include depression, head tilt, torticollis, and circling. Evidence for CAEV includes CSF pleocytosis and increased CSF protein and a positive CAEV (agar gel immunodiffusion, or AGID) or enzyme-linked immunosorbent assay (ELISA) test.[58] Both the neurologic form of CAEV and enzootic ataxia carry a poor prognosis.

VetBooks.ir

A complete neurologic examination is an important component of the work-up of the weak neonate. In particular, it should be noted if the weakness is accompanied by signs of depression and diffuse cerebral disease. Strength is preserved if ataxia is caused by cerebellar disease. Limb reflexes should be tested to establish whether components of the spinal reflex pathways are involved in the disease process (sensory nerve, lower motor neuron, neuromuscular junction, muscle). Animals with other types of spinal cord disease (e.g., trauma, vertebral malformations, enzootic ataxia) may also show weakness and ataxia yet appear clinically to have normal cerebral function. Virtually any severe systemic disease such as generalized infection can cause both profound depression and weakness in a neonate without the presence of actual brain pathology. Intermittent signs of severe weakness and depression may be caused by the narcolepsy-cataplexy syndrome.

Respiratory Difficulty

Sheila M. McGuirk

Respiratory conditions of the neonatal ruminant can be attributed to upper airway problems, pulmonary pathology, CNS dysfunction, cardiac disease, metabolic derangements, or other nonpulmonary disorders (Box 20.2).

BOX 20.2

Causes of Respiratory Distress

Upper Airway Conditions

Pharyngeal trauma
Necrotic laryngitis
Choanal atresia (nasopharyngeal atresia)
Laryngeal edema
Tracheal malformation: stenosis, collapse

Developmental Disorders

Pulmonary hypoplasia
Diaphragmatic hernia

Lung Parenchymal Diseases

Pneumonia (bacterial or viral)
Atelectasis
Hyaline membrane disease
Pulmonary edema, congestion
Aspiration syndromes
Air leaks (e.g., pneumothorax)
Pulmonary hemorrhage
Transient tachypnea syndromes

Nonpulmonary Causes

Congestive heart failure
Central nervous system lesions
Metabolic derangements (e.g., acidosis, hypoglycemia)
Severe anemia
Hypovolemia
Fractured ribs
Nutritional myodeneration of thoracic muscles or diaphragm
Persistent pulmonary hypertension
Birth asphyxia
Pain, abdominal crisis
Fever, high environmental temperatures
Excitement
Pleural effusion (e.g., pleuritis)
Endotoxemia and gram-negative sepsis

Examination

A complete examination of the neonate is essential when clinical signs are indicative of a respiratory condition. When a single individual is involved, observation from a distance, recording of vital signs, and a physical examination guide the clinician to select appropriate diagnostic tests to establish a cause, make a diagnosis, and evaluate the prognosis. For respiratory conditions that affect a flock or herd of animals, the examination of affected individuals remains an essential component of the diagnostic work-up, but evaluation of records, the environment (housing and other animals), nutrition, colostrum, treatment, and vaccination protocols is also needed.

From a distance, mentation, posture, respiratory rate, breathing effort, characters of nasal and ocular discharge, and spontaneous coughing can be evaluated. Abnormal postures exhibited by patients with respiratory conditions may be recumbency, open-mouth breathing, abnormal extension of the head and neck, head tilt, or reluctance to lie down. Abnormal breathing characteristics include prolongation of the inspiratory or expiratory phase of respiration, an expiratory abdominal press or snap, marked tachypnea, frequent spontaneous coughing, stridor, and inspiratory or expiratory noises.

When in contact with the patient, assess airflow from each nostril and evaluate ocular, oral, pharyngeal, and vaginal mucous membrane characteristics, including temperature, color, moisture, and capillary refill time. The hard and soft palates should be evaluated. Animals with cleft palate may have milk run from the nose and are prone to developing aspiration pneumonia. Gray or cyanotic mucous membranes are associated with severe hypoxia (i.e., PaO_2 <35 to 40 mm Hg) and/or circulatory collapse as seen with hypotensive, endotoxic, or hypovolemic shock. Cardiac and pulmonary causes of cyanosis must be distinguished. Cyanosis from congenital cardiac disease of the neonatal ruminant frequently reflects right-to-left shunting of blood that may be from a tetralogy of Fallot, transposition of the aorta, great vessel anomalies, or Eisenmenger's complex. Absence of cyanosis is not a reliable indicator of adequacy of oxygenation in the neonate, since the partial pressure of oxygen may reach very low levels (<35 to 40 mm Hg) before cyanosis is observed.

Auscultation of the trachea, thorax, and occasionally the nasal passage are essential elements of the respiratory examination. Tracheal compression should not induce multiple coughs. Lung sounds of neonates are typically easier to hear than those of adults, but lung sounds do not always correlate well with the severity of respiratory condition that is present. Interpretation of the intensity of thoracic breath sounds can be validated by comparison to tracheal breath sounds. The intensity of tracheal breath sounds is gradually attenuated as the stethoscope is moved from the trachea to the lung hilus and again to the anteroventral thorax and finally to the caudal thorax in normal animals. Loud tracheal breath sounds that are not attenuated over the thoracic area may be indicative of atelectasis, lung consolidation, or cardiac enlargement. Added breath sounds such as crackles or wheezes should be noted but may not be heard without augmenting the depth and frequency of the breathing effort with the use of a rebreathing bag. Cardiac auscultation will determine heart rate, rhythm, and the presence of murmurs. Abnormal radiation of heart sounds caudal to the fifth intercostal space or dorsal to the level of the scapulohumeral joint on either side of the thorax should be noted. Thoracic percussion may be used to identify the presence of thoracic fluid, cranioventral consolidation, or atelectasis in neonatal ruminants. During the examination the ribs should be palpated to detect fractures.

Heart and respiratory rates vary with activity, excitement, and feeding. Tachypnea can be attributed to elevated temperature humidity index, fever, thermoregulation dysfunction,

excitement, pain, stress, respiratory disease, hypoxia (cardiac disease, pulmonary disease, shock), dehydration, shock, toxemia, or metabolic acidosis. Periodic apnea and abnormally slow respirations are often the result of metabolic disturbances (hypoglycemia, hypocalcemia), hypothermia, prematurity, or hypoxia-induced suppression of the respiratory center.

Abnormal posture of the head and neck are exhibited by neonates with respiratory difficulty, particularly upper airway obstruction, but meningoencephalitis, otitis media, hypernatremia, polioencephalomalacia, congenital defects of the CNS, and lasalocid toxicity should be considered.

Conditions causing occlusion of the upper airway, such as choanal atresia, necrotic laryngitis, and pharyngeal swelling or edema, often induce pronounced inspiratory dyspnea, stridor, and/or open-mouth breathing. Expiratory stridor and increased and prolonged expiratory effort are usually associated with lower airway disease. A malodorous breath may be present with necrotic pharyngeal injuries, necrotic laryngitis, cleft palate, or aspiration pneumonia. Inspiratory stridor is often a feature of extrathoracic airway obstruction, and increased abdominal effort on expiration is often an indication of pulmonary disease causing reduced lung compliance.

Lung disease in the newborn is usually diffuse and is the result of infection acquired in utero or postpartum and/or lung atelectasis associated with immaturity, recumbency, or surfactant dysfunction. Signs of lung disease include increased work of breathing characterized by nostril flare, rib retractions, and increased abdominal effort. A cough and nasal discharge, salient features of respiratory disease in older neonates, are infrequent findings in newborns with lung disease. Animals with few or no audible thoracic abnormalities may have severe respiratory disease.

Respiratory Condition Diagnostic Testing

A complete blood cell count, a serum chemistry profile, electrolyte concentrations, arterial or venous blood gas concentrations, and a test of immune transfer status provide useful information to the clinician concerned about a respiratory condition in a neonatal ruminant. Normal values for neonatal calves are presented in Table 20.4.

Knowing whether there is anemia, evidence of infection, endotoxemia, organ dysfunction, metabolic abnormalities, hypercarbia, hypoxemia, or FPT of immunity may distinguish upper airway problems from lower airway disease or pulmonary disease from a nonpulmonary cause of respiratory difficulty.

Arterial blood gas concentrations provide a useful measure of respiratory function. Optimal sites for collection of arterial blood samples from neonatal calves are the brachial artery proximomedial to the elbow[61] or the caudal auricular artery.[62] Normal arterial blood gas values for neonates of different postnatal and gestational ages are presented in Table 20.5.

Several factors can interfere with accurate interpretation of blood gases in the neonate. First, significant inaccuracies can occur if the blood sample is collected, handled, or measured improperly. The most common artifact is the introduction of room air into the sample, resulting in an artificially increased PaO_2, decreased $PaCO_2$, and more alkaline pH. The position of the patient and amount of struggling during sample collection may also potentially cause transient changes in all blood gas values. The inspired oxygen concentration should always be considered when analyzing arterial blood gas values. With supplemental oxygen, PaO_2 is increased variably, depending on the inspired oxygen concentration (FiO_2), the amount of pathology present (particularly the extent of right-to-left shunting), and the respiratory rate and tidal volume. Hypoxemia due to hypoventilation is usually addressed by increasing inspired PO_2 via a face mask or intranasal oxygen.

Common patterns of arterial blood gas derangement in the neonatal ruminant include hypoxemia (PaO_2 <70 mm Hg) with low or normal $PaCO_2$ and hypoxemia with hypercapnia ($PaCO_2$ >50 mm Hg). If hypercapnia and resulting respiratory acidosis exist, ventilation is inadequate or there is ventilation-perfusion

TABLE 20.5

Normal Arterial Blood Gas Values for Calves

Age-Group	O_2 (mm Hg)	CO_2 (mm Hg)	pH	HCO^-_3 (mEq/L)
1 hour	58.43 ± 11.61	50.40 ± 5.27	7.30 ± 0.05	23.52 ± 2.78
4 hours	62.30 ± 9.27	47.92 ± 3.97	7.34 ± 0.03	24.49 ± 2.35
12 hours	67.23 ± 9.32	45.36 ± 3.97	7.38 ± 0.03	25.74 ± 2.37
24 hours	70.53 ± 11.47	44.04 ± 3.45	7.40 ± 0.03	26.44 ± 1.87
48 hours	63.85 ± 10.82	45.25 ± 3.69	7.42 ± 0.01	27.98 ± 1.91

inequality. Hypoventilation in neonatal ruminants may reflect depression of the respiratory center, medullary trauma, ischemia, hemorrhage or encephalitis, lack of surfactant in the premature neonate, compromised muscle function (white muscle disease), or fractured ribs.

Interpretation of venous blood gas can be deceptive and should be limited to evaluation of metabolic conditions such as metabolic acidosis but not considered adequate for assessment of pulmonary gas exchange. To avoid problems associated with regional blood sampling, peripheral venous blood should be taken from a free-flowing jugular vein, since the metabolic status of the head is usually stable.

Plasma lactate measurement may provide prognostic value for calves with acute bronchopneumonia.[63] Acute phase proteins such as haptoglobin, fibrinogen, serum amyloid A, and lipopolysaccharide-binding protein have also been evaluated for diagnostic and prognostic value in bovine respiratory disease (BRD), but they are not specific for BRD, vary with etiology and stage of infection, and do not offer a clear distinction between normal and abnormal animals.

Thoracic radiographs are helpful in diagnosing the presence, type, and extent of respiratory disease in neonatal ruminants. Shortly after birth the smaller vessels posterior to the heart and in the caudodorsal lung fields should be clear. The heart, posterior vena cava, and aorta should be clearly defined. When the radiographic appearance of the lung fields is evaluated, the type of infiltrate (interstitial, nodular, alveolar, mixed), severity, and location (diffuse, cranioventral, caudodorsal) should be noted. Other soft tissue structures (including the heart, vessels, and diaphragm) and bones (ribs, vertebrae, long bones of the forelimb) should also be evaluated. Thoracic radiographs are routinely taken in the standing or lateral recumbent position in calves. Cranioventral consolidation is a common radiographic finding of infectious bronchopneumonia in calves. Radiographic changes may either follow or precede changes in clinical condition, and sometimes major changes can occur surprisingly rapidly. Clinical signs of pneumonia frequently resolve earlier than the thoracic radiographs return to normal.

Ultrasonographic evaluation of the neonatal ruminant thorax is useful for identification of aspiration of amniotic fluid, atelectasis, pleural effusion, nonventilated lung, pleuritis, and chest wall abscesses, and for detecting congenital heart defects. It appears most suitable for detecting pathologic processes close to the pleura.[64]

Respiratory endoscopy can be used for evaluation of the nasal cavity and septum, oropharynx and nasopharynx, epiglottis, larynx, and trachea. It is particularly useful for diagnostic evaluation of neonatal ruminants with respiratory stridor, stertorous breathing, malodorous breath or nasal discharge, inspiratory dyspnea, or related clinical signs indicative of upper airway problems.

Airway sampling is useful to determine presence, type, and etiology of respiratory inflammation and infection of neonatal ruminants. Deep pharyngeal swabs with a guarded catheter, transtracheal fluid aspirate, tracheobronchial lavage fluid, or bronchoalveolar lavage fluid analyses and cultures have been described. Techniques, sample handling, and interpretation are described in Chapter 31. For a neonate in respiratory distress, airway sampling may not be indicated until the patient is stabilized. Selection of the appropriate airway sampling method will depend on the patient condition and demeanor, supplies and equipment, test cost, technical assistance, clinician preference, anticipated etiology, sample handling, processing, and interpretation expertise. Specific airway sample, culture, polymerase chain reaction (PCR), ELISA, and other available tests for respiratory bacterial, *Mycoplasma*, *Chlamydia*, and viral pathogens are discussed in Chapter 31. Test positive and negative predictive values may be improved when used for herd-level testing rather than for individual animal test interpretation.

Postmortem examination is a useful diagnostic tool for evaluation of respiratory conditions of neonatal ruminants. In addition to the examination of the upper and lower respiratory tract, brain, heart, GI tract, immunologic sites, navel, other mucosal surfaces, and cavity fluids can provide information pertinent to a diagnosis. Lung culture, pathology, and immunohistochemistry (IHC) results can be particularly useful.

Upper Respiratory Tract Disorders

Conditions of the upper airway of neonatal ruminants are not common, but choanal atresia, stenotic nares, congenital cysts, cleft palate, pharyngeal trauma, pharyngeal and laryngeal edema, pharyngeal dysfunction, necrotic laryngitis, and tracheal collapse have been described. With the exception of necrotic laryngitis, most upper respiratory conditions of neonatal ruminants are present within the first week of life but may become progressive with age. Upper airway conditions, particularly those affecting pharyngeal and laryngeal function, predispose to aspiration pneumonia.

Diagnosis of most upper airway disorders can usually be made with a careful physical examination in combination with arterial blood gas concentrations, radiography, and/or endoscopy. Clinical signs of upper airway conditions include inspiratory effort, dyspnea, upper respiratory noise, stridor, malodorous nasal discharge, and cough. Dysphagia, poor appetite, milk reflux from the nostril, and aspiration pneumonia may be noted. Dyspnea is likely to result in failure to thrive and malnourishment.

Impaired pharyngeal and laryngeal function may result from physical deformation or neuromuscular disorders. Sporadic outbreaks of pharyngeal and laryngeal injuries are often associated with improper application or use of damaged feeding tubes and oral medication equipment. Compression of the larynx by a retropharyngeal abscess or mass tends to cause inspiratory dyspnea. Edema and necrosis of the larynx may be observed with infectious bovine rhinotracheitis virus infections in neonatal calves.[65,66] *Fusobacterium necrophorum* typically causes necrotic laryngitis in weaned calves but sporadically infects neonates following pharyngeal trauma.[67] Necrotic laryngitis is frequently detected only when clinical signs of dyspnea with stridor are evident. By this stage the disease tends to be chronic, and the response to systemic antimicrobial and antiinflammatory

VetBooks.ir

treatment is generally poor.[68] Partial occlusion of the upper airway induces turbulent airflow and subsequent mucosal edema. Placement of a tracheostomy tube provides an alternate, sometimes life-saving airway and rests the inflamed mucosa. Surgical intervention may be required; tracheotomy, tracheostomy, laryngotomy, laryngostomy, and tracheolaryngostomy have been described, with variable outcomes.[67-69]

Nutritional myodegeneration and botulism may induce laryngeal paresis. Dysphagia and subsequent aspiration pneumonia are common sequelae. Collapsed trachea is a rare congenital or acquired condition. In this condition, there is a dynamic dorsoventral collapse of the trachea during inspiration, but no stenosis is present. The caudal cervical and cranial thoracic sections of the trachea in the area of the thoracic inlet are most frequently affected. Acquired tracheal collapse is commonly associated with fractured ribs and compression of the trachea at the thoracic inlet by the bony callus that develops with healing. Clinical signs include an intermittent honking cough, stridor, and dyspnea with mild exercise. Treatment of collapsed trachea in the calf by surgical reconstruction has been attempted, but the prognosis is poor.[70-73]

Respiratory Infection

A number of respiratory disease syndromes may be observed in neonatal calves. Pneumonia in calves younger than 5 days of age is most likely hematogenous in origin, a consequence of neonatal septicemia or aspiration pneumonia from inhalation of fetal fluid, meconium, colostrum, or milk as a complication of recumbency, obtunded mentation, large volume forced feeding, large holes in teat nipples, poor esophageal tubing technique, or pharyngeal dysfunction (white muscle disease). Fever, cough, and nasal discharge are not consistently present in the early stages of pneumonia in the neonate. With hematogenous pneumonia, evidence of infection in other organs, including omphalophlebitis, meningitis, enteritis, and polyarthritis, is frequently present. Without early and aggressive treatment, sepsis can progress to shock, multiple organ dysfunction, and death relatively rapidly. *E. coli* or other gram-negative bacterial organisms are the most common culprits. With aspiration pneumonia, a mixture of gram-positive, gram-negative, and anaerobic bacteria can be cultured from the lungs, inciting a severe inflammatory response, toxemia, and occasionally sepsis. For hematogenous and aspiration pneumonia, broad-spectrum antimicrobial coverage must be instituted early and accompanied by antiinflammatory drug therapy, fluid therapy, nutritional supplementation, and supportive care. Long-term treatment is frequently necessary, and prognosis for survival is guarded.

Bacterial pneumonia of dairy calves, frequently described as affecting calves 2 to 6 months of age, may occur as early as 2 weeks of age and frequently peaks in incidence at 5 to 6 weeks of age. In bacterial pneumonia of calves, inhaled pathogens first colonize the bronchoalveolar junction, overcome host defenses, incite inflammation at that site, and go on to spread through the contiguous airways or through adjacent lung tissue. Pneumonia occurs as an endemic problem on many farms but can also occur as an outbreak. Frequently the problem is multifactorial, including bacterial organisms, individual and farm, or environmental risk factors.

Clinical signs of bacterial pneumonia in young calves usually include a combination of the following: fever, nasal discharge, lacrimation or ocular discharge, cough (spontaneous or inducible by tracheal compression), depression, reduced appetite, rough hair coat, expiratory effort, and abdominal breathing effort. Concurrent signs of otitis may be noted. Subjective parameters like attitude, appetite, appearance, activity level, or respiratory character that are used to detect pneumonia on farms can be insensitive and delay the pneumonia diagnosis and treatment. Remote recording devices that monitor objective parameters such as core body temperature, activity levels and behavior, and frequency and volume of milk consumption are becoming more common and will improve farm pneumonia detection. Automatic or computerized calf feeding is gaining popularity, providing opportunities to monitor calf feeding behavior. Parameters commonly measured include milk volume consumed, drinking speed, rewarded visits to the feeder (calf is fed), and unrewarded visits to the feeder (calf is not fed, as the interval from the last feed is too short). Calves with respiratory disease have been observed to have reduced milk intake and a reduced number of unrewarded visits. The changes in calf behavior were detectable 3 days prior to clinical recognition of disease and persisted for 7 days following identification of respiratory disease.[74] Similar changes have been reported by others, including reductions in drinking speed, milk volume consumed, and rewarded and unrewarded visits. However, these behavioral changes were found to be less sensitive at detecting calves with respiratory disease compared to calves with diarrhea.[75]

Bacterial agents are frequently the primary pathogens in calf pneumonia. Alone or in combination, *Mannheimia haemolytica*, *Pasteurella multocida*, *Mycoplasma bovis*, or *Mycoplasma dispar* are the most common bacterial isolates cultured from airway samples early in the infection. *Histophilus somni* or *T. pyogenes* is found in more advanced pneumonia cases. While any *Salmonella* species can cause pneumonia, *Salmonella dublin* can be the cause of fulminating pneumonia in 1- to 8-month-old calves. Outbreaks of respiratory disease in this age-group may be associated with mixed bacterial infections, including *M. bovis*, or with primary or concurrent viral infection with bovine respiratory syncytial virus (BRSV), bovine coronavirus (BCV), or bovine viral diarrhea virus (BVDV) infection. Viral infections increase the risk of opportunistic bacterial infections by their immunosuppressive effects and damage to the respiratory epithelium and pulmonary clearance mechanisms. Pleuritis is an uncommon feature of most neonatal respiratory infections but may be a manifestation of a generalized polyserositis with specific pathogens such as *Mycoplasma* infections of ruminant neonates[76] and occasionally *Pasteurella* infections in lambs.[77]

FPT of immunity is one of the most important risk factors for the development of calf pneumonia in individual animals and in herds. Calves with FPT had 1.6 times greater odds of being treated for respiratory disease.[78] In this study the prevalence of FPT was 32%, and the attributable fraction of BRD associated with FPT was 21%, suggesting that 1 in 5 cases of respiratory disease could have been avoided among calves with FPT if they had had adequate passive transfer.[78]

Poor nutrition is another risk factor for pneumonia in dairy calves that are limit-fed milk or milk replacer. A number of pathogens capable of causing respiratory disease are shed in milk. These include *Mycoplasma* spp.,[76,79,80] CAEV,[81,82] and *S. dublin*. The practice of feeding unpasteurized mastitic milk or nonsaleable milk to neonates increases the risk of disease transmission, including *S. dublin*, an invasive host-adapted *Salmonella* serotype, to cattle, *Mycoplasma* spp. infections to goat kids and calves, and CAEV to goat kids. CAEV produces a number of disease syndromes in goats, including mastitis, arthritis, encephalitis, and pneumonia. Encephalitis and subclinical respiratory disease typically occurs in kids 2 to 4 months of age and occasionally in kids as young as 1 month of age.[81,83] Goat kids infected with *Mycoplasma mycoides* subsp. *mycoides* (large colony type) are often in a lot of pain, febrile, and reluctant to stand, and have multiple hot, swollen joints from acute polyserositis. Approximately 50% of kids develop pneumonia or pleuropneumonia manifested by an increase in respiratory rate and auscultable lung sounds.[76] Outbreaks of *Mycoplasma* pneumonia in calves are usually caused by feeding waste milk contaminated with *M. bovis*.[84,85] Clinical signs include an increased rate and effort of breathing associated with

VetBooks.ir

pneumonia, joint and tendon sheath distention reflecting arthritis, polyserositis, tenosynovitis, auricular discharge, and a head tilt reflecting otitis media or interna[79,85]; decubital abscesses are a less common manifestation.[86] Clinical signs associated with *Mycoplasma* otitis include cranial nerve 7 and 8 deficits, unilateral or bilateral ear droop, ptosis, epiphora, head tilt, and recumbency in severely affected calves. Pasteurization of milk fed to goat kids and calves is recommended.

Additional environmental risk factors for pneumonia include extremes of temperature, poor ventilation, dust, ammonia, and overcrowding. Overcrowding, especially with commingled age-groups of calves, creates a high risk for pneumonia. Housing factors associated with reduced respiratory disease prevalence in naturally ventilated dairy calf barns are solid panels between calves that prevent contact, deep bedding, and low airborne bacterial counts.[87] A minimum space requirement of 2.2 to 3 m^2 per calf is associated with low airborne bacterial counts and less respiratory disease for calves in individual and group pens. Increased time between successive occupants of individual or group calf pens reduces the environmental exposure to disease organisms. An all in–all out housing system on farms reduces the chance for endemic pneumonia problems. Other risk factors for pneumonia include poor-quality feed, limited availability of water, stress, inappropriate medications, overvaccinating, parasitism, and concurrent infection.

Herd-based pneumonia problem solving is needed where respiratory disease in calves is endemic. Routine calf care, herd vaccinations, navel care, colostrum feeding, feed types, amounts, times, and additives are important. Learn the pneumonia definition, screening method, and treatment protocols. Review records to find seasonal trends, relationship to passive transfer of immunity, age at first diagnosis, and related management factors. Survival curves and incidence calculations can be useful. Observe people and procedures, and examine animals. Determine how many current cases have been detected and treated. Successful management of endemic pneumonia problems requires early detection, effective treatment, and resolution of the most important risk factors.

For treatment consideration, many antibiotics are labeled for BRD. Treatment plans for individual animals or farm protocols should be based on valid diagnostic information, recent examinations, and responsible use of antibiotics. Compliance with prescribed dose, route, and frequency of administration is factored into antibiotic selection. For one-dose respiratory treatment protocols, enrofloxacin, tulathromycin, ceftiofur, florfenicol, gamithromycin, or tildipirosin may be considered. For antibiotics like spectinomycin, enrofloxacin, ceftiofur, and florfenicol, multiple-dose treatment protocols are also effective for BRD.

Mycoplasma spp. are susceptible to antimicrobial agents that affect DNA, RNA, protein synthesis, or the integrity of the cell membrane. *Mycoplasma* spp. are not susceptible to agents that interfere with synthesis of folic acid or that act on the cell wall. Tylosin, tetracyclines, erythromycin, tilmicosin, tulathromycin, gamithromycin, florfenicol, aminoglycosides, and fluoroquinolones have been shown to have activity against one or more *Mycoplasma* spp.[88] However, the efficacy of antimicrobial therapy to eliminate the organism is limited, and while animals may recover, chronic infections may persist.[89]

Prevention of neonatal ruminant respiratory conditions includes appropriate vaccination programs, frequent observation of adults and neonates, uncomplicated births, adequate colostrum, navel care, optimal nutrition, and housing that is clean, dry, and draft free.

Neonatal Apnea and Irregular Breathing Patterns

Periods of apnea in the neonate are commonly associated with nonrespiratory factors, including infection, CNS disorders, hypothermia, and metabolic causes such as hypoglycemia. Seizure activity may be expressed by changes in breathing rate and pattern, and neonatal asphyxia may induce respiratory depression, whether or not cerebral lesions are present.[90] Neonatal respiratory distress may also cause apnea resulting from respiratory center depression or diaphragmatic fatigue. There are two mechanisms of apnea: central apnea, resulting from cessation of diaphragmatic activity; and obstructive apnea, resulting from obstruction of the airway, usually at the pharyngeal level.

Abdominal Distention

Geoffrey W. Smith

Ruminal Bloat

Ruminal bloat is uncommon in calves younger than 5 weeks of age because of the relatively undeveloped state of the neonatal rumen. Causes of ruminal bloat in calves include ruminal putrefaction, obstruction of the cardia or esophagus, and vagal indigestion (Box 20.3).

Ruminal bloat must be differentiated from abomasal bloat, which is much more common in young calves. However ruminal bloat can occur as a consequence of inadequate esophageal groove closure in young calves. The esophageal groove is a continuation of the lower esophagus, passing the medial wall of the reticulum and terminating in the reticulo-omasal orifice. The closure reflex is maintained by the suckling activity of the calf, and the groove is not properly closed if the calves

BOX 20.3

Causes of Abdominal Distention

Obstruction
Foreign body (hairballs in calf)
Malformation (atresia coli, recti, ani)
Intussusception
Volvulus, torsion, or strangulation

Uroperitoneum
Ruptured bladder (uncommon)
Torn or necrotic urachus, ureter

Peritonitis
Generalized infection
Devitalized bowel
Perforated gastric or intestinal ulcer
Severe umbilical infection

Gas and Fluid Accumulation in Abomasum, Intestinal Tract
Intolerance to diet
Ileus
Gastric, abomasal, duodenal ulceration
Necrotizing enterocolitis
Ruminal bloat

Miscellaneous
Hemoperitoneum
Ruptured umbilical vessels
Ruptured spleen or liver
Congenital tumor

Ascites
Severe liver or renal failure
Severe hypoproteinemia

FIG. 20.2 Classic appearance of a rumen drinker calf. The calf is extremely depressed from systemic acidosis with abdominal distention. Note the front legs extended caudally, which can often be seen in these cases.

drink out of buckets. It may also not close if milk temperatures are variable, the calves are under stress, the calves are fed too low to the ground, or milk flow rates are too high.[91] Failure of esophageal groove closure leads to rumen drinking, where greater than normal amounts of milk enter the ruminoreticulum instead of the abomasum. Prolonged retention of milk in the rumen results in anaerobic bacterial fermentation and production of lactic acid,[92] leading to both a ruminal and a systemic (metabolic) acidosis.[93] Clinical findings in ruminal drinker calves include refusal of milk, poor suckle reflex, recurrent ruminal bloat, and splashing sounds on the left side of the distended abdomen in young calves (Fig. 20.2). Calves are frequently depressed and dehydrated and may die due to the severity of the metabolic acidosis. Treatment primarily involves rumen lavage with a stomach tube to siphon off the fermented milk remaining in the rumen, along with fluid therapy to correct the acidosis. Although ruminal drinker syndrome has been described in calves representing multiple breeds, it appears to be most common in Simmental calves from Germany and Switzerland.[94] Reducing the volume of milk fed per feeding, feeding from nipples rather than buckets, and introducing calf starter to promote ruminal development help prevent the condition. Antimicrobial therapy may also help affected calves by killing the putrefactive gut flora.

Bloat is occasionally observed as a complication of severe bronchopneumonia in calves as a consequence of swollen mediastinal lymph nodes compressing the esophagus or compression or inflammation of the vagus.[95] Relief of rumen distention is important for return of rumen function. Chronic ruminal bloat may be relieved by placement of a rumen fistula. Correct placement of the trocar, as described by Dirksen and Garry,[95] reduces the risk of inducing peritonitis. The rumen must be bloated so that it lies firmly against the body wall as the trocar is screwed into place. The site for the trocar is shaved and scrubbed, a small skin incision is made, and the trocar is quickly and forcefully screwed into the belly wall and rumen. After removal of the stylet, the outer rim of the trocar is kept under constant outward tension so that the ruminal wall is held tightly against the parietal peritoneum by the last ridge of the screw. To fix the trocar in this position, gauze soaked in antibiotic should be wrapped around the stem of the trocar between the outer rim and the body wall.[95]

Abomasal Ulcers

Abomasal ulcers are usually asymptomatic in young calves, but if perforation occurs, peritonitis and shock rapidly develop. It is often difficult to determine the underlying cause of abomasal ulcers; however, several possibilities have been identified, including trauma to the mucosa from the addition of coarse roughage feeds, pica resulting from enteritis, abomasal bezoars, environmental and physical stress, hyperacidity, vitamin E deficiency, lactic acidosis, mycotic infection, and low immune status associated with copper deficiency.[96-98] Inconsistency of milk fed to calves (varying osmolality or total solid levels) and/or inconsistency of feeding schedules also appear to be significant risk factors. Several bacteria, including *E. coli* and *Sarcina* and *Clostridium* species, have also been isolated from various calves with ulcers.[99] Although no definitive infectious component has been identified in cattle, some authors have hypothesized that a bacterial component is likely in some cases.[100] This could be similar to humans, in which *Helicobacter pylori* and gastric ulcers routinely occur together.

Four categories of ulcers are described in calves[97,98]:

Type 1: Nonperforating ulcer—The ulcer does not perforate the abomasal wall, and intraluminal hemorrhage is minimal. (Fig. 20.3, *A*)

Type 2: Nonperforating ulcer with severe blood loss—The ulcer does not perforate the abomasal wall but erodes a major vessel in the submucosa, resulting in severe intraluminal hemorrhage.

Type 3: Perforating ulcer (Fig. 20.3, *B*) with local peritonitis—The ulcer perforates the abomasal wall, and abomasal contents leak into the peritoneal cavity or omental bursa. Peritonitis is localized by fibrin deposition, and the abomasum becomes adhered to the peritoneum, omentum, or surrounding viscera.

Type 4: Perforating ulcers with diffuse peritonitis—The ulcer perforates the abomasal wall, and abomasal contents quickly leak into and spread throughout the peritoneal cavity, resulting in diffuse peritonitis.

Abomasal ulcers can be very difficult to diagnose antemortem in calves. Clinical signs are vague and include sudden death, abdominal distention, pain on abdominal palpation, expiratory grunt, drooling saliva, bruxism, and melena. Less commonly, a syndrome of chronic abdominal pain is observed after abomasal perforation.[101] Absence of inflammatory changes suggests that the gut is unlikely to be perforated or necrotic. Severe hypoproteinemia is common with diffuse peritonitis, presumably because of the combination of poor colostral uptake and loss of protein into the abdominal exudate. Obtaining peritoneal fluid from normal calves is difficult; if peritonitis is suspected, collection of abdominal fluid is facilitated by locating pockets of peritoneal fluid via abdominal ultrasound.

In general, treatment is limited to calves with bleeding or deep, nonperforated ulcers. Therapy can include blood transfusions, antibiotic administration, changes to the diet, oral administration of antacids, and administration of histamine H_2-receptor antagonists. Aluminum hydroxide/magnesium hydroxide—$Al(OH)_3/Mg(OH)_2$—antacids neutralize acid in the abomasum and require three doses per day. Antacids are an inexpensive option for treatment of cattle with ulcers and

VetBooks.ir

FIG. 20.3 Abomasal ulcers in calves can range from small reddish erosions **(A)** to perforated lesions that lead to diffuse peritonitis **(B)**.

have a potential therapeutic advantage. $Al(OH)_3$ directly absorbs pepsin, thus decreasing the proteolytic action of pepsin in the stomach.[102] Also, $Al(OH)_3$ and $Mg(OH)_2$ bind bile acids, thus protecting against ulceration caused by bile reflux.[102] Ahmed and colleagues found that healthy calves given 25 to 50 mL of oral antacid had a transient increase in abomasal luminal pH.[103] This effect appeared to be dose related, and the extent of the acid neutralization was increased when not given with milk replacer.

Histamine H_2-receptor antagonists reduce acid secretion of parietal cells by selective and competitive antagonism of histamine at H_2 receptors on the parietal cells. Cimetidine and ranitidine are synthetic H_2-receptor antagonists that inhibit basal as well as pentagastrin- and cholinergic-stimulated gastric acid secretion. Daily oral administration of cimetidine at 10 mg/kg for 30 days in veal calves was found to aid healing of abomasal ulcers.[104] Oral administration of cimetidine (50 to 100 mg/kg q8h) and ranitidine (10 to 50 mg/kg q8h) caused a dose-dependent increase in abomasal luminal pH, and ranitidine had greater potency than cimetidine.[105] Omeprazole, a proton pump inhibitor, has also been studied in calves. Once-daily oral administration of omeprazole (4 mg/kg) to calves increased the mean 24-hour luminal pH by 1.3 pH units; however, this increase in pH was less pronounced with subsequent daily treatments.[106]

Surgical repair of ulcers can be performed on selected cases. Calves need to be in an operable condition and have isolated ulcers. Surgery needs to be performed early in the disease process. Typically ulcers are diagnosed during a laparotomy and either they can be resected or the serosa can be inverted with a mattress suture. One study reported a survival rate of 74% following surgical repair, with survival being defined as calves living at least 3 months past surgery date or dying because of another disease.[107]

Abomasal Displacement

Abomasal displacement is rare in neonatal ruminants. Clinical signs include reduced appetite, poor weight gain, recurrent tympany (left side), and diarrhea. An association of left-sided abomasal displacement with pneumonia in calves suggests that altered vagal function may be involved in the pathogenesis of the condition.[108,109] Typically, left-sided abomasal displacement in calves occurs between 6 and 14 weeks of age, but younger calves may be affected. Displacement of the abomasum is diagnosed by auscultation and percussion; affected animals may have a hypochloremic metabolic alkalosis. Correction can be attempted by rolling the calf on its back or by surgery.

Abomasal Bloat

A number of reports on a complex syndrome known as abomasal tympany, abomasal bloat, braxylike disease, and abomasitis have been published.[98,110,111] This syndrome in young calves is characterized by anorexia, abdominal distention (often bilateral), bloat, and often sudden death within 48 hours. In mild cases clinical signs are described as diarrhea, watery fluid in the abomasum, and depression. Hyperglycemia (10.5 to 28 mmol/L) accompanied by glucosuria (3 to 6 mmol/L) was also reported in those calves. Severely affected calves show perceptible dehydration, colic, prominent abdominal distention, diarrhea, and recumbency. Systemic acidosis, as evidenced by low blood pH, low serum bicarbonate concentration, and base deficit, was also reported for calves with abomasal bloat.[112] Calves typically exhibit abdominal distention on the right side of the abdomen or potentially on both sides as the abomasum fills up with gas and occupies the majority of the abdominal cavity. At necropsy most of these calves present with abomasal tympany, forestomach and abomasal edema, hemorrhage, mucosal inflammation, erosion and necrosis, and occasionally mural emphysema. Emphysematous bullae are present in the stomach walls of these calves.[111]

Abomasal bloat most commonly occurs in dairy calves and seems to have a sporadic occurrence, with some farms having multiple outbreaks at times.[98] Abomasal bloat has been identified on farms using conventional milk replacers, "accelerated growth" milk replacers, and both pasteurized and unpasteurized whole milk. No single diet type or feeding method emerged as a

VetBooks.ir

conspicuous risk factor for abomasal bloat in this survey. Other risk factors that have been reported for abomasal bloat include high-osmolality milk replacers or oral electrolyte solutions, improper mixing of milk replacers, feeding a large volume of milk in a single daily feeding, cold milk (or milk replacer), not offering water to calves, erratic feeding schedules, and FPT.[98]

A bacterial etiology is often mentioned in association with abomasal bloat. The most frequently incriminated bacterial pathogens are *Clostridium perfringens* along with *Campylobacter* and *Sarcina* species.[111,113] These pathogens have also been associated with abomasal bloat in small ruminants.[114,115] Additional bacterial pathogens isolated from calves affected with abomasal bloat include alpha streptococci, other *Streptococcus* species, and *E. coli*. *C. perfringens* is most frequently seen as type A, E, or C, producing beta toxin.[112] Beta toxin damages the intestinal microvilli, mitochondria, and terminal capillaries in the mucosa. Progressive necrosis of the mucosa follows, and a large number of gram-positive bacilli invade those areas. *C. perfringens* type A was identified as the causative agent in a case report of 24 dairy calves dying from severe acute abomasal disease.[116] In another report, *Sarcina*-like bacteria were reported to contribute to the development of abomasal bloat in goat kids.[114] Histologic evidence of *Sarcina ventriculi* and *Sarcina maxima* was detected in the superficial mucosa, but no bacteria could be cultured from the lesions.[117] Vatn and colleagues reported that evidence of *Sarcina* could be identified in the abomasal wall of all lambs with bloat; however, the bacteria could be isolated in only one case.[115] Intraruminal inoculations of *C. perfringens* type A into healthy dairy calves resulted in anorexia, depression, bloat, diarrhea, and death.[118] The authors assumed that esophageal groove dysfunction allows abnormal amounts of milk to enter the abomasum, where bacteria like *C. perfringens* find a suitable environment for proliferation and invasion of the abomasal mucosa, resulting in abomasitis.

Experimental induction of abomasal bloat in calves was achieved by drenching Holstein calves younger than 10 days of age with a carbohydrate mixture containing milk replacer, corn starch, and glucose mixed in water to provide a meal with excessive fermentable carbohydrate.[119] The authors suggested that the syndrome of abomasal bloat in calves is multifactorial and proposed that the pathophysiology primarily involves excess fermentation of high-energy GI contents in the abomasum (from milk, milk replacer, or high-energy oral electrolyte solutions), along with the presence of fermentative enzymes (produced by bacteria), leading to gas production and bloat. This process would be accelerated by anything that slowed abomasal emptying or caused GI ileus. Ultimately the exact etiology of abomasal bloat is unknown, but it likely involves both bacteria that produce gas and something that slows down abomasal emptying.

Treatment generally involves placing the calf in dorsal recumbency and inserting a needle or catheter into the abomasum to relieve the gas.[120] Attempting to deflate the bloat in a standing calf is often unrewarding, since this approach generally fails to completely drain the abomasum and carries a high risk of inducing peritonitis.[120,121] The best results occur when the calf is turned upside down and the abomasum is deflated with a 14-gauge, 50-mm needle inserted into the highest point of the abdominal wall between the umbilicus and xiphoid.[120] With this technique, 20 of 21 calves with abomasal tympany were successfully managed without complications. Repeated paracentesis carries a high risk of inducing peritonitis; if after paracentesis the calf's condition deteriorates or tympany recurs, a right flank laparotomy is performed to correct a possibly torsed abomasum.[122] Intravenous fluids are administered to correct dehydration and electrolyte and metabolic derangements. Antibiotic therapy may also be indicated in these calves (most likely parenteral procaine penicillin or oral β-lactam antibiotics to target *Clostridium* bacteria).

Control of abomasal bloat problems on a dairy farm generally begin with a thorough evaluation of the nutrition program to see if any changes need to be made. This evaluation would include what type of milk or milk replacer is being fed, volume fed at each feeding, feeding schedule, temperature of milk fed to calves, how the milk replacer is mixed, how feeding equipment is sanitized, and possibly even a water analysis in some cases. Recording the total solids of the milk replacer and potentially even measuring osmolality will provide additional information about the density and mixing consistency of the milk replacer being fed. Anecdotally, focusing on controlling abomasal bloat through nutritional approaches and minimizing feeding practices that slow abomasal emptying is often much more successful than trying to control the problem by instituting *C. perfringens* vaccination.[123] However, specific data on the efficacy of clostridial vaccines to control bloat have not been published.

Abomasal bloat is a significant problem in artificially raised lambs. Feeding systems that allow lambs to drink large quantities of milk replacer at infrequent intervals and housing lambs on litter are predisposing factors.[124,125] Proliferation of *Lactobacilli*, *E. coli*, and *C. perfringens* has been implicated in the disease process.[125,126] Fermentation of sugars contained in milk replacer produces carbon dioxide, distending the abomasum.[127] Lambs may die within hours because of acute abdominal tympany compromising vascular return and respiration. Early treatment of bloated lambs with oral doses of antibiotics is sometimes an effective treatment. Addition of 0.1% formalin (37% formaldehyde) to milk replacer reduces the incidence of the condition.[126]

Intestinal Atresia

Intestinal atresia is the most common cause of abdominal distention of calves in the first week of life. Typically calves are born normally but develop progressive abdominal distention shortly after birth. Signs of mild colic are occasionally observed. The spiral loop of the ascending colon is usually the site of atresia.[128] Other congenital abnormalities may also be present (18% of cases).[128,129] Historically there was some thought that pregnancy diagnosis by palpating the amniotic sac before 40 days of gestation may cause colonic atresia in cattle[130]; however, recent studies have not supported that theory.[131,132] An autosomal recessive inheritance in Holstein cattle has also been proposed.[133] Surgical repair of atresia ani that can be treated with a perineal incision and rectal pull-through carries a good prognosis. However, surgical repair by resection of the distended proximal blind end and anastomosis of the proximal segment of intestine to the descending colon or use of a colostomy has a guarded to poor prognosis.[128,129,134]

Intussusception

Intussusception occurs most commonly in the jejunum, but the frequency of ileocecal and colon intussusceptions appears to be higher in calves than adults.[135] Commonly there is a history of diarrhea. Clinical signs may include intermittent colic, absence of feces, and melena; however, these are inconsistent. The inconsistency of clinical signs and inability to perform a rectal examination make the diagnosis more difficult in calves than adults.[135] Abdominal ultrasound may be useful. The prognosis following surgical correction is strongly influenced by the duration of the condition prior to correction.

Twisting of the intestinal mass around the cranial root of the mesentery is a rare event but occurs more frequently in calves than adults.[135] Clinically the condition is characterized by a sudden onset of severe colic (kicking at the abdomen, dropping to the ground) that rapidly progresses (abdominal enlargement, tachycardia, tachypnea, reduced or absent fecal

passage) to signs of shock and recumbency. Early diagnosis and rapid surgical correction, using either a right paralumbar or a ventral midline, together with a supportive fluids approach allow for a good prognosis.

Diarrhea

Alison A. Gunn • Mathew Izzo • John K. House

Herd management variables that affect the risk of neonatal death losses in housed calves include efficiency of passive transfer, calf nutrition and environmental management (pathogen exposure), calving area sanitation, and cow vaccination status and health. Successful calf rearing is based on good management. A goal of less than 3% death loss from diarrhea is achievable. With neonatal death losses in pasture or range animals, it is important to evaluate the dystocia rate, physical management and nutritional status of the calving and nursing herds, cleanliness of the calving and nursing areas, provision of shelter from wind, and any biosecurity risks.

Rotavirus, cryptosporidia, coronavirus, enterotoxigenic *E. coli*, and *Salmonella* are recognized as the major pathogens associated with diarrhea in calves (Table 20.6). Rotavirus, cryptosporidia, coronavirus, and enterotoxigenic *E. coli* are common pathogens in beef calves.[136-139] Salmonella is more frequently implicated in intensive calf-rearing systems.[138-140] Enteropathogenic strains of *E. coli* are occasionally implicated in calf diarrhea, but the true prevalence of disease associated with these strains is unknown due to the lack of routine definitive diagnostic tests. Torovirus has been associated with neonatal calf diarrhea (NCD) in Canada, the United States, and Europe.[141-144] Bovine virus diarrhea is infrequently associated with diarrhea in young calves.[145,146] More recently, norovirus and nebovirus have been implicated as causes of neonatal diarrhea, but their prevalence and importance in the field situation is unclear. Infectious agents implicated as causes of neonatal diarrhea are presented in Table 20.7. The incidence of the various etiologic agents varies with the age of the calf, and this is useful in establishing the likelihood that a particular agent is involved (Fig. 20.4). It is usually impossible to make a definitive etiologic diagnosis on clinical grounds. It is possible to detect signs of straining or passage of frank blood and mucus that suggest the presence of colitis, implicating possible salmonella, coronavirus, bovine viral diarrhea, enteropathogenic *E. coli*, or coccidial infections.

Pathogenesis

Diarrhea can be the result of either increased secretion or decreased absorption. Bacteria such as enterotoxigenic *E. coli* and to some extent *Salmonella* cause neonatal diarrhea by secreting enterotoxins that stimulate increased intestinal secretions.[147,148] These changes are thought to be mediated by cyclic adenosine monophosphate (AMP) or cyclic guanosine monophosphate (GMP), calmodulin, and changes in tyrosine kinase activity.[149-151] The cell's structure is not affected, but the activity of the membrane pumps is altered, and there is increased secretion of chloride, bicarbonate, and potassium.[151-153] Heat-stable enterotoxin also induces bicarbonate secretion through the tyrosin kinase pathway and inhibits the sodium hydrogen exchanger, reducing absorption of sodium from the GI tract.[153] Sodium absorption linked to glucose and amino acid transport across the mucosal epithelium is not affected.[154,155]

Protozoa and enteric viruses cause neonatal diarrhea as a result of the destruction of the absorptive villous epithelial cells.[156-159] Diarrhea results because intestinal digestive secretions continue while absorption is impaired.[160,161] In rotavirus and coronavirus infections this is further exacerbated by compensatory hyperplasia of the crypt cells. The crypt cells have secretory functions, and their multiplication adds to the secretory load.[160] Rotavirus can also stimulate intestinal secretion both at a cellular level and by stimulation of the enteric nervous system. This is associated with a viral nonstructural protein, NSP4.[162,163] NSP4 causes increases in intracellular calcium and inhibits the sodium glucose cotransporter. Increased intracellular calcium inhibits the translocation of disaccharidases from the intracellular vesicles to the luminal surface, decreasing the ability to digest carbohydrates and contributing to maldigestion.[151]

TABLE 20.7

Evaluation of the Pathogenicity of Various Infectious Agents as Gauged by Their Ability to Experimentally Produce Diarrhea in Calves, Field Surveys of the Incidence of Infection in Diarrheic and Healthy Calves, and Similarity in the Distribution of Intestinal Pathology and the Infectious Agent

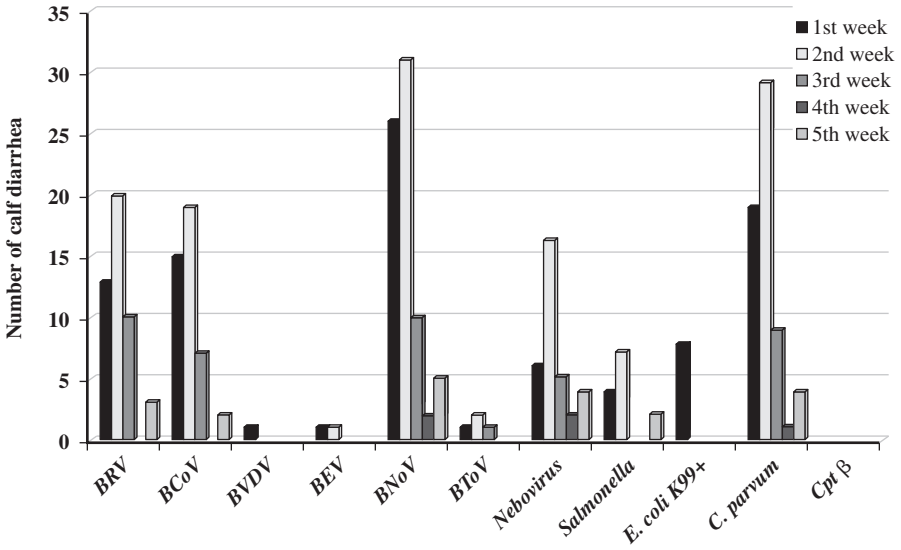

FIG. 20.4 Age distribution of diarrheic calves whose feces were positive for one or more enteric pathogens. Animals of 0 to 4 weeks of age are classified on a weekly basis after birth based on the information provided by submitting veterinarians. These data were compiled from submissions to the Iowa State University Veterinary Diagnostic Laboratory and represent approximately even numbers of beef and dairy calves. *BCoV,* Bovine coronavirus; *BEV,* bovine enterovirus; *BNoV,* bovine norovirus; *BRV,* bovine rotavirus; *BVDV,* bovine viral diarrhea virus; *C. parvum*, *Cryptosporidium parvum; Cpt β, Clostridium perfringens* beta toxin; *E. coli* K99+, *Escherichia coli* K99+. *(From Cho Y-I et al.: Case-control study of microbiological etiology associated with calf diarrhea.* Veterinary Microbiology, *166(3–4):375–385, 2013.)*

VetBooks.ir

Continued feeding may result in more nutrients presented to the small intestine than the damaged villi can absorb[164,165]; excess nutrients are fermented in the large intestine, promoting bacterial overgrowth[149,166] and generation of organic acids and other deleterious compounds. The osmotic effect of the unabsorbed nutrients drags water into the gut and contributes to the diarrhea.[160] Marked inflammation is a feature of salmonellosis and clostridiosis. This contributes to diarrhea by increasing mucosal pore size and hydraulic pressures within the intestinal wall, by destroying absorptive cells, and by increasing prostaglandin production, which in turn stimulates secretory mechanisms within the enterocytes.[149,160]

On an individual animal basis, diarrhea is significant because of fluid and electrolyte losses. As long as the neonate can compensate for these losses, it will remain fairly bright and continue to suck. If the losses exceed intake, systemic effects of dehydration (salt and water loss) or acidosis are seen. Fluid is lost preferentially from the vascular compartment,[167,168] and cardiovascular collapse results. Acidosis has several causes, including fecal loss of bicarbonate, endogenous synthesis of L-lactic acid in response to dehydration and poor tissue perfusion, and D-lactic acid production through bacterial fermentation of undigested or malabsorbed milk within the GI tract.[169-174] Acidosis contributes to the calf's malaise by increasing vascular resistance, impairing cardiac function by direct effects, and inhibiting the action of catecholamines. Esophageal groove function may be compromised in acidotic calves, promoting ruminal drinking with the consequences of further production of D-lactic acid in the rumen and subsequent ruminal acidosis.[174,175]

The neonate becomes depressed, loses its suck reflex, and becomes weak; if the disease progresses, recumbency and coma may develop. One cause of death is believed to be heart failure as a result of myocardial potassium imbalance due to the combined effects of potassium losses into the GI tract and the redistribution of potassium from the cells to extracellular fluid as a result of acidosis.[176-178] Hypothermia will also contribute to cardiac failure. In cases of enterotoxigenic *E. coli*, cryptosporidia, rotavirus and coronavirus infections, correcting the fluid, electrolyte, and acid-base imbalances restores the neonate's ability to walk and suck. A residual degree of malaise may persist, which can be attributed to inflammation within the gut wall and damage to the integrity of the mucosal barriers allowing invasion of enteric microbes or their toxins. If malabsorption persists, cachexia can develop—particularly if milk continues to be withheld as part of therapy—and death from malnutrition or hypoglycemia may occur.

Salmonella are invasive and release endotoxins in the systemic circulation. Clostridia produce exotoxins. Both endotoxins and exotoxins have profound systemic effects, which are often directly responsible for malaise, microcirculatory failure, and cardiovascular collapse. Correcting fluid and electrolyte disturbances in these infections will aid the neonate but will not overcome the effects of toxemia or bacteremia.

Etiology

Bacteria

ESCHERICHIA COLI. *E. coli* are part of the normal flora of the bovine GI tract. Pathogenic strains of *E. coli* possess virulence attributes that are involved in the pathogenesis of disease. Virulence attributes include adhesins, enterotoxins, and cytotoxins. Pathogenic strains of *E. coli* may be shed by adult cattle with transmission to neonates by the fecal-oral route. Sick neonates amplify environmental contamination via prolific fecal shedding.

ENTEROTOXIGENIC *E. COLI*. Enterotoxigenic *E. coli* (ETEC) possess two virulence factors: fimbriae (pili) and enterotoxins. F5 (K99) and/or F41 fimbriae mediate adherence, and thermolabile (LT) and thermostable (STa and STb) enterotoxins stimulate a secretory response by intestinal crypt cells. Expression of fimbriae is influenced by the pH, with expression occurring at a pH of 6.5 or greater.[179] The distal small intestine is the initial site of colonization because the pH of intestinal fluid increases as it moves caudally, reaching this threshold at the ileum.[151] Bicarbonate-containing oral replacement fluids may favor the proliferation of ETEC, expression of the K99 antigen, and secretion of STa.[151] Oral electrolyte solutions containing acetate are recommended for treatment of ETEC diarrhea.[151]

Although some bovine-origin ETEC produce LT, most strains that cause diarrhea in neonatal calves produce STa heat-stable enterotoxin.[180] The STa enterotoxin and F5 antigen are plasmid-mediated virulence factors. Susceptibility to ETEC is age dependent according to the binding specificity of pili antigens to immature enterocytes.[181] Disease is typically observed in calves younger than 3 days of age, but concurrent infection with rotavirus may extend this window to 7 to 14 days of age.[182,183] Intestinal cells of calves older than 2 days of age acquire natural resistance to F5 adhesion.[181] Despite this, F5-positive *E. coli* have been isolated from healthy 4- to 12-week-old calves, and F5-positive ETEC are shed in feces for several weeks following experimental infection of newborn calves.[184] A recent worldwide study has shown that the prevalence of F5-positive ETEC appears to be decreasing.[185]

ATTACHING AND EFFACING *E. COLI* AND SHIGA TOXIN-PRODUCING *E. COLI*. Attaching and effacing *E. coli* (AEEC) and Shiga toxin–producing *E. coli* (STEC) have also been identified as causes of diarrhea and dysentery in calves.[186,187] Disease is mediated by cytotoxic damage to the intestinal mucosa. Lesions may be observed in the ileum, cecum, and descending colon.[188] AEEC (verotoxin- or HeLa toxin–producing) induce a mucohemorrhagic colitis, with petechial or ecchymotic hemorrhages in the wall of the colon and rectum.[189-191] *E. coli* that carry this toxin often belong to O serogroups 5, 26, 111, 118, and 145.[190,192] Naturally occurring outbreaks have been reported in 2-day-old to 4-week-old calves.[193] Diarrhea and enteritis has been associated with naturally occurring *E. coli* 0157:H7 in 1- to 3-week-old calves in Argentina, the United Kingdom, and Korea.[194-196] The most common clinical sign is diarrhea, but dysentery, dullness, reluctance to move, weight loss, anorexia, abdominal pain manifested by bruxism, and dehydration are seen in some cases. The feces of affected calves can appear normal, but more commonly feces are watery yellow with blood.

STEC serotypes associated with dysentery in calves include O5:H-, O26:H11, O111:H-, and O113:H21[197]; these serotypes may produce Shiga toxins, those that are immunologically similar to the Shiga toxin produced by *Shigella dysenteriae* (STx1) and those that are immunologically distinct from *S. dysenteriae* Shiga toxin (STx2).[198] Bovine STEC produce either STx1 or STx2, or both.[199] AEEC that cause disease and do not produce enterotoxins or Shiga toxin is referred to as enteropathogenic *E. coli* (EPEC).

The prevalence of AEEC and STEC in calves and the incidence of disease caused by these strains are not clearly defined, as most diagnostic laboratories do not routinely screen for AEEC and STEC. A recent meta-analysis investigated the prevalence of STEC in 8053 isolates from calves in 19 countries included in 61 publications. The average prevalence of STEC isolated from healthy animals was 19.4% and from diseased animals was 18.2%. Moreover there was a significant decrease of STEC from pre-1990 to the present.[185] Similarly, in a study aimed at determining the clinical significance and prevalence of AEEC in Swiss cattle, fecal swabs of 93 cattle from two farms with calf diarrhea and of 54 cattle from two similar farms

without clinical problems were screened for AEEC by PCR and colony-blot hybridization. On average, 21% of all cows were positive for AEEC by PCR, with no differences between farms with and without diarrhea problems. By contrast, AEEC were detected by PCR in 60% of animals younger than 2 years from farms with diarrhea problems, whereas only 32% of comparable control animals from farms without clinical problems had AEEC.

The relevance of AEEC and STEC has increased in recent years due to the zoonotic potential of the organisms. Cattle are a major reservoir of STEC and enterohemorrhagic *E. coli* (EHEC), including *E. coli* 0157:H7, which is the EHEC serotype most often associated with hemorrhagic colitis and hemolytic uremic syndrome in humans.[196,200]

SALMONELLA. There are more than 2600 reported serotypes of *Salmonella*, yet fewer than 2% of these account for approximately 80% of the disease reported in livestock.[201] In cattle, more than 95% of salmonella associated with disease is in serogroups B, C, D, and E. *Salmonella* induces a wide spectrum of disease in cattle of all ages, ranging from inapparent subclinical infections to acute fulminant bacteremia, endotoxemia, and death. The variable manifestations of disease reflect the tissue trophisms of different *Salmonella* serotypes and the influence of challenge dose and host immunity. Common clinical signs associated with "salmonellosis" include fever, diarrhea, anorexia, depressed mentation, and dehydration. Many of the clinical signs are associated with endotoxemia. Systemic signs of endotoxemia include fever, tachypnea, tachycardia, scleral injection, leukopenia or leukocytosis, and weakness. Some serotypes, particularly *Salmonella typhimurium*, have a tendency to induce severe inflammation of the bowel mucosa, resulting in dysentery and passage of fibrin and mucosal casts. Fluid, electrolyte, and protein loss may progress rapidly and become life threatening if not corrected. With severe disease, animals rapidly become emaciated due to the catabolic state induced by release of tumor necrosis factor (TNF)–α. Sequelae occasionally observed following invasive *Salmonella* infections in neonates include septic osteoarthritis and meningitis.

Immunity to *Salmonella* changes rapidly during the first 3 months of life. At 2 weeks of age the LD_{50} for some virulent strains is 10^5,[202] at 6 to 7 weeks is 10^7, and at 12 to 14 weeks is 10^{10}.[203] In contrast, administration of 10^{10} *Salmonella* to 24- to 28-week-old calves failed to induce clinical signs of disease.[203] The numbers cited reflect the influence of age on immunity but should not be interpreted as absolute. Different age predilections, manifestations of disease, and virulence are observed between *Salmonella* serotypes and between different strains of the same serotype.[204,205] Although adults may serve as carriers and a source of infection of *S. dublin* infection for neonates, disease in adults is less common in mature cattle compared to calves. In contrast, *S. typhimurium* tends to manifest disease in an epidemic manner, causing illness in all age-groups. Environmental stressors such as heat, cold, and inadequate nutrition often play a role in herd disease outbreaks via compromising host immunity. Environmental conditions also influence the dynamics of *Salmonella* in the environment and subsequently the challenge dose encountered. *Salmonella* may proliferate in manure packs when they become wet; warmth promotes this process.

Calves on endemically infected farms may be infected in utero.[206] *Salmonella* challenge frequently occurs during the first 24 hours of life.[207] Exposure may occur via contaminated colostrum or milk, surface contamination of teats and udder, personnel, equipment, or the environment. Chronically infected carriers may shed 2.5×10^8 *Salmonella* in milk per day (25 kg of milk containing 10^5 *Salmonella*/mL).[208] Feeding utensils and personnel often play a significant role in transmitting *Salmonella* between calves.[209] *Salmonella* infects the salivary glands and is shed in saliva and nasal secretions.[210,211] Adequate cleaning and disinfection of feeding and medicating utensils is necessary to remove *Salmonella* contamination. *Salmonella* is sensitive to most disinfectants, but removal of contaminating organic debris is imperative, as the activity of disinfectants is reduced by the presence of organic matter.[212]

Flys, birds, and rodents may also play a role in disseminating *Salmonella* in feed, the environment, and between calves.[213,214]

CLOSTRIDIA. Although Clostridia are not commonly considered a major pathogen causing NCD, they are recognized as a cause of enteritis and abomasitis. In contrast to the other enteric pathogens, the disease tends to be more sporadic. Prerequisites for disease include the presence of the organism in the GI tract, sufficient carbohydrate or protein nutrients to support bacterial growth, and reduced GI motility that allows segmental overgrowth of bacteria within the GI tract.[215]

Clinical disease is associated with rapid bacterial overgrowth within the GI tract and subsequent exotoxin release. Passage of soluble carbohydrates or protein into the small intestine may induce rapid replication of Clostridia and elaboration of toxins from the vegetative state. Neonates are more susceptible due to the presence of trypsin inhibitors, which attenuate the digestion of clostridial exotoxins, in colostrum and milk for up to the first 10 to 21 days after parturition. Disease can occur in older ruminants if bacterial or plant-derived trypsin inhibitors are present in the feed.[215]

Management practices that increase the risk of clostridial-associated enteritis and abomasitis in beef calves include calf separation or environmental conditions that delay or interrupt normal nursing patterns.[215] Poor milk hygiene, intermittent feeding of large volumes of milk, and milk replacers with higher carbohydrate or protein concentrations contribute to increased risk in dairy calves. Variables associated with delayed abomasal emptying include feeding large volumes in single feedings, feeding with an esophageal tube, high caloric content, and high osmolality milk.[123,215]

C. perfringens (see also Chapter 32) is the most important cause of clostridial enteric disease in calves. Although limited tissue invasion by *C. perfringens* does occur, most local and systemic lesions result from the effects of potent exotoxins. Some types of *C. perfringens* (mainly type A) are consistently recovered from the intestinal tracts of animals and from the environment, whereas others (types B, C, D, and E) are less common in the intestinal tracts of animals and can occasionally be found in the environment in areas where disease produced by these organisms is enzootic.[216] All five genotypes produce alpha toxin; type B also produces beta and epsilon toxin, type C produces beta toxin, type D produces epsilon toxin, and type E produces iota toxin. Multiplex PCR is used to identify *C. perfringens* genotypes from anaerobic culture of samples.

C. perfringens type A has been associated with acute hemorrhagic abomasitis in neonatal calves. Clinical signs include acute abdominal distention, colic, depression, and sudden death. Onset of clinical signs is rapid; affected animals become anorexic, depressed, or restless. Signs of abdominal discomfort are observed in approximately half of the cases and include treading on the spot and kicking at the abdomen. On physical examination, splashing and metallic sounds are heard on succussion of the distended abdomen; passage of a stomach tube fails to relieve the distention. Fecal output is reduced, and melena may be observed. Gross pathology may include abomasal ulcers, abomasitis, and abomasal tympany.[112,118] Trace mineral deficiencies of copper and/or selenium may also be involved in the pathogenesis of the condition.[217] A decreased prevalence of abomasal tympany and ulceration was reported in neonatal calves from herds having a history of these problems following implementation of a *C. perfringens* vaccination program.[217,218] Enterotoxemia caused by *C. perfringens* type A has been described in 2- to 4-month-old calves, with the condition

observed more often in beef than dairy calves.[219] The disease is characterized by a high case fatality rate, sudden deaths, lesions of necrotic and hemorrhagic enteritis of the small intestine, and, most often, an absence of other clinical signs.[220]

C. perfringens type B is not commonly associated with neonatal diarrhea in calves. *C. perfringens* type C infections are most frequently observed in neonates younger than 10 days of age, reflecting the trypsin inhibitors attenuating the digestion of beta toxin.[215,221] Vigorous, healthy calves develop hemorrhagic, necrotic enteritis and enterotoxemia, often accompanied by evidence of abdominal pain and neurologic signs that may include frenzied bellowing, aimless running, tetany, and opisthotonus. Death may be peracute, occasionally without other clinical signs, but may also follow a clinical course of several days.

Clostridium difficile has recently emerged as a pathogen in both human and veterinary medicine. Toxins released cause epithelial cell death and activation of the enteric nervous system, resulting in a malabsorptive and secretory diarrhea.[222] The role of *C. difficile* as a primary pathogen has not been established, as it has been detected in both healthy and diarrheic calves[223] and experimental infection has not induced disease.[224]

CAMPYLOBACTER SPECIES. The clinical significance of *Campylobacter* spp. in calf scours is inconclusive. *Campylobacter* spp. are part of the normal intestinal flora. Experimental challenge studies have demonstrated the capacity of *Campylobacter jejuni* to cause enteritis in calves.[176,225-227] However, there is a paucity of convincing reports that demonstrate a causal association in naturally occurring cases.[228]

Viruses

Intestinal viruses multiply within enterocytes. As the epithelial cells are destroyed, villous atrophy develops. The various agents cannot be readily separated on clinical grounds. Diarrhea can vary in severity from soft to watery feces.

ROTAVIRUS. Rotaviruses are the most common cause of neonatal diarrhea in calves.[229,230] Affected calves are generally 5 days to 2 weeks of age, although disease can occur at 24 hours, particularly in colostrum-deprived calves (see Fig. 20.4).[231,232] This age predilection is thought to exist because many cows secrete antirotavirus antibody in their colostrum, which confers local protection against rotavirus attack until antibody levels in milk decline 48 to 72 hours postpartum.[233,234] Resistance to infection is not age dependent, but age-dependent resistance to clinical disease has been demonstrated.[235] Age restriction may be related to acquired immunity, as neutralizing antibodies increase with age and virus exposure. In addition, the expression of intestinal mucins and the rate of epithelial cell replacement and fluid absorption are also age dependent and have been shown to affect rotavirus infection and disease expression.[236]

Mature villous enterocytes of the small intestine are the main target for rotavirus.[159] Infected enterocytes are rapidly shed and replaced with immature squamous and cuboidal cells from the crypts, resulting in villous blunting.[159,237] Intestinal secretions are increased due to the compensatory hyperplasia of crypt cells and enterotoxigenic activity of the viral nonstructural protein NSP4.[162,163] Both increased secretory load and impaired absorption due to villus hypoplasia contribute to the diarrhea. It is thought that virulent strains replicate more quickly and infect a larger area of epithelium. Difference in rotavirus replication rates in the gut and age-dependent differences in the rate of enterocyte loss and natural replacement rate may explain the differences in clinical outcome. Concurrent infection with ETEC has also been shown to cause clinical signs at a later age than a single infection of either agent alone.[238]

Rotavirus of calves, lambs, kids, pigs, foals, mice, and children are morphologically identical. They are classified by the antigenic properties and/or sequence of the genes encoding the viral capsid proteins. Viral protein (VP) 6 is used to separate them into nine antigenically distinct serogroups, A to FI. Rotaviruses from serogroups A, B, and C have been isolated from cattle, and serogroup A is the most common cause of diarrhea in calves. Group B rotaviruses have been isolated from calves and adult cattle, but there is less information regarding their significance and prevalence in cattle.[239-243] Group B rotaviruses are more common in lambs than calves.[244] Group C rotaviruses have been isolated only from adult cattle.[242] Each serogroup may be classified further by G-types (glycoprotein) and P-types (protease-sensitive protein), which correlate to the serotype and/or genotype of capsid proteins VP7 and VP4, respectively.[245] A range of both serotypic and genotypic diversity and virulence has been reported within serogroup A.[235,246-248] Rotavirus is shed in the feces of infected animals, and transmission is primarily through the fecal-oral route. Clinical signs occur 1 to 3 days after infection and last for 5 to 9 days. Virus excretion commences with the onset of clinical signs and continues for 3 to 7 days.[235,249] Adult cows can be subclinically infected and intermittently shed the virus during pregnancy and especially at parturition.[250-252] It is likely that this is the most common source of infection, with carrier cows infecting their calves and then these calves infecting other calves.[253] Calves from carrier cows have a significantly higher risk of clinical disease, and the birth of calves from known carrier cows have been associated with the beginning of an outbreak. Recovered calves can become reinfected and shed virus.[254]

The environment may be an important source of infection. Rotaviruses can survive in fresh water for more than 2 weeks at 23° C and for months in water or soil at less than 5° C.[255] They are also stable in feces and effluent for up to 9 months and therefore are likely to remain in calving areas from year to year.[256]

CORONAVIRUS. BCV commonly causes diarrhea in calves 5 days to 1 month of age.[138,143,257,258] Disease can occur within 24 hours in colostrum-deprived calves and has also been recorded in calves up to 5 months of age.[259] Respiratory infections are common in older calves and may be important in the epizootiology of enteritis.[259]

Calves may be infected with coronavirus by the oral or respiratory route.[249] Fecal shedding commences 3 days after infection and persists for up to a week; nasal shedding can be detected 2 days after infection and persists for 2 weeks. Once infected, calves initially excrete high levels of virus and are potent sources of contamination. Infection persists for weeks in apparently recovered calves, and they excrete low levels of virus for weeks.[260] Subclinical infection is common. Disease is more common in the winter months, and coronavirus survives in the environment from year to year.

Calves may be infected by virus shed by persistently infected cows.[261] Coronavirus has been detected in the feces of more than 70% of clinically normal cows.[252] The rate of virus excretion increases at parturition and in the winter months.[250,262] Calves born to carrier animals are at a significantly increased risk of developing diarrhea.[250]

The pathology of coronavirus is often more severe than rotavirus, resulting in a mucohemorrhagic enterocolitis. The virus infects both the small and the large intestine. In the spiral colon there is widespread destruction of the cells of the colonic ridges.[156,158] Virus replication occurs in the surface epithelium, especially in the distal half of the villi, resulting in stunting and fusion of the villi. Immature cells replace epithelial cells, and in severe infection there can be areas of complete desquamation. Intestinal secretions continue, and absorption is impaired by reduced surface area. Undigested lactose accumulates in the intestinal lumen, often resulting in a secondary bacterial overgrowth, fermentation, lactate production, and an osmotic

VetBooks.ir

imbalance that draws fluid into the intestinal lumen. Most infections are self-limiting because the virus rarely attacks crypt epithelial cells.[261] In response to infection, the mitotic rate of crypt cells increases, producing immature cells that are more resistant to virus infection and that migrate up the villi to replace the damaged cells.

In experimental challenge studies, diarrhea develops 48 hours after infection. Calves are initially depressed and anorexic for the acute phase and may become dehydrated and pyrexic in a severe infection.[261] Severe infections can result in death due to dehydration, acidosis, shock, and cardiac failure. Respiratory signs are generally mild. Rhinitis, sneezing, and coughing may occur. Lesions may be found in the lungs but clinical signs of pneumonia are rare, except when secondary infection occurs.

BOVINE VIRAL DIARRHEA VIRUS. BVDV occasionally causes diarrhea and thrombocytopenia in young calves outside the confines of the persistently infected disease model.[145,146] Colostral antibodies generally protect young calves from BVDV infection, but disease may occur due to FPT or the introduction of novel BVDV strains with new cattle or viral mutation in persistently infected homegrown cattle. BVDV is also thought to exacerbate infections due to other pathogens.[263] It has also been implicated in necrotic enteritis, an acute enteritis of 7- to 12-week-old beef calves reported in the UK.[264] Affected calves usually show oral ulcerations, particularly on the hard and soft palate. The buccal papillae are often blunted, and the tips may be ulcerated.[265] Some variants of the virus produce intestinal bleeding, petechiation, ecchymosis, or prolonged bleeding from venipuncture sites secondary to thrombocytopenia.[145,266-268] Hematologic findings often include leucopenia and thrombocytopenia. The disease must be differentiated from other causes of enteritis that are complicated by bovine papular stomatitis infection. Bovine papular stomatitis (see Chapter 32) is common in neonatal calves. It produces oral lesions that are hyperemic and red, with a central white area of necrosis and often a raised rim of proliferating epithelial cells. These lesions often involve the mucosa around the molars. They are usually of little consequence and their importance lies in the fact that they may be confused with BVDV. One feature that helps identify BVDV ulcers is that they lack the zones of epithelial proliferation seen in bovine papular stomatitis.

BOVINE TOROVIRUS (BREDA VIRUS). Bovine torovirus has been detected worldwide[269-272] and has recently been implicated as an important cause of calf diarrhea.[141,142] Initially known as Breda virus, it is part of the *Coronaviridae* family. It has been relatively infrequently reported because it is difficult to recognize by electron microscopy (EM) and it cannot as yet be grown in cell culture, which has precluded the development of routine immunospecific diagnostic tests.[141] Laboratory studies using PCR have implicated it as the sole pathogen isolated in 25% to 30% of fecal samples from calves with diarrhea younger than 6 weeks of age.[141,142] It is also found in the feces and nasal secretions of asymptomatic animals,[141,143] implicating that the epizootiology is likely to be similar to that of rotavirus and coronavirus, with asymptomatic carriers acting as a reservoir of infection within a herd.[250] It is mainly a disease of calves younger than 3 weeks of age, with diarrhea commencing as early as 1 to 3 days after birth,[271,272] but clinical signs have been observed up to 10 months of age.[142,273] Clinically it produces mild to moderate diarrhea in calves under both experimental and field conditions.[272,274] The virus infects the distal half of the ileum, jejunum, and colon, resulting in necrosis of the crypts and villous enterocytes.[275,276] Clinical signs develop 24 to 72 hours after experimental infection.[272] It has also been isolated from the respiratory tract of cattle and associated with respiratory signs in calves at 1 month and 4 to 6 months of age.[277]

OTHER VIRUSES. Norovirus, nebovirus, torovirus, astrovirus, enterovirus, kobuvirus, adenovirus, parvovirus, and picobirnavirus have all been associated with neonatal calf diarrhea.[278-283] The pathogenicity and contribution of these viruses to field outbreaks is uncertain. In a larger case control study, nebovirus and norovirus were isolated in higher frequency from diarrheic calves, suggesting they may play a role in neonatal scours in the United States.[284] The lack of readily available diagnostic assays for detection of these viruses in veterinary diagnostic laboratories limits their routine detection. As with rotavirus and coronavirus, the different viruses have been isolated from both healthy and diseased calves. Some of the viruses such as norovirus and nebovirus do induce lesions in experimental infections of gnotobiotic calves. Others such as kobuvirus, astrovirus, enterovirus, and torovirus have not been demonstrated to or inconsistently induce pathology in gnotobiotic calves.[283]

Protozoa

CRYPTOSPORIDIUM. Four species of *Cryptosporidium* have been identified in cattle: *Cryptosporidium parvum*, *Cryptosporidium andersoni*, *Cryptosporidium bovis*, and *Cryptosporidium ryanae*.[285] Conventional understanding has been that *C. parvum* is mostly found in preweaned calves, and numerous studies have shown a significant correlation between its occurrence and diarrhea.[286-289] *C. andersoni* is seen in low prevalence in asymptomatic adult cattle, and the two other common species, *C. bovis* and *C. ryanae*, usually infect weaned calves and yearlings and are generally nonsymptomatic.[287,288,290]

However, similar to the situation in humans, it is becoming apparent that the distribution of *Cryptosporidium* spp. varies between geographic regions.[291] In China, where preweaned calves are mostly infected with nonpathogenic *Cryptosporidium* spp., *C. parvum* is starting to appear in dairy calves associated with concentrated animal feeding operations.[292] However, in Sweden, studies have shown *C. bovis* to be the dominant species in dairy calves, even in this age-group,[293,294] and in suckler beef herds all four species were detected in calves younger than 3 months of age.[295]

C. parvum was initially thought to be a single species that affected both humans and a broad range of animals. Later, it was recognized that two distinct genotypes were present: type 1, which was found in human sources; and type 2, which was considered to be zoonotic and could be isolated from bovines and other farm animals such as sheep and goats.[296,297] The most recent molecular work recognizes that *C. parvum* genotype 1 isolates are *Cryptosporidium hominis*, a human-specific pathogen that is responsible for the majority of cases of cryptosporidiosis in humans in the United States.[298] Calves generally become infected between 1 and 4 weeks of age and display clinical signs for 4 to 14 days. Animals of all ages can be infected, but diarrhea is mainly associated with calves before weaning.[299] Cryptosporidial infections are asymptomatic in cattle older than 4 months of age. *C. parvum* mainly infects the distal small intestine, but lesions are also found in the cecum and colon and occasionally the duodenum.[300] The parasite invades the superficial cells of the mucosa in the intestine but is surrounded by an invagination of the host cell membrane and remains extracytoplasmic. Parasitic invasion of the mucosa leads to epithelial destruction and mild to moderate villus atrophy, with microvillus shortening and destruction. This leads to impaired nutrient digestion and malabsorption diarrhea. Increased mucosal prostaglandin secretion promotes crypt secretion of chloride and bicarbonate and inhibits villus sodium chloride absorption.[301]

Affected calves often show no sign other than diarrhea but can show depression, dehydration, and anorexia.[302] Pyrexia and tenesmus have been noted.[303,304] Variable levels of morbidity have been reported, and mortality is generally low.[302,303,305] Other pathogens can be involved and are likely to contribute

VetBooks.ir

to the severity of the disease. Affected calves can take 4 to 6 weeks to recover. Cryptosporidiosis occurs less frequently in suckler calves at pasture, but when these calves are affected, outbreaks were reported to be more severe than those found in dairy calves, with mortality rates of up to 30%.[306] High mortality rates have been attributed to lack of herd immunity in seasonal calving herds where the transmission cycle is broken. Neutralizing antibodies in colostrum and milk reduce infectivity by immobilizing the parasite, blocking invasion, and inhibiting adhesion to host cells or direct cytotoxicity to *Cryptosporidium* sporozoites.[307] High mortality rates have also been associated with concurrent low levels of selenium, inadequate nutrition, presence of concurrent enteric infections, and specific management practices.[306]

Transmission is fecal-oral by ingestion of an encysted, sporulated oocyst. Transmission can be direct from host to host, by ingestion of contaminated food or water, and probably mechanically via flies.[308] A study of oocyst shedding in experimentally infected neonatal calves demonstrated a prepatent and a patent period ranging from 3 ± 6 and 4 ± 13 days, respectively.[286] The parasite is capable of autoinfection, sporulating within the intestine and immediately infecting adjacent cells, which can result in protracted clinical illness and relapses. The ability to autoinfect results in huge parasite burdens following very small infective doses. Calves 1 week to 4 months of age are most likely to be actively shedding significant numbers of oocysts, with peak shedding occurring between 1 and 3 weeks of age.[286,299,309,310] Infected calves can shed in excess of 10^6 oocysts/g of feces.[286,311] *C. parvum* oocysts have also been isolated from adult cows, with herd prevalence ranging from 7% to 100%.[299,312-314] Mean shedding intensity reported for adult cows has ranged from 3 to 900 oocysts/g of feces.[314-316] It is likely that carrier cows are a source of infection for young calves.

The most critical factor affecting environmental oocyst survival is the temperature. Drying of oocysts has been shown to dramatically reduce their viability and infectivity in mice.[317,318] Oocysts can enter watercourses and groundwater by direct contact with cows or from runoff of rain or irrigation water from pastures and manure storage areas.[306,319] *Cryptosporidium* oocysts have been shown to survive in water for at least 12 weeks at 4° C.[320] Oocysts are resistant to chlorination of water and most disinfectants.[306] They have also been shown to survive in silage.[321] Wildlife may be a significant reservoir for *C. parvum* and act as a method of amplification and infection in the environment.[312,322,323]

Cryptosporidium spp. cause diarrhea and sometimes death in 3- to 30-day-old lambs. Protracted infections and mortality are most common in lambs infected in the first few days of life, as age resistance is seen after about 3 weeks of age.[169,324-326] Cryptosporidiosis has also been described in goats, where it affected 5- to 20-day-old kids, signs lasted from 3 to 7 days, relapses were not uncommon, and there was a moderate mortality rate.[327]

People working with diarrheic neonates should be warned of the risk of zoonotic disease. An outbreak of cryptosporidiosis has been described in caregivers in a veterinary hospital treating diarrheic calves. Affected people suffered from watery diarrhea, cramping, flatulence, and headache.[328] One person became infected as a result of handling soiled clothing.

GIARDIA. *Giardia* is often found in diarrheic calves in association with other pathogens, but its relevance as a pathogen in its own right is unclear. Several authors have documented cases of diarrhea where *Giardia* infection has been implicated as the causative agent either by itself or in conjunction with *C. parvum* and *rotavirus*.[329-331] Affected calves are at least 2 weeks old, and often older than 1 month of age, with infection often becoming chronic and lasting for several months.[309,329,332-334] *Giardia* has a prepatent period of 7 to 8 days, and the delayed interval between birth and infection likely relates to high levels of colostral protection against *Giardia* but low protective levels in milk.[335] Many calves were shown to have a poor specific immune response to the infection, accounting for the chronicity of the infection.

The significance of *Giardia* as a primary pathogen has been questioned by the observation of similar or lower rates of infection in calves with diarrhea compared to asymptomatic calves.[309,336] Treatment of affected calves with fenbendazole reduces the duration but not the number of diarrhea episodes.[331]

COCCIDIOSIS. Thirteen species of *Eimeria* have been reported in cattle.[337] *Eimeria bovis* and *Eimeria zuernii* have historically been the most common pathogenic species, but there are increasing reports of *Eimeria alabamensis* causing disease.[338-340] Transmission is fecal-oral. Infected animals pass unsporulated oocysts in their feces that sporulate and become infective. The sporulated oocysts are protected from the environment by a double cyst wall.[341] Moist, temperate, cool conditions favor sporulation, and oocysts can survive for several years. Sporulated oocysts can resist freezing to –8° C for several months but are destroyed by high temperatures and dry conditions within a few weeks.[342] Under optimal conditions, sporulation can occur within a few days. The prepatent period of the two main pathogenic species is 15 to 20 days, and the patent period is around 11 days. *E. alabamensis* has a prepatent period of only 8 days and a patent period of 5 days.

Calves start shedding at about 1 month of age and shed for 3 to 4 months. *E. bovis* and *E. zuernii* schizonts first reproduce in the lower small intestine and then produce second-generation schizonts and gamonts in the cecum and colon, where they attack crypt cells.[337] These latter stages induce both local and more extensive lesions.

Outbreaks of disease in calves and lambs are often related to overcrowded and confined conditions. Up to 95% of infections are subclinical, causing decreased growth rates that are often unnoticed.[343] Clinical disease can be chronic or acute and is generally found in calves ages 3 weeks to 6 months, although animals of 2 years of age or older may be affected. In beef cattle the most common reports of clinical disease are associated with weaning stress.[344] Clinical signs may include diarrhea, ill thrift, increased susceptibility to pneumonia, tenesmus, increased mucus in feces, and hematochezia. Pyrexia, dehydration, and anemia may also be observed. The disease is usually self-limiting without reinfection. Chronic disease is often underdiagnosed.[343] Calves appear weak and listless with pasty feces, drooping eyes, and a staring coat. Fecal oocyst count is low or negligible. Disease results from continual reinfection due to a heavily contaminated environment.

Nutritional Diarrhea

Producers often express the opinion that scours is caused by calves consuming too much milk. However, there is no documented research in healthy calves to support this. Calves fed 16% to 20% of body weight per day or allowed ad libitum access to milk have not developed problems with diarrhea.[345,346] However, in studies where calves are also infected with enteric pathogens, the diarrhea and depression were exacerbated by feeding normal amounts of whole cows milk in the early stages. Villous atrophy as a result of attack by an enteropathogen reduces the ability of the calf to digest nutrients,[161,165] and this predisposes to GI overload with fermentation of milk in the large intestine. Deliberate underfeeding of healthy calves also predisposes to diarrhea.

Studies in Scotland have shown that poor clotting ability of milk is associated with diarrhea and abdominal distention in calves 1 to 3 weeks of age in beef suckler herds.[347-349] Milk should clot within 7 minutes when incubated with rennet; the

VetBooks.ir

milk from the affected cows took at least 1 hour to clot and in some cases took more than 24 hours. Diarrhea may be caused by the rapid passage of undigested milk through the bowel or be secondary to infection by enteric pathogens facilitated by the conditions created in the bowel. Milks with poor clotting ability were shown to have low ultrafilterable calcium levels and low total magnesium levels.[349] Calves responded to treatment with 30 mL of 1 molar solution of calcium chloride (CaCl) administered three times daily orally (PO) and relapsed when this treatment was stopped. The majority of the milk samples clotted when 100 µL of 1 mol/L CaCl solution was added prior to the addition of rennet. The exact cause of the impaired clotting ability was not determined. The diet of one group of affected cows was shown to be low in calcium.[347,348] After a mineral mixture containing additional calcium was added to the diet of these cows, the clotting time was reduced to less than 12 minutes, treatment of the calves was stopped, and there was no recurrence of clinical symptoms.[347]

Calves seem to experience more problems with diarrhea when fed certain milk replacers. One study showed that calves performed well on milk replacers containing soy protein when healthy, but that during an outbreak of salmonellosis there was better weight gain and less mortality in calves fed whole milk.[350]

Establishing an Etiologic Diagnosis

An etiologic diagnosis is useful in selecting specific diagnostic and preventative regimes for bacterial infections. Establishing an etiologic diagnosis for viral infections will allow establishment of specific control methods and development of an appropriate vaccination strategy. Diagnosis of salmonellosis, cryptosporidiosis, and giardiasis can have public health implications. Once an agent has been identified, one of the major problems is in interpreting whether or not that agent is responsible for diarrhea in the individual or herd, since most agents can also be found in a percentage of normal calves (see Table 20.6).

Sample Collection

Appropriate selection of diagnostic specimens is required to achieve a meaningful diagnosis. Best results are obtained when fresh samples and specimens are collected from calves early in the course of disease. To establish causality, a fresh necropsy is informative, as it provides an opportunity to relate the presence of pathogens to a disease process. The quality of the information gathered is to a large extent determined by the quality of the samples submitted to the diagnostic laboratory. Autolysis and bacterial invasion of gut mucosa begin within 5 minutes of death. Autolysis is a common cause of poor tissue sections for histopathology; this may reflect prolonged postmortem interval or poor tissue preparation, handling, or transport. To avoid autolysis, formalin needs to distribute into the lumen of intestinal sections, hence intestinal specimens should be no longer than an inch long and the tissue to formalin ratio should be no greater than 1 to 10.

Diagnostic Tests

Bacterial Pathogens

ESCHERICHIA COLI. *E. coli* is a normal inhabitant of the GI tract. Isolation of *E. coli* from fecal samples or gut contents is therefore of no significance unless the isolates are demonstrated to possess virulent attributes that are consistent with the clinical and or pathologic presentation. Virulence attributes include adhesins, enterotoxins, and cytotoxins. Enterotoxigenic *E. coli* adhere to enterocytes in the jejunum and ileum.[351] On gross pathology, enterotoxigenic *E. coli* is associated with fluid-distended loops of bowel without enteritis.[352] Calves infected with enterotoxigenic *E. coli* have a mild inflammatory reaction in the small intestinal wall and some villous atrophy. In fresh specimens, sheets of gram-negative bacilli can be seen adhering to the small intestinal wall.[351] Definitive diagnosis of enterotoxigenicity rests on demonstration of the ability of the *E. coli* to dilate intestinal loops.[353] Enterotoxigenic *E. coli* can also be identified by the presence of F5 (K99) using antigen-specific immunoassays, including latex agglutination,[354] ELISA,[355] fluorescent antibody,[356] slide agglutination,[356] multiplex PCR,[199] real-time PCR (RT-PCR),[357] and rapid dipstick tests. A potential limitation of immunoassays is the specificity of the antibodies used, as strains of enterotoxigenic *E. coli* using non-F5 fimbriae will not be detected by these tests.[187,358]

Attaching and effacing *E. coli* (AEEC) and Shiga toxin–producing *E. coli* (STEC) mediate disease by cytotoxic damage to the intestinal mucosa. The confirmatory diagnosis of AEEC is made by microscopic examination of the small intestine and colon. A distinct histologic appearance occurs at the attachment sites, where clusters of gram-negative rods attach and form a scalloped appearance to the epethelial cells.[193,359] Diagnosis of *E. coli* infection may be achieved using phenotypic differentiation of pathogenic strains from nonpathogenic normal flora *E. coli* via bioassays or immunoassays for toxins and fimbriae. Immunoassays have been developed to identify the presence of STx1 and STx2 in feces as a presumptive test for the detection of STEC in cattle feces.[360-362] An alternative approach to identifying and differentiating ETEC, AEEC, and STEC is to use PCR to identify virulence-associated genes commonly found in these *E. coli* strains (F5, F41, enterotoxin, intimin, STx1, and STx2).[199] The significance of STEC, EPEC, and AEEC in bovine enteritis is unknown due to a lack of appropriate assays for routine detection and because of the widespread presence of verotoxin producing *E. coli* strains in healthy cattle that complicate the interpretation of detecting fecal shedding in sick animals.[363-365] Demonstration of verotoxin in cultures from bovine enteritis is not sufficient to imply a causative association.

***CLOSTRIDIUM* SPECIES.** *Clostridium perfringens* has been associated with enterotoxemia and hemorrhagic abomasitis in calves.[216,220] *C. perfringens* are normal flora of the GI tract, hence isolation of *C. perfringens* from feces is not in itself diagnostic. Pathogenic strains of *C. perfringens* produce exotoxins, five of which (α, β, ε, ι, and enterotoxin) are involved in the pathogenesis of disease.[216] Production of specific toxins can only be demonstrated in a proportion of cases.[366] Isolation of toxin-positive *C. perfringens* from intestinal contents does not confirm a clinical diagnosis of bovine enterotoxemia, as almost as many *C. perfringens* isolates from normal calves produce toxin and toxin production cannot be demonstrated in as many as 40% of affected calves.[367]

A fresh necropsy is required to definitively diagnose clostridial enteritis. Observing many gram-positive bacilli in the mucosa associated with hemorrhagic enteritis is suggestive of clostridial enterotoxemia. Quantitative bacterial counts of intestinal contents at the site of the lesion have proven to be one of the most reliable methods for diagnosing enterotoxemia.[220] A *C. perfringens* count greater than 10^6/mL of intestinal contents is consistent with a diagnosis of enterotoxemia.[220] Demonstrating the presence of *C. perfringens* toxins or the capacity to produce toxins provides support for the diagnosis. Tests for detecting toxins or the bacteria's capacity to produce toxins include bioassays, immunoassays, western blot, and PCR.[368] The basis of the bioassay is to demonstrate protection of mice using antitoxin. *C. perfringens* enterotoxin is produced during sporulation. In vitro detection of enterotoxin production capacity by a *C. perfringens* isolate using western blot or immunoassays requires sporulation to occur. In vitro techniques to induce sporulation are not 100% efficient, so detection of enterotoxin using these methods are less sensitive than PCR is at detecting the genes required to produce enterotoxin.[369]

VetBooks.ir

***SALMONELLA* SPECIES.** Salmonellae are capable of causing disease in cattle of all ages. Neonatal infections are common. The classic pathologic lesion is fibrinous or fibrinonecrotic to ulcerative enteritis.[370] The severity of lesions is usually greatest in the distal small intestine and proximal large bowel. Hypertrophy of the mesenteric lymph nodes is a common finding.[371] Serosal hemorrhages may be observed in the small and large intestine. Septic infarcts in the kidneys and inflammation of the gallbladder are less common findings. Pneumonia is a common finding with *S. dublin* infections, and gangrenous necrosis of distal extremities may also be observed.[372] Bacteremia is a feature of neonatal salmonellosis and may manifest as osteomyelitis and/or meningitis.

Isolation of salmonella from feces of calves with diarrhea is consistent with a diagnosis of salmonellosis but in itself does not necessarily establish causality, as salmonella may be isolated from the feces of apparently healthy calves.[373] Isolation of salmonella from tissues at necropsy is indicative of invasive salmonellosis. A definitive diagnosis of salmonellosis is based on the clinical presentation, pathologic lesions, and isolation of salmonella from tissues at necropsy.

There are numerous methods for isolating and detecting the presence of salmonella. These include direct culture, enrichment cultures, PCR (both conventional and real-time), immunoseparation, and immunoassays.

The process of directly inoculating tissues or other samples onto selective plating media, except in the case of acute infections, is usually nonproductive. Typically, with subclinical infection the number of salmonellae shed in feces is low relative to the high number of other bacteria. Fecal samples should be inoculated into selective enrichment media for optimal recovery of *Salmonella*. Selective-enrichment broths are formulated to selectively inhibit other bacteria while allowing *Salmonella* to multiply to levels that may be detected after plating. Internal organs that are normally sterile do not need to be inoculated on selective media; rather, they should be inoculated onto nonselective (blood agar) or weakly selective (MacConkey agar) media.

A number of rapid detection methods have been developed to expedite the detection of salmonella. These methods include electrical conductance and impedance, immunologic techniques, nucleic acid–based assays, and PCR. These methods generally take 24 to 52 hours to screen for or detect and identify salmonella. The majority of these tests, particularly the enzyme-linked immunologic techniques, require 10^5 cells/mL for reliable results. Accordingly, all of these tests involve a pre-enrichment stage, and some also involve a selective enrichment culture.[374] When salmonella is causing disease, clinically affected calves may shed 10^9 salmonella/gram of feces.[375] Detection of salmonella in clinical samples when it is the inciting cause of the disease process is not normally difficult when multiple samples are collected from a representative sample of the affected population.

Viral Enteropathogens

Viruses are usually identified by direct examination of the feces, immunoassays, or fluorescent antibody examination of intestinal mucosa. Molecular techniques involving PCR and RT-PCR have been described for most pathogens but are not routinely available in all diagnostic laboratories. Electron microscopic examination of feces is not a sensitive means of detecting virus particles, but it has the advantage that many different types of viruses can be detected, including those such as parvovirus that are not recognized as common causes of diarrhea. The recent development of relatively inexpensive immunoassay diagnostic test kits makes these an attractive option; limited test-specific data regarding test sensitivity and specificity limit the application of some of these tests.

CORONAVIRUS. Coronavirus replication occurs in the epithelial cells of the distal half of the villi of the lower small intestine and colon. Infected cells die, slough, and are replaced by immature cells. In the small intestine these changes result in stunting and fusion of adjacent villi, and in the large intestine they lead to atrophy of the colonic ridges. On histopathology the tall columnar epithelial cells are replaced by cuboidal and squamous epithelial cells, and in severe infections there may be areas of complete desquamation.[376] Virus is shed in respiratory secretions and feces. There are several methods for detecting bovine coronavirus in feces. These include isolation of the virus in cell culture,[377] EM,[378] immunoelectron microscopy,[259] immunoassays[252,355,379-382] and molecular techniques including dot blot hybridization assays,[383] and conventional and real-time PCR.[384-387] Isolation of bovine coronavirus using cell culture techniques is not often performed in diagnostic laboratories, as the technique is difficult and requires viable virus (fresh samples or samples shipped on dry ice).[388] EM has been used as a standard diagnostic method for bovine coronavirus. Although the intact virion of bovine coronavirus is fairly characteristic in appearance, it is not uncommon for the identifying surface projections of the virus to be lost during sample preparation or storage, making it difficult to properly identify virus particles by EM.

Numerous ELISAs have been described for the detection of BCV antigen in feces. A number of companies have developed commercial kits using this technology. The use of monoclonal antibodies rather than polyclonal antibodies is reported to increase the sensitivity and specificity of bovine coronavirus ELISAs.[382] The limit of detection for ELISAs range from 10^4 to 10^5 virions/mL of feces.

A one-step RT-PCR assay, targeting a 730-bp fragment of the nucleocapsid gene of bovine coronavirus, and a nested PCR assay, targeting a 407-bp fragment of the nucleocapsid gene, have been developed to detect bovine coronavirus. Compared to an antigen capture ELISA, the limit of detection for the RT-PCR and nested PCR was 10^3 and 10 virions/mL, respectively, compared to 10^5 virions/mL for the ELISA.[389,390]

Two quantitative RT-PCR methods have been used for detection of coronavirus in feces: TaqMan and SYBR Green.[386,387] Detection levels achieved using the TaqMan assay for coronavirus have been in the order of 10^1 to 10^9 RNA copies and were shown to be 1 log more sensitive than gel-based RT-PCR. The SYBR Green chemistry assay had similar detection levels but was unable to differentiate between different coronaviruses like the TaqMan assay.

ROTAVIRUS. Bovine rotavirus infects enterocytes of the intestinal villus; infected cells are predominantly in the distal third to half of the villus. The age at time of infection influences the distribution of the virus in the GI tract and the number of virions shed in feces. In experimental challenge studies, infection of 1-day-old calves resulted in a uniform distribution of virus throughout the small intestine.[391] Challenge of 10-day-old calves led to a patchy distribution of the virus, with maximal viral load observed in the mid small intestine.[391] Villus stunting is more pronounced in young calves.

Methods for detection of rotavirus include cell culture, fluorescent antibody staining, EM, immunoelectron microscopy, immunoassays, electrophoretic procedures, and conventional and real-time PCR.[239-243,354,355,380,392-395] Bovine rotavirus is difficult to isolate in cell cultures because of the cytotoxic nature of feces and fecal filtrates and because the virus is inconsistent in production of cytopathic effects.[393] The fluorescent antibody technique is simple, rapid, and specific, but rotaviral antigen is usually difficult to detect within 24 to 72 hours after the onset of diarrhea because rotavirus-infected epithelial cells are rapidly shed from the tips of the villi.[396] Comparative studies evaluating methods of detecting rotavirus

VetBooks.ir

in feces give good agreement between antigen capture assays (ELISA, latex agglutination) and EM.[354,380,393,397] Direct immunoflorescence testing of fecal samples gives good agreement (90%) with electron microscopic examination for rotaviruses when samples are collected during the 24 hours following the onset of diarrhea[398] but poor agreement (33%) for field specimens submitted to a diagnostic laboratory.[393]

RT-PCR detection for rotavirus has been shown to be both highly sensitive and specific when the correct primers and probes are identified.[395] RT-PCR assays have the ability to increase the sensitivity of detection by up to 100-fold when compared to one-step RT-PCR.[399]

BOVINE VIRUS DIARRHEA. Bovine viral diarrhea virus rarely causes diarrhea in neonatal calves.[146] Sporadic disease may be observed in persistently infected calves. Pathologic lesions include ulceration of the oral cavity, particularly on the hard and soft palate, and blunting of the buccal papillae.[265] Erosions may be observed in the esophagus, and necrosis of Peyer's patches may be observed in the ileum. Thrombocytopenia has been observed with BVD type II infections. Outbreaks of neonatal disease have been observed with this strain. Petechial and ecchymotic hemorrhages are a feature of this condition.[145,267,268] Hematologic findings often include leucopenia and thrombocytopenia.

Several options are available for the detection of BVD, including virus isolation,[400,401] RT-PCR,[402] immunohistochemistry,[403] and antigen capture ELISA.[404] Immunohistochemistry and antigen capture ELISA are used in most commercial laboratories (see Chapter 32 for more on this). Maternal antibodies reduce the sensitivity of the ELISA in young calves.[402]

BOVINE TOROVIRUS (BREDA VIRUS). Bovine torovirus produces cytolytic infections of villi and crypt enterocytes in the small and large intestine.[405] Bovine torovirus does not grow in tissue culture, cell culture, or embryonated eggs.[406] Therefore the large-scale preparation of reference antisera and antigens for the development of diagnostic tests has been precluded. Torovirus is capable of causing diarrhea in cattle, with disease observed most frequently in calves younger than 3 weeks of age.[143,272,274,276,407,408] Like other enteric viruses, bovine torovirus has been detected in feces of normal calves; therefore detection of the virus in feces from diarrheic cattle cannot be interpreted as causal. The lack of diagnostic reagents has limited the study of bovine torovius, leaving questions about its epidemiology and relative importance in calf diarrhea.[142] Diagnostic methods that have been used to detect bovine torovirus include EM, immunofluorescence, antigen capture ELISA, and RT-PCR[142,272]

Protozoa

***EIMERIA* SPECIES.** *Eimeria* spp. are host specific. *E. bovis* affects primarily the mucosa of the cecum and the proximal part of the large intestine, whereas *E. zuernii* affects the mucosa of the cecum as well as the entire large intestine, including sometimes the rectum.[409] The clinical signs of bovine coccidiosis are associated with the final stages of the eimerian life cycle and commence shortly prior to oocyst shedding. Gross lesions in the cecum and large intestine range from semiliquid contents with little or no blood and few areas of epithelial sloughing to extensive hemorrhage and large areas of epithelial sloughing and necrosis of the mucosa.[409] The serosal surface is often reddened opposite the affected mucosal area and the submucosa and external muscular layers thickened by edema.

Oocysts usually can be recovered 2 to 4 days after the onset of diarrhea.[410] Oocysts can be identified microscopically either by direct smear or preferably following flotation or centrifugation methods. The sensitivity of coproscopical methods is reduced in diarrheic feces due to dilution[411] and particularly in severe *E. bovis* or *E. zuernii* infections when large amounts of blood, tissue, or mucus are shed. Oocysts become trapped within tissue and fibrin and are thus obscured in conventional coproscopy.[411,412] Oocyst counts of 5000 per gram of feces or greater are considered significant in cattle.[341] Identification of oocysts in feces is not diagnostic for clinical coccidiosis, as the parasite is frequently detected in small numbers in the feces of healthy cattle.[413] When investigating scour problems, multiple samples should be collected for oocyst counts to provide an indication as to the level of infection within the group. The potential for discord between clinical signs and fecal shedding limits the diagnostic utility of a single sample from an individual animal.

GIARDIA. *Giardia* infection is not associated with changes in intestinal villus height or crypt depth. However, transmission EM has been used to demonstrate a reduction in microvillus surface area.[414] Diagnostic methods for detection of *Giardia* include direct microscopy, immunomagnetic separation, fluorescent antibody staining,[330,415] ELISA,[416] and PCR.[417,418] When using direct microscopy, fecal samples should be examined within 24 hours of collection. Trophozoites and cysts are concentrated via density gradient centrifugation or filtration.[309,419,420]

CRYPTOSPORIDIA. Cattle are commonly infected with four *Cryptosporidium* spp.: *C. parvum*, *C. bovis*, *C. ryanae*, and *C. andersoni*. *C. parvum* is of most concern due to the potential of some subtypes to infect humans.[291] No matter which PCR tool is used in genotyping or subtyping *Cryptosporidium*, all broadly specific tools have the problem of detecting only the dominant genotype in the specimen because of the inherent nature of exponential amplification by PCR, and consequently mixed infections are difficult to detect.[291] *Cryptosporidium* infections are mainly concentrated in the distal small intestine, but lesions may also be found in the cecum and colon, and occasionally in the duodenum.[421] The pathologic findings associated with *Cryptosporidium* are a mild to moderate villous atrophy, villous fusion, and changes in the surface epithelium with infiltration of mononuclear cells and neutrophils in the lamina propria.[421]

Calves infected with *C. parvum* usually develop diarrhea in 72 to 96 hours; diarrhea is observed for 4 to 23 days,[422] during which time oocysts are excreted in feces. *C. parvum* and *C. andersoni* have morphologically distinct oocysts and differ genetically.[423] *C. bovis* and *C. ryanae*, which are morphologically identical to *C. parvum*, are mainly responsible for diarrhea in weaned calves,[289,424-426] but they have also been found in all age-groups of cattle.[295,427] Oocysts are stable in feces for many days at room temperature.[428] Laboratory methods for the diagnosis of cryptosporidial infections include microscopic examination of fecal smears or fecal preparations, immunoassays, and PCR. Cryptosporidia oocysts are small (4 to 6 μm in diameter) and easily missed on a fecal smear. Because fecal smears do not concentrate the oocysts, this technique is less sensitive than fecal flotation. Concentration of the protozoa is achieved by salt[429] or sugar flotation. Special stains may be used to facilitate detection of cryptosporidia during microscopic examination. Differential staining techniques are useful to distinguish cryptosporidium oocysts from other fecal components (especially some yeasts) of similar size and shape.[430-433]

A number of immunoassays have been developed for the detection of cryptosporidia. The detection threshold of the different methods have been reported to be 3×10^5 oocysts/g for a monoclonal antibody–based antigen capture ELISA, compared with 1×10^6 oocysts/g detected by examination of acid-fast stained fecal smears and 1×10^3 oocysts/g detected by indirect immunofluorescence.[434] The detection threshold may be further enhanced by using a combination of immunomagnetic separation coupled with immunofluorescent microscopy. With this combination it is possible to detect as

VetBooks.ir

few as 10 oocysts/g.[435] A number of dipstick immunoassays have also been developed. The detection threshold for this technology is reported to be 1×10^3 oocysts/g.[436] This technology offers the potential for rapid, cost-effective detection of cryptosporidia in fecal specimens.

Molecular techniques have been described for detection and typing of cryptosporidia.[296,425] The capacity to differentiate the different genotypes makes this approach useful for epidemiologic studies of cryptosporidia.[425]

Multiplex RT-PCR

Several multiplex RT-PCR assays have been developed for the simultaneous detection of the major enteric pathogens.[437] The multiplex quantitative RT-PCR offers significant advantages over individual pathogen testing in that 96 fecal samples can be tested at the same time within 4 hours. This offers increased efficiency through decreased cost, labour, and turnaround time. Another major advantage of RT-PCR is the ability to detect and measure the accumulation of amplicon during the reaction, thus allowing precise quantification, which can be important in determining causation.

Risk Factors for Neonatal Calf Diarrhea

It is important to identify risk factors, both to set up effective preventive programs and to initiate control in the face of a disease outbreak. The etiology of calf diarrhea is multifactorial, so it is common for several factors to contribute to the outbreak and perpetuation of disease in a herd.

Dystocia

Dystocia is associated with neonatal calf diarrhea in more intensive beef and dairy systems[137,438] and is a risk for preweaning mortality, with more than 40% of preweaning deaths occurring in calves born to cows suffering dystocia.[439-441] Dystocia affects the ability of the calf to suckle colostrum, resulting in decreased serum IgG levels; consequently calves that survive dystocia are two to four times more likely to become sick in the first 45 days of life.[442-444] Calves that experience dystocia are likely to have edema of the head and tongue, making suckling difficult. They are weak, exhausted, and likely to be recumbent for longer, increasing exposure to fecal pathogens.[257]

Stocking density and cow grouping of preparturient cows, timing of calving, breed, cow pelvic area, multiple calvings, calf sex, gestation length, and dam nutrition all influence the risk of dystocia.[445,446] Low- and high-birth-weight calves are at greater risk of mortality.[440] Small calves experience greatest mortality at parities greater than one, and large calves experience greatest mortality at first parity.[447] Increased feed intake before calving will increase calf birth weight but does not increase the risk of dystocia unless cattle become obese.[448-450] Weight loss is associated with prolonged labor, increased dystocia, and increased perinatal mortality.[450,451]

Dam Parity

Calves born to first- and second-parity cows have an increased mortality compared with those born to older cows, and the risk of diarrhea in calves born to heifers is 3.9 times greater than those born to cows.[440,452,453] Heifers have an increased risk of dystocia, lower colostrum quality, and inferior mothering ability.[442,443,453-455] The difference in the rate of dystocia between the first and second parity is usually much greater than between the second and subsequent parities.[456] The stocking density of heifers is often increased prior to calving to facilitate observation, with the consequence of exposing their calves to a greater environmental pathogen load. These factors are all likely to contribute to increased morbidity, and consequently the percentage of heifers in the herd will affect the risk of diarrhea. Calves from carrier heifers shedding rotavirus and bovine coronavirus are more likely to develop clinical disease than calves born to carrier cows.[250] Studies in dairy herds have shown that there is a positive correlation between the number of young stock in the herd, the overall herd size, and herd production with the risk of neonatal calf diarrhea.[457-459]

Colostrum Management

Many studies have shown that FPT results in increased risk of neonatal calf diarrhea in beef and dairy herds.[460-467] Calves are able to absorb immunoglobulins only for a limited time after birth, and the subsequent serum Ig concentration is determined by the perinatal state of the calf, the timing of colostrum ingestion, and the mass of Ig consumed.[468] Colostrum also provides local (enteric) immunity, with the major benefits lasting for about 3 to 4 days after birth.[469-471] After this period, milk contains little Ig, and most colostral antibody has been cleared from the intestine. Colostral antibodies protect against rotaviral infections in the first 4 days of life[233,234]; in contrast, anti-F5 (K99) *E. coli* antibody is present in low amounts in unvaccinated cows,[472] and enteric *E. coli* infections are usually seen in very young calves. After 4 days the protective effects of colostrum are primarily due to systemic antibodies, and there is evidence that these can leak back into the gut and probably give limited long-term protection against diarrhea.[473] Colostral quality is affected by colostral volume, genetics, nutrition, parity, timing of collection, climate, and periparturient vaccination.

Beef Cow Herd Management

In beef herds, high stocking rates in the calving area and the use of one calving area are major risks for neonatal calf diarrhea.[474,475] The practice of leaving nursing dams and calves with calving cows further increases stocking rates and promotes disease transmission.[462] The weather at calving affects both pathogen survival and calf comfort, and shelter in the nursing area is associated with decreased mortality due to neonatal calf diarrhea.[452] Major calf scour pathogens can survive in the environment for months or years in cool, wet conditions, and consequently both the incidence and mortality from diarrhea increase with prolonged use of the same paddock or a longer calving season, and the incidence of diarrhea increases as the calving season progresses.[441,452,453] Adverse weather conditions cause cows to move to shelter and shade, concentrating cows and calves in small contaminated areas. Calves born into a contaminated environment potentially become infected during or shortly after birth and shed enteropathogens even when they remain clinically normal. This further increases the environmental load of infectious agents, infecting adult cattle as well as calves. The outcome of host-pathogen interactions is largely influenced by the pathogen challenge dose and the age of the animal, with clinical disease becoming more frequent both in younger animals and as pathogen exposure increases (Fig. 20.5).

Farms that purchase replacement calves younger than 4 weeks old have an increased mortality due to neonatal calf diarrhea.[452] Purchased calves may introduce new pathogens that challenge a susceptible population. Stress from transport and arrival at a new location may increase shedding and predispose to clinical disease, increasing the environmental pathogen load. The risk of pathogen introduction increases when introduced calves are commingled from multiple properties prior to introduction.

Intensive Calf-Rearing Systems

Intensively reared calves have an increased risk of diarrhea associated with housing, nutrition, and weaning. Variables that have been observed to increase the risk of scours include feeding milk once versus twice a day within 14 days of birth,[476] placing preweaned heifers in groups of seven or more, damp versus

VetBooks.ir

FIG. 20.5 Areas where cows and calves camp can act as a significant reservoir of calf diarrhea pathogens in a pasture-based suckler beef system.

dry bedding,[476] a male having primary responsibility for the care and feeding of preweaned heifers, calves not receiving hay or other roughages until more than 20 days old, and feeding mastitic or antibiotic milk versus whole milk.[477] Use of individual calf hutches has been reported to increase the risk of scours but also to reduce mortality.[476]

Factors associated with a decreased risk of cryptosporidia infection include ventilation in calf-rearing areas, daily addition of bedding, daily disposal and cleaning of bedding, and use of antibiotics.[478] The effect of feeding milk replacer versus whole milk on shedding of *Cryptosporidium* has varied between studies.[478-480] Postweaning practices that reduce risk of infection include moving animals after weaning, cleaning soiled bedding, and use of antibiotics and ionophores as preventive measures.[478] Maternity management factors that reduce risk of infection include vaccination of the dam against *E. coli*, rotavirus, and coronavirus; removal of the calf from the dam within 1 hour of birth; use of fresh colostrum to feed calves; and having a concrete floor in the calving area.[478-480] The reduced *Cryptosporidium* shedding in calves from vaccinated cows is unlikely to be a direct effect but more likely reflects a better standard of management. General management factors that influence risk include the total number of dairy cattle, the total number of other species of livestock on the farm, and the distance of the barn water source from the septic system.[478]

Herd Strategies to Prevent Neonatal Diarrhea

Management practices that reduce the risk of calf scours also promote good health, improve growth rates, and reduce the risk of transmitting other enteric pathogens such as *Mycobacterium paratuberculosis*.

The principles of prevention are to:

1. Minimize pathogen exposure
2. Ensure adequate colostral intake
3. Boost specific and nonspecific immunity
4. Promote farm biosecurity

It is good practice to conduct a risk assessment for calf scours as part of any herd health program in beef or dairy cattle, as well as when investigating an outbreak. The risk assessment should (1) thoroughly evaluate all potential risks that may affect the four principles above, (2) determine what actions are needed and at what relative cost to mitigate those hazards, (3) share the action plan with all members of the team, as well as keep records to show what was done and whether the actions were successful.[481]

Minimizing Pathogen Exposure

Enteric pathogens may be shed in large numbers by calving cows, scouring calves, and asymptomatic cohorts, especially those up to 4 months of age. All enteric pathogens can survive in the environment for months or years in moist, damp conditions. Other sources of infection include people that have treated or handled infected calves, contaminated water, contaminated colostrum, milk, or solid feed and equipment that has been used to feed or medicate infected calves.[210,250,252,306,315,482-484]

MINIMIZING PATHOGEN EXPOSURE IN DAIRY HERDS. Strategies to prevent disease in dairy calves focus on calving cows in a clean environment; removing calves from cows at birth; feeding adequate good-quality colostrum; placing calves in a clean, dry environment separate from other stock; feeding good-quality milk or milk replacer; providing adequate shelter; and providing access to water and high-quality calf pellets. Microbial contamination is an important determinant in the quality of colostrum and milk. Good sanitary practices are required for the harvest, storage, and feeding of both products. Microbial contamination of colostrum compromises passive transfer and in the case of pathogens like salmonella may lead to a direct pathogen challenge. Similarly, feeding milk with a high bacteria count increases the risk of diarrhea. On-farm heat treatment of colostrum (60° C for 1 hour) significantly decreases bacterial numbers without affecting IgG levels.[485] Calves that are fed heat-treated colostrum have significantly higher IgG levels and lower incidence of neonatal calf diarrhea when compared to calves fed untreated colostrum.[486]

In dairy systems, where calves are reared by hand, the number of young stock on the farm and the incidence of respiratory disease are positive predictors for calf diarrhea.[457] Cleanliness of the calving area is important; bedding should be changed between each calving, and large numbers of cows should not be cycled through a few stalls.[457] Prior to calving the udder and the perineum of the cow should be cleaned. The calf should receive adequate colostrum.[475] In recent years the use of calf hutches has gained widespread acceptance for managing calves after they have been separated from their dam. This system provides individual isolated housing for each calf. Cleaning is facilitated because the hutches can be moved to new sites between calves. Keeping preweaned calves in groups larger than six puts them at increased risk of diarrhea.[459]

Cleaning and disinfection after each calf batch plays an important role in reducing contamination in housed calves. The key to decontamination is the physical cleaning. Physical removal of organic contamination through scrubbing is preferred to application of high-pressure sprays, which can aerosolize organisms and allow dissemination. On smooth, ideal surfaces, physical removal of visible contamination by thorough washing with soap and water removes 99% of the microbial load (2 logs). However, on typical housing surfaces, washing removes only 90% (1 log). Application of disinfectant after washing is important to eliminate remaining pathogens and to prevent bacterial pathogens from proliferating. Physical cleaning cannot be replaced by applying disinfectants in larger quantities, as organic material neutralizes most disinfectants. In regard to disinfectants, pathogen elimination is time dependent.[487] Other important variables that influence the effectiveness of disinfectants and rate of pathogen reduction include concentration, temperature, pH, and water hardness.

In addition to cleaning between batches, it is important to clean nipple buckets and other feeding utensils between each feed. Separate equipment should be used to administer oral electrolytes and colostrum. *Salmonella* and coronavirus are shed in saliva and can contaminate equipment used for oral

VetBooks.ir

medication. Washing with warm, soapy water is required to remove the fat residue left by milk- and colostrum-handling equipment

Several microbial characteristics should be considered when disinfecting equipment that contacts calves. Rotavirus is susceptible to sodium hypochlorite but is relatively resistant to many common disinfectants, such as chlorhexidine. As a nonenveloped virus, rotavirus is not affected by soaps; washing with soap alone actually may spread the virus around on the washed surface.[488] Coronavirus is an enveloped single-stranded RNA virus and is not as stable in the environment as rotavirus. Because of their envelope, these viruses retain infectiousness better at lower rather than higher relative humidity[489] and are considerably more sensitive to soaps and common disinfectants than are nonenveloped viruses. Because *Cryptosporidium* can autoinfect the original host, the infectious dose can be small. In the environment, cryptosporidia are extremely resistant to most veterinary disinfectants except 5% ammonia, 6% hydrogen peroxide, 10% formalin, or 2% cresolic disinfectants.[317,490-492] They survive very well in water, requiring 4 to 11 weeks to decline by one log.[493] On the other hand, cryptosporidia are susceptible to drying, with oocyst infectivity declining in 1 to 4 days.[318]

The most readily cleaned surfaces are made of smooth, impervious materials such as plastic and varnished wood (Table 20.8). Usually buildings are cleaned and then either disinfected or fumigated.[494] Many disinfectants are inactivated by organic matter; viruses, coccidia, and particularly cryptosporidia may be resistant to their action (Table 20.9). Disinfectants may also be toxic and are best applied by personnel wearing rubber gloves and respirators (if indoors). In general, potent phenolics such as cresol (cresylic acid) are very useful for disinfecting dirty surfaces because they are not inactivated by organic matter and are effective against gram-negative bacteria and viruses. The phenolics are highly toxic and leave lingering odors. Hypochlorite solutions (5 g available chlorine/L) have a broad spectrum of action but are rapidly inactivated by organic matter. They would be useful as a final disinfectant on previously cleaned surfaces. Because hypochlorite is unstable, it is unlikely to leave toxic residues. Iodophors are not very effective against rotavirus, particularly if organic matter is present. Virkon S™, a disinfectant/cleaner containing potassium monopersulfate as the active ingredient, is effective for all pathogens except cryptosporidia. Normally a 1% solution is used and is prepared by mixing 10 g of powder in 1 L of water. Contact time should be a minimum of 10 minutes. Virkon S™ has the advantage of having a detergent action that facilitates cleaning.

Formaldehyde is one of the few agents that is effective against cryptosporidia. It requires a long contact time and is highly toxic. It is usually used for terminal fumigation in buildings that can be tightly sealed. Formaldehyde gas is best generated by heating paraformaldehyde (5 g/m^3 of building) in an electrically heated pan at 204° C. Some manufacturers of paraformaldehyde provide pans specially designed for this purpose. The pans should be placed no more than 30 m apart and arranged so that electricity to the pan can be controlled from outside the building. There must be a safety mechanism to ensure that the pan does not overheat and cause a fire. The building must be sealed for at least 24 hours and cannot be entered until it has been thoroughly ventilated. Formaldehyde gas can also be generated by boiling formalin or by adding potassium permanganate to formalin. The latter method generates a violent chemical reaction and carries risks of explosion. Formalin aerosol generators are ineffective.[495] After cleaning and disinfection one should allow a rest period for

the building to ventilate before reintroducing calves. It is very important that cleaning and disinfection be thorough. Attention should also be given to rodent control, since rodents can be a reservoir for *Salmonella*.[496]

MINIMIZING PATHOGEN EXPOSURE IN BEEF HERDS. In beef herds, calving areas should be located to take advantage of natural shelter and drainage and rotated from year to year to avoid pathogen buildup.[455,474,497,498] Pregnant cattle are moved into a clean paddock no more than 2 weeks prior to the start of calving. It is best that cows and heifers are managed separately until after calving. This gives the opportunity to provide better feed to the heifers and to minimize infection between the groups. Confined, wet, or muddy areas should be avoided for calving cows, and where they need to be used, the stocking rate should be decreased. Feed-out areas should be rotated to encourage cow disposal and separated from watering points. When pasture for calved cows is limited, supplementary feed should be fed to dry cows to ensure enough fresh pasture for calving and nursing cows. Clean water should be available in a trough that is accessible to cows and calves. Chronically sick animals, weak calves, and cows with no milk should be removed from the calving paddock and kept isolated from the herd.

Grazing and reproductive management have a significant impact on pathogen load. Where appropriate to grazing management, calving paddocks should be left vacant during the summer. In colder spring calving systems that hold cattle on a small protected site during the winter, use of this same area as spring calving pastures can significantly affect the incidence and severity of calf scours. The buildup of pathogens and organic matter is problematic where there is a heavy stocking density. These areas should be avoided for calving or should be adequately cleaned and rested to minimize the disease load. For producers that manage periparturient cows in smaller calving paddocks to facilitate supervision, the emphasis should be on minimizing the stocking density in the calving paddock by removing cows and calves shortly after parturition.[474,497] Alternatively, cows can be moved away from cows with calves every 1 to 2 weeks or more frequently in large herds. Young calves in the calving paddock will markedly increase the rate of pathogen buildup and the subsequent challenge to newborn calves. Moreover the increased stocking rate will amplify stress, affecting both transfer of passive immunity and the ability of young calves to rest. During its first 6 weeks of life, a healthy calf will spend 75% of its time each day lying.[499] Often calving areas are small due to the perceived need to assist cows for dystocia.[498] Well-grown and appropriately fed heifers mated to suitable sires can minimize the need for assistance. Beef cows with calves at foot moved from the calving paddock should be moved into nursing groups that have a maximum age range of 4 weeks and a low stocking rate. Groups should not be mixed until all calves are at least 4 weeks old.[474,497,498] Reproductive management influences pathogen load by determining the age spread of the calves. Sick calves amplify environmental contamination. A prolonged calving period leads to a buildup of contamination so that calves born later in the calving period experience an increased pathogen challenge. It is desirable to maintain a calving period that is less than 60 days.

One system that meets these requirements is the Sandhills calving system.[481] This management system minimizes contact among beef calves by (1) segregating calves by age to prevent direct and indirect transmission of pathogens from older to younger calves, and (2) scheduled movement of pregnant cows to clean calving pastures to minimize pathogen dose-load in the environment and contact time between calves and the larger portion of the cow herd. The objective of the system is to recreate the more ideal conditions that exist at the start of the calving season during each subsequent week of the season.[500] Rather than using a single large calving pasture, the Sandhills calving system divides large pastures into a series of smaller ones based on length of the calving season and the predicted calving pattern of the cows. Pregnant cows are placed in the first of the smaller pastures. After cows have been calving for a week, cows that have calved remain in the pasture with their calves, and cows that have not yet calved are moved to an adjacent small pasture. After another week of calving in the second pasture, those that have calved are left in the pasture with their calves, and those that have not calved are moved to the next pasture. This is repeated throughout the calving season. The result is cow-calf pairs distributed over multiple pastures, each pasture containing calves within 1 week of age of each other. Cow-calf pairs from different pastures may be commingled after the youngest calf is 4 weeks old and all calves are considered low risk for neonatal diarrhea.[481,500] This system can be adapted depending on the size of the herd; in some herds, moving cows every 10 to 14 days may be appropriate. Early pregnancy testing combined with good record keeping will also allow later-calving cows to be added to the system after 3 to 4 weeks. To implement this system, a plan is required well in advance of the calving system that identifies pastures of appropriate size with suitable pasture, water, and shelter, and the feed available in them managed in accordance with the calving pattern.

Boosting Specific and Nonspecific Immunity

Ensuring adequate passive transfer is necessary to achieve enhanced pathogen-specific immunity through maternal vaccination. Colostrum management is discussed in detail in Chapter 19.

ENTEROTOXIGENIC *E. COLI*. The protective efficacy of enterotoxigenic *E. coli* bacterins is well documented[501-504] (also see Chapter 48). Because ETEC scours occurs during the first 3 days of life, the neonate does not have time to mount a protective immune response to vaccination. Protection is afforded by vaccinating cows in late gestation so as to ensure high concentrations of anti-K99 colostral antibodies. Good maternal management is required to ensure that the calf receives the maternal antibodies. Anti-pilus antibodies block the adhesion of the pathogen to enterocytes and subsequently prevent disease. In general, it is recommended that the vaccines are given 6 and 3 weeks prior to calving. Studies with some vaccines have shown that the vaccine is still effective if the priming dose is given 18 months before calving and boosting is carried out in the second half of gestation.[505] Clinical experience in beef farms suffering severe outbreaks of *E. coli* F5 (K99) diarrhea indicates that vaccinating cows that are more than 10 days from parturition can give considerable protection against death from enterotoxigenic *E. coli* infection.

Products containing monoclonal antibodies against F5 (K99) antigen have been shown to reduce the severity of diarrhea when calves are experimentally challenged a few hours after receiving the product.[506] In field situations, however, monoclonal products can have a low efficacy, presumably because a single dose only provides a short period of enteric protection. Antibody supplements are expensive, and vaccination of the dam to boost colostral immunity usually will be more cost-effective. On farms experiencing an outbreak of neonatal diarrhea caused by F5 (K99) *E. coli*, there may be a place for the use of these products until vaccinated cows begin to calve. However, short-term administration (once a day for the first 3 days of life) of an antibiotic to which the *E. coli* is susceptible is also highly effective in preventing diarrhea in herds experiencing outbreaks of enterotoxigenic *E. coli*.

***SALMONELLA*.** The successful reduction of *Salmonella* prevalence in livestock on a national level via implementation of a *Salmonella* control program emphasizing immunoprophylaxis

with modified live and killed *Salmonella* vaccines indicates the potential benefits that can be derived from the application of effective *Salmonella* vaccines.[507] *Salmonella* vaccine studies in cattle have focused on killed whole cell (bacterins), bacterial fractions (subunit), and attenuated modified live *Salmonella*.

There are conflicting reports regarding the efficacy of *Salmonella* bacterins. The reported efficacy of *Salmonella* bacterins ranges from good to ineffective.[508-516] The overall consensus of these reports is that vaccination of cattle with *Salmonella* bacterins provides partial protection against *Salmonella* challenge. In the only reported controlled field trial, an autogenous *Salmonella* bacterin was not found to have any effect.[516] Adverse reactions in the form of anaphylactic reactions are occasionally reported in cattle vaccinated with *Salmonella* bacterins. The cause of these reactions is unknown but has been suggested to be associated with the lipopolysaccharide content of these products. Similar allergic-type reactions in humans caused by *Salmonella* bacterin vaccination during typhoid outbreaks are well documented.[517]

A commercial subunit vaccine, which is based on purified extracts of siderophore receptors and porins (SRP) of *Salmonella newport*, has become available in the United States.[518] The SRP proteins are critical for iron acquisition and are highly conserved between most gram-negative organisms.[519] Vaccination of dry cows has been demonstrated to increase the titer of anti-*Salmonella* antibodies in colostrum, but this has not been demonstrated to reduce the risk of disease in calves.[520] There are no peer-reviewed studies examining the efficacy of the vaccine for the prevention of neonatal salmonellosis.

Several naturally occurring and genetically manipulated attenuated *Salmonella* strains have been used to immunize cattle against salmonellosis. The most widely tested genetically altered *Salmonella* mutant vaccines in cattle are the auxotrophic strains. Aromatic amino acid (aro) and purine (pur) auxotrophs of *Salmonella* are attenuated and have decreased virulence.[521-527] Comparative vaccine trials indicate that modified live attenuated *Salmonella* vaccines provide greater protection against virulent *Salmonella* challenge than *Salmonella* bacterins.[514,527,528] Vaccination with modified live *Salmonella* vaccines attenuates the severity of clinical signs and pathologic lesions and reduces *Salmonella* shedding and mortality.[507,523,529]

Calves immunized with modified live *Salmonella* vaccines are protected from homologous and heterologous *Salmonella* serotypes when challenged within 3 weeks of vaccination.[530-532] Live *Salmonella* vaccines induce transitory T-cell independent nonspecific protection, which disappears about 1 month after immunization following clearance of the organisms from the reticuloendothelial system. Thereafter protection to oral challenge is species and serotype specific, with recall of immunity presumably involving specific antigen recognition.[533,534]

The level of passive protection of calves achieved via feeding colostrum from vaccinated cows is questionable. A number of reports suggest immune colostrum provides passive protection, and others report no protective effect. In trials where protection was achieved, calves were challenged at 1 week of age; trials where no protection was observed involved challenging calves at 3 weeks of age, suggesting that the duration of passive immunity associated with colostral transfer is relatively short. Considering that many calves are exposed to *Salmonella* in the first week of life, colostral protection may be useful.

ROTAVIRUS AND CORONAVIRUS. Bovine coronavirus is associated with a number of diseases in cattle; all BCV isolates are believed to belong to a single serotype.[535] Differences in hemagglutination-inhibition characteristics have been used to classify strains as types 1 through 3.[536] There are seven serogroups of rotavirus, with group A accounting for the majority of pathogenic isolates. Members of the group A rotaviruses are further classified according to antigenic and genetic differences in their outer capsid proteins, G and P. Both of these proteins are involved in neutralization of infectivity in vitro and in vivo.[537] In the United States, eight G serotypes/genotypes and four P serotypes/genotypes have been identified in cattle isolates.[246] The genome of rotavirus is composed of 11 gene segments that can be exchanged among isolates when animals are infected by more than one virus at the same time.[538] Genetic reassortment can generate new progeny viruses that can evade what was once a protective immune response, thus allowing persistence of rotavirus in susceptible populations.[537]

Two approaches have been taken with immunoprophylaxis against rotavirus and coronavirus infections in calves. The first approach involves oral vaccination of neonatal calves with a modified live vaccine. Calves begin producing detectable levels of local secretory IgM within 4 to 6 days of vaccination.[539] Calves are resistant to challenge from the initial appearance of local IgM antibodies.[539] To consistently elicit an effective immune response, the vaccine must be administered orally, immediately after birth, and before the calf has nursed because the colostrum of most cows contains virus-neutralizing antibodies that interfere with the vaccine.[540] There are conflicting reports of efficacy with these type of vaccines. In double-blind field studies that include vaccinated and nonvaccinated calves, the vaccine was not shown to be effective.[541] Conversely, when all calves were either vaccinated or not vaccinated in sequential comparisons, morbidity and mortality were significantly reduced.[541]

The second approach involves intramuscular vaccination of pregnant cows with either modified live vaccine or inactivated viral vaccines to stimulate high levels of specific virus-neutralizing antibodies in colostrum and milk during the first several days of the calf's life. Infectious viral particles are neutralized within the gut lumen, preventing infection of intestinal villus enterocytes. One advantage of passive immunization is the fact that cross-protection between serotypes is less of a problem. This is due to the fact that vaccination of a mature cow that has had natural rotavirus exposure leads to cross-serotype stimulation of heterotypic antibodies.[542] Single-serotype vaccination therefore stimulates antibody production to a wide range of rotavirus serotypes, negating the need for multivalent rotavirus vaccines. Passively absorbed anti–bovine rotavirus IgG1 antibodies are transferred to the small intestinal lumen, where they protect against experimental challenge.[543] Antigen-sensitized maternal lymphocytes also confer partial protection against challenge with virulent bovine rotavirus.[544] Colostrum and milk with a high virus-neutralizing antibody titer are highly protective while they are being consumed by the calf. For example, administering 400 mL of immune colostrum daily to calves from day 2 to day 12 reduced the incidence of diarrhea from 41% to 3% in one study.[545] The concentration of rotavirus- and coronavirus-neutralizing antibodies in milk of vaccinated cows falls below protective levels by 3 to 7 days after parturition.[546-548] In lieu of complete protection, the manifestations of passive immunity to bovine rotavirus often noted are (1) a delay of a few days in the onset of clinical signs, and/or (2) a reduced severity of clinical signs, and/or (3) a reduction in the length of the period of viral shedding associated with infection.[549] Although there are reports of successful field trials involving bovine rotavirus/bovine rotavirus-coronavirus–vaccinated cows,[503,550,551] negative results have also been reported.[552] A common problem with commercial vaccines on the market in the United States and Europe is a lack of vaccine-specific data supporting efficacy claims. Protection correlates with serum titers; independent studies have sometimes failed to demonstrate effective seroconversion with some products.[553]

Nonspecific Immunity

DIET. The two most important dietary variables affecting the risk of calf scours are nutrient delivery and microbial quality.

VetBooks.ir

When calves are limit-fed milk or milk replacer to drive starter intake, the availability of nutrients from milk or milk replacer is typically adequate for maintenance at birth but inadequate to support significant growth and then drops below maintenance requirements by about 1 week of age.[554] With limit feeding, growth is derived from calf starter intake. Good-quality starter with an effective delivery system is required to promote starter intake. If starter quality or delivery is inadequate, calves become nutritionally stressed. Poor body condition is a feature of this scenario and should trigger an investigation of calf nutrition. High morbidity and mortality are common in nutritionally stressed calves.

The microbial quality of the diet is an important factor in preventing diarrhea. Calves that are fed milk from mastitic quarters or antibiotic-containing milk are at increased risk of diarrhea.[459] Following fresh colostrum feeding, young calves have less diarrhea if placed on whole milk rather than other diets. Pasteurizing surplus colostrum and waste milk reduces the incidence of diarrhea on these diets.[555] It is also important to offer good-quality calf starter from about 2 to 3 days of age; initially intakes will be low, so a small amount is offered daily to keep it fresh. Spoiled starter should be disposed of rather than adding fresh starter to spoiled feed.

Recent studies in dairy calves have shown that administration or stimulation of glucagon-like peptide 2 (GLP-2) can be used prophylactically to reduce intestinal damage, improve barrier function, and increase nutrient absorption in calves subsequently infected with cryptosporidia.[556] It is proposed that GLP-2 treatment reduces the ability of *C. parvum* to attach to the microvilli and penetrate the host epithelium. GLP-2 can be stimulated by supplementing milk with Sucram (Pancosma, Geneva, Switzerland) at 400 mg/kg dry matter (DM) of milk replacer.[557]

Some producers routinely administer vitamin A to neonatal calves. Many but not all studies in children indicate that supplementation can reduce the incidence of diarrhea in areas where clinical and subclinical vitamin A deficiency is endemic.[558] Neonates normally derive fat-soluble vitamins (A, D, and E) from colostrum; deficiency is most likely when colostrum is heat treated and a diet of unsupplemented straw and grain is fed. Calves born to cows fed good-quality, green forage or cattle receiving a vitamin A supplement should not require supplementation, particularly if they received adequate fresh colostrum. Enteric absorption of vitamin A is diminished in calves with cryptosporidiosis, so the systemic route should be used in calves with this type of infection.[559]

Fermentation products derived from *Saccharomyces cerevisiae* are reported to improve enteric health and increase leukocyte function.[560,561,562] SmartCare (SC) and XPC (both Diamond V, Cedar Rapids, Iowa) are *S. cerevisiae* fermentation products that can be supplemented to calf diets via milk (or milk replacer) and starter grains, respectively. In a *Salmonella* challenge trial, the combination of SC and XPC *S. cerevisiae* fermentation products were associated with significant reductions in pyrexia, diarrhea, and intestinal colonization following experimental *S. typhimurium challenge*.[561] These results were consistent with improvements in GI health observed in supplemented preweaned dairy calves naturally exposed to *Salmonella*.[560] In a more recent study, supplementing preweaned Holstein calves with both SC in milk replacer and XPC in calf starter improved starter intake and fecal consistency following a mild *Salmonella enterica* challenge, but there was no reduction in *Salmonella* shedding.[563]

PROBIOTICS. Calves are born with a sterile GI tract that is rapidly colonized by microbes from the dam and the environment. The developing microbial community of commensals and their metabolites influences the health of the gut mucosa and associated immune cells.[564,565] The composition of the microbiota is unstable in the first month of life, influenced by colostrum intake, nutrition, stress, antibiotic use, and environment, and hence varies at an individual and farm level.[566,567-570] Stresses such as abrupt diet changes and weaning can result in dysbiosis, the loss of commensal bacteria providing opportunity for pathogenic microorganisms to proliferate.[569,571]

Probiotics are viable, nonpathogenic microorganisms that, when ingested, are expected to confer beneficial physiologic effects to the host animal. The addition of both prebiotics and probiotics to milk in the first weeks of life is thought to prevent the establishment of opportunistic pathogenic bacterial populations and result in both an increase in the ratio of lactic acid bacteria (LAB) to coliforms and a reduction in the prevalence of diarrhea.[572,573] Probiotic additives generally contain LAB, primarily *Lactobacilli* but also *Streptococcus* and *Enterococcus* species. LAB commonly used include *Enterococcus faecium*, *Lactobacillus acidophilus*, *Lactobacillus lactis*, *Lactobacillus paracasei* subsp. *paracasei*, *Lactobacillus plantarum*, *Lactobacillus rhamnosus*, *Lactobacillus salivarius*, *and Streptococcus salivarius* subspecies thermophiles. *Bifidobacterium bifidum*, *Aspergillus oryzae*, *Candida pintolepesii*, and more recently *Faecalibacterium prausnitzii* may also be included in some combinations.

General mechanisms of action ascribed to probiotics include immune system stimulation, such as production of anti-inflammatory cytokines, excretion of antimicrobial substances such as bacteriocins (nisin and pediocin), and competition with pathogens for intraluminal nutrients and receptor sites on the intestinal surface.[574,575] *Lactobacilli*, one of the most common probiotics used in calves, bind or chelate iron, a nutrient essential for most bacteria, hence limiting the availability to pathogenic microorganisms.[575]

Several studies demonstrate improved fecal consistency and reduced incidence of undifferentiated diarrhea. A meta-analysis of trials involving calves that were supplemented with LAB from younger than 10 days of age demonstrated a significant reduction in the incidence of diarrhea, particularly in calves fed whole milk supplemented with a multistrain inocula.[572] LAB were also administered to calves that were subsequently infected with *S. dublin*, leading to a reduction in the severity of histopathologic lesions.[571] Another study showed a significant reduction in the incidence of diarrhea when the nonpathogenic *E. coli* strain Nissle 1917 was administered to calves from birth for the first 10 to 12 days of life.[576]

More recently, additional species of bacteria have been tested as next-generation probiotics. This includes an obligate anaerobe belonging to the phylum Firmicutes, *F. prausnitzii*. Oral administration of viable *F. prausnitzii* from less than a week of age to calves fed ad libitum acidified nonsaleable milk reduced the incidence of diarrhea and mortality and improved weight gain.[577]

It can be concluded that feeding probiotics containing multispecies LAB, *E. coli* strain Nissle 1917, or *F. prausnitzii* to calves from less than a week of age that are fed whole milk has the potential to positively influence the microbiome of the neonatal calf and provide a protective effect, reducing the incidence of diarrhea. However, the benefits in healthy calves are likely to be small, and the protective effect will not overcome an overwhelming challenge. Due to the potential range of bacterial species that can be included in a probiotic mix, experimental data should be examined for any commercial product. This is particularly important in light of a study in foals where administration of a lactobacilli probiotic resulted in an increase in morbidity and diarrhea.[578]

PREBIOTICS. Prebiotics are carbohydrates or other organic compounds that are not hydrolyzed or absorbed in the upper part of the GI tract and affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon that can improve host health.[579] The most

VetBooks.ir

well-studied prebiotics are nondigestible oligosaccharides. These compounds stimulate the growth and activity of LAB, promoting production of short-chain fatty acids that lower intraluminal pH, preventing adhesion of Enterobacteriaceae to the intestinal epithelium, most notably *E. coli* and *Salmonella*.[573,580,581]

Prebiotics studies in calves have examined mannan-oligosaccharides, which are complex mannose sugars and components of yeast cell walls, galacto-oligosaccharides produced from lactose or lactulose, and fructo-oligosaccharides that naturally present in some edible plants such as Jerusalem artichoke tubers and chicory roots.[573,580] These studies have not conclusively demonstrated a reduction in the incidence of diarrhea, and hence currently these prebiotics cannot be recommended as a preventive measure.[580,582-586]

LACTOFERRIN. Lactoferrin is an iron-binding milk glycoprotein naturally found in colostrum that has antimicrobial, antiviral, antiinflammatory, and immunomodulatory effects. It has been extensively investigated as a prophylactic to prevent sepsis in high-risk infants and as an intervention strategy to reduce *E. coli* O157:H7 carriage in ruminants.[587,588]

There are several studies investigating its use in calves both as prevention and treatment for diarrhea and as a growth promoter. Two studies using lactoferrin prophylactically have demonstrated a significantly reduced incidence of diarrhea as assessed by fecal consistency scores.[589,590] In one of these studies lactoferrin was combined with another bioactive protein lactoperoxidase system.[590] That study also demonstrated that significantly reduced numbers of *E. coli* in the colonic digesta and feces of the treated calves. On postmortem the villi in the distal jejunum of calves from the treatment group were significantly longer.

BIOSECURITY. Infectious diseases are often purchased with brought-in stock. Operations that buy in calves for rearing purposes should be encouraged to buy from as few sources as possible. Direct purchase from one farm is best; assembling collections of calves through auction markets should be avoided if possible.

Treatment of Individual Calves

Examination

Physical examination of the diarrheic calf is the first step in establishing therapeutic needs. It is important to determine the presence of any intercurrent disease, as concurrent CNS disease, ileus/abdominal emergency, or orthopedic problems result in an increased likelihood of mortality.[591] Treatment of uncomplicated cases of diarrhea depends on the estimation of dehydration, severity of acidosis, likelihood of intercurrent infection, presence or absence of hypothermia, and hypoglycemia. The severity of dehydration is gauged from the eyeball position and skin tent (Table 20.10). In acute diarrhea the degree of enopthalmos is the most reliable indicator of dehydration, but because the position of the eye within the orbit is also dependent on body fat stores, the skin tent in the cervical region may be the most reliable indicator in calves with chronic diarrhea or cachexia.[592] Skin tent can be measured over the eyelids and neck. Best results are obtained when the neck is held straight and the skin of the mid-neck is tented in the direction of the long axis of the neck to avoid the natural skin folds that run across the neck. Estimation of severity of acidosis from either laboratory or physical findings is very important to the successful therapy of severely depressed calves. The degree of acidosis should be assessed separately to the degree of dehydration, as there is little relationship between them.[593] Strong ion (metabolic) acidosis in calves with diarrhea is due to fecal loss of sodium as well as dehydration and reduced tissue perfusion. The calves will also have a variable degree of hyper-D-lactatemia, and studies have shown that clinical signs originally attributed to the base excess values are primarily due to hyper-D-lactatemia.[172,175,594,595] Hyper-D-lactatemia may not affect the sucking reflex but will result in an impaired palpebral reflex and significant neurologic defects such as depressed mentation, staggering, drunken gait and tottering, standing with a lowered head and drooping ears, and eventual recumbency.[595,596] A significant correlation exists between D-lactate concentrations and base excess values, allowing clinical signs to still be used to estimate the degree of metabolic acidosis in calves with naturally acquired diarrhea (Fig. 20.6).[35,175,591,597,598]

Rectal temperature measurement will determine whether or not the calf is hyperthermic or hypothermic. Heart rate is variable in diarrheic calves. Bradycardia (<90 beats/minute) is clinically important and may indicate the presence of hypothermia, hypoglycemia, or hyperkalemia. Cardiac arrhythmias[599] are usually caused by severe hyperkalemia (K^+ above 8 mEq/L; Fig. 20.7). Severe hyperkalemia in diarrheic calves may be characterized by a general weakness similar to D-lactic metabolic acidosis. The impairment or promptness of the palpebral reflex was found to be a good clinical indicator that allows a distinction to be made between these two disorders. Potassium and D-lactate concentrations are negatively correlated in diarrheic calves, which makes the simultaneous occurrence of D-lactic acidosis and hyperkalemia unlikely.[597,600] Hyperkalemic arrhythmia usually can be differentiated from arrhythmia due to cardiomyopathy (selenium deficiency) because the heart rate is not elevated. The presence of bradycardia or arrhythmia indicates the need for immediate fluid therapy with bicarbonate-containing solutions to prevent death.

Body condition is usually good at the onset of diarrhea. Poor condition often indicates chronic infection, mismothering, or poor feeding programs, which may be exacerbated by milk withdrawal. Advanced cachexia in diarrheic calves is a reliable indicator of mortality.[591]

It is important to check for intercurrent infections; these are easily missed even with careful examination. The lungs should be examined for signs of pneumonia; the navel palpated for pain, swelling, and wetness; and the joints checked for signs of distention and lameness. The boundary between calves in which the primary insult is septicemia with a secondary diarrhea and those in which primary diarrhea is complicated by septicemia is blurred. Calves that are recumbent, under 1 week

TABLE 20.10

Guidelines for Assessing Dehydration in Neonatal Calves

% Dehydration	Eyeball Sunkenness	Neck Skin Tent (Seconds)	Mucous Membranes
0	None	<1	Moist
1–5	None to slight	1–4	Moist
6–8	Slight separation of eyeball and globe	5–10	Tacky
9–10	Gap, <0.5 cm, between eyeball and orbit	11–15	Tacky to dry
11–12	Gap, 0.5–1 cm, between eyeball and orbit	16–45	Dry

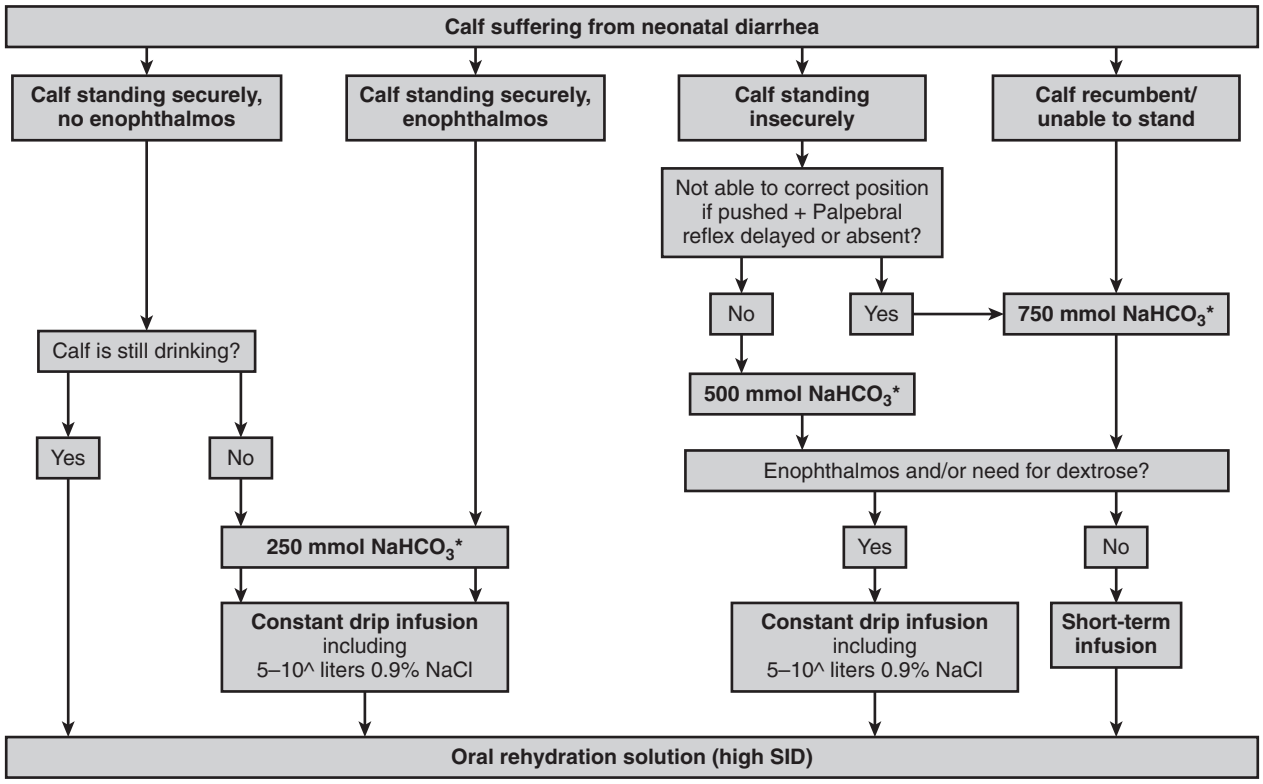

FIG. 20.6 A treatment decision tree for calves with diarrhea. Ability to stand, eye position, and reflexes may be used to predict the severity of metabolic and/or D-lactate acidosis and determine the treatment required. *(From Trefz, FM et al.: Construction and validation of a decision tree for treating metabolic acidosis in calves with neonatal diarrhea.* BMC Veterinary Research, *8:238; 2012.)*

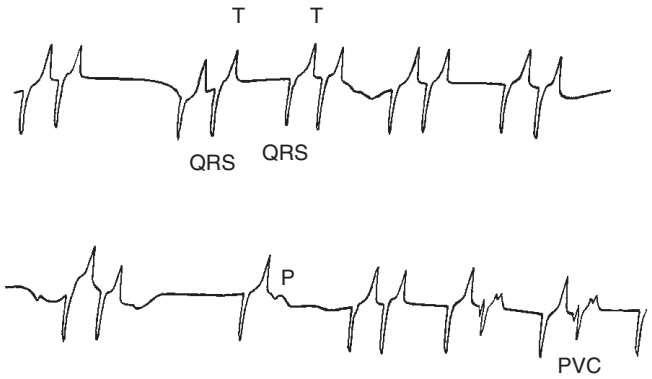

FIG. 20.7 Bradycardia and atrial standstill in a severely hyperkalemic diarrheic calf. Heart rate is 84 beats/minute. There is bigeminy, and the T waves are abnormally large. There is only one P wave, and it is not conducted. Serum potassium was 8.9 mmol/L, and sodium was 116 mmol/L.

of age, have lost their suck reflex, or have evidence of intercurrent infection are more likely to be septicemic and require concurrent antibiotic therapy.[21] Calves in which septicemia has progressed to produce signs of meningitis (e.g., extended neck with reluctance to flex the neck), joint involvement, or ophthalmic signs (congested scleral vessels with hypopyon or iridospasm) carry a poor to very poor prognosis. It is best to identify these cases prior to instigating therapy so that the owner can decide whether treatment is economically feasible.

The laboratory is useful in quantifying metabolic disturbances in diarrheic calves. Blood gas analysis will accurately determine the degree of metabolic acidosis. The development of point-of-care devices (such as i-STAT [Abbott Laboratories, Abbott Park, Ill.]) that are relatively affordable have enabled practitioners to evaluate acid-base abnormalities in the field. The portable analyzers are capable of quantifying concentrations of Na^+, K^+, iCa^{2+}, and tCO_2 as well as determining pH, $paCO_2$, paO_2, base excess, and hematocrit. Correlations between the i-STAT and a reference analyzer in cattle and sheep were good or excellent for most variables.[601] Alternatively, blood can be collected into a heparinized syringe, capped, placed in a styrofoam cup surrounded by ice, and transported 4 hours or more to a laboratory. The practice laboratory may also have a total CO_2 (Harleco) analyzer or access to serum bicarbonate estimation as part of serum chemistry profile. Total CO_2 or bicarbonate is a useful index of the severity of metabolic acidosis. Blood glucose and D-lactate can be readily determined using test-specific point-of-care handheld meters.

Treatment Goals

The primary goals of treating calf diarrhea are as follows[602]:

1. Correct free water and electrolyte abnormalities
2. Correct acid-base deficits (acidemia)
3. Provide nutritional support
4. Treat or prevent bacterial infections if indicated

The first of these goals can be met with fluid therapy.

Fluid Therapy

The most common causes of death in diarrheic calves are dehydration and acidosis.[603] The immediate objective in treating depressed diarrheic calves is to restore them to a normal systemic state. In some calves it may also be necessary to correct hypoglycemia or hypothermia, restrict milk intake, or give antibiotics.

The estimated severity of dehydration can be combined with estimates of losses through diarrhea and for the maintenance of essential functions to give the total daily fluid requirement (see Table 20.10). The hydration status of the calf can be estimated from the degree of enopthalmus and the degree of skin tent on the neck and by evaluating the mucous membranes (see Table 20.10). The volume (L) required to replace the deficit is Percent dehydration × Calf body weight (kg). The ongoing losses through diarrhea should be estimated from the nature and volume of the diarrhea. Fecal losses can range from 1 to 6 L in diarrheic calves.[604] Maintenance requirements have been estimated at 50 to 100 mL/kg/day.[36,604] The degree of hydration and the volume of feces passed should be reassessed daily and the treatment adjusted accordingly. Only 60% to 80% of oral fluids are absorbed, and this needs to be accounted for in the calculation.[605]

Bicarbonate requirements can be calculated from base deficit values (based on blood gas measurements or estimated from physical findings) as follows:

$$\text{mmol Bicarbonate} = \text{Body weight (kg)} \times \text{Base deficit (mmol/L)} \times \text{Volume of distribution (0.6 in calves)}$$

A chart of bicarbonate requirements for various body weights and base deficit values is available (Table 20.11).

Measurements of serum total carbon dioxide content or bicarbonate are also reliable estimates of bicarbonate requirements.[606] Bicarbonate requirements are:

$$\text{mmol Bicarbonate} = \text{Body weight (kg)} \times (30 - tCO_2) \times 0.6$$

For example, a 40-kg calf has a serum bicarbonate or tCO_2 of 10 mmol/L. The calf has a bicarbonate deficit of 30 mmol/L – 10 mmol/L = 20 mmol/L, so 40 kg × 20 mmol/L × 0.6 = 480 mmol bicarbonate is required to replace existing deficits. Ongoing diarrhea may require additional bicarbonate.

Calves that are unwilling to suck and severely depressed are best treated with intravenous fluids. Calves that are only moderately depressed may also be treated with intravenous fluids if the condition is worsening rapidly. Catheterization is easier if a no. 15 scalpel blade is used to nick the skin. If it proves very difficult to catheterize the calf, the calf can be suspended upside down so that blood will pool and distend the jugular veins. The calf's neck should be clipped and prepared prior to inversion, and the calf laid flat as soon as the catheter is placed. It should be possible to place a catheter in less than a minute even in severely dehydrated calves using this technique. Alternatively, the auricular vein can be easily catheterized using a 20-gauge catheter, or fluids may be administered by intraosseous infusion in the critically ill neonate when intravenous access is not possible. In calves, intraosseous fluids may be administered via placement of a 16- or 14-gauge needle in the head of the femur or humerus. A 16- or 14-gauge needle is inserted in a longitudinal plane. Neonatal bones are soft, so the needle can be drilled into the bone using finger pressure. Commonly a core of bone will plug the needle, requiring the drilling needle to be discarded and replaced with a new needle placed in the same hole. After placement of the needle, attach a 60-cc syringe and inject sterile saline under slight pressure to start the flow. As the fluid is administered, check for subcutaneous leakage to ensure that the needle is correctly placed within the bone marrow. One to two liters of saline or isotonic bicarbonate administered to the severely dehydrated calf is often sufficient to restore blood pressure enough that an intravenous catheter can be placed.

Once the catheter is placed, fluids can be administered. If the calf is hypothermic, these should be warmed prior to administration because cold fluids can decrease cardiac output and may kill a critically ill calf. Fluids can be warmed using a number of methods; one convenient technique is to run the fluids through a coil of tubing immersed in a bucket of hot water (check the temperature regularly) on the way to the calf.

Saline-based fluids are suitable for rehydration (Table 20.12), but most severely depressed calves are acidotic, and more consistent recovery is obtained if an alkalizing agent is also used. A wide variety of alkalizing agents are available (lactate, acetate, gluconate), but clinical trials show that only bicarbonate is consistently effective in severely acidotic calves (Fig. 20.8).[170,607] Many diarrheic calves require large amounts of bicarbonate to correct their acidosis (see Table 20.11).[168] An isotonic solution (156 mmol/L) of bicarbonate can be readily made by dissolving 13 g of sodium bicarbonate (baking soda) in 1 L of water.[608] Sodium bicarbonate solutions can be mixed with saline; there is a possibility that precipitates may form if bicarbonate is mixed with calcium containing solutions such as Ringer's solution.

It is not always necessary to completely correct acidosis; a blood pH from 7.25 to 7.45 has little adverse affect (normal

TABLE 20.11

Calculation of Bicarbonate Requirement From Calf Body Weight and Severity of Acidosis

Calf Weight (kg [lb])	Base Deficit (mmol/L)	Bicarbonate Requirements (mmol)	Volume 1.3% $NaHCO^-_3$ (L)[a]

TABLE 20.12

Fluids Commonly Used in Intravenous Therapy

Item	Concentration (mmol/L)									
	Na^+	K^+	Ca^{++}	Mg^{++}	Cl^-	HCO^-_3	$Lactate^-$	$Acetate^-$	$Gluconate^-$	Glucose
0.9% saline	155				155					
1.3% sodium bicarbonate[a]	156					156				
Ringer's	147	4	5		156					
Lactated Ringer's[b]	130	4	2.7		109		30			
Ionalyte (diluted)[b]	139	10		3	101			55		167
Normosol R[b]	140	5		3	98			27	23	
Plasmalyte 148[b]	140	5		3	98			27	23	
5% dextrose (D_5W)[c]										278

[a]Do not mix sodium bicarbonate with calcium-containing solutions; precipitates may form. Mixtures of 1.3% sodium bicarbonate and saline are usually used for treating recumbent diarrheic calves.

[b]Multiple electrolyte solutions are equivalent, with the exception that one should be careful of using Ionalyte in severely hyperkalemic neonates. All are suitable for rehydrating neonates that can stand.

[c]Intravenous fluids are often spiked with 50% dextrose to give a final concentration of 5% dextrose in the drip when hypoglycemia is suspected.

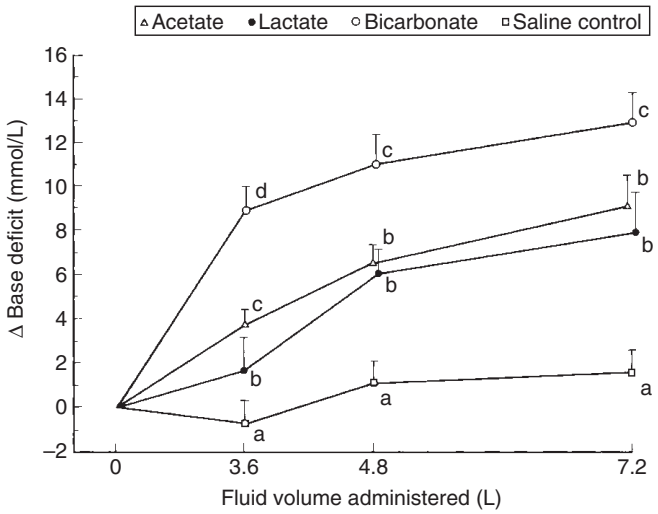

FIG. 20.8 Comparison of the alkalizing effect of various bases in diarrheic calves with severe dehydration and acidosis. At the start of the trial, all calves were at least 8% dehydrated and had a mean blood pH of 7.032 and a base deficit of 18 mmol/L. All calves received a total of 7.2 L of fluid containing 102 mmol/L of saline plus 50 mmol/L of the sodium salt of the respective alkalizing agent. Letters *(a, b, c, d)* are statistically different ($P < 0.5$) from one another at that point. *(From Kasari TR, Naylor JM: Clinical evaluation of sodium bicarbonate, sodium L-lactate, and sodium acetate for the treatment of acidosis in diarrheic calves,* J Am Vet Med Assoc *187:392; 1985.)*

calves have a venous blood pH of 7.34, bicarbonate of 30 mmol/L, and base excess of 5 mmol/L). Ideally, dehydration and acidosis should be corrected over a 24-hour period. However, it is unusual to see problems when the fluid and acid-base deficits are corrected over 4 hours, although the calf may continue to improve after this period. Rapid resuscitation techniques include the administration of either hypertonic saline (± dextran) or hypertonic sodium bicarbonate. Hypertonic saline (7.2% NaCl) or hypertonic saline dextran (7.2% NaCl containing 6% dextran 70) administered at 4 mL/kg body weight during a 4-minute period concurrently with an isotonic alkalizing oral electrolyte solution is effective in resuscitating dehydrated calves with diarrhea.[609,610] Hyperosmotic sodium bicarbonate solutions may also be used to rapidly resuscitate acidotic dehydrated calves.[611] The base deficit can be corrected by administering 8.4% sodium bicarbonate intravenously at a rate of 1 mL/min/kg over 15 minutes.[612,613] Hypertonic bicarbonate has also been shown to have clinical advantages for the rapid resuscitation of hyperkalemic diarrheic calves, compared to hypertonic NaCl or glucose solutions.[591] Although calves with diarrhea lose potassium through the intestines, hyperkalaemia is often found due to acidosis. Hypertonic fluids should always be given concurrently with an isotonic oral electrolyte solution. After 24 hours of appropriate therapy one would expect the calf to be standing and show a good suck reflex. Persistent depression is usually a sign of uncorrected acidosis or toxemia.

Most diarrheic calves are not markedly hypoglycemic, but glucose supplementation is needed to treat severe hypoglycemia (glucose concentrations <2 mmol/L or <36 mg/dL). Glucose concentrations less than 2 mmol/L are associated with a significantly reduced chance of survival.[38] These animals often have clinical and/or necropsy evidence of septicemia, and generally this is a result of a peritonitis. Severe hypoglycemia is treated by adding glucose to the intravenous fluids to a final concentration of 2.5% to 5%. Severe hyperkalemia is seen in some dehydrated diarrheic calves, but this responds to rehydration (restores renal perfusion and dilutes out potassium) and correction of acidosis (redistributes potassium into the cells). Nutritional support is not needed if the calf is in good body condition but should be given if the calf is emaciated or if the calf has been deprived of milk for more than 3 days.

There are increased losses of potassium in diarrhea, and potassium depletion can result in weakness. When necessary, potassium supplementation can be estimated using the following equation:

$$\text{Replacement K (mEq)} = 0.4 \times \text{Body weight (kg)} \times \text{K deficit (mEq)}$$

Potassium can safely be added to fluids at a rate of 20 to 30 mEq/L. The rate of potassium administration should not exceed 0.5 mEq/kg/h. If acidosis is present, hydrogen ions are exchanged for intracellular potassium ions, resulting in a relative increase in serum [K]. As the acidosis is corrected, there will be an influx of K ions back into cells, resulting in potential hypokalemia, which must be anticipated during fluid therapy.

Oral Electrolyte Therapy

Once the calf is able to nurse or drink, therapy is usually switched to oral electrolytes, which should continue for as long as the calf has diarrhea. This is also the route of choice for treatment of mildly affected calves on the farm. Calves with weak suck reflexes and calves that are unused to hand feeding can be tubed.

VetBooks.ir

Oral electrolyte solutions need to supply sufficient sodium to facilitate normalization of extracellular fluid deficits, nutrients (glucose, citrate, acetate, propionate, or glycine) to facilitate absorption of sodium from the intestine, alkalizing agent to treat metabolic acidosis, and supplemental energy because most calves that have diarrhea are in a state of negative energy balance.[614,615] The first two requirements depend on the coupled active transport of glucose and sodium ions across the brush border membranes of enterocytes, which results in passive absorption of water and other electrolytes.[616] This function remains largely intact in calves with enterotoxigenic *E. coli* diarrhea, but where there is endothelial damage it may be impaired. Much of the research into oral electrolyte solutions has been conducted in healthy calves. Although the current understanding of the advantages and disadvantages of the different electrolytes is presented here, it is important to recognize that milk clotting, abomasal luminal pH, and abomasal emptying rates could differ between diarrheic and nondiarrheic calves.

The ideal sodium concentration for oral rehydration therapy in calves is thought to be between 90 and 130 mmol/L.[615] Lower concentrations of sodium will not adequately correct dehydration. Products with a sodium concentration greater than 130 mmol/L should be avoided, as they may predispose to hypernatremia and can also delay abomasal emptying rates because of increased osmolality.[617] The osmolality of the electrolyte solution is primarily determined by the concentrations of sodium and glucose. Commercially available oral electrolyte products in North America can range from approximately isotonic (280 to 300 mOsm/L) to extremely hypertonic (700 to 800 mOsm/L), with the greatest variation being in the amount of glucose added. The osmolality at the tip of the villi is approximately 600 mOsm/L, and use of solutions up to this osmolality will provide additional nutritional support.[602] However, extremely hyperosmotic electrolyte solutions (700 to 717 mOsm/L) have the potential to increase dehydration and have been shown to have a slower abomasal emptying rate than calves fed iso-osmotic solutions (300 to 360 mOsm/L), increasing the risk of bloat or abomasitis and resulting in a slower rate of plasma expansion.[602,617-619] Calves that are deprived of milk will lose more weight when fed isotonic low-glucose solutions.[620]

Oral electrolyte solutions should contain between 40 and 80 mEq/L chloride and 10 and 30 mmol/L potassium. Potassium is lost in the feces of calves with diarrhea, and with dehydration there can also be increased potassium losses from the kidney. Consequently calves with chronic diarrhea may have profound hypokalemia resulting in severe muscular weakness.[602]

Severely acidemic calves are unable to correct their metabolic acidosis when rehydrated with nonalkalinizing solutions, and consequently fluid therapy must be designed to address the strong ion (metabolic) acidosis and hyper-D-lactatemia.[602,607,615] The ability to counteract acidosis varies greatly between oral electrolyte products. These differences are therapeutically important and are responsible for differences in survival rates between products. It is important that an oral electrolyte solution contains greater than 50 mmol/L of an alkalizing agent and has a strong ion difference ($[Na^+]+[K^+]-[Cl^-]$) of at least 60 to 80.[602] Commercial oral electrolyte solutions use acetate, propionate, bicarbonate, and citrate as alkalizing agents.

Understanding of the attributes of the alkalizing agents has evolved over the past few years, but there is little consensus on which is most suitable. Bicarbonate combines with hydrogen ions directly, whereas the other agents remove hydrogen ions during their metabolism within cells.[604] Several studies have shown that oral electrolyte solutions containing bicarbonate (≤62 mmol/L) and citrate (≤12 mmol/L) do not interfere with milk clotting in vivo.[619,621,622] Many authors still prefer bicarbonate precursors such as acetate or propionate for their energy value once metabolized, their water absorption capabilities, and the fact that they do not alkalinize the abomasum.[602] It is important that solutions containing acetate and propionate also have a high strong ion difference to ensure a rapid restoration of base excess. Solutions containing bicarbonate alkalize the GI tract of milk-fed calves, and several authors have expressed concern that this may result in bacterial overgrowth in the small intestine as well as ETEC attachment and toxin production.[602,623] In reality, concerns about the effects on milk clotting have been alleviated for most electrolyte solutions; it is likely that feeding a sufficient volume of an oral electrolyte solution with a recommended strong ion difference has the most significant impact on the rapid correction of dehydration and acidosis.[594,621]

There are a wide variety of oral electrolyte preparations on the market (Table 20.13), and many do not meet the requirements stated above, so care should be taken to select an appropriate solution. Beware of products that are designed for medicating hundreds of liters of water, as the final solution is often very dilute (<10 g electrolytes/L) and will not rehydrate sick calves. These products are often marketed as "boosters" and "stress relievers."

Neutral amino acids such as glycine, alanine, or glutamine are usually added to oral electrolyte solutions to facilitate sodium absorption in the small intestine by a mechanism similar to that of glucose. Research in humans has shown that adding glycine to solutions containing 110 mmol/L of glucose aids rehydration. It is probable, however, that there is little additional benefit to supplementing solutions that contain more than 200 mmol/L of glucose with glycine. Glutamine is also an important fuel for the GI tract and can promote mucosal repair. A recent review concluded that addition of glutamine to a high-calorie oral electrolyte solution results in improved clinical recovery from diarrhea in preweaned calves.[624] Volatile fatty acids such as acetate or propionate also facilitate sodium absorption in the gut.[625,626] These appear to use a different mechanism to facilitate sodium absorption to that of glucose or amino acids, and consequently significant increases in intestinal sodium absorption can be expected in electrolyte products containing volatile fatty acids, even when they already contain high concentrations of glucose and/or amino acids.[624]

Solutions that contain large amounts of glucose are hyperosmolar and are absorbed more slowly than isotonic solutions, but the differences are too small to be clinically important.[627] The ionic composition also affects absorption; mixtures of sodium chloride and citrate, bicarbonate, or acetate have improved absorption over chloride salts alone. Oral electrolyte solutions are almost completely absorbed in healthy calves, but absorption can be as low as 60% in severe *E. coli* diarrhea.[628]

Psyllium has been added to some oral electrolyte solutions for a number of perceived benefits, but controlled studies show no clinical advantages, although there may be some moderation of bacterial fermentation within the GI tract.[629,630]

The other problem to be considered in the chronically scouring calf is the need for nutritional support (Fig. 20.9). Maintenance metabolizable energy requirements for a 50-kg calf are about 2000 kcal, and 3500 kcal are required to support a weight gain of 0.5 kg/day. These requirements can be met by 3.3 and 5.7 L of whole cow's milk, respectively. Comparative studies indicate that weight loss in calves fed oral electrolytes are inversely proportional to the energy content of the solutions.[620] Assuming a 4-L daily intake and 100% digestibility of oral electrolyte nutrients, regular electrolyte solutions supply between approximately 15% and 25% of energy needs. As a result, diarrheic calves that are held off milk for prolonged periods lose weight[631] and can become emaciated. When maintaining body condition is a concern and little milk or solid food is being ingested, a high-energy oral electrolyte should be fed. Products such as Biolyte, Lifeguard/Enterolyte HE and RESTART H.E. provide about 50% of energy

This table does not include every available product. Information updated based on Table 20-12 in *Large Animal Internal Medicine*, Fifth edition. Calculated from information listed in the *Compendium of Veterinary Products*, U.S. edition, 2018, available online at https://pbs.cvpservice.com, and on product labels. Additional information obtained from Smith GW, Berchtold JF: Fluid therapy in calves, *Veterinary Clinics of North America Food Animal Practice*, *30*(2):409–427, 2014; Jones C, Heinrichs J: *Comparison of commercial electrolyte products*, Pennsylvania State University, PennState Extension, College of Agricultural Sciences, 2017, available at https://extension.psu.edu/table-comparison-of-commercial-electrolyte-products; and Smith G: *Analysis of oral calf electrolytes*, 2017, available at https://www.techmixglobal.com/sites/default/files/doc/reference/Oral%20Electrolyte%20Analysis_Dr%20Smith_2017_0.pdf

Note: Concentrations of calcium, magnesium, phosphate, and sulfate are not included. Molarities assume that all compounds dissociate completely in solution. Where a maximum and minimum value for a compound was provided, the mean value has been used.

[a]Nutrient is provided by the product, but label contains insufficient information to calculate concentration.

[F,M,L,S,A]In addition to glucose, product contains another carbohydrate source: F = fructose, M = maltodextrin, L = lactose, S = sucrose, A = amylose.

[1]Instead of glucose, product contains 96 mmol/L of lactose (glucose and galactose).

[2]Contains maltodextrins instead of or as well as glucose; value listed for glucose is glucose equivalents.

[3]Energy source is organic sugar; label does not specify the form.

[4]Energy source is not specified; contains reed-sedge peat and organic dried kelp.

[5]Instead of glucose, contains sucrose.

[6]Energy source is not specified; contains roughage products, reed-sedge peat, and dried kelp.

?, Published information insufficient to provide reasonable estimate; *SID*, strong ion difference.

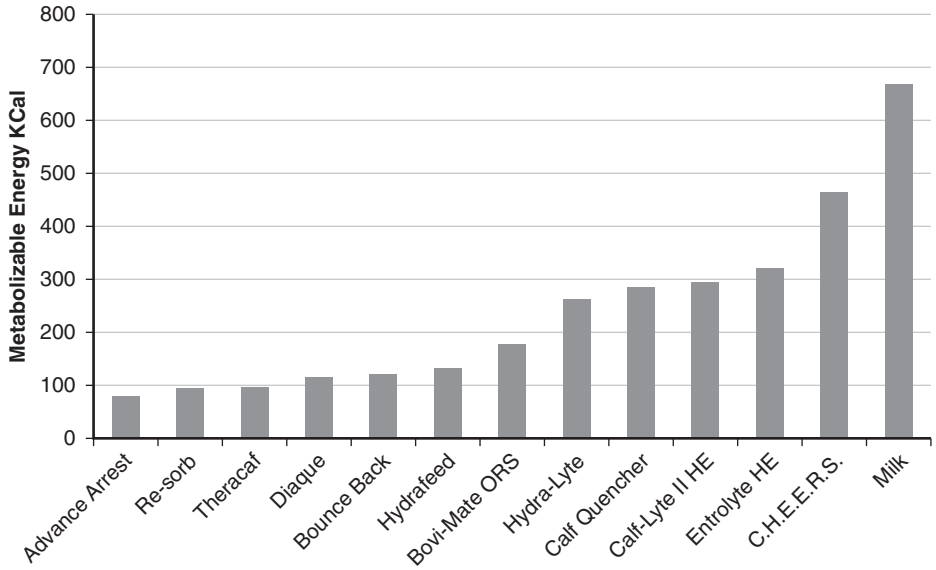

FIG. 20.9 Comparison of the energy content of various electrolyte solutions. Milk is shown for comparative purposes. Metabolizable energy content for products other than milk is estimated from glucose and other water-soluble carbohydrates of the as-fed electrolyge solution. Calculations are made with the assumption that 1 g of carbohydrate equals approximately 4 Kcal of metabolizable energy. This figure applies to electrolyte solutions fed to neonatal calves prior to rumen development. See text for manufacturers.

requirements if fed twice a day (total intake 4 L) and about 75% if fed three times a day (total intake approximately 6 L).

Milk withdrawal can reduce the severity of diarrhea and depression in severe scours. This is because malabsorption exacerbates diarrhea through the osmotic effect of unabsorbed milk nutrients and also promotes bacterial overgrowth and D-lactic acidosis. Milk also has a trophic effect on epithelial cells and maintains higher GI tract enzyme activities as well as providing protein for repair of damaged intestinal epithelium.[632] In experimental trials, continued feeding of milk maintained weight gain; however, when calves were fed enough milk to fully meet their requirements and the undrunk milk was tube fed, calves initially had greater inappetence.[633,634] Withdrawal of milk without a high-energy alternative can rapidly result in cachexia and malnourishment.[633] In many calves, particularly the less severely affected, there is often a considerable degree of residual absorptive capacity, enough to support body weight gain if limited amounts of milk are fed. Milk withdrawal for up to 12 hours is recommended if the calf is depressed and not interested in sucking. In most cases electrolyte therapy will restore a calf's vigor and sucking drive within 1 to 2 days. Milk can then be reintroduced in small amounts (e.g., 1 L given two to four times daily). However, forced feeding (by tubing or drenching), dysfunction of the reticular groove reflex, or reflux of abomasal contents may result in ongoing acidosis due to the production of D-lactate from fermentation of carbohydrates entering the reticulorumen.[600] If the calf is not interested in drinking or becomes depressed when reintroduced to milk, a high-energy oral electrolyte preparation can be tried instead. Studies indicate that diarrheic calves have a generalized malabsorption rather than specific lactose intolerance.[165] Thus it may be more important to manage calves with milk intolerance by giving smaller amounts of milk in each feed rather than by changing carbohydrate source. There is little point in withdrawing milk from calves that remain alert and interested in nursing, as it is unlikely to result in clinical improvement. This is particularly likely to be the case when the calf receives whole cow's milk in frequent small quantities (i.e., by natural sucking of the dam).

Role of Antimicrobials

The majority of calves with diarrhea do not require treatment with antimicrobials, and since use of antimicrobials in neonatal calves is a driver of antimicrobial resistance (AMR) on farms, they should be used judiciously.[635] Antimicrobial use in calves with diarrhea should be based on a protocol that (1) details the clinical signs indicating the use of antimicrobials; (2) specifies an antimicrobial product, dose, and duration of treatment that is appropriate for the likely pathogen and is likely to maintain a therapeutic concentration at the site of infection (small intestine and blood); (3) avoids the use of "medically important" antibiotics, unless indicated by culture results or when treatment with other antimicrobials has not been effective; (4) advocates antimicrobials registered for treating diarrhea in calves and as directed on the label or by a veterinarian whenever possible; and (5) avoids adverse local or systemic effects and violative residues. The use of antibiotics should always be accompanied by an infection control plan. The practice of continually feeding antibiotics to calves has been prohibited in many countries, but prophylactic antibiotics are still commonly used in some countries to prevent calf diarrhea.[636,637] Although older studies generally demonstrated a reduction in the duration and severity of the diarrhea, there was little or no effect on diarrhea incidence or mortality rates.[638] More recent studies have demonstrated benefits from stopping prophylactic and routine treatment with antimicrobials. A large study in the United States found a decrease in the prevalence of diarrhea in calves given targeted treatment for diarrhea with specific symptoms, compared with calves given both prophylactic antibiotics in the milk and routine antibiotics for all clinical cases.[639] Another study demonstrated that there was no increase in mortality when a protocol for selective treatment of systemically ill calves was introduced on two large farms that had previously been using antibiotics in more than 75% of their calves with diarrhea.[640] Moreover, a change in the fecal microbiota was observed in calves on both farms 12 months after the introduction of the new protocols. Although the relative proportions of the different bacteria were not always consistent across the two farms, both farms had a significant reduction in the percentage of Enterobacteriaceae isolated in healthy calves 12 months after the protocols were introduced.

THERAPEUTIC TARGETING. The bacterial pathogens commonly associated with neonatal calf diarrhea are *Salmonella* and *E. coli*. Coliforms are normal inhabitants of the GI tract and one of the most common representatives of the aerobic

gram-negative microbiota. Calves with diarrhea often have significantly increased coliform bacterial numbers in the small intestine, regardless of etiology,[641-643] and this colonization is associated with altered small intestinal function, morphologic damage, and increased susceptibility to bacteremia.[643] Bacterial overgrowth and subsequent fermentation in the GI tract results in the production of D-lactic acid. D-lactic acid is a major component of acidemia in diarrheic calves and is accompanied by systemic signs of weakness and ataxia. Calves with diarrhea are more likely to have failure or partial failure of passive transfer, and this group of calves, in turn, is more likely to be bacteremic.[24,644] Blood cultures indicate that gram-negative bacteria account for approximately 80% of bacterial isolates, and *E. coli* is the most common bacteria isolated.[18,19,644] In a study of 190 recumbent calves on a large calf-raising facility, 31% were determined to be bacteremic; *E. coli* accounted for 51% of the isolates, other gram-negatives for 25%, gram-negative anaerobes for 5.9%, gram-positive cocci for 11.8%, and gram-positive rods for 5.9%.[644]

Antimicrobial therapy must be targeted at a specific bacterial enteric pathogen isolated from sick calves or used in severely ill calves (as manifested by reduced suckle reflex, >6% dehydration, weakness, inability to stand, or clinical depression) to manage the risk of bacteremia. The antibiotic selected should be directed toward gram-negative organisms, particularly *E. coli*.

ANTIMICROBIAL SUSCEPTIBILITY. Antimicrobial susceptibility testing of fecal isolates should be specifically directed at enterotoxigenic *E. coli* and *Salmonella* spp. During a suspected outbreak of salmonellosis, fecal samples from 10 calves in the affected age-group should be cultured using an enrichment media, and antimicrobial susceptibility should be determined from the isolates obtained.[645] Multiple isolates of ETEC should also be tested to determine antimicrobial susceptibility, where this is shown to be a primary etiology.

When antibiotics are used to prevent coliform septicemia, fecal samples cannot be used to determine the correct antimicrobial. The predominant strain of *E. coli* in the feces of a scouring calf can change several times during an episode of diarrhea, and one study has shown that 9 of 20 calves with diarrhea had different strains of *E. coli* isolated from upper and lower small intestines.[646,647] Hence fecal *E. coli* strains may not be representative small intestinal *E. coli* strains, and multiple studies have shown that determining the appropriate antibiotic from fecal isolates is not a good predictor of clinical outcome.[648-650]

Antimicrobial susceptibility testing has more clinical relevance for predicting the clinical response to antimicrobial treatment when applied to bacteria isolated from blood or tissues of bacteremic calves, because the minimal inhibitory concentration break points are based on achievable antimicrobial concentrations in human plasma and MIC_{90} values for human *E. coli* isolates, which provide a reasonable approximation to achievable MIC values in calf plasma and MIC_{90} values for bovine *E. coli* isolates.[647] Within a given herd there will be a diversity of bacteria isolated from bacteremic calves, so the collection of blood cultures and assessment of antimicrobial susceptibility does not necessarily provide information applicable to the next case.

When determining the correct antibiotic for prevention of septicemia in the absence of postmortem or blood cultures, antimicrobial efficacy is best evaluated by the clinical response of a number of calves to treatment, with calves randomly assigned to treatment groups, rather than the results of in vitro antimicrobial susceptibility testing performed on fecal *E. coli* isolates.[647]

MINIMIZING ANTIBIOTIC RESISTANCE. The young, preweaned calf rapidly acquires multiple-resistant commensal *E. coli* enteric flora within days of birth.[651-654] Although colonization with *E. coli*–carrying AMR genes occurs regardless of antimicrobial exposure, the proportion of antimicrobial-resistant *E. coli* on a farm is driven by the antibiotic use on that farm.[655-659] Although these coliforms are generally not pathogenic, they serve as a reservoir of AMR genes that can be shared between bacteria, including *Salmonella* spp., in both humans and animals.[660,661]

Several dietary and environmental factors influence the proportion of AMR coliforms shed. However, administration of antibiotics both fed in milk and given parenterally is a key driver, with preferential growth of antimicrobial-resistant *E. coli* strains starting within 3 hours of antimicrobial administration.[655,659,662-666] Administration of antibiotics also converts the opportunistic pathogenic bacteria in the respiratory tract into reservoirs of AMR.[659,666] As the calf gets older, changes in the commensal enteric microflora occur that result in an intestinal microbiota that is more effective at excluding these bacteria, and the proportion of resistant *E. coli* reduces.[651,652,659,667] The prevalence of these bacteria also decreases when antibiotics are withdrawn, but a high number of resistant *E. coli* are sustained in the bedding for more than 1 month.[668-670] Use of florfenicol and ceftiofur in one pen also results in an increase in the proportion of resistant bacteria shed by calves in adjacent pens.[670] Consequently, administration of antibiotics to neonatal calves, more so than other age-groups, has been shown to be one of the key drivers of the development of AMR on a farm.[635]

Particularly concerning is the relationship between use of third- and fourth-generation cephalosporins on farms and the emergence and spread of broad-spectrum β-lactamase–producing *E. coli*.[656,670-672] Broad-spectrum β-lactamases are a significant resistance mechanism that is a serious threat to the currently available antibiotic armoury, conferring resistance to some of the most commonly used antibiotics in humans, including penicillins, cephalosporins, clavulanic acid, and monobactams. In addition, these organisms are commonly multidrug resistant.[673-675] It is now evident that the use of antimicrobials in calves is a major risk factor for broad-spectrum β-lactamase–producing *E. coli*, which is consistent with the rapid increase in antimicrobial-resistant coliforms observed following antimicrobial use in this age-group.[635,667] Also of concern is the strong relationship demonstrated between the use of fluoroquinolones and the development of multidrug antimicrobial resistance, as is the co-selection of broad-spectrum β-lactamase resistance when cattle are treated with florfenicol.[665,670,676]

Third- and fourth-generation cephalosporins and fluoroquinolones have been identified as "highest priority critically important antimicrobials" for human medicine by national and international bodies, including the World Health Organization (WHO), Food and Agriculture Organization of the United Nations (FAO), and World Organisation for Animal Health (OIE). Hence it is imperative that veterinarians consider the impact that their selection of antimicrobial, where indicated, will have on the development of resistance. Critically important antimicrobials must not be used as the initial treatment in a disease outbreak; instead their use should be limited to those cases where culture and sensitivity has ruled out the use of other antimicrobials with likely efficacy or cases where lower priority antimicrobials result in a poor response. In some countries, the use of some of these antibiotics in food-producing animals is already banned. Logically, the range of antimicrobials used in calves on any farm should be limited, and when resistance becomes apparent, the antimicrobial type should then be changed. This strategy is likely to result in a slow decrease in resistance to that antimicrobial. However, the epidemiology of antimicrobial resistance is extremely complex, and experience in cattle and other species has shown that a reduction in resistance at a farm level can be slow.[677-679] The development of AMR in *Salmonella* is also of concern, with cattle acting as an important reservoir of multidrug resistance.[680] Administration of antibiotics or feeding of medicated milk to young calves may result in the transfer of resistance to *Salmonella*,[664] but feeding medicated milk to young calves tends to

reduce fecal *Salmonella* shedding and counterintuitively was not associated with increased shedding of antimicrobial-resistant *Salmonella* in epidemiologic studies.[652] The presence of β-lactamase–secreting *E. coli* can protect other Enterobacteriaceae, such as *S. enterica*, without evidence of gene transfer.[681] Asymptomatic *Salmonella* shedding is common. Because *Salmonella* spp. can be recovered from dairy cattle for up to 3.5 years after clinical infection, the prevalence of AMR in *Salmonella* creates a risk for people in direct contact with the animal, its feces, or milk.[682-685] Although several studies in the United States have failed to show a significant increase in the prevalence of AMR in *Salmonella* in the last 10 to 15 years, this has been attributed to variation in strain prevalence, with common cattle strains showing an increase in multidrug resistance.[677,686]

ANTIMICROBIAL SAFETY. A number of antimicrobials have been demonstrated to produce deleterious effects when administered orally to healthy milk-fed dairy calves. Administration of neomycin sulfate (300 mg PO q24h for the first 4 days of life) tended ($P = .060$) to increase the proportion of calves developing diarrhea (99 of 233 = 43%) compared with the proportion in an untreated control group (58 of 174 = 33%).[687] Administration of neomycin sulfate (25 mg/kg PO q6h, n = 10), ampicillin trihydrate (12 mg/kg PO q8h, n = 6), or tetracycline hydrochloride (11 mg/kg PO q12h, n = 6) for 5 days increased the occurrence of diarrhea and decreased glucose absorption through unknown mechanisms compared with untreated controls (n = 6).[688] Two other studies did not observe adverse side effects in calves administered tetracycline hydrochloride (40 mg PO q12h; 11 mg/kg PO q12h).[689,690] Parenteral administration of aminoglycosides is prohibited in many countries due to prolonged slaughter withdrawal times (18 months), but there is also a potential for nephrotoxicity in dehydrated calves.

EFFICACY OF ORAL ANTIMICROBIAL THERAPY. The response to oral antimicrobial therapy is variable, with many formulations failing to demonstrate a beneficial effect.[647] Oral antimicrobials may be used to treat *E. coli* overgrowth of the small intestine in mildly sick calves. Calves with diarrhea and moderate to severe systemic illness should be treated with parenteral antimicrobials. Efficacy of oral antimicrobials will vary depending on whether they are a liquid that will bypass the rumen or a capsule that will be deposited into the rumen. Due to reduced transit times in diarrheic calves, the antimicrobial concentration in the small intestinal lumen is lower than in healthy calves, and the rate of antimicrobial elimination is faster.[662]

Efficacy in either reducing mortality or reducing the duration of naturally acquired diarrhea has been demonstrated using either apramycin administered orally at either 20 or 40 mg/kg for 5 days or marbofloxacin (a fluoroquinolone) at 1 mg/kg/day for 3 days.[691,692] The calves treated in the marbofloxacin study were younger than 5 days of age, and ETEC was isolated from more than 50% of the cases. Similarly, aminoglycosides and aminocyclitols are very poorly absorbed from the GI tract and are therefore only useful for the treatment of a confirmed enterotoxigenic *E. coli* infection and not for treatment of septicemia. Cephamycin C (0.75 to 20 mg/kg bid for 3 to 6 days), a broad-spectrum β-lactam antimicrobial, and enrofloxacin (5 mg/kg PO q24h for 3 days) have been shown to significantly reduce mortality in experimentally induced enterotoxigenic *E. coli* infections.[693,694] However, it is illegal to use both fluoroquinolones and third-generation cephalosporins in some countries, as they are critically important antimicrobials for human medicine; therefore other antimicrobials should be used when indicated.

Trials with orally administered neomycin reduced the duration of diarrhea but did not reduce mortality.[695,696] Similarly, trials with orally administered ampicillin failed to demonstrate a significant reduction in mortality, although the lack of success in this study was later attributed to a delay in commencement of antibiotic treatment.[697] Conversely, orally administered amoxicillin trihydrate has been demonstrated to reduce mortality and the duration of diarrhea when administered at a dose of 10 mg/kg PO q12h.[154,698] Amoxicillin is absorbed from the GI tract more effectively than ampicillin and can be used in combination with clavulanate potassium, providing potent irreversible inhibition of β-lactamase and increasing the antimicrobial spectrum of activity.

The results of trials with orally administered trimethoprim have been variable, with no significant improvement in outcome observed in a large field trial[699] and a significant reduction in mortality observed in an experimental *Salmonella* challenge study where calves were administered 5 mg/kg of trimethoprim and 25 mg/kg of sulfadiazine PO daily for 5 days.[700]

EFFICACY OF PARENTERAL ANTIMICROBIAL THERAPY. The frequency of bacteremia is sufficiently high in calves with diarrhea that are severely ill (as manifested by reduced suckle reflex, >6% dehydration, weakness, inability to stand, or clinical depression) that routine treatment should include antimicrobials, with an emphasis on treating potential *E. coli* bacteremia.[647]

Antimicrobial drugs with an appropriate gram-negative spectrum of activity include potentiated penicillins (amoxicillin), trimethoprim-sulfonamide (TMS) combinations, aminoglycosides, sulfonamides, florphenicol, fluoroquinolones, third-generation cephalosporins (ceftiofur), and tetracyclines. There is a paucity of efficacy data to support the use of aminoglycosides, tetracycline, and nonpotentiated sulfonamides.

Potentiated sulfonamides have been evaluated in enterotoxigenic *E. coli* and *Salmonella* challenge experiments. Mortality was reduced in 2- to 3-week-old calves medicated with trimethoprim/sulfadiazine (in a 1:5 ratio) for 5 days 24 hours after an *S. dublin* oral challenge.[700] Administration of either sulfadiazine or trimethoprim alone did not reduce mortality.[700] TMS may be used to treat sepsis in neonatal calves, but its half-life rapidly declines as rumen function develops. In ruminating (6- to 8-week-old) calves, subcutaneous or oral administration of TMS leads to high serum levels of sulfadiazine but little or no serum trimethoprim.[701]

Intramuscular administration of amoxicillin reduced mortality in *S. dublin*–challenged calves.[702] In a comparative trial of amoxicillin and trimethoprim/sulfadiazine, both drugs were found to have equal efficacy in reducing adverse clinical signs of disease when dosage regimens were based on the MIC of the pathogen.[703] A large study of calves with naturally acquired diarrhea demonstrated a decrease in mortality after treatment with ampicillin, and the efficacy was increased further with β-lactamase inhibition.[704] Parenteral apramycin (20 mg/kg q24h, unstated route, for 5 days) significantly decreased the mortality rate of calves in a similar study.[691] Fluoroquinolones are efficacious against both experimental challenge and natural ETEC infections.[705,706] Florfenicol (20 mg/kg) given IM every 48 hours for two doses has been shown to be efficacious in treating salmonella.[707] There are concerns about its use in treating a coliform septicemia because the MIC_{90} for *E. coli* is very high and can be achieved for only a short period when administered at 20 mg/kg IV.[647,708] In most countries florfenicol is only labeled for intramuscular or subcutaneous use.

Ceftiofur has an appropriate antimicrobial spectrum, and therapeutic drug concentrations can be maintained with once-daily dosing. In a *S. typhimurium* challenge experiment, intramuscular administration of ceftiofur hydrochloride (5 mg/kg q24h for 5 days) reduced the severity of clinical signs and reduced fecal shedding of *Salmonella*. The MIC of the challenge strain in this experiment was 1 μg/mL, and the therapeutic protocol maintained plasma concentrations above this concentration for the duration of therapy.[375] Ceftiofur is a third-generation cephalosporin and is listed by the WHO in the

highest priority of critically important antibiotic. Its use should be limited to appropriate cases.

A national survey in the United States found bacterial isolates to frequently be resistant to tetracycline, streptomycin, ampicillin, and ceftiofur. Less AMR was observed with aminoglycosides, fluoroquinolones, and trimethoprim-sulfas.[709] The therapeutic options are subsequently limited, as the U.S. Animal Medicinal Drug Use Clarification Act prohibits extralabel use of fluoroquinolones, ceftiofur, and certain sulfonamides. In addition, there is a voluntary ban on the use of aminoglycosides, such as gentamicin and amikacin, in food-producing animals because of long-term tissue residues.[710]

In summary, parenteral administration of a broad-spectrum β-lactam antimicrobial—amoxicillin or ampicillin (10 mg/kg IM q12h) or trimethoprim/sulfadiazine (20 mg/kg sulfadiazine with 5 mg/kg trimethoprim IV or IM q24h for 5 days)—is recommended for treating calves with diarrhea and systemic illness (note that these are off-label doses and require an extended meat withholding period). Antimicrobial therapy is not recommended for calves with diarrhea and no systemic illness (i.e., normal appetite for milk or milk replacer, no fever).[647]

ALTERNATIVES TO ANTIBIOTICS. Prebiotics and probiotics have been investigated as alternatives to antibiotics, but to date there is no evidence of clinical efficacy. The use of prebiotics and probiotics to prevent diarrhea is discussed in the Nonspecific Immunity section earlier. Lactoferrin is an iron-binding milk glycoprotein naturally found in colostrum that has antimicrobial, antiviral, antiinflammatory, and immunomodulatory effects. It has some efficacy as a preventive but has also been used in a large trial to treat calves with diarrhea on an organic farm. There was no difference in clinical scores compared with controls post treatment, but there was a significantly reduced risk of mortality and culling by 60 days in the subset of calves with severe diarrhea at enrollment.[711]

Antiprotozoal Drugs

Drugs reported to have some efficacy against cryptosporidia in calves include halofuginone,[712-719] paromomycin,[720,721] azithromycin,[722] decoquinate,[723,724] and β-cyclodextrin.[725] Halofuginone appears to be the most efficacious, but it is not licensed in all countries. A meta-analysis of 15 cohort and clinical studies showed that prophylactic use of halofuginone delayed the shedding of *Cryptosporidium*, with a lower prevalence of shedding at days 4 and 7 but a higher prevalence at day 21 when treated calves were compared to controls.[726] Prevalence of diarrhea was also lower on days 4 and 7 in treated calves. Because calves frequently become infected with cryptosporidia during the first 24 hours of life, prophylactic use of halfuginone administered to calves daily for the first week of life is effective at reducing disease when husbandry procedures are implemented to minimize cross-infection between calves.[727] The efficacy of decoquinate is questionable, with the only controlled clinical study failing to demonstrate a beneficial therapeutic effect with treatment at 2 mg/kg/day.[724] Lasalocid has been trialed for treatment of cryptosporidia. Using a toxic dose of 8 mg/kg, it was found to reduce the shedding of cryptosporidia, but the calves suffered adverse side effects. At a dose of 0.8 mg/kg, lasalocid was not effective.[728] The registered dose for preventing coccidiosis in calves is 1 mg/kg per head per day.

Coccidiosis is uncommon in calves younger than 6 weeks of age. In hand-reared calves, coccidiostats (lasalocid, amprolium, or decoquinate) may be added to milk replacer. Prophylactic options for beef calves are restricted to coccidiostat-medicated pellets (monensin, lasalocid, amprolium, or decoquinate) or water (amprolium or sulfonamides). Therapeutic options include amprolium or sulfonamides such as sulfadimidine.

Both fenbendazole (5 mg/kg PO once daily for 3 days) and albendazole (20 mg/kg PO once daily for 3 days) have been shown as effective treatments for *Giardia*.[331,414,729] Due to the high level of subclinically affected animals, all cows and their dams need to be treated, and reinfection is likely to occur unless calves are removed from environmental sources of infection.

Antiinflammatory Drugs

The routine administration of an NSAID is recommended for a calf with diarrhea that is systemically ill. It is important that administration of NSAIDs occurs after fluid therapy has commenced due to the risk of reduced renal perfusion. To avoid damaging the abomasal mucosa, no more than three doses should be given, particularly in intensive calf-rearing facilities with a history of calf deaths due to perforated abomasal ulcers.[730] Although the benefits of NSAIDs have been demonstrated clinically, the underlying pathophysiology has yet to be determined and could be due to their analgesic, antiinflammatory, antisecretory, or antipyretic properties. Clinical trials have been performed with meloxicam and flunixin. Meloxicam 0.5 mg/kg SC given at the onset of diarrhea increased feed intake, hydration score, and fecal consistency and decreased signs of visceral pain compared to administering a placebo.[731,732] A nonstatistical trend toward decreased morbidity has been reported in a study evaluating the benefits of a single or double injection of flunixin meglumine in scouring calves, but only when fecal blood was present.[733] The routine administration of a corticosteroid to calves with diarrhea is not recommended, as corticosteroids suppress the immune system and diarrheic calves have been shown to have high levels of plasma cortisol when compared to healthy calves.[734]

Intestinal Protectants

A number of products that include intestinal protectants are marketed for treatment of calves with scours. Intestinal protectants include bismuth subsalicylate, kaolin or pectin, and activated charcoal. No efficacy data are available regarding the use of kaolin in scouring calves. Suggested advantages of bismuth subsalicylate are its neutralization of bacterial toxins and antisecretory effect through its local antiprostaglandin activity.[735,736] The results of one prospective study indicated that the aforementioned nonantibiotic treatments for calf diarrhea resulted in a longer duration of treatment and increased morbidity and mortality when compared to medicated milk replacer and parental antibiotic treatment.[737]

Recent studies demonstrated that a commercially available standardized crofelemer extract, a natural product with antisecretory properties, increased fecal dry matter and reduced the severity of dehydration in both an experimental and a natural outbreak of calf scours.[738,739]

Prognosis

The prognosis for recovery decreases with the severity of depression. Severe hypothermia and the presence of intercurrent disease are grounds for a guarded prognosis.[740-742] An initial examination should be performed. Calves with a primary problem of septicemia are not usually worth treating because of the poor prognosis. The severity of dehydration, hypothermia, and acidosis should be estimated. Recumbent calves are usually treated intravenously with a saline-based rehydrating fluid (0.9% saline, Ringer's, lactated Ringer's, etc.) and isotonic sodium bicarbonate (especially for older and comatose calves). Calves that can suck are treated with oral electrolytes that contain 50 to 80 mmol/L of alkalizing agent. Products that use mainly acetate as the alkalizing agent are best for calves that are still drinking cow's milk (small quantities, frequently). Any alkalizing agent is likely effective in calves held off milk.

Summary

Calf scours is caused by a variety of infectious agents. At the present time, the need to make a definitive diagnosis of

enterotoxigenic *E. coli* and *Salmonella* infections has been established; these diseases can be controlled by antibiotics and prevented by vaccination.[743] There are public health implications to the diagnosis of cryptosporidiosis and salmonellosis. New vaccines may facilitate controlling rotavirus and coronavirus infections. Treatment of neonate diarrhea is primarily based on correcting dehydration and acidosis through the use of oral and intravenous electrolytes. Only in the case of bacterial infections can direct action be taken against the invading organism, but antibiotics may still be useful in preventing secondary bacteremias. Colostrum feeding will help reduce diarrhea in the first days of life. Management is very important in the control of diarrhea, and since infectious agents are almost always present at some exposure level, the underlying theme is to minimize the level of pathogen exposure and stress on the calf. In approaching a problem of neonatal death losses, the areas to examine should include calf immunoglobulin status, calf feeding, calf housing, cleanliness of environment, calving area, cow vaccinations, diagnosis of specific infectious agents, and treatment protocols.

Lameness and Reluctance to Walk

John K. House

Septic Arthritis

Septic arthritis may result from direct trauma or contamination of the joint, from extension of periarticular infection, or via hematogenous spread from another site. Systemic sites of infection include enteritis, pneumonia, and inflamed umbilical structures. FPT increases the risk of sepsis. Destruction of the epiphysis and extension of infection into the joint may be primary in some cases, rather than starting as a primary synovial membrane infection that spreads to the epiphysis or physis. The most common pathogens isolated from septic joints of neonatal calves are enteric organisms, including *E. coli* and *Salmonella* spp. *Streptococcus* spp., *Staphylococcus* spp., and *T. pyogenes* are less common isolates. *T. pyogenes* is the most frequently isolated organism from joints of older calves.[744-746] Vertebral body osteomyelitis is another manifestation of hematogenous bacterial spread, with localization of bacteria in the vertebral veins. The presumed origin of the bacteremia most frequently is pulmonary or umbilical infections in calves and tail docking wounds in lambs.[747] The etiologic agent usually is *T. pyogenes* or *F. necrophorum*, alone or as part of a mixed infection.[748] The clinical signs vary depending on location of the compressive abscess. Affected animals often have clinical signs pertaining to other body systems (e.g., coughing, diarrhea, decreased weight gain compared with herdmates) before the onset of neurologic signs. The diagnosis of vertebral osteomyelitis is made by history, clinical signs, laboratory findings suggestive of chronic infection (elevated fibrinogen, globulin, and neutrophil count), and radiographs that demonstrate the affected vertebrae. Spinal fluid analysis is variable, but in most cases it is normal or has a pleocytosis (macrophages and some neutrophils) caused by chronic inflammation of the dura mater.[747]

Bacteria commonly isolated from septic joints in lambs include *Streptococcus* spp., coliforms, *Arcanobacterium pyogenes*, *Erysipelothrix rhusiopathiae*, and *F. necrophorum*.[455] Predisposing factors include poor docking hygiene and contaminated sheep dip. Sporadic outbreaks of polyarthritis in lambs, kids,[76,749,750] and calves[751] are associated with *Chlamydia* and *Mycoplasma* spp. infections. *Chlamydia* infections may occur in utero or postnatally, whereas *Mycoplasma* infections often result from ingestion of *Mycoplasma*-contaminated milk.

Diagnosis of septic arthritis is based on the combination of clinical signs, radiographic examination, bacterial culture, and cytologic analysis of synovial fluid. A bacterium is isolated in only 60% of cases of septic arthritis in bovine medicine.[752] Synovial fluid cytologic analysis is useful for the differentiation between infectious and noninfectious arthritis. Trauma is the chief differential. Lambs and kids with septic arthritis often fail to nurse and may present with significant weight loss. Typically polyarthritis caused by *Mycoplasma* spp. and *Chlamydia* is associated with high fevers and respiratory and occasionally neurologic disease. High morbidity and mortality are common. Conjunctivitis is commonly observed with chlamydial infections.[749] Cytologic findings consistent with septic arthritis include a synovial fluid total protein concentration greater than 4.5 g/dL, a nucleated cell count greater than 25,000 cells/mL, a polymorphonuclear cell count greater than 20,000 cells/mL, and a percentage of polymorphonuclear cells greater than 80%.[753] Chlamydial inclusions may be found in Giemsa-stained smears of synovial cells and the organism isolated from joint fluid or plasma in early cases.[749] Isolation of *Mycoplasma* spp. requires specific media (Hayflick media) and microaerophilic conditions. Normal synovial fluid does not rule out septic physitis or osteomyelitis because the infection may be in the physis or small tarsal bones.

Careful examination of high-quality radiographs is important for the detection of bone lysis indicating infection. Initial radiographs may be normal because the degree of damage is often not detectable for 10 to 14 days after initial infection occurs. Radiographic features of septic arthritis include soft tissue swelling, widening or collapse of the joint space, osteoporosis, and osteosclerosis. Ultrasound may be used to confirm involvement of the joint and rule out periarticular or tenosynovial infection to avoid iatrogenic contamination of the joint during arthrocentesis. Joint distention and hyperechogenic fragments in the synovial fluid are suggestive of septic arthritis. Normal synovial fluid is anechoic.

Acute septic arthritis in neonatal ruminants may be treated effectively via joint lavage combined with systemic and local antimicrobial treatment. Typically, however, neonatal ruminants are presented with a chronic disease process. Treatment options include joint lavage or arthrotomy to remove destructive inflammatory products and long-term antimicrobial therapy. Joint lavage is rarely efficacious in the treatment of chronic septic arthritis in calves, as accumulation of fibrin and pocketing of purulent material often make adequate joint drainage impossible.[754] Joint lavage may be facilitated via use of a rigid arthroscope or, in the case of simple joints (elbow and stifle), arthrotomy.[755] Empirical antimicrobial therapy should include a gram-negative and gram-positive spectrum. Culture of synovial fluid facilitates antimicrobial selection.

Therapeutic synovial concentrations of penicillin, oxytetracycline, ampicillin, and cephapirin can be attained in inflamed and normal joints of calves following systemic administration.[756-759] The distribution of trimethoprim/sulfadiazine, penicillin, oxytetracycline, and cefapirin in joints is not enhanced or reduced by inflammation.[756-758] Penicillin, trimethoprim, and sulfadiazine equilibrate in 0.5 to 1 hour, and oxytetracycline equilibrates in 4.5 to 6 hours.[757] The subsequent decline in antibacterial drug concentration in synovial fluid parallels that in serum.[756] Synovial inflammation accelerates distribution of antimicrobial drugs into joints[757] but has little effect on the peak drug concentration achieved in synovial fluid.[756,757] The peak concentration of ampicillin in synovial fluid following a single intramuscular injection of ampicillin trihydrate at a dosage of 10 mg/kg is higher in normal and inflamed synovial fluid than in sera.[759] There is a paucity of bovine-derived data regarding the distribution of the newer-generation antimicrobials into synovial fluid following systemic administration. Studies in other species suggest that most classes of antibacterial drugs are capable of crossing the synovial membrane. Synovial tissue is very vascular and does not have a basement membrane. In humans synovial fluid concentrations of most antibacterials generally average at least 60% to 70% of serum drug concentrations at the time of peak serum concentrations and frequently exceed those in serum immediately before the subsequent systemic dose in

VetBooks.ir

patients with septic arthritis.[760] Antimicrobial dosing is targeted to achieve a peak antibacterial concentration that exceeds the MIC of the infecting organism by fivefold to tenfold.[760] The duration of therapy depends on the antimicrobial sensitivity of the pathogen and the immune status of the patient; prolonged (4 to 8 weeks) antimicrobial therapy is commonly required. In a review of 81 cases of septic arthritis in cattle, a 72% recovery was achieved with a combination of surgical treatment (opening of the joint capsule; débridement; and excision of the synovium, infected cartilage, and bone), joint immobilization, and systemic antibiotic therapy. Of cattle treated conservatively with systemic and intraarticular antimicrobials, 43% recovered.[761]

Noninfectious Lameness

Neonatal ruminants with nutritional myodegeneration often have a stiff, stilted gait. Lambs and kids may have difficulty nursing if they are unable to lift their head and may cry with pain when assisted to stand (see Chapter 42).

Contracture of joints or tendons of the limbs produces difficulty in movement and predisposes to FPT by impeding the ability to adequately nurse. Degree of contracture varies from mild to severe and may be associated with scoliosis and/or torticollis. Conservative therapy consisting of splinting the front limbs to induce tendon laxity may be helpful. Calves with severe digital flexor tendon contractures often require surgical resection of one or both digital flexor tendons, followed by bandaging or casting and stall rest for 3 to 4 weeks.

Peripheral nerve injuries may occur secondary to dystocia, trauma, or injection site reactions, causing damage to peripheral nerves in the proximity of the injection site. The femoral nerve and brachial plexus are more commonly affected in calves. Femoral nerve damage is usually secondary to stretching the nerve during a "hip lock"dystocia. Clinical signs of femoral nerve paralysis include inability to extend the stifle and advance the limb and analgesia of the medial aspect of the limb down to the tarsus. Atrophy ("dished-out appearance") of the quadriceps is noticeable in 7 to 10 days if there is complete tearing of the femoral nerve.[747] Atrophy of the quadriceps predisposes to patella luxation. Complete or partial avulsion of the brachial plexus has also been observed in calves following dystocia.[762] The clinical presentation will depend on the severity of the injury. Clinical signs include abnormal positioning of the limb, abnormal locomotion, paresis, muscle atrophy, hyporeflexia, and sensory loss.[747]

Umbilical Enlargement

The umbilicus consists of three types of structures and undergoes functional and anatomic changes at birth. Two umbilical arteries connect internal iliac arteries to the placenta. These later regress and become the round ligaments of the bladder. One umbilical vein connecting the placenta to the liver and porta cava regresses to become the round ligament of the liver within the falciform ligament. The urachus connects the fetal bladder to the allantoic cavity.

Patent Urachus

Patent urachus is a persistence after birth of the tubular connection between the bladder and umbilicus. The urachus drains the bladder into the allantoic sac during gestation. Urine flow should gradually change, with some urine entering the amniotic sac through the urethra in later gestation. At birth, with umbilical cord rupture the urachus should be closed, and urine should be voided through the urethra. Neonates with a patent urachus may dribble urine from the urachus during or after urination or may simply present with a constantly wet umbilical stump.

Differentials include concurrent infection of the navel (omphalophlebitis). Ultrasound may assist the diagnosis and determine the involvement of umbilical arteries or vein. Moist hairs around the umbilicus and visualization of fluid coming from the navel are diagnostic. A complete physical examination should be performed. If abnormalities are noted, serum IgG, complete blood cell count, and urinalysis are helpful for detecting susceptibility to infection and presence of systemic or urinary tract infection. Surgical resection of the urachus to the tip of the bladder is the treatment of choice. Associated arteries and veins should be ligated and removed if they are infected or necrotic. Merely ligating the exterior stump can trap organisms and cause infection.

Omphalitis

Omphalitis is inflammation of umbilical structures that may include the umbilical arteries (omphaloarteritis), umbilical vein (omphalophlebitis), urachus, or tissues immediately surrounding the umbilicus. Umbilical infection is one of the most common diseases in newborn calves, occurring in 1.3%[763] to 29.9% of newborn calves.[764]

Umbilical abscess or infection of any of the three components of the umbilicus may produce local infection or be a source of septicemia. The source of infection is most commonly the external environment, coupled with FPT. Bacteria isolated from calf umbilical cord remnant infection include *T. pyogenes*, *E. coli*, and *Proteus* and *Enterococcus* spp. Herd management variables that influence the risk of umbilical infection include maternity pen hygiene, cleanliness of the newborn calf environment, effectiveness of passive transfer, and umbilical cord management.[765]

The urachus is the most commonly affected structure in calves, and the umbilical arteries are the least affected.[766] Omphalophlebitis may extend the length of the umbilical vein into the liver and result in liver abscessation. When the umbilicus is enlarged and draining purulent material, infection is easily noted. When the urachus is fixed to the abdominal wall, calves are prone to cystitis and may show signs of pollakiuria and dysuria. In other cases the umbilicus may be dry and larger in diameter than expected. In addition, neonates may have a completely normal-appearing, dry external navel and be severely ill from infection of the urachus, umbilical arteries, or umbilical vein. In a septic neonate without external signs of infection, involvement of the umbilicus can be difficult to determine. Abdominal palpation of the umbilical vein and arteries is a useful, simple, and effective means of assessing their size and detecting pain associated with these structures. Inflamed structures may be identified by standing behind the neonate and pressing the hands together above the umbilicus. Ultrasound is also a useful ancillary diagnostic aid.[767] Persistent dilation of the umbilical vein or arteries with a hypoechoic-to-echogenic fluid, intraluminal gas, and wall thickening are findings consistent with infection. In calves, the urachus normally retracts up into the abdomen at birth, and ultrasonographic identification of a urachal remnant is abnormal.[768]

Overt signs of infection are heat, swelling, purulent discharge, or pain. Concurrent signs of systemic infection such as joint infection, pneumonia, diarrhea, meningitis, or uveitis may be noted. Calves with urachal abscesses may show signs of dysuria or pollakiuria.[769,770] Infection in more than one umbilical vessel in the neonate is common, and urachal involvement is frequent. Umbilical abscessation that is walled off and does not involve deeper structures is a less severe problem and may be treated with drainage without surgical removal of the entire umbilicus.

Early treatment with antibiotics and supportive care may allow resolution before development of abscessation and distention of the urachus or the umbilical arteries and vein. Established infection usually requires surgical removal of involved structures in addition to medical therapy.[766] When omphalophlebitis extends into the liver, the umbilical vein may be marsupialized

VetBooks.ir

to facilitate drainage and flushing.[771] Prognosis is improved when adequate passive transfer of colostral immunoglobulins has occurred and when joints or other structures are not involved. Sequelae such as renal abscessation, joint or bone infection, peritonitis, and other complications described for septicemia may develop if therapy is started too late or discontinued prematurely.

Anemia

Anemia in the neonate should be interpreted in the context of the realization that normal hematologic values of the neonate may vary from the adult. In calves, the incidence of anemia (hemoglobin <10 g/dL) is quite high, ranging from 15% to 30% in many herds,[772,773] and is normocytic, normochromic, and poikilocytic. Anemia is reported to be secondary to iron deficiency.[772,773] Potential causes are reduced amounts of iron in milk, poor placental transfer of iron, or decreased intestinal absorption. Anemic calves with poikilocytosis have similar levels of serum iron, total iron binding capacity, and marrow iron and plasma copper levels compared with normal calves.[774] Anemic calves do not appear to have an increased incidence of disease or decreased growth rates.[775] An overall higher plane of nutrition versus iron supplementation alone produces higher packed cell volumes (PCVs) and hemoglobin levels.[774] Calves younger than 6 weeks of age have three types of hemoglobin in various amounts (adult 28%, fetal 40%, and neonatal 25%). The poikilocytosis may be a function of erythrocyte membrane defects or maturation transitions.[774]

In addition to frank blood loss from an injury, diseases causing anemia in the neonate include neonatal isoerythrolysis (NI), non-NI immune-mediated hemolytic anemia,[776] blood loss caused by gastric ulcer, anemia secondary to bone marrow necrosis, and anemia of chronic disease associated with localized infections. Hemolytic disease of newborn calves is uncommon but has occurred after vaccination of pregnant cows against anaplasmosis or babesiosis. The presence of red cell antigens in the vaccine causes the production of antierythrocyte antibody, primarily against the A and F systems.[777] Cows mated to bulls carrying these red cell antigens may have hemolytic disease develop in their A- and F-positive calves after ingestion of colostrum-containing alloantibodies.

Hemolytic disease processes produce signs of weakness, pale or jaundiced mucous membranes, fever, and depression. Blood loss produces weakness and pale mucous membranes. Intestinal parasitism does not normally lead to anemia during the neonatal period. Intravascular hemolysis may produce hemoglobinuria and hemoglobinemia. Icterus develops when the ability of the liver to conjugate bilirubin is exceeded. Mainly, indirect bilirubin is elevated. Anisocytosis is observed in responsive anemias. Nonspecific stimulation of bone marrow may produce a leukocytosis.

Anemia has also been reported in calves infected with bovine viral diarrhea virus, secondary to bone marrow necrosis.[778]

Determination of the nature of the anemia may allow specific treatment. Blood transfusion may be indicated when anemia develops rapidly or PCV drops below 14%. Associated conditions such as metabolic acidosis and hypoglycemia should be corrected. Anemia of chronic disease requires correction of the primary disease condition.

Fever

Differentials for fever in neonates include bacterial or viral infections, excitement, seizures with subsequent generation of heat by muscular overactivity, and environmentally induced hyperthermia. Fever is an unreliable indicator of sepsis in neonatal calves.[23] Septic neonates often have a normal or subnormal temperature. Older ruminants with localized infection such as in joints or bone are more likely to have fever. Fever may be beneficial. The need to administer antipyretics to the febrile neonate is controversial. Body temperatures lower than 40.8° C (105.4° F) are not considered detrimental unless they are associated with heat stroke or seizures,[779] in which case cooling and antipyretics are indicated. Because many antipyretics are antiprostaglandins that can cause deleterious GI and renal effects, these agents should be used judiciously. Correction of the initiating cause and maintaining fluid balance are also important.

Cyanosis

Cyanosis is the purple-blue coloration observed on mucous membranes or skin caused by reduced or poorly oxygenated hemoglobin in blood.[780] Cyanosis may be caused by congenital heart disease, respiratory impairment, or any circulatory condition that produces a right-to-left shunt (Box 20.4). The degree of cyanosis depends on the arterial oxygen saturation, hemoglobin concentration, pH, peripheral circulation, and temperature of the neonate.[780] Shock and hypothermia are important causes of peripheral cyanosis. The affinity of hemoglobin for oxygen is reflected in the standard oxyhemoglobin dissociation curve. This curve is similar for neonates but is affected by the amount of 2,3-diphosphoglycerate (DPG) in the erythrocyte. Calves' erythrocytes have higher levels of 2,3-DPG, but the higher levels do not affect the affinity of hemoglobin for oxygen. A separate fetal hemoglobin exists in calves to increase affinity for oxygen.[781] Severe hypothermia and acidosis cause the oxygen dissociation curve to shift to the right and therefore contribute to tissue hypoxia. Cyanosis can be either central or peripheral.[780]

BOX 20.4

Causes of Cyanosis

Cardiovascular Origin

Tetralogy of Fallot
Tricuspid atresia
Truncus arteriosus
Pentalogy of Fallot
Double outlet right ventricle
Single ventricle
Eisenmenger complex
Ventricular septal defect
Patent ductus arteriosus

Respiratory Causes

Alveolar hypoventilation
Drug-induced central nervous system (CNS) depression
CNS trauma or hemorrhage
Hypoglycemia or hypocalcemia
Altered neurologic function of spinal nerves (of respiratory muscles)
Thoracic cage abnormalities: pneumothorax, fractured ribs
Diaphragmatic hernia
Upper airway obstruction
Restrictive pleural space disorders: hemothorax, pleuritis
Hypoplastic lung

Impaired Diffusion

Pulmonary: pneumonia, edema, atelectasis
Shunting
Anatomic (congenital heart defects)
Pathologic: pulmonary hypertension
Ventilation-perfusion mismatch

VetBooks.ir

Peripheral cyanosis results from increased peripheral extraction of oxygen from normally saturated blood or a significant decrease in the perfusion to an extremity.[780] In the neonate, causes include septic shock and severe hypothermia. Central cyanosis is more common in neonates and is related to congenital heart disease that causes right-to-left shunting or severe respiratory conditions that result in hypoxia. Examination and clinical pathologic evaluation for metabolic causes of cyanosis, hypothermia, and cardiac abnormalities should be conducted. History, medication use, auscultation, thoracic radiographs, and arterial blood gases are useful in determining the degree of respiratory component to cyanosis. Echocardiography may be required for identification of cardiac anomalies.

Heart Murmur

Heart murmurs in the neonate may be heard normally before physiologic closing of the ductus arteriosus during the first 1 to 5 days of life. Other causes of murmurs include congenital anomalies, severe anemia, or infectious valvular disease. Physical examination for other signs of heart disease helps determine the severity of the murmur. Jugular pulse, weak or irregular arterial pulse, and palpable thrill indicate a serious condition. Dyspnea, cyanosis, tachypnea, and failure to gain weight are common signs of congenital heart disease in calves. Timing and location of the heart murmur should be determined. Thoracic radiography may aid in determining heart size and in detecting pulmonary edema or distended pulmonary vessels. Echocardiography may reveal atrial or ventricular enlargement, thickened ventricular walls, anomalous orientations of outflow tracts, or ventricular septal defects.

Patent ductus arteriosus (PDA) produces a continuous murmur localized over the left heart base. The diastolic component may not be heard with auscultation over other parts of the heart. As pulmonary hypertension develops, the murmur is shortened to a holosystolic type with normal arterial pulse. Large shunting of blood produces a bounding arterial pulse caused by wide fluctuations of systolic and diastolic pressures. Radiographs may reveal an enlarged heart with increased vascularity due to left-to-right shunting of blood. Echocardiography may reveal an increased left atrial and left ventricular diastolic dimension or volume and hyperdynamic septal and left ventricular wall systolic motion (depending on the degree of right-to-left shunt).

Ventricular septal defect (VSD) produces a large, harsh, holosystolic murmur that is heard loudest on the right cranial region of the thorax and is softer over the left heart base. Radiography may reveal heart size increase, left atrial enlargement, and dilated pulmonary vasculature. Two-dimensional echocardiography may show aortic and septal discontinuity. Injection of saline bubbles into the left ventricle and observation of bubbles in the right atrium or ventricle document a left-to-right shunting of blood. Tetralogy of Fallot or other types of complex malformations often produce loud murmurs and are associated with cyanosis, weakness, fatigue, and stunted growth. Tetralogy of Fallot produces a systolic ejection murmur heard at the left heart base. Echocardiography may reveal a thickened right ventricular wall, septal echo dropout in the area of the VSD, rightward displacement of the aortic root, and an abnormal pulmonary outflow region. Saline injection into the jugular vein demonstrates right-to-left flow from the right ventricle to the left ventricle or the aorta.

Icterus

Icterus is a relatively uncommon finding in neonates. It may be observed with sepsis, anorexia, liver disease, and hemolytic anemia. Liver disease in the neonate may be caused by exposure to hepatotoxins or sepsis-producing bacterial hepatitis, or it may be secondary to hypoxia. *C. perfringens* type A has been implicated in an enterotoxemic condition in nursing lambs, kids, and calves characterized by icterus, hemoglobinuria, anemia, and intravascular hemolysis.[112]

Bleeding Disorders

Bleeding disorders are relatively uncommon in calves. In 2007 a bleeding disorder characterized by trilineage hypoplasia of bone marrow was recognized in Europe. Affected calves were 1 to 4 weeks of age. A strong association between the condition and vaccination of the dam with the bovine viral diarrhea virus vaccine Pregsure was established.[782] It is believed that vaccination induced colostral alloantibody-mediated destruction of hematopoietic progenitor cells in bone marrow, causing cytopenias, including thrombocytopenia, and hence bleeding. The condition was subsequently recognized in the UK in 2009.[782] Differential diagnoses include thrombocytopenia secondary to septicemia and disseminated intravascular coagulation (DIC), Type II BVD infection, acute braken toxicity, and trichothecene mycotoxicosis.

Failure to Thrive: Cachexia and Weak Calf Syndrome

John Maas

In calves, the weak calf syndrome has been reproduced by feeding low-protein diets to prepartum cows that subsequently calved in environments in which the temperature was well below the thermoneutral zone for calves.[783] The dietary recommendation for crude protein intake for third-trimester pregnant cows and heifers is 0.9 kg (2 lb) of total crude protein per day. This is particularly important for heifers and cows calving early in the spring calving season, when temperatures well below freezing can occur. Cold rains, however, also can produce the hypothermic conditions that aid in precipitating this syndrome.

Cows weighing 450 kg (1000 lb) therefore need to consume 9.9 kg (20 lb) dry matter of good- to excellent-quality hay that is 10% or more crude protein. A quadratic equation has been developed to predict crude protein (CP) intake of the dams if their serum total proteins, urea nitrogen, and creatinine are known.[784] This equation predicts the daily crude protein intake on a continuing basis.

$$\text{Daily CP consumption (kg)} = 0.1806 + 0.04327\,(\text{BUN}) - 0.33497\,(\text{creat}) + 0.06963\,(\text{TP}) - 0.00025\,(\text{BUN})^2 + 0.06049\,(\text{creat})^2 - 0.00666\,(\text{BUN} \times \text{creat})$$

where *BUN* is blood urea nitrogen (mg/dL), *creat* is serum creatinine (mg/dL), and *TP* is serum total protein (g/dL).

Also, the use of this formula could predict CP intake for pregnant heifers and pregnant cows. This relationship may prove to have important clinical applications when weak calf syndrome or protein-calorie malnutrition is suspected and the gestation diet of the dams is not available for analysis (as under some range conditions). Supplements such as molasses licks that contain urea may tend to overestimate CP intake.[785]

Colostrum and Milk Replacers

SANDRA GODDEN and ROBERT E. JAMES, *Consulting Editors*

MAJOR CLINICAL SIGNS OR PROBLEMS ENCOUNTERED

Colostrum supplements and replacements, 382

Milk replacers, 387

The goals of colostrum and milk feeding programs for preweaned calves and small ruminants are to achieve optimal rates of gain, support and develop a strong immune system, maximize health, and stimulate ruminal development, all in a cost-effective manner. Although feeding high-quality, clean maternal colostrum and whole milk may be considered by many to be gold standards, the use of high-quality colostrum replacement products and milk replacers may be attractive to producers for a variety of reasons, including consistency, convenience, as a means of breaking the transmission cycle of some infectious diseases, or simply to capture economic efficiencies. This chapter reviews important considerations in the manufacture, selection, and use of high-quality colostrum replacement and milk replacer products.

Colostrum Supplements and Replacements

The principles of colostrum management are reviewed in Chapter 19. Although feeding 3 to 4 L of clean, high-quality maternal colostrum shortly after birth remains the gold standard, farms can experience periods when an adequate supply of high-quality fresh or stored maternal colostrum is not available. Also, it may not always be practical or convenient to harvest first milking colostrum from fresh cows within a timely manner after calving (<1 to 2 hours). Contributing to this shortage, some producers may discard colostrum from cows that test positive to such pathogens as *Mycobacterium avium* subsp. *paratuberculosis* or *Mycoplasma bovis*.[1-3] Under such circumstances, feeding commercially available colostrum replacement (CR) products may offer a simple, consistent, and convenient means of delivering the necessary immunoglobulins (Ig) to newborn calves while reducing the risk of pathogen exposure. In addition, if cowside testing indicates lower-than-desirable colostrum quality (e.g., colostrum IgG <50 g/L, as indicated by Brix refractometer reading <22%),[4] then supplementing maternal colostrum feeding with a colostrum supplement (CS) may be beneficial; however, the optimal protocols and efficacy of this strategy require further study. This chapter section discusses types of CS and CR products, manufacture and licensing, evaluating product efficacy, impact of Ig source on antibody profiles, monitoring passive transfer, and use of CR or CS products in minor species. Although some studies have demonstrated that supplementation of the milk diet with Ig from either maternal colostrum or CS may reduce the severity of rotavirus or coronavirus scours occurring during the first 14 days,[5-7] the current discussion is limited to use of CS and CR products in the first 24 hours after birth.

Colostrum Supplements Versus Colostrum Replacements

Colostrum supplements, which typically cost between $13 and $19 USD per package, are designed to provide exogenous IgG to calves to supplement low-volume or poor-quality maternal colostrum (colostral IgG <50 g/L).[8] Most CS products provide between 25 and 60 g of IgG per package. Feeding one package (packet) of a CS will not provide a sufficient mass of IgG to prevent failure of passive transfer (FPT) in young calves, nor will it provide sufficient levels of nutrients necessary for calf survival or optimum growth.[8,9] By comparison, CR products, which typically cost between $26 and $40 USD per package, are designed to be fed instead of maternal colostrum. They should provide a minimum of 100 g of IgG per package and should also provide sufficient levels of nutrients to the calf to support metabolic needs in the first day of life. It should be noted that feeding multiple packages of some CS products can achieve the same result. For example, HeadStart®/Calf's Choice Total® Gold CS in a 60-g IgG package is licensed as a CR product for prevention of FPT when fed at 180-g IgG (3 packs) in the United States or at 2 packs in Canada. However, it can also be used as a supplement if producers elect to feed fewer packages. Some CR products are also labeled with directions for feeding lesser amounts to supplement rather than replace maternal colostrum. It is recommended that CS or CR products be mixed in water, according to the manufacturer's directions, and fed in conjunction with any available high-quality colostrum.[10]

VetBooks.ir

Manufacturing

Immunoglobulins in commercial CR and CS products are most often derived from spray-dried bovine colostrum or spray-dried bovine serum or plasma. For colostrum-derived CR products, sometimes referred to as lacteal derived, fresh frozen bovine colostrum is collected from Grade A dairies and assembled at a manufacturing plant where it undergoes pooling, heat treatment or irradiation, spray drying, testing for IgG concentration, and packaging. Immunoglobulins may also be sourced from milk or whey for some products not licensed by the Center for Veterinary Biologics (CVB). For colostrum-derived products, the concentrations of most non-Ig colostral components (e.g., nutrients, hormones, growth factors), with the exception of cellular fractions (i.e., leukocytes, bacteria), should be similar to maternal colostrum unless the colostrum has been fully or partially defatted and/or casein and other whey proteins have been removed to enhance the proportion of IgG in the final product.

For serum-derived CR or CS products, blood is collected from abattoirs under U.S. Department of Agriculture (USDA) inspection, centrifuged to separate plasma and/or serum from red blood cells, ultrafiltered, spray dried to produce a concentrated powder containing approximately 20% Ig, and then mixed with other ingredients (e.g., lactose, dry fat blend consisting of animal and/or vegetable fats, dextrose, vitamin and mineral premix). Because fat is entirely supplemented, crude fat concentrations will vary among CS products, with low levels (<10%) in some products. Serum-derived products will contain some of the same bioactive compounds as colostrum, since many are derived originally from serum (e.g., insulin-like growth factor 1 [IGF-1], trypsin inhibitor), but may have reduced or nondetectable concentrations of other bioactive compounds found in maternal colostrum (e.g., lactoferrin). The final product may be irradiated. Exact manufacturing methods vary among manufacturers and products.

Is the Colostrum Replacer or Colostrum Supplement Licensed?

Licensed CR products are allowed the following label claim: "to aid in the treatment of failure of passive transfer (FPT)." In Canada it is required that all CR and CS products be licensed through the Canadian Food Inspection Agency (CFIA), Canadian Center for Veterinary Biologics (CCVB, Ottawa, Ont.).[11] Serum- and plasma-derived CR or CS products are not permitted in Canada. In the United States only some manufacturers have acquired a license for certain CR products through the USDA CVB (Ames, Iowa). The IgG in licensed CR products must come from bovine colostrum collected from Grade A dairies and be processed by heat treatment or ionizing radiation using accepted protocols, and every serial release (batch) made for sale and distribution must be tested for purity and potency at a minimum.[12,13] Data on product (efficacy, safety, purity, and potency) must be submitted to and reviewed by the CFIA or USDA before licensing. Purity requirements allow a specified total bacteria and fungi count. However, coliforms and *Salmonella* spp. must not be present. Potency tests require a minimum IgG content for products with an FPT claim. In the United States efficacy testing for licensed FPT products requires that, in 90% of animals, the increase in IgG concentration (pretreatment vs 24 hours posttreatment) must be at least equal to concentration of the IgG Species Standard approved by the USDA's Animal and Plant Health Inspection Service (APHIS) (e.g., approximately ≥10 to 11 g/L serum IgG for neonatal calves) (USDA: 9 CFR 113.450; 9 CFR 113.499).[12] Also, the overseeing regulatory body completes an approximately annual site inspection to review processes and records. As such, licensed products can guarantee safety, potency, purity, efficacy, and traceability. Products licensed by regulatory agencies as bovine IgG for treatment of FPT may not claim nutrient profiles on the label, so this information must be obtained from manufacturers' promotional materials. Table 21.1 lists licensed products currently available in Canada and the United States.

Although products that do not have a USDA CVB license are not legally able to claim to supply IgG or to purport to be used for the prevention of FPT, their use for this purpose is widespread in the United States. Bovine colostrum and dried bovine colostrum are official feed ingredients under the Association of American Feed Control Officials (AAFCO) guidelines (www.aafco.org). As such, claims for nonlicensed CR or CS products must adhere to nutrition-based claims but can make no immunity claims. Under AAFCO guidelines, every state (i.e., state Department of Agriculture) adopts and regulates its own animal feed per its applicable laws and regulations relating to label specifications or guaranteed analysis. Although all U.S. manufacturers of non–CVB-licensed CR and CS products will conduct some kind of internal quality control testing, the design of these programs are at the manufacturer's discretion. External product testing or plant inspections by regulatory authorities (e.g., state Department of Agriculture) are not typically completed for non–CVB-licensed products unless a problem or complaint is brought to their attention.

Evaluating the Efficacy of Colostrum Replacement Products

Producers are strongly encouraged to consult their veterinarian and to select CR or CS products that have undergone independent evaluation of efficacy in controlled field studies. Evaluation of efficacy should ideally consider passive transfer of adequate IgG, nutritional support, and calf health and performance. In addition to the age of the calf at time of feeding, passive transfer of IgG will be determined primarily by the mass of IgG (g) administered as well as the apparent efficiency of absorption (AEA %) of the IgG; AEA % is a calculated estimate of the percentage of IgG administered that is absorbed systemically.[14] Each product must be independently evaluated, since differences in manufacturing processes can have a significant impact on both AEA % and final mass of IgG in a package.[14,15] Head-to-head studies are necessary to make valid comparisons between products. Table 21.2 presents the results of field efficacy studies for commercially available CR and CS products that were mixed and fed according to label directions.

MASS OF IGG PROVIDED IN COLOSTRUM REPLACEMENTS.

Although experts originally estimated that producers should feed a minimum mass of 100 g of IgG in the first colostrum feeding, and this has been demonstrated to be sufficient under ideal conditions, most recent studies, especially if conducted under field conditions, have shown that at least 150 g, and preferably 200 g, of colostral IgG must be fed to consistently achieve acceptable passive transfer (APT; serum IgG ≥10 g/L) in the majority (≥90%) of calves.[16-19] This dose effect was demonstrated in one study wherein three groups of calves fed either 100 g or 200 g of IgG in a colostrum-derived CR product or 3.8 L of fresh maternal colostrum achieved a mean serum IgG concentration at 24 hours of 9.6 g/L (46% with FPT), 19.0 g/L (0% with FPT), and 20.7 g/L (9% with FPT), respectively (see Table 21.2).[19] Although many CR products are packaged to provide 100 to 130 g IgG per pack, some CR products now provide a larger mass of IgG per pack (e.g., 150 g) and/or provide label directions that suggest feeding increased masses of IgG, at the discretion of the producer.

APPARENT EFFICIENCY OF ABSORPTION (AEA %) OF IGG.

When considering how APT can be achieved in calves, grams of IgG should be considered more important than absorption percentages. Under most circumstances, the *total mass* (g) of

Land O' Lakes COLOSTRUM REPLACEMENT	Manufacturer: SCCL (Sask., CA) Distributor: Land O' Lakes (Minn., US)	US	100 g in 470-g pack
COLOSTRUM PLUS 100 with *Escherichia coli* Antibody	Manufacturer & Distributor: La Belle Associates (Wash., US)	CA US	100 g in 500-g pack
COLOSTRX CR Colostrum Replacer	Manufacturer: La Belle Associates (Wash., US) Distributor: AgriLabs (Mont., US)	US	100 g in 500-g pack
PREMOLAC PLUS Colostrum Replacement	Manufacturer: Zinpro Corp. (Minn., US) Distributor: Milk Products (Wis., US)	US	152 g in 375-g pack
Land O' Lakes COLOSTRUM REPLACEMENT for Kid Goats & Lambs	Manufacturer: SCCL (Sask., CA) Distributor: Land O' Lakes (Minn., US)	US	50 g in 235-g pack
HeadStart Hi-Cal for Lamb & Goat Kids	Manufacturer and Distributor: SCCL (Sask., CA)	CA	100 g in 700-g pack
LambGRO/KidGRO Colostrum	Manufacturer: SCCL (Sask., CA) Distributor: Grober Nutrition (Ont., CA)	CA	100 g in 700-g pack
PureStart Colostrum for organic use	Manufacturer: SCCL (Sask., CA) Distributor: Alta Genetics (Wis., US)	US	100 g in 700-g pack
Colostrum Supplement Products			
Supplement 57	Manufacturer: SCCL (Sask., CA) Distributor: MWI Animal Health (Idaho, US)	US	57.5 g in 320-g pack
CALF'S CHOICE TOTAL Gold	Manufacturer: SCCL (Sask., CA) Distributor: Alta Genetics (Wis., US)	US	60 g in 225-g pack
HeadStart	Manufacturer & Distributor: SCCL (Sask., CA)	CA	60 g in 225-g pack
COLOSTRX CR Colostrum Supplement	Manufacturer: La Belle Associates (Wash., US) Distributor: AgriLabs (Mont., US)	US	50 g in 300-g pack
Colostro	Manufacturer: SCCL (Sask., CA) Distributor: Federated Coop (Sask., CA)	CA	50 g in 235-g pack
Bovine Dried Colostrum	Manufacturer & Distributor: SCCL (Sask., CA)	CA	50 g in 350-g pack
FIRST COLOSTRUM 50 Colostrum Supplement	Manufacturer: La Belle Associates (Wash., US)	CA US	50 g in 350-g pack
Immu-Start 50 with *Escherichia coli* Antibody	Manufacturer: Imu-Tek Animal Health (Colo., US)	CA US	50 g in 400-g pack
Just Like Mom	Manufacturer: SCCL (Sask., CA) Distributor: Aspen Veterinary Resources (Mont., US)	US	50 g in 300-g pack

[a]Product list may change in future. Specifications may change in future; read the label. Licensing bodies: Canadian Center for Veterinary Biologics, Canadian Food Inspection Agency[11]; Center for Veterinary Biologics, U.S. Department of Agriculture.[62] IgG source for all licensed products is bovine colostrum.

IgG, Immunoglobulin G.

IgG fed and the *age of the calf* at feeding are the most important predictors of APT in calves fed CR products. That said, simply examining the mass of IgG provided by the CR is not an adequate predictor of product efficacy.[20] There can be significant differences in AEA % among products due, but not limited, to such factors as manufacturing methods and IgG concentration after reconstitution, as well as inclusion of other nutrients or additives in the product. Controlled field studies using commercially available CR or CS products, mixed and fed according to label directions, have reported widely varying AEA % values (see Table 21.2). The AEA % reported for CS products has ranged between 16% and 28%.[21,22] The AEA % reported for CR products has ranged between 14% and 51%.[19,23-30] In comparison, the AEA % of IgG reported for calves fed 3 to 4 L of fresh maternal colostrum within 6 hours of birth has ranged between 21% and 36%.[19,21,22,28,30]

Studies to date have generally reported the AEA % to be significantly higher for colostrum-derived CR products compared to serum- or plasma-derived CR products. In one early CS study in which calves were fed two packs of a colostrum-derived CS (50 g IgG), two packs of one of two different serum-derived CS products (60 g or 90 g Ig, respectively), or 3.8 L of maternal colostrum, the AEA % reported for the colostrum-derived CS (16%) was inferior to that of the two serum-derived CS products (24% and 28%) and the maternal colostrum (22%) (see Table 21.2).[21] However, because all three CS products delivered an

insufficient mass of IgG compared to maternal colostrum, all three CS products failed to provide APT to calves.

To date, three head-to-head controlled field studies have compared the AEA % of commercially available serum-derived and colostrum-derived CR products. In one study calves fed 150 g of a colostrum-derived CR had significantly improved AEA % and serum IgG concentrations (AEA % 38.2%, serum IgG 14.7 g/L) compared to calves fed 130 g of a serum-derived CR (AEA % 28.4%, serum IgG 9.6 g/L) (see Table 21.2).[27] In this study the improved final serum IgG values for the colostrum-derived CR group were attributed to both increased mass fed (g) and improved AEA %. In another study calves fed 150 g of a serum-derived CR had inferior AEA % (21.6%) compared to calves fed 100 g of a colostrum-derived CR (38.8%).[31] In a third recent, randomized controlled study, newborn calves fed 150 g of Ig from a serum-derived CR product had significantly lower serum IgG at 24 hours (median 9.3 g/L, range 6.8 to 12.3 g/L) compared to calves that received 150 g of IgG from a colostrum-based CR product (median 13.8 g/L, range 12.4 to 19.4 g/L).[32] Based on the present body of research, it appears that a higher total mass of Ig needs to be fed if using serum-derived CR products to achieve the same final serum IgG concentration that is achieved by feeding colostrum-derived CR products.

PASSIVE TRANSFER LEVELS, HEALTH, AND PERFORMANCE OF CALVES FED COMMERCIAL CS OR CR PRODUCTS. If given alone as a single package, CS products (given the lower mass of IgG delivered) will result in significantly lower serum IgG concentrations and a high risk of FPT in calves as compared to feeding 3 to 4 L of maternal colostrum (see Table 21.2).[20-22,33,34] Furthermore, there is no added benefit to feeding a CS if calves are fed 3 to 4 L of high-quality maternal colostrum.[35,36] Although an opportunity may exist for producers doing on-farm testing of colostrum using such instruments as the Brix refractometer for the purpose of supplementing poor-quality colostrum with a CS, the effectiveness of this strategy requires further study.[4,37] Several commercially available CR products, when administered at a high enough IgG mass (150 to 200 g IgG) within a few hours after birth, can provide acceptable to very good serum IgG concentrations and APT rates in calves (goal: ≥90% of calves with serum IgG ≥10 g/L) (see Table 21.2).[19,24-27,29,30,34,38] However, unless fed under ideal management conditions,[23] low APT rates are achieved if an insufficient mass of Ig (<150 g) is fed in either maternal colostrum or a CR product.[19,23,27,28]

Studies comparing the health of calves fed CR or maternal colostrum have reported equivocal results, with between-study differences likely attributable in large part to significant differences in the mass of Ig provided in the CR versus maternal colostrum treatment groups. In one early study of 457 calves on 12 Upper Midwest dairy farms, there was no significant difference in morbidity or mortality in 218 calves assigned one package of a serum-derived CR product providing 125 g of Ig, compared to 239 calves fed 3.8 L of fresh maternal colostrum, despite the fact that the CR group had lower serum IgG concentrations and higher FPT rates than the calves fed maternal colostrum (see Table 21.2).[39] In a study conducted by Pithua and colleagues, calves fed the CR product at birth were at reduced risk to test positive for infection with *M. avium* subsp. *paratuberculosis* as adults (7.6% test positive; odds ratio 0.52 [0.27 to 1.003]), compared to control calves fed maternal colostrum (11.9% test positive), demonstrating that CR products may be a useful management tool for dairy herds attempting to reduce the prevalence of Johne's disease.[40] In addition, Pithua and colleagues determined that the colostrum treatment group had no significant effect on longevity, milk production, or reproductive performance during the first three lactations.[41] In a different study of 147 calves at a Florida dairy, the percentage of calves with FPT, preweaning morbidity rates, and preweaning mortality rates for 49 calves fed 150 g of a plasma-derived CR were as follows: FPT 71%, morbidity 71.4%, and mortality 16.3%. For 49 calves fed 100 g of a colostrum-derived CR, these rates were FPT 51%, morbidity 67.3%, and mortality 24.5%. For the remaining 49 calves fed 3.8 L of maternal colostrum, with average IgG intake estimated to be 190 g, these rates were FPT 8%, morbidity 46.9%, and mortality 8.2%.[31] The authors concluded that, under the conditions of the study, maternal colostrum was superior to CR, primarily due to an insufficient mass of Ig fed in the CR groups.

Conversely, two more recent studies that fed higher levels of colostrum-derived CR products reported similar or improved health in CR-fed calves compared to calves fed maternal colostrum. In a study of 1220 Jersey and Jersey-Holstein calves born at one California dairy, calves fed 150 g of IgG from a colostrum-derived CR product had lower, but still acceptable, mean blood IgG and serum total protein (STP) concentrations (IgG 19.6 g/L, STP 5.16 g/dL) compared to calves fed 2.8 L of maternal colostrum (IgG 23.4 g/L, STP 5.84 g/dL).[38] Evaluating STP to classify calves as APT or FPT is discussed in detail later in this chapter. In that study, the preweaning risk for treatment for scours (CR 85.8%, maternal colostrum 89.0%), risk for treatment for pneumonia (CR 55.2%, maternal colostrum 58.6%), and risk for death (CR 9.4%, maternal colostrum 7.1%) were not different between treatments, although CR-fed calves were 1.5 kg lighter at weaning (CR 47.1 kg, maternal colostrum 48.6 kg).[38]

A second randomized controlled study of 568 calves at another California dairy reported higher serum IgG concentrations and improved health and growth in calves fed 200 g of IgG in a colostrum-derived CR at birth (serum IgG 15.2 g/L, scours 15.9%, weaning weight 58.9 kg) compared to calves fed 3.8 L of maternal colostrum (serum IgG 7.5 g/L, scours 24.5%, weaning weight 57 kg) ($P < 0.05$).[42] In this second study CR was superior to maternal colostrum, but this was most likely attributable to the fact that the calves fed maternal colostrum were fed very poor-quality maternal colostrum, averaging only 21 g/L of IgG (average dose: 78 g IgG) (see Table 21.2).[30,42] Clearly, if producers hope for CR-fed calves to match or exceed the health and performance of calves fed 3 to 4 L of high-quality maternal colostrum, they will need to feed a sufficiently high mass of Ig from the CR—at least 150 g and preferably 200 g.

Does Ig Source Affect the Antibody Profile in CR or CS Products?

Veterinarians frequently ask if the antigen-specific antibody profile in CR products will complement the antigen profile on their clients' dairy farms. Because the colostrum used to manufacture CVB-licensed colostrum-derived CR or CS products is collected from cows living on commercial North American Grade A dairy farms, these authors consider it a safe assumption that the cows will have been exposed to, and therefore produce colostral antibodies against, most of the common pathogens endemic on most commercial dairies (e.g., *Escherichia coli*, rotavirus, coronavirus, *Cryptosporidium* spp.), whether achieved through natural exposure and/or through vaccination programs. However, published studies to verify this hypothesis are extremely limited for colostrum-derived CR products and lacking entirely for serum-derived CR products. One recent Alabama field study reported that calves fed 200 g IgG of a colostrum-derived CR had greater levels of bovine viral diarrhea virus (BVDV)–neutralizing antibodies in serum, and similar levels of antibodies to bovine herpesvirus 1 (BHV-1), bovine respiratory syncytial virus (BRSV), and parainfluenza type 3 virus (PI3V) in serum, as compared to calves fed 3.8 L of maternal colostrum.[43] Additional studies are needed to describe antigen-specific antibody concentrations,

particularly to enteric pathogens, found in calves fed CR or CS products.

Another frequent question relates to whether the antibody profile in colostrum-derived CR products is superior to that in serum-derived products. Although the concentrations of the subclasses IgG1 and IgG2 are approximately equal in serum (50:50 ratio, or 50% IgG1), IgG1 naturally occurs in much higher concentrations than IgG2 in colostrum (7:1 ratio, or approximately 90% IgG1) due to the selective transfer of IgG1 into the mammary secretions of cows.[44-46] Immunoglobulin G is the main class of Ig secreted into the bovine intestinal tract.[47-49] Furthermore, IgG1 is the predominant Ig subclass secreted into the bovine intestinal tract, lungs, nasal secretions, vaginal secretions, and saliva.[50-52] Secretion of serum IgG1 rotavirus immunoglobulin into the intestinal lumen, if in sufficient quantity, provides protection against rotavirus infection.[47,49,50,53-55] In a review of this topic, Thornsberry and Wood (2011) stressed the importance of newborn calves consuming a sufficient mass of IgG1 prior to closure of intestinal absorption of Ig molecules.[14] All else being equal, one could theorize that the increased proportion of IgG1 found in colostrum-derived CR products (90% IgG1) should result in improved calf health, as compared to serum-derived CR products (50% IgG1). Ellis and colleagues reported higher levels of IgG1 BRSV-specific antibodies in the nasal secretions of calves fed equal IgG mass (150 g IgG) of a colostrum-based CR compared to calves fed a serum-based CR product.[32] It has been argued that the relative content of IgG1 in a CR may be immaterial for consideration (provided that a sufficient total mass of IgG is provided) because studies have demonstrated that both colostrum- and serum-derived CR can achieve desired goals of calf production.[14] Further research on the health implications of calves fed serum-based CR versus colostrum is needed.

Monitoring Passive Transfer Rates When Feeding CR or CS Products

Measurement of STP by handheld refractometer offers a simple, rapid, and inexpensive method by which producers can monitor the colostrum program when feeding maternal colostrum. However, producers must be cautious if trying to use STP measures to monitor passive transfer rates in groups of calves fed CR or CS products, since the proportions of IgG and non-IgG proteins can be different than in maternal colostrum. For calves fed maternal colostrum, it is well established that STP test end points of 5.0 or 5.2 g/dL most accurately predict APT (serum IgG ≥10.0 g/L, sensitivity >0.80, specificity >0.80, proportion classified correctly >0.85).[56,57] However, these same STP cut-points are not necessarily accurate predictors of APT when feeding a CR or CS. Three studies of calves fed colostrum-derived CR products have reported that, similar to maternal colostrum, an STP cut-point of 5.0 or 5.2 g/dL most accurately predicts APT.[27,30,31] However, a significant association was not found between STP and serum IgG in one study wherein calves were fed a colostrum-derived CS product.[34] For serum-derived CS or CR products, the relationship between STP and serum IgG in calves may vary dramatically among products, depending on the source, level of inclusion, and/or degree of absorption of non-Ig proteins. Studies of different serum-derived CS or CR formulations have reported widely varying STP cut-points ranging between 4.2 and 5.6 g/dL.[15,27,31,59,58] Given the large variation in predicted STP cut-points, and particularly for the serum-derived CR products, veterinarians are encouraged to use refractometry to monitor the effectiveness of a CR feeding program only if independent studies are available describing the relationship between STP and serum IgG for the specific commercial CR product in use on the farm. If such studies are not available, veterinarians are advised to periodically submit frozen serum samples for serum IgG analysis using direct methods such as radial immunodiffusion or turbidimetric immunoassay.[56,59,60]

Use of Colostrum Supplements or Replacements for Organic Producers or Minor Species

While most CS and CR products target calves, products also exist for minor species, including goat kids, lambs, foals, llama or alpaca cria, pigs, fawns, and elk calves (see Table 21.1). Although many products available for minor species are not licensed, CVB-licensed products do exist for goat kids and lambs, meeting CFIA and USDA standards guaranteeing purity, potency, safety, efficacy, and traceability (see Table 21.1).[61] Because the dose of IgG required for multispecies CR or CS products will vary by species, producers should follow individual product label directions for feeding. Currently one CVB-approved CR product, PureStart™ Colostrum (Manufacturer: SCCL; Distributor: Alta Genetics), is approved for use on organic dairy farms in the United States (see Table 21.1).

Summary

High-quality CR products can offer a consistent and convenient source of Ig and nutrients for newborn calves when clean, high-quality maternal colostrum is not available, plus they may be a useful management tool to help break the transmission cycle of some infectious diseases (e.g., Johne's disease). Additional controlled field studies are needed to further describe and compare efficacy among various CR products and particularly to describe the effects of feeding CR on short- and long-term health and performance outcomes. However, studies conducted to date demonstrate that when fed a large enough dose (150 to 200 g IgG) of a high-quality CR product within a short period of time after birth, calves can achieve passive transfer levels and health outcomes at least equal to those of calves fed fresh maternal colostrum. Given the significant differences in quality and efficacy among various commercially available products, producers may want to consider whether a product is CVB licensed and are strongly encouraged to select CR or CS products that have demonstrated efficacy in independently conducted controlled field studies.

Milk Replacers

The digestive anatomy of the newborn calf consists of a four-compartment stomach like the adult stomach, but the abomasum predominates with 60% of the total stomach capacity. During the first weeks of life the calf is essentially monogastric as milk is shunted directly to the abomasum by closure of the esophageal groove. Closure is stimulated as a behavioral response associated with milk feeding by bottle or bucket. During this time the calf depends on the consumption of highly digestible nutrients provided by food-grade feedstuffs, as it depends on enzymatic digestion of proteins, fat, and simple sugars in the form of lactose. The consumption of limited quantities of dry feed along with free-choice water stimulates rapid colonization of the stomach with ruminal microorganisms and rapid differential growth of the stomach tissue, which enables it to digest more complex carbohydrates and vegetable proteins. The impact of diet on rumen development is depicted by Heinrichs.[63]

There are multiple goals in feeding the preweaned calf, which requires a degree of compromise. Ultimately the goal should be to provide the environment and nutrient supply that enable the calf to achieve its genetic growth potential with minimal health problems at a reasonable cost. There are different philosophies as to what constitutes a successful calf-rearing program. A goal favored in more traditional programs has been limit feeding of the liquid diet to encourage dry feed intake and encourage early weaning. This practice reduces daily feed costs during the preweaning period, and there has been the perception that digestive disturbances could be substantially reduced by transitioning the calf to a dry diet as soon as possible. This

feeding program frequently provides only enough energy from the liquid diet to meet maintenance requirements under thermoneutral conditions, with enough remaining to support only very modest growth. This is especially true during the first weeks of life when calves consume negligible amounts of calf starter grain. More recent research supports calf feeding programs that provide nutrients to encourage more biologically normal growth rates of 700 to 1000 g/day during the preweaning period. These programs cost more per day but frequently result in lower costs per unit of gain. Higher protein and energy intake results in lower morbidity and mortality in dairy calves, particularly during the winter months.[64] Ultimately the goal for the milk feeding program should be to foster the growth of the animal, which results in the most economical lifetime performance rather than the lowest daily rearing cost during the preweaning period. Recently, Soberon and Van Amburgh demonstrated that enhanced feeding programs providing 28% crude protein and 0.3 Mcal of metabolizable energy/kg of body weight (4.2 to 8.4 Mcal/day) compared to those providing only 2.8 Mcal/day resulted in greater mammary secretory tissue in young heifer calves.[65]

Liquid Diets for the Dairy Calf

Calves can grow well on whole milk, waste milk, or milk replacers. Although the most recent National Animal Health Monitory System (NAHMS)[66] survey indicates that more than 50% of calves are fed milk replacer, there is increased interest in the use of waste milk for calves, particularly on larger farms that pasteurize it prior to feeding to reduce risk of disease. Pasteurized waste milk has been viewed as a means of increasing nutrient intake and reducing feed cost. However, the manager must be aware of the challenges involved in these feeding systems, which include monitoring efficacy of the pasteurizer and milk solids level and accounting for variation in supply.[67,68]

Milk replacers were first developed in the early 1950s with the goal of reducing costs and increasing the convenience of feeding dairy calves. These milk replacers resembled gruels and frequently resulted in poor calf performance. The challenge in using milk replacers is to provide sufficient nutrients to encourage acceptable growth at less cost than feeding whole milk. Table 21.3 compares the nutrient content of 4 L of average-quality whole milk and 4 L of a typical 20% protein–to–20% fat milk replacer diluted to approximately 12.5% solids. These milk replacers fed in the limited amounts shown here allow for lower daily feed costs and encourage early starter intake but at reduced rates of gain and possibly impaired health. More recent research has been directed toward achieving gains closer to those of whole milk feeding programs. The quality of milk replacers and expected performance is influenced by the ingredients used and manufacturing practices and quality control.

Ingredients Used in Milk Replacers

Ingredients used in milk replacers providing the protein, fat, carbohydrate, and minerals should be of high digestibility and low bacteria count for the young calf. Traditionally these ingredients originate as products from the processing of milk, as shown in Fig. 21.1. The skim milk and cream portions, although highly desirable, are generally too expensive to be considered in milk replacer manufacture.

TABLE 21.3

Comparison of Four Liters of Whole Milk to Four Liters of a 20:20 Milk Replacer Diluted to 12.5% Solids

Parameter	Whole Milk	20:20 Milk Replacer

PROTEIN SOURCES. Common proteins used in the manufacture of milk replacers can be classified as either milk or alternative proteins. Most milk-derived proteins used in milk replacers have originated from the whey fraction. Whey can be processed through evaporation or filtration to separate the lactose and minerals from whey proteins to yield ingredients commonly used in milk replacers. The nutrient value of these different fractions is shown in Table 21.4.

Many feeding trials have evaluated the nutritional value of different protein sources on calf growth, health, and feed efficiency. Variation in nutrient content and digestibility of whey proteins is due to the type of cheese being manufactured and the efficacy of the different processes used. Special care must be taken during the drying process to prevent denaturation of the protein. Digestibility of whey-based ingredients generally exceeds 85% and more commonly exceeds 90%. One concern with the use of whey-based proteins is that, unlike casein in skim milk protein, these proteins do not form a clot in the abomasum shortly after being consumed. It seems that the failure to clot would impair protein digestion and use by the calf. However, Terosky and colleagues[72] formulated milk replacer diets containing 0%, 33%, 67%, and 100% replacement of skim milk protein with whey protein concentrate. During the 8-week experiment, daily gains were similar, although calves in which 100% of the protein was from whey protein concentrate experienced a slightly lower incidence of scouring.

The value of whey protein concentrate has fluctuated considerably from approximately $0.34/lb in 1985 to as much as $1.50/lb in 2012 followed by a drop to $0.72/lb in early 2018. Although whey prices have fluctuated over the years, it is apparent that whey proteins will continue to find favor in the human health food market. As a result, the use of alternative proteins in calf milk replacers continues to be an active field of research. The nutritional content of milk-derived and alternative ingredients found in milk replacers is shown in Table 21.4. There are two major concerns with the use of alternative proteins. One is the digestibility by the calf, particularly for the calf less than 2 weeks of age. Research on the alternative proteins has shown a wide range in digestibility of these proteins from as low as 54% to more than 90%. Variation is due to the processing and the age of the calf receiving the liquid diet. Soy proteins probably offer the greatest promise. Untreated soybean protein is strongly antigenic, causing infiltration of the lamina propria of the small intestine with T and B lymphocytes, hypersensitivity reactions, villous atrophy, and decreased intestinal absorptive ability.[73] Soybeans are treated to remove the fat and all or part of the carbohydrate and reduce these antigenic properties. Soy flour represents the least processing, whereas isolated soy protein results from extensive processing with an alkali wash, acid precipitation, alkali resolubilization, and drying. Tomkins and colleagues[71] noted that feed conversion by calves 1 to 14 days of age fed soy protein concentrate containing milk replacers was reduced by as much as 30%. However, more recent research has shown improved responses. Unfortunately, due to extensive processing, the cost of isolated soy protein is not always economically feasible.

Wheat gluten is protein derived from wet milling of wheat after separation of the starch. The protein is rather insoluble and has antigenic properties that cause reactions by intestinal tissue. However, acid treatment to partially hydrolyze the wheat protein increases its solubility and reduces antigenicity. Although the digestibility of wheat gluten is comparable to that of whey proteins, it is deficient in lysine. Wheat gluten proteins have found wide use in veal-type diets, but research has shown that growth in replacement heifers less than 14 days of age may be depressed. At higher rates of feeding in younger calves, the depression in average daily gain becomes ever more evident.[73]

Animal plasma proteins from porcine or bovine blood have been used in milk replacers. The protein has an excellent amino acid profile that compares well with skim milk protein.[74,75] Calves fed milk replacers in which 25% of the whey proteins had been replaced with plasma proteins were found to grow at a slightly lower rate during the first 28 days; however, growth rates were similar over a 56-day feeding period.[74,75]

Spray-dried whole egg is an undesirable alternative protein in milk replacers, as incorporation at levels above 5% of the total dry matter result in reduced rates of calf growth.[76]

Other proteins—including pea, lupine, potato, fish, red blood cells, meat solubles, yeast, and bacterial proteins—have shown be unacceptable sources of protein for milk replacers due to poor solubility, low digestibility, or inadequate amino acid content.[77]

Supplementation of plasma protein with isoleucine and threonine[78] and vegetable protein-based milk replacers with lysine and methionine may have merit.[79,80] At present, there are no data to support supplementation of milk protein–based milk replacers with amino acids.

CARBOHYDRATES. During the first weeks of life, the intestine of the young calf has limited carbohydrase activity except for lactase. The only carbohydrates usable in large amounts are lactose, glucose, and galactose. Lactose from whey is the main carbohydrate source in milk replacers. Whole milk contains approximately 29% lactose, 29% fat, 20% casein, 5% whey protein, and 5% ash on a dry matter basis. The most popular milk replacers containing 20% protein and 20% fat

VetBooks.ir

have substantial space for the addition of more lactose than is present in whole milk, given that high levels of ash are undesirable. Consumption of higher amounts of lactose from milk replacer than might be present in whole milk does not appear to be a concern.[70] The inclusion of starch and other carbohydrates in milk replacers is not advised for calves younger than 2 to 3 weeks of age due to limited amylase and maltase activity. Toullec and colleagues[81] suggest a limit of 2% to 3% starch in dry matter intake for younger calves.

LIPIDS. Milk fat is highly digestible; however, it is too expensive to be included in milk replacers. Tallow, lard, choice white grease, and coconut and palm oil are the primary sources of fat used in milk replacers. A comparison of the fatty acid composition of a tallow-based milk replacer with that of one based on coconut oil to whole milk is shown in Table 21.5. Although digestibility of tallow and lard is somewhat lower than milk fat, performance is adequate. In general, highly unsaturated vegetable oils are poorly tolerated by the young calf.

Two fat sources that have been used are palm and coconut oil. These fats are higher in medium chain fatty acids found in milk fat. Mills and colleagues[82] studied the effect of adding medium chain fatty acids at a rate of 32% of the fat as coconut oil or oil high in caprylate. No differences were found in body composition, intake, or fecal score between the animal fat–based milk replacer or coconut oil treatments. Empty body fat was about 5% higher, and livers in heifers fed coconut oil contained 15% more fat than those in heifers fed animal fat. Hill and colleagues[83,84] replaced part of the animal fat in a milk replacer with low levels of coconut oil or blends of coconut and canola oil and found higher average daily gains and less scouring than calves fed diets with only animal fat. The formulation of milk replacers with special attention to fatty acid composition is an active field of research.

VITAMINS AND MINERALS. Vitamins and minerals are generally added to milk replacers to provide levels similar to those found in whole milk. The most recent (seventh) edition of *Nutrient Requirements of Dairy* Cattle (NRC)[85] recommended a substantial increase in vitamin A from 4000 to 9000 IU/kg of dry matter. Vitamin E recommendation was increased from 40 to 50 IU/kg of milk replacer dry matter. These levels are sufficient to prevent deficiencies under stressful conditions of digestive or respiratory disease and to avoid a toxic response with higher levels of milk replacer observed with more intensive feeding programs. Recommended vitamin D is 600 IU/kg of dry matter. Water-soluble vitamin and trace mineral recommendations are described in the seventh edition of the NRC.[85] Osorio and colleagues[86] evaluated the impact of supplementing organic trace minerals to calves fed diets formulated for a low or high plane of nutrition (568 g vs >1000 g milk replacer solids). Calves fed at a high plane, but not those fed at a low plane, of nutrition responded with increased growth. This suggests that growth of calves at a lower feeding rate was limited by factors other than trace mineral nutrition.

Recommended Protein and Fat Levels in Milk Replacers

The most important factors influencing the price of a milk replacer are the protein and fat content and the source of each. Replacers labeled as "all milk usually contain blends of dried whey, delactosed whey, and "whey protein concentrate." Milk replacers with alternate proteins will have some of the whey proteins (up to 50%) replaced by soy, wheat, or animal plasma proteins. Table 21.6 represents industry classification of the suitability of protein sources for milk replacers.

It should be noted that dried skim milk and casein are rarely present in milk replacers in sufficient amounts to affect nutrient content or quality due to their high cost. For calves younger

Classification of Protein Sources Used in Milk Replacers Suitable for Young Calves[77]

Acceptable Milk Ingredients	Acceptable Nonmilk Ingredients	Not Acceptable
Dried whey protein concentrate	Soy protein isolate	Meat solubles
Dried skim milk	Protein-modified soy flour	Fish protein concentrate
Casein	Soy protein concentrate	Wheat flour
Dried whey	Animal plasma	Soy flour
Dried whey product	Wheat gluten or isolate	Egg products

VetBooks.ir

than 3 weeks of age, digestibility and amino acid content of milk-derived proteins tend to be more suitable.

Commercially available milk replacers contain between 18% and 28% protein. The level of protein and fat depends on the desired performance and conditions of the calf's environment. The seventh edition of the NRC[85] continued to recommend limited feeding of milk and milk replacer solids to calves (454 g/day) to encourage the early intake of calf starter and early weaning. At this level of intake, 18% to 20% protein is adequate with minimal rates of daily gain. However, more recent work focused on the nutritional requirements of calves growing to their genetic potential has resulted in the manufacture of milk replacers with higher protein content fed in amounts as high as 1.1 kg of milk or milk replacer solids.[87-90] Work by Blome and colleagues[87] suggests that lean tissue growth is optimal between 26% and 28% crude protein at higher feeding rates.

Calf milk replacers usually contain between 10% and 25% fat. This is lower than the level found in cow's milk, which would be in excess of 28%, with milk containing 3.6% fat on a liquid basis. The impact of the fat content of the milk replacer on body composition and calf growth depends on the feeding rate and environmental conditions. At lower feeding rates (454 g solids/day), body fat deposition increases as the level of fat increases in the milk replacer. The optimal level of body fat for the preweaned calf has not been determined. Body fat at birth is heavily dependent on the body condition of the dam. During the end of the first week of life, it is not uncommon for calves to have less than 2% body fat.[90] This is probably an inadequate reserve should the calf become ill, decrease dietary energy intake, and have increased energy requirements due to environmental temperature or the response to disease. Therefore, there is probably some benefit to the calf experiencing accretion of body fat, especially during the first weeks of life. Jersey calves fed a moderate amount of milk solids (700 g/day) were found to have approximately 9% body fat at 5 weeks of age.[90] As fat percentage and daily fat intake from milk replacer increases, calf starter grain intake is delayed or occurs at a lower rate. Most milk replacers contain approximately 10% to 20% fat, which is adequate over a wide range of intake levels and protein percentages. Bascom and colleagues[90] suggested that smaller calves would benefit from higher levels of fat in the diet during periods when the environment is below the thermoneutral zone. However, during warmer months there appears to be little benefit to milk replacers with more than 15% fat. Milk replacers specially formulated to contain desired fatty acid composition with 10% fat provide sufficient energy for desired growth during summer months.

It is important to note that the grams of nutrient intake and megacolories (Mcal) of energy intake are more important in meeting the calf's nutrient requirements than percentages. Therefore, greater attention should be paid to the amount of solids intake rather than percentages of protein or fat.

Manufacturing Milk Replacers

Production of milk replacers begins with procurement of quality ingredients and enactment of a strict quality assurance program at the manufacturing facility.[91] Whey products are monitored for protein, fat, ash, pH, sodium, moisture, color, solubility, dispersibility, bacterial growth, lactic acid production, and evidence of overheating. With fats and oils, color, melting point, odor, peroxide, free fatty acid content, and fatty acid profile are considered. Most manufacturers rely on supplier histories as each incoming load of ingredient is tested. The main variables influencing the nutritional value of whey proteins are the type of cheese produced, heating history, length of storage, and sanitation. Sanitation factors are critical since they influence microbial and peroxide loads of the final product. Standard plate count must be less than 30,000 cfu/g, less than 10 cfu coliforms/g, less than 10 mold or yeast colonies/g, and no detectable *Salmonella*. Excessive heating can lead to denaturation of the protein, whereas underheating can contribute to excessive microbial growth. Reputable manufacturers use only ingredients that are edible by humans rather than feed grade.

The next process in producing a milk replacer is to combine the ingredients into a product that has good wettability and mixability characteristics and does not separate. *Wettability* is a measure of how fast the powder breaks water tension and drops below the surface of the water. A test used is the amount of powder that drops below the surface of the liquid within 60 seconds. Wettability is related to ingredients used and the amount of surfactant added. *Mixability* is how completely the powder goes into solution and stays in suspension. Although wettability appears to make the product more convenient, mixability is more important to the calf. *Separation* is how much the ingredients separate from the rest of the solution, including those that float to the surface and those that sink to the bottom. Ingredients low in fiber (milk proteins, plasma, wheat gluten, and soy isolate) have better mixing characteristics than soy protein concentrate or flour. A powder that has all of the nutritional characteristics of a desirable milk replacer must also have physical characteristics that enable the calf to consume a uniform, digestible, and palatable product.

Several methods are used in manufacturing milk replacer powders: dry blending, chilling towers, and agglomeration. Each method can provide a finished product of desirable nutrient content. However, differences in the three characteristics mentioned previously may affect the nutrients consumed by the calf. Dry blending is the simplest method because the dry protein and fat sources are mixed together, and additional liquid fat is sprayed on later. The issue with dry blended products is getting fat into suspension, since it is very hydrophobic. The nature of the fat product greatly determines how this is accomplished. Some fats used in milk replacers have protein sprayed on their surface, which improves mixing, whereas others use higher amounts of emulsifiers. Milk replacers may also be agglomerated to enhance wettability and mixability. These processes result in encapsulation of difficult ingredients such as fat with more hygroscopic ingredients and an increase in particle size, resulting in a powder that goes into solution quicker and stays in suspension. The process of agglomeration generally provides a finished product that is easiest to mix on the farm. Ideal mixing temperature for a milk replacer is heavily dependent on the ingredients and processing method used. Excessive temperature can result in disruption of the agglomerated product and separation of the fat and protein. Low temperatures will result in inadequate mixing. One must closely follow the recommendations for mixing temperature provided by the manufacturer. Typically, dry blended milk replacers require higher mixing temperatures.

Another small but important detail is how milk replacer powder is mixed. Ideally about 50% to 70% of the total water needed for a batch is added to a receiving container followed by addition of the prescribed amount of powder. After initial mixing the remaining water is then added for the final mixing. During cold weather the temperature at the end of mixing should be warmer (46.1° C/115° F), as the liquid will cool prior to feeding, especially in slower feeding systems. A thermometer should always be used to check mixing temperatures (see manufacturer recommendations) and feeding temperature (37.8° to 40.6° C/100° to 105° F).

Ideally both the water and the powder should be weighed for each batch of milk replacer liquid. Most milk replacer powders are approximately 96% to 97% dry matter. When powder is diluted, the final solution should be fed at a solids concentration of 12% to 15%. The influence of solids level on calf performance is relatively small within this range. However, formulation of liquid diets with higher dry matter percentages permits delivery of more nutrient solids within a

VetBooks.ir

given volume. Delivery of adequate nutrients to support desired growth can be challenging with feeding systems using 2-L bottles and twice-daily feeding. Under such systems it is difficult to deliver more than 500 g of milk solids per day to calves. Feeding milk replacer at solids levels above 15% has been associated with increased scouring in calves, especially if free-choice water is not available. For this reason, many calf operations have switched to the use of 3- to 4-L bottles or have fed calves in buckets allowing larger meal sizes.

A degree of confusion exists on many operations about how to calculate the level of milk solids in a liquid feeding system. Adding 150 g of powder to 1 L of water does not result in a 15% solids solution, as 150 g of powder plus 1000 g of water equals 1150 g of final weight (150/1150 = 13.04% solids).

The quality of water used to mix milk replacers has received increased emphasis, as it can influence how the final liquid is digested and metabolized by the calf. Suggested guidelines for water quality are shown in Table 21.7.

Acidification of Milk Replacers

Workers in Canada[93] have described a system of free-choice feeding either cold milk or milk replacer treated with formic acid, which lowers the pH of the liquid to approximately 4.5. This system results in higher levels of liquid diet intake and lower initial calf starter intake but noticeable improvements in gains and labor efficiency. However, currently, formic acid is not permitted as a feed ingredient in the U.S. dairy industry. Nocek and Braund[94] observed more gain in calves fed *ad libitum* to 35 days as compared to limit-fed calves offered a nonacidified milk replacer. However, there were no significant differences in scouring, and calves of both treatments reached 136 kg of body weight in the same number of days, likely due to weaning challenges and postweaning diets that were not adjusted for body weight differences. Jaster and colleagues[95] compared calves fed twice daily at 10% of body weight either "sweet" or acidified milk replacers containing 12.5% solids. Citric acid was used to decrease the pH to 5.3. No differences were found in gains, and there was a slight reduction of scours in calves fed the acidified replacer. Acidified milk replacers using combinations of organic acids other than formic acid are commercially available. Cold liquid feeding systems will reduce feed efficiency due to the impact of liquid temperature on the energetic requirements of the calf. Additional challenges of free-choice systems using acidified milk include low palatability of the milk for calves during the first week of life. However, they tend to adjust to the taste and frequently consume more than 10 L/day. Higher levels of milk intake present challenges in weaning calves to dry feeds.

Additives to Milk Replacers

Before 2010, neomycin and oxytetracycline were added to milk replacers to aid in the control of bacterial enteritis. However, the Veterinary Feed Directive enacted in January 2017[96] restricts the use of oxytetracycline, chlortetracycline, and neomycin by or on the order of a licensed veterinarian. Commonly used milk replacer medications are shown in Table 21.8.

Other additives used in milk replacers include yeast products, probiotics, and fermentable fibers. Heinrichs and colleagues[97] found similar performance of calves fed a milk replacer diet with no additives or supplementation with the pre-2010 level of oxytetracycline/neomycin or with 4 g/day of mannan oligosaccharide (MOS). Addition of either the antibiotic or MOS reduced scours. Calf starter intake increased at a faster rate for those calves fed MOS. Inclusion of fermentable fibers from psyllium to a milk replacer powder at 1.1% of the dry matter intake increased populations of bifidobacteria and lactobacilli in the rumen and reticulum of preweaned dairy calves. It also increased the mass of the gastrointestinal tract.[98] Daily addition of probiotics in the form of *Lactobacillus acidophilus* had no effect on body weight over a 6-week trial, but calf health and growth were improved during the first 2 weeks of life.[99] Harris and colleagues[100] found that supplementing milk replacer with yeast fermentation products improved calf starter intake and

TABLE 21.8

Commonly Used Milk Replacer Medications[77]

Medication	Use Level	Statement	Withdrawal
Diflubenzuron	9.1-22.6 g/ton	Larvicide prevents house flies, stable flies, face flies, and horse flies from maturing into breeding adults.	None
Decoquinate	12.9-90 g/ton to provide 22.7 mg decoquinate/100 lb body weight	For prevention of coccidiosis in calves and cattle caused by *Eimeria bovis* and *Eimeria zuernii*.	None
Lasalocid	1 mg lasalocid/2.2 lb body weight	For control of coccidiosis caused by *E. bovis* and *E. zuernii*.	None

improved fecal consistency after a mild *Salmonella enterica* challenge. The study of the efficacy of additives will continue as those in the milk replacer industry seek to find replacements for antibiotics in milk replacers.

Feeding Recommendations for Dairy Calves

Traditional calf feeding programs consisted of daily consumption of 454 g of milk or milk replacer solids in 4 L of liquid divided into two daily feedings. These recommendations existed solely to encourage calves to begin consumption of dry feed and promote early weaning. There is little evidence to support this from a biological perspective, as such limited intake during the first 2 to 3 weeks of life barely provides sufficient energy and protein to meet maintenance requirements in calves under thermoneutral conditions between 10° and 25° C. During periods of cold stress, intake of milk or milk replacer should increase by 30% to 50%. More recently, research has shown the benefits of "accelerated" or "intensive" calf feeding programs where liquid diet intake of milk or milk replacers with up to 28% protein is fed at rates up to 1 to 1.2 kg of solids per day. These terms are probably a misnomer, as the intake of milk or milk replacer are more similar to liquid feeding programs for sheep, pigs, and beef cattle. Ollivett and colleagues[101] showed that calves challenged with *Cryptosporidium parvum* recovered faster and gained weight shortly after challenge if fed this more appropriate plane of nutrition, whereas controls fed the traditional diet continued to lose weight. The seventh edition of the NRC[85] uses the factorial approach to estimate requirements for growth and maintenance with consideration of environmental temperature. More progressive calf feeding programs encourage enhanced growth, higher feed efficiency, and more economical gains, especially during the first 3 weeks of life, when calf starter intake is minimal. One concern expressed is that calf starter intake is delayed. However, calves quickly adjust, and weaning by 6 weeks of age is achievable.

The seventh edition of the NRC[85] was published in 2001. An eighth edition was in preparation as this chapter was being written. The reader is encouraged to consult this updated version for nutrient requirement recommendations for pre-weaned calves.

Urinalysis, 418

Laboratory data are discussed in relation to case management. The focus is on interpretation of an abnormal finding in the typical clinical situation. An in-depth pathophysiologic explanation of these alterations is beyond the scope of this section. Should additional information be required, a textbook on veterinary clinical pathology should be consulted.[1,2]

All samples should be submitted with specific objectives in mind, following laboratory submission guidelines. In general, these objectives fall into one of the following categories:

- Evaluating organ system involvement or functional impairment
- Confirming a diagnosis or ruling out a disease condition
- Directing therapy formulation
- Assessing response to therapy
- Determining a more accurate prognosis

Submission of Laboratory Samples

Veterinary Diagnostic Services

The clinician must be aware of inherent limitations of laboratory testing in certain clinical settings. In general, veterinary diagnostic laboratories are preferred to human medical laboratories because these latter laboratories will be unfamiliar with animal diseases, normal physiology, and the responses of animals to disease. There may also be significant differences in test methodology and normal reference ranges. These species differences can cause confusion when results are evaluated on the basis of human reference intervals, which are not applicable to animals.

Various desktop or portable handheld point-of-care devices (POCD) are available to veterinarians for determination of serum chemistry, electrolytes, and acid-base balance. Point of care (POC) refers to any laboratory testing done outside the conventional laboratory and in close proximity to the patient. Many of these devices use self-contained strips, cartridges, or rotors and thus reduce errors associated with the maintenance, measurement, and mixing of reagents. Some of these devices can use heparinized whole blood or plasma. Some POCDs require refrigerated storage of reagent cartridges, which must then be warmed to room temperature before use. There are relatively few independently published data comparing the results obtained with these POCDs with standard laboratory procedures. Many of these POCDs need species-specific controls and reference intervals, as well as validation.[3] Given these requirements, the American Society for Veterinary Clinical Pathology (ASVCP) has recommended the following guidelines when using them: taking a formal approach to POC testing including development of written policies regarding use, operator training, assessment of instrument analytical performance, use of validated reference intervals, and checks on accuracy of patient results reporting.[4] A widely used handheld device (iSTAT) has been shown to yield comparable results to standard laboratory techniques when blood electrolyte concentrations and acid-base balance are determined in dogs and horses.[5] However, it was noted

*Contributions to previous editions by Gary P. Carlson are acknowledged.

VetBooks.ir

that the correlation between results from this device and from standard laboratory techniques was poor for sodium in the dog and for hematocrit in the horse. A study using the same handheld device in cattle, horse, and sheep showed that, except for sodium concentration and hematocrit in horses and sheep, correlation was good or excellent for most variables reported.[5] Portable POCDs can provide rapid, accurate, and relatively inexpensive results. As technology continues to improve, wider and more general application of these devices is taking place in many large animal practice settings.

Selection of Procedures

Selection of specific laboratory tests fosters logically integrated thinking and concentrates on evaluation of the primary medical problems. However, the sophisticated autoanalyzers used by large commercial laboratories can perform a battery of tests quickly and efficiently with little additional cost. These panels may be broadly defined (e.g., a general large animal health panel) or may offer a more focused evaluation of a specific organ system (e.g., liver, kidney, or muscle). The clinician must ensure that the panel selected contains all the appropriate tests for a thorough evaluation of the individual patient's medical problems identified.

The following recommendations for diagnostic panels are intended to provide a clear indication of organ damage and/or dysfunction. The most directly applicable diagnostic procedures are listed under "Recommended," and additional procedures that may be of benefit in certain circumstances are listed under "Optional."

GENERAL PANEL. The broad-based general chemistry panel should provide a balanced evaluation of the most likely medical problems, and reports should include reference intervals for each analyte and for each species from which the sample was obtained.

Recommended

Glucose
Serum/plasma urea
Creatinine
Creatine kinase (CK)
Aspartate aminotransferase (AST)
Sorbitol dehydrogenase (SDH)
γ-Glutamyltransferase (GGT)
Glutamate dehydrogenase (GLDH)
Alkaline phosphatase (ALP)
Bilirubin (direct, indirect, and total)
Total protein
Albumin
(Globulin) (calculated: total protein concentration–albumin concentration)
Albumin/globulin ratio (A/G ratio)
Haptoglobin (mostly food animals)
Serum amyloid A (equine)
Bicarbonate or total carbon dioxide (TCO_2) (often routinely reported)
Sodium
Potassium
Chloride
Calcium
Phosphate
Magnesium (total Mg)

Optional

Fibrinogen
Venous or arterial blood gases
Ionized calcium
Ionized magnesium

MUSCLE PANEL. The muscle panel should detect active skeletal and cardiac muscle injury (rhabdomyolysis) and the degree of secondary renal damage. The possible causative factors are evaluated as optional procedures, depending on the history, clinical findings, or special circumstances. Muscle biopsy with special staining may be critical to the diagnosis of specific muscle diseases such as polysaccharide storage myopathies, immune-mediated myopathy, and mitochondrial myopathy. Special tests for muscle function and the genetic basis for some myopathies are discussed in the chapters on muscle and genetic tests (see Chapters 42 and Chapter 52).

Recommended

CK
AST
Muscle biopsy
Urinalysis
Blood urea nitrogen and creatinine

Optional

Alanine aminotransferase (ALT)
Myoglobin
Blood selenium/Vitamin E
Venous blood gases including L-lactate
Deoxyribonucleic acid analysis (hyperkalemic periodic paralysis [HYPP], polysaccharide storage myopathy type 1; type 2 offered but not currently recommended)
Calcium (ionized and total)
Magnesium (ionized and total)
Fractional excretion of:
  Sodium
  Potassium
  Chloride
  Myoglobin
  Calcium
Cardiac troponin I (evaluation of cardiac muscle)

LIVER DISEASE PANEL. The liver panel should detect active damage to the hepatic parenchyma, involvement of the biliary system, and alteration in hepatic function.

Recommended

SDH
GDH
AST
GGT
ALP
Blood urea nitrogen (BUN)
Serum bile acids (good diagnostic utility in Equidae; insensitive in ruminants)
Blood glucose
Fibrinogen
Total protein
Albumin
Globulin
Bilirubin (direct also called *conjugated*, indirect also called *free* or *unconjugated*, and total bilirubin)
Complete urinalysis

Optional

Liver ultrasound
Liver biopsy/culture
Blood ammonia (arterial preferable to venous samples and always run with a control animal sample)
Coagulation panel
Bromsulphalein clearance halftime test (BSP $t/_{1/2}$)

RENAL DISEASE PANEL. The kidney panel and urinalysis provide an estimation of renal function and should indicate the location and nature of the damage to the urinary tract.

Recommended

BUN (or serum/plasma urea)
Creatinine
Na
K
Cl

Calcium
Phosphate
Total protein
Albumin
Globulin
Complete urinalysis

Optional

Renal ultrasound
Renal biopsy
Urine culture
Urine/plasma osmolality ratio
Fractional excretion of:
- Sodium
- Potassium
- Chloride
- Calcium (ruminants)
- Endogenous creatinine clearance
- Sodium sulfanilate clearance

GASTROINTESTINAL DISEASE PANEL. The gastrointestinal disease panel should include evaluation of acid-base status, fluid and electrolyte balance, and renal function, which are common complicating features of gastrointestinal diseases. Additional optional or special diagnostic procedures may be necessary in calves or foals with neonatal diarrhea, in horses with colic, and in ruminants with gastrointestinal stasis or displacements.

Recommended

Packed cell volume (PCV)
Total protein (TP)
Sodium
Potassium
Chloride
Calcium (ionized and total)
Venous blood gases, pH, bicarbonate
Strong ion difference (SID) calculation
Anion gap
Strong ion gap calculation
BUN (serum/plasma urea)
Creatinine
Glucose
Peritoneal fluid cytology
Peritoneal fluid protein
Fecal occult blood
Fecal parasites
Ruminal fluid pH and analysis
Rumen fluid chloride concentration

Optional

Peritoneal fluid (glucose, L-lactate, Serum Amyloid A (SAA), and pH)
Serum immunoglobulin
Plasma lactate (D and L forms)
Fecal protozoa
Fecal culture
Fecal *Clostridium difficile* toxin testing
Fecal *Clostridium perfringens* Enterotoxin A
Fecal cytology
Rectal biopsy (histology, culture)
Absorption tests:
- Glucose
- D-Xylose
- Oral lactose tolerance test

Metabolic Profiling

The health status and productivity of dairy cattle, swine, and other food animals maintained in large confined groups involve a delicate balance among metabolic events, nutrition, agents of disease, management, and environmental factors. In these production units, the health status of the herd as a whole is of paramount importance. Subclinical disease and physiologic or nutritional imbalances may contribute to suboptimal productivity. Most productivity problems in these settings are multifactorial.[6] Defining and finding solutions to these problems can be a difficult and complicated task. Sequential assessment of weight gains, body condition scores, milk quality (fat and protein concentrations), and milk production are useful measures of the presence of subclinical production disorders but do not identify the cause. Metabolic profiling is a tool that has been used with mixed results. Blood samples are drawn from a number of randomized individuals as representative of the group as a whole. Some have recommended the submission of pooled serum samples from representative individuals, much like the use of bulk tank tests as a reflection of the general level of mastitis in a herd; however, sampling may also be done routinely and sequentially (longitudinally). In dairy cattle this may be done during gestation or lactation but frequently focuses on the periparturient period when a combination of nutritional and metabolic events often contributes to costly production disorders. Metabolic profiles might include most of the parameters listed under the recommended general panel with the addition of magnesium, total cholesterol, nonesterified fatty acids (NEFA), and β-hydroxybutyrate (BHB). BHB, NEFA, and cholesterol may provide an indication of energy balance, whereas serum/plasma urea, creatinine, total protein, albumin, globulin, and CK may be helpful in assessing protein status along with urea levels in milk. In certain settings, trace minerals or fat-soluble vitamin concentrations may be important indicators of underlying nutritional problems. Milk citrate measurement is a promising biomarker of physiologic imbalance in postpartum cows on farm.[7] To monitor specific subclinical entities such as subacute ruminal acidosis (SARA), subclinical hypocalcemia and subclinical ketosis, measurements of rumen pH, urine pH, and β-hydroxybutyrate in blood for each disease, respectively, have been used.[8] It has been suggested that the interpretation of the herd test results should depend on the biology of the specific metabolic disease. When assessing a metabolite that is associated with disease depending if it is above or below a cut point, this test should be interpreted as a proportional outcome above the cutoff point.[9] Metabolic profiling is not a substitute for careful clinical examination, analysis of husbandry practices, and ration analysis, but it may play a useful role in some modern large-scale operations in which a variety of subclinical, mostly management-related problems may quickly translate into financial disaster.

Sources of Variation in Normal Values

Laboratory

One of the most commonly overlooked sources of variation in clinicopathologic data is the difference in results obtained by different laboratories in comparison with one another and especially to POCD. This can result in a 5- to 10-fold difference in the normal range of certain enzyme activities among laboratories using similar but not identical methodologies. The standard method of representing serum enzyme activity is in international units per liter (IU/L), which is used in this text. Correction factors for converting the commonly used but older units of measure to international units are given in Table 22.1. The normal values given in Tables 22.2 and 22.3 are those currently used at the Ontario Veterinary College (Animal Health Laboratory: American Association of Veterinary Laboratory Diagnosticians full accreditation) or are from the literature.[2] It is always best and crucial to use validated reference intervals established for the species, age, and production type by the diagnostic laboratory to which samples are submitted.

Species

There is relatively modest variation among species for most clinicopathologic parameters. Notable exceptions are plasma

electrolyte concentration; erythrocyte potassium concentration in some breeds of horse, pigs, llamas, cattle, and sheep; and serum bilirubin concentration, which is higher in horses than in other species. Urea nitrogen (UN) is a less reliable indicator of renal function in ruminants and horses than creatinine because UN can be metabolized by the intestinal microflora. Donkeys and burros have a much higher γ-glutamyltransferase (GGT) level than horses and cattle. Young calves of up to 1 month have high GGT levels compared with other species because of increased concentrations of this enzyme in bovine colostrum.

Breed

Significant differences in hematologic parameters exist between hot- and cold-blooded horses. Hot-blooded horses include most of the athletic breeds of horses (Thoroughbred, Quarter Horse, Standardbred, and Arabian breeds). Cold-blooded horses include the pony and draft breeds. Cold-blooded horses have lower red blood cell (RBC) values both at rest and after exercise and maintain a slightly lower leukocyte count; they also have lower resting and fasting indirect bilirubin concentrations.

Age

Several important differences in hematologic and clinical chemistry findings exist between neonatal and adult animals within species. The effects of age have been studied most carefully in horses and cattle. In comparison to adult animals, suckling neonatal animals tend to have lower BUN, slightly lower total protein and globulin, moderately higher GGT and phosphate, and markedly greater alkaline phosphatase. Creatinine in foals can be a bit higher in well-muscled foals (up to 2.5 mg/dL; 221 µmol/L) and occasionally very high (up to 8 mg/dL; 707 µmol/L) shortly after birth and returning to normal values within 24 to 72 hours with maintenance fluid support, and it is thought to be due to defective placental transfer (spurious hypercreatinemia).[10]

Sex

With the obvious exception of sex hormone concentrations, there are few recognized differences in clinical chemistry values between sexes. In most domestic animals the intact male tends to have a slightly higher erythrocyte count, hemoglobin concentration, and PCV than the female or neutered male.[11] This sex-related difference has been demonstrated most clearly in the horse.

Factors Influencing Results or Their Interpretation

Many factors influence the reliability and interpretation of results obtained by laboratory analysis. The main factors are quality of the sample (preanalytic phase), quality of the laboratory analysis (analytic phase), and quality of results dissemination and record keeping (postanalytic phase).[12] Sample

TABLE 22.4

Recommended Anticoagulants for Hematologic or Clinical Chemistry Evaluation

Anticoagulant	Specimen	Test or Procedure
Ethylenediaminetetra-acetic acid (EDTA)	Whole blood	Complete blood count, cross-match, platelet count (hematologic testing preferred anticoagulant)
	Whole blood	Blood selenium
	Plasma	Refractometric protein and fibrinogen
	Peritoneal fluid	Fluid analysis
	Bone marrow	Hematologic evaluation
	Synovial fluid	Fluid analysis
Heparin	Whole blood	Blood pH, blood gases, electrolytes, lactate, ionized calcium, glucose (automated BG machines)
	Plasma	Electrolytes, osmolality
	Synovial fluid	Mucin clot test
Fluoride and oxalate	Plasma	Lactate
Citrate	Whole blood	Blood typing
	Plasma	Coagulation tests (PT, PTT, factor analyses)
None, serum separator tubes	Serum	Most chemistries, electrolytes, osmolality, trace elements (Se, Cu, etc.) Protein electrophoresis Hormones (cortisol, T_3, T_4) Immunoglobulins (IgG, IgM, IgA)

PT, Prothrombin time; *PTT*, partial thromboplastin time; T_3, triiodothyronine; T_4, thyroxine.

Tube selection guide at: http://www.eclinpath.com/chemistry/sample-collection-chem/ and https://ahdc.vet.cornell.edu/docs/Blood_Tubes_and_Labeling_Guidelines.pdf.

Modified from Brobst DF, Parry BW. Normal clinical pathology data. In Robinson NE, editor: *Current therapy in equine medicine*, ed 2, Philadelphia, 1987, Saunders.

collection and handling are important. The sample collection site (e.g., jugular vein, mammary vein, tail vein, cephalic vein, lateral thoracic vein, ear vein or carotid artery, transverse fascial artery, metatarsal artery) can have an important effect on the results of tests such as blood gas evaluation, glucose, or ketones. The choice of anticoagulants depends on whether the samples are to be submitted for serum, plasma, or whole blood analyses. The specific sample requirements for the most commonly ordered clinical chemistry determinations are listed in Table 22.4. Serum is required for most chemistry analytes, and serum separator tubes work well in most settings. There have been some indications that results of some serum hormone assays may be influenced by collection of blood in serum separator tubes. Lithium heparin is the anticoagulant of choice for most chemical determinations requiring plasma. Historically fluoride-oxalate was the anticoagulant of choice for blood glucose determination because it did slow down glycolysis by the RBCs. However, fluoride may interfere with certain chemical procedures (specifically the glucose oxidase method for blood glucose determination) and should be used only for blood lactate determination or in selected circumstances in which glucose determinations are required and samples must be held for some period of time without refrigeration. Citrate is the required anticoagulant for clotting tests and blood typing. Ethylenediaminetetraacetic acid (EDTA) is the anticoagulant most often used for hematologic evaluation. Both citrate and EDTA are chelating agents, which will interfere with calcium determination and, in the case of EDTA, spuriously increase potassium.

Samples should be submitted as soon after collection as possible, but circumstances may require storage of some samples for 12 to 24 hours. For collection of serum, whole blood should be allowed to clot before refrigeration. Serum should be separated from the RBCs immediately after clot formation and then kept refrigerated. Serum samples should be stored in clean containers (e.g., plain tubes) free from

VetBooks.ir

exposure to sunlight, medications, or chemicals. If whole blood is left at room temperature for longer than 60 minutes, blood glucose will be falsely decreased as a result of RBC glycolysis. Storage of whole blood may result in in vitro hemolysis, with the potential for misleading increases in the serum or plasma enzymes AST and lactate dehydrogenase (LDH) and potassium and phosphorus concentrations as a result of hemolysis. In addition, failure to separate serum or plasma from the RBCs within an hour of collection may lead to leakage of erythrocyte potassium and a falsely elevated serum or heparinized-plasma potassium concentrations.

Stress, transportation, excitement, and handling produce physiologic responses in animals that affect a variety of hematologic and biochemical parameters. This is most evident in the horse, which shows marked increases in RBC mass and to a lesser extent plasma protein concentration in response to excitement, exercise, or catecholamine administration. The RBC count, hematocrit, and hemoglobin concentration can increase by as much as 50%, whereas plasma protein concentration may increase by 1 to 2 g/dL (10 to 20 g/L). Leukocytosis, mainly seen as neutrophilia, is induced as the marginating leukocyte pool is mobilized into general circulation. Prolonged stress results in the release of endogenous corticosteroids, which produce the typical "stress response" leukogram. A similar leukogram is found in racehorses some 4 to 6 hours after racing. The combination of catecholamine and glucocorticoid release associated with stress, transport, and excitement, as well as with many gastrointestinal catastrophes, may result in markedly elevated blood glucose concentrations (up to 400 mg/dL; 22 mmol/L). Modest elevations (twofold to fourfold increase) in muscle-derived enzymes occur in association with prolonged transport or endurance exercise.

Large losses or compartmentalization of sodium-containing fluid accompanies many systemic disorders, particularly digestive problems such as diarrhea, colic, displacement of viscera, excessive sweat losses, and some urinary tract diseases. These forms of dehydration lead to decreases in plasma volume, which are indicated by moderate-to-marked increases in the PCV and TP concentration. The concentration of other compounds dissolved in the plasma may also increase as a result of decreases in the plasma volume. The concentrations of compounds that are largely protein bound, such as calcium, are generally closely related to albumin concentration. Up to 50% of serum calcium is bound to proteins, predominantly to albumin. Increases or decreases in plasma protein concentration normally result in proportional changes in total serum calcium concentration, whereas the physiologically active ionized calcium may remain unchanged.

Diseases that cause a reduction in effective circulating fluid volume often also cause alterations in renal function. This so-called prerenal azotemia results in moderate to marked elevation in BUN and creatinine. Although this is generally considered primarily a prerenal azotemia, real pathologic changes in the kidneys often are associated with the systemic processes initiated by these disorders. Longitudinal reevaluation of renal function (urinalysis, serum BUN, and creatinine) in these patients during the course of disease is important because it assists with prognosis, assesses response to fluid administration, and therefore the potential for nephrotoxicity and systemic toxicity of a variety of chemotherapeutic agents used in such patients.

Fasting laboratory data are important for evaluation of many disease conditions in human and small animal patients. Truly fasting conditions are rather difficult, given the large and complex gastrointestinal tract of most herbivores, and are thus seldom used. The feeding of animals in relation to sample collection, however, can have an impact on the data obtained. Hay feeding in horses is reported to affect sodium, potassium, and protein concentrations within the first few hours after feeding. Animals feeding on lush green pasture or large amounts of silage may have slightly different parameters from those fed high-concentrate rations. The anion-cation balance of the ration has an impact on relative serum electrolyte concentration, acid-base balance, and urine pH and urinary electrolyte excretion. Lactescent (cloudy from chylomicrons) plasma may be observed in samples from nursing foals or calves. The fluid intake of the normal nursing neonate may range from 100 mL/kg/day to more than 250 mL/kg/day. This high fluid intake is reflected by a commensurately high output of urine with a low specific gravity and low osmolarity.

The administration of certain medications may have an impact on some laboratory parameters. Tranquilization may be necessary for restraint and safe sample collection. The practitioner should be aware that tranquilizers often decrease RBC mass and plasma protein concentration. This is particularly true of the phenothiazine-derivative tranquilizers when used in the horse. Xylazine administered to large animals produces a modest catecholamine release, which may be evidenced by the slight sweating response seen in many horses sedated with this drug. Glucose concentration will increase modestly in response to the xylazine-induced catecholamine release. Repeated intramuscular injections with certain antibiotics (especially erythromycin and tetracycline) or other preparations that are locally irritating may produce slight-to-moderate elevations in muscle-derived serum enzyme activities. Intravenous administration of certain drugs and compounds such as dimethyl sulfoxide (DMSO) can produce intravascular hemolysis and hematuria. The amount of hemolysis in these circumstances is relatively small and of little consequence, except that it can cause confusion as to why hemoglobinuria occurred.

Fluid and Electrolyte Balance

Packed Cell Volume and Total Plasma Protein

PCV and total plasma protein (TPP) concentration are simple and convenient indicators of acute fluid alterations. Changes in the plasma volume generally are reflected by changes in the PCV and the TPP concentration. In dehydrated humans, changes in the PCV are believed to be the more reliable guide to changes in plasma volume because substantial protein fluxes into and out of the circulation have been shown to occur. However, in most animal species the range of normal for the PCV is much wider than for the TPP concentration. This is particularly true of horses, in which excitement, pain, or catecholamine release can produce variable mobilization of splenic erythrocytes, making it difficult to obtain a truly resting PCV. For these reasons, precise quantitative estimation of a change in plasma volume using these parameters is more complex and less reliable in large animal species. As plasma volume increases or decreases, the change in the PCV is always less than the change in the TPP concentration. However, a large disparity in the changes in the PCV and the TPP concentration in a patient with a history of loss of sodium-containing fluid and clinical evidence of reduced effective circulating fluid volume suggests blood or protein loss. Marked increases in the PCV with a normal-to-low TPP concentration frequently are encountered in animals with acute protein-losing enteropathies such as salmonellosis or equine toxic enteritis, or enterocolitis. In horses undergoing treatment for diarrhea, the excessive administration and retention of sodium-containing fluids is a key factor in the development of edema and hypoproteinemia. Blood loss generally results in a decrease in both PCV and TPP concentration with a lag time of up to 24 to 48 hours.

Serum Sodium

The serum sodium concentration is a function of the exchangeable cation content (i.e., the exchangeable sodium [Na] in the extracellular fluid [ECF] volume plus the exchangeable

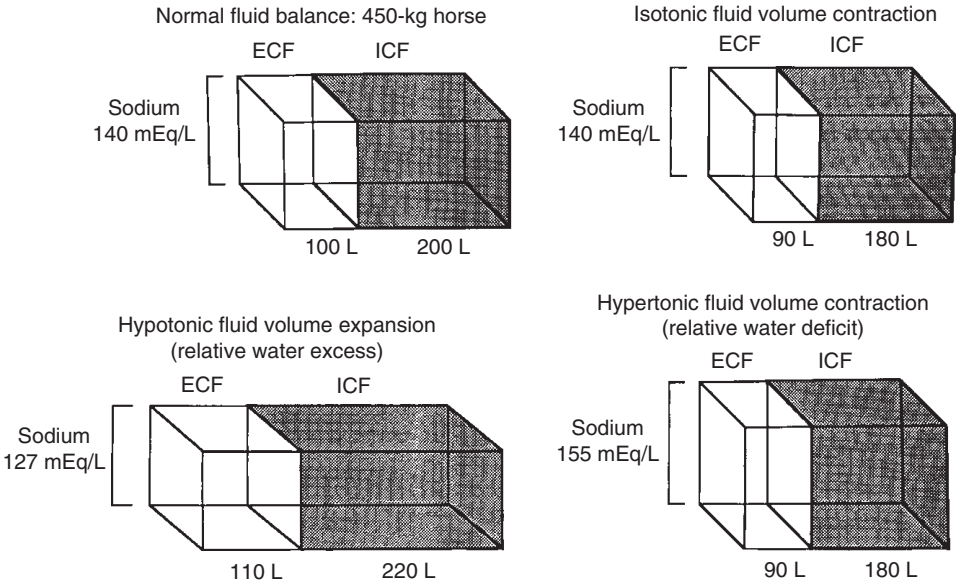

FIG. 22.1 Compartmental distribution of fluid between the extracellular fluid (ECF) volume and the intracellular fluid (ICF) volume in a 450-kg horse with normal fluid balance, isotonic fluid volume contraction, hypotonic fluid volume expansion, and hypertonic fluid volume contraction. *(Modified from Kaneko JJ, Harvey JW, Bruss ML, editors:* Clinical biochemistry of domestic animals, *ed 6, New York, 2008, Elsevier Academic Press.)*

potassium [K] in the intracellular fluid [ICF] volume relative to total body water). The ECF *sodium* content determines the ECF volume, whereas the ICF volume is a function of ICF *potassium* content.

Changes in the sodium concentration reflect the net changes in this relationship and often do not represent accurately the changes in sodium balance. Changes in water balance are thus primarily responsible for changes in the serum sodium concentration, and one should always consider the hydration status of the patient for sodium concentration interpretation. Hyponatremia is an indication of a relative water *excess*, whereas hypernatremia is an indication of a relative water *deficit*.

Dehydration is defined as a loss of body water (fluid volume contraction). It occurs in a variety of clinical circumstances. The serum sodium concentration provides a means of categorizing dehydration in a physiologically meaningful way. Hypertonic dehydration, which occurs when water losses exceed the losses of sodium and potassium, is indicated by hypernatremia (free water loss or hypotonic fluid losses). The response of horses to feed and water deprivation is an example of this form of dehydration. Isotonic dehydration occurs with a balanced loss of water and electrolytes—that is, approximately 140 to 150 mEq of sodium plus potassium (Na + K) for each liter of water lost. Because the relative water balance has not changed, the serum sodium concentration remains unchanged despite the accumulation of what may have been a substantial body sodium deficit. The early stages of acute diarrhea and the dehydration of heavily sweating endurance horses are examples of isotonic dehydration. Hypotonic dehydration occurs when the losses of exchangeable cations (Na + K) exceed the net change in water balance; this condition is indicated by hyponatremia. Hypotonic dehydration often is seen in animals with subacute or chronic diarrhea that develop substantial water and electrolyte deficits but then replace part of the water deficit through water consumption. Fig. 22.1 shows the compartmental distribution of fluid between the ECF volume and ICF volume in four situations.

HYPONATREMIA. Hyponatremia results from retention of free water or excess loss of sodium. It is often but not invariably associated with conditions that cause sodium depletion such as vomiting, diarrhea, excessive sweat losses, and adrenal insufficiency. The fluid losses in these conditions are most often hypotonic or isotonic, and initial fluid and electrolyte deficits do not result in hyponatremia until water intake, renal water retention, or both disturb the balance between the remaining exchangeable cations and the total body water.

The accumulation of sodium-containing fluid in body cavities or the gut lumen caused by ascites, peritonitis, or rupture of the bladder or by displacement, torsion, or volvulus of the gut is referred to as a *third-space problem*. When such accumulations develop rapidly, the plasma volume is reduced and the serum sodium concentration subsequently may decrease as compensating renal responses cause water retention. Rupture of the bladder in neonatal foals is associated with marked hyponatremia and hypochloremia. As fluid intake continues and dilute urine accumulates in the abdomen, sodium, chloride, and other ions are drawn from the rest of the ECF into this accumulating fluid. No sodium or chloride has been lost from the body, and the observed decreases in the electrolyte concentration are caused by changes in the relative water balance ("water follows solute"). The neurologic signs seen in these foals are largely caused by the effects on the central nervous system of the rapidly developing and marked hypotonic hyponatremia. Progressively severe neurologic disturbances may be seen as the serum sodium concentration falls below 115 mEq/L and then below 100 mEq/L. The severity of the neurologic abnormalities is a function of both the rate at which hyponatremia develops and the absolute degree of hyponatremia. Neurologic disturbances can occur iatrogenically if excessive amounts of free water (usually given as 5% dextrose) are administered to patients with altered renal function.

Mastitis results in an increased loss of sodium in the milk, and a low-grade mastitis problem in a dairy herd on a marginal dietary salt intake may result in sodium depletion and medullary washout. Decreased milk production, polyuria, hyposthenuria, and a low urine sodium level may be noted, although the serum sodium concentration may remain within the lower range of normal.

The most common causes of hyponatremia are listed in Box 22.1. Marked hyperlipidemia or hyperproteinemia produces a falsely low sodium concentration value because lipid or protein occupies a significant volume in the serum or plasma sample and because sodium is present only in the aqueous phase. This potential cause of hyponatremia is indicated by an increase in

VetBooks.ir

BOX 22.1

Causes of Hyponatremia

Common Causes

Relative water excess
- Loss of sodium-containing fluid (decreased effective circulating volume)
- Diarrhea
- Excessive sweating
- Blood loss
- Fluid drainage
- High-volume gastric reflux
- High-volume pleural drainage

Adrenal insufficiency

Sequestration of fluid (third-space problems)
- Peritonitis
- Ascites
- Pleuritis
- Ruptured bladder
- Torsion or volvulus of the gut
- Excessive administration of 5% dextrose to patient with renal disease

False hyponatremia
- Hyperlipidemia
- Hyperproteinemia
- Hyperglycemia

Uncommon Causes

Water retention with normal effective circulating volume
- Psychogenic polydipsia
- Renal disease
- Inappropriate antidiuretic hormone secretion
- Use of diuretics

BOX 22.2

Causes of Hypernatremia

Common Causes

Pure water losses
- Panting
- Water deprivation

Sodium excess (water restriction)
- Salt poisoning
- Feeding only electrolytes, no free water

Uncommon Causes

Water loss exceeds electrolyte loss
- Vomiting
- Diarrhea
- Burns
- Intrinsic renal disease
- Diuretics
- Diabetes insipidus
- Central
- Nephrogenic
- Hypertonic saline or sodium bicarbonate administration
- Mineralocorticoid excess

the osmolar gap between measured and calculated osmolality. The use of direct ion-selective electrodes (direct potentiometry; all modern blood gas machines; and modern multianalyzers of big laboratories) for electrolyte determinations avoids this potential cause of a falsely low sodium concentration value.

Marked hyperglycemia causes a reduction in the measured serum sodium concentration of approximately 1.6 mEq/L for every 100 mg/dL increase in the glucose concentration. Increases in the plasma glucose concentration generate osmotic forces that result in the movement of cellular water into the ECF, diluting the plasma sodium concentration.

HYPERNATREMIA. Hypernatremia can develop if water is lost in excess of sodium or if sodium is ingested in excess of water. Hypernatremia can occur in the initial stages of diarrhea, vomiting, or renal disease if water loss exceeds electrolyte loss (Box 22.2). When water losses are replaced by increased water consumption, enhanced renal water retention, or both, the serum sodium concentration decreases. Food and water deprivation in normal horses and cattle is associated with substantial reduction of renal and fecal output, but continued cutaneous and respiratory insensible water loss may result in hypernatremia (primary water loss). Hypernatremia may occur transiently as a result of sodium excess after administration of hypertonic saline or hyperosmolar sodium bicarbonate if water intake is restricted or impaired. Hypernatremia has been reported in calves fed an inappropriately mixed oral electrolyte replacement solution as their only fluid intake.[13] The hypernatremia observed with salt poisoning in cattle and swine is the result of water restriction in animals that have been maintained on a high-salt intake.

Serum Potassium

Potassium is the major intracellular cation. Between 60% and 75% of total body potassium is found within muscle cells and in bones. Only 5% is in the ECF and is not always a reflection of total body potassium. The serum potassium concentration is influenced by factors that alter internal balance (the distribution of potassium between the ECF and the ICF) and those that change external balance (potassium intake and output). Potassium is higher in foals compared with adult horses. Generally, herbivores have a net positive intake in potassium, which is usually carefully regulated by the renal system. Serum potassium concentrations correlate relatively well with total body potassium content in cattle but not in horses. Changes in the serum potassium concentration occur in a wide variety of clinical circumstances and have profound neuromuscular effects that are largely the result of changes in cell membrane potential. The responses to dehydration and acid-base imbalance often complicate the evaluation of the potassium concentration. For example, calves with acute diarrhea often develop body potassium depletion because of excessive losses and inadequate intake, but the serum potassium concentration of these animals is usually normal to increased as the result of renal shutdown and the metabolic acidosis induced by dehydration, sodium depletion, and hypovolemia. Hypokalemia may become evident only as other fluid and electrolyte losses are replaced.

Measuring the erythrocyte potassium concentration is relatively easy and has been suggested as an aid in assessing the need for potassium supplementation in racehorses with recurrent muscle disease or in alert downer cows early postpartum. However, experimental studies in horses indicate that the erythrocyte potassium concentration does not always accurately reflect potassium deficits.

HYPOKALEMIA. Hypokalemia increases resting membrane potential, resulting in muscle weakness, impaired urine concentration ability, and arrhythmias. Hypokalemia may result from depletion of the body's potassium stores or from a redistribution of potassium from the ECF into the ICF space (Box 22.3). Hypokalemia is most commonly seen with altered intake and absorption and with excessive potassium losses from the gastrointestinal tract caused by vagal indigestion, torsion of the abomasum, ileus, or diarrhea. Excessive renal loss may result from mineralocorticoid excess, certain diuretics, or altered renal function, as reported in horses with renal tubular acidosis. Marked hypokalemia develops when reduced dietary intake

VetBooks.ir

BOX 22.3

Causes of Hypokalemia

Common Causes

Altered External Balance[a]

Vomiting
Vagal indigestion with internal vomiting
Diarrhea
Third-space problems (gut or abomasal torsion or volvulus; peritonitis)
Excessive sweat losses
Dietary deficiency
Prolonged anorexia

Altered Internal Balance

Metabolic alkalosis

Uncommon Causes

Altered External Balance

Mineralocorticoid excess
Use of corticosteroids with mineralocorticoid activity
Diuretics
Renal tubular acidosis
Postobstruction diuresis

Altered Internal Balance

Excessively rapid sodium bicarbonate administration
Insulin and/or glucose administration
Catecholamine administration or endogenous release

[a]External balance refers to the relative changes in potassium intake and output; internal balance refers to the distribution of potassium between the extracellular and intracellular fluid compartments.

BOX 22.4

Causes of Hyperkalemia

Common Causes

False hyperkalemia
  In vitro hemolysis
  Prolonged storage of blood (over 6 hours) without separation of serum or plasma
Altered external balance
  Hypovolemia with renal shutdown
Altered internal balance
  Metabolic acidosis
  Vigorous exercise
Uroperitoneum

Uncommon Causes

False hyperkalemia
  Markedly elevated leukocyte or platelet count
Altered internal balance
  Hyperkalemic periodic paralysis in Quarter Horses
  Diabetes mellitus
  Tissue necrosis
  Renal disease
  Addison disease

caused by anorexia is associated with excessive potassium losses (e.g., causing muscle paresis in dairy cows early postpartum). A hypokalemia syndrome has been observed in cattle,[14] mainly in postpartum lactating cows, but also in younger animals. The exact causes have not been completely elucidated except for isoflupredone administration. The syndrome is characterized by muscle weakness, severe depression, recumbency, tachycardia, cardiac arrhythmia, and abnormal neck posture. The lowest reported serum potassium concentration levels are between 2.2 and 2.5 mmol/L.

Hypokalemia without potassium depletion results from the movement of extracellular potassium to the intracellular space. This form of hypokalemia occurs in response to an acute alkalosis and the administration of insulin or glucose. Overzealous and rapid administration of sodium bicarbonate can produce an alkalosis with a profound and rapidly developing hypokalemia. Animals with moderate potassium deficits that are vigorously treated with sodium bicarbonate to correct a coexisting mild metabolic acidosis may be particularly prone to this problem. The initial response to catecholamine administration is a modest, transient increase in potassium caused by α-adrenergic stimulation, which is often followed by hypokalemia caused by β-adrenergic receptor responses.

Pseudohypokalemia is seen in severe lipemia with potassium measured with indirect potentiometry (e.g., older automated profile chemistry analyzers).

HYPERKALEMIA. Hyperkalemia may develop in vitro as a result of hemolysis or leakage of erythrocyte potassium after storage of whole blood (Box 22.4). The release of potassium from leukocytes or platelets into the serum after clot formation is a potential cause of hyperkalemia if marked leukocytosis or thrombocytosis is present. Hyperkalemia also results from renal potassium retention in Addison disease, acute renal failure (ARF), and renal shutdown. A number of factors contribute to the movement of intracellular potassium into the ECF, resulting in hyperkalemia. Hyperkalemia is often associated with metabolic acidosis, particularly when the acidosis results from volume depletion and is complicated by renal shutdown. Hyperkalemia has been reported in animals with massive muscle necrosis, but neither hyperkalemia nor metabolic acidosis is a common feature in horses with exertional rhabdomyolysis. Vigorous short-term exercise of horses at high intensity results in a marked but transient hyperkalemia (9 to 10 mEq/L) that may be associated with the profound lactic acidosis seen with anaerobic workloads.[15] Potassium returns to normal within minutes, and often a modest hypokalemia occurs later in the recovery period. Episodic hyperkalemia and muscular weakness are associated with the condition of HYPP.[16] HYPP is inherited as an autosomal-dominant trait in horses, with a specific Quarter Horse lineage having a sodium channel defect[17] (see Chapter 42 for a more complete discussion of this disorder). The disease is the result of a single DNA base pair substitution that leads to the production of an abnormal voltage-regulated sodium channel at the cell membrane.[18] Sudden marked increases in the serum potassium concentration, up to 8 to 9 mEq/L, are the result of transcellular movement of potassium and are associated with profound electrocardiographic abnormalities and fluid shifts.

In drug-induced hyperkalemia, trimethoprim has been associated with hyperkalemia by inhibiting normal sodium reabsorption in the cortical renal collecting duct.

Serum Chloride

Chloride is a major ECF anion and important with sodium for osmolality and acid-base balance. Together with sodium it is the main component of the strong ion difference (SID). Alterations in the chloride concentration are usually associated with nearly proportional changes in the sodium concentration as the result of changes in relative water balance. In addition, the chloride concentration tends to vary inversely with the bicarbonate concentration; therefore when disproportionate changes in the chloride concentration relative to sodium occur, significant acid-base imbalances should be anticipated. Disproportionate increases in chloride are associated with a normal-to-low anion gap hyperchloremic metabolic acidosis, but they also are seen as a result of the compensating responses for a primary

Without Proportional Decrease in Sodium

Common Causes

Metabolic alkalosis
- Exhaustive disease syndrome
- Abomasal torsion
- Vagal indigestion with internal vomiting
- Response to furosemide in horses

Uncommon Cause

Compensation for respiratory acidosis

respiratory alkalosis (Box 22.5). A striking hyperchloremic metabolic acidosis has been reported in horses with renal tubular acidosis.[19,20] Iatrogenic hyperchloremic acidosis can be induced by overzealous NaCl fluid treatment.[21]

Disproportionate decreases in chloride relative to sodium are characteristically seen in metabolic alkalosis but also may be seen as part of the compensating response for chronic primary respiratory acidosis (Box 22.6). Hypochloremic metabolic alkalosis is a common feature in many digestive disorders of ruminants and is caused by loss of chloride-rich fluids or sequestration of such fluids in the abomasum and forestomachs. It is also seen in horses with diarrhea as chloride is absorbed in the ileum and colon. Horses treated with diuretics (e.g., furosemide-induced metabolic alkalosis) may show hypochloremia.[22] Heavy sweating in horses is associated with hypochloremic metabolic alkalosis.

Osmolality

ECF osmolality is maintained around 300 mOsm (isotone). Measurement of the serum osmolality provides an indication of relative water balance in much the same way the serum sodium concentration does. In most circumstances these parameters are closely correlated. Comparing the measured osmolality with the calculated osmolality, as determined from the measured concentrations of the major solutes in serum (sodium, chloride, glucose, and urea), provides a means of determining if the serum water content deviates widely from normal or if foreign, low-molecular-weight substances are present in the blood. The difference between the measured osmolality and the calculated osmolality is called the *osmolar gap*. Decreases or increases in the osmolar gap could indicate laboratory error, but increases of >10 mOsm/kg generally are the result of either a decrease in serum water content (caused by hyperlipidemia or hyperproteinemia) or the presence of abnormally high concentrations of low-molecular-weight substances in the serum. These substances can include a variety of exogenous and potentially toxic compounds such as mannitol, ethanol, methanol, propylene glycol, ethylene glycol, isopropanol, ethyl ether, acetone, trichloroethane, and paraldehyde. All hypernatremic animals are hyperosmolal. Hypo-osmolality is always associated with hyponatremia, but not all cases with hyponatremia are hypo-osmolal (e.g., concurrent hyperglycemia).

Serum Calcium

Calcium plays a vital role in many of life's processes including maintenance of neuromuscular excitability, permeability of cell membranes, conduction of nerve impulses, muscle contraction, and blood clotting. For these reasons the serum calcium concentration or, more correctly, the ionized calcium concentration is normally maintained within a relatively narrow range, despite wide variation in intake and output. Calcium metabolism is regulated by dietary factors, vitamin D and its active metabolites, and the hormones parathormone and calcitonin. Compared with ruminants in horses, a relatively larger percentage of calcium is excreted in the urine. The serum calcium concentration is maintained by adjusting intestinal absorption, renal excretion, and mobilization of available calcium from the large stores in bone. Calcium exists in the serum in three forms: ionized calcium, complexed calcium, and protein-bound calcium. Ionized calcium, which normally constitutes 50% to 60% of the total calcium, is the physiologically active form of calcium. Protein binding can cause confusion (protein-bound calcium normally constitutes 40% to 50% of the total calcium, and most of it is bound to albumin). Hyperalbuminemia may result in a modest hypercalcemia, whereas hypoproteinemia, especially hypoalbuminemia, regularly results in a moderate hypocalcemia.

VetBooks.ir

The ionized calcium concentration, usually measured with ion selective electrodes, generally remains within normal limits, despite increases or decreases in total calcium associated with the change in protein concentration. The acid-base balance has additional influence on the amount of ionized and protein-bound calcium. Alkalosis reduces ionized calcium and increases protein binding, whereas acidosis produces the opposite effect. Ion-specific electrodes are available for determining the ionized calcium level, which can be useful if blood samples are handled appropriately. Most diagnostic laboratories provide the total serum calcium value, which is composed of ionized, complexed, and protein-bound calcium.

HYPOCALCEMIA. Large increases or decreases in the serum calcium concentration generally are the result of a failure in the normal mechanisms of calcium homeostasis rather than a reflection of absolute calcium deficits or calcium-phosphorus imbalances. Hypocalcemia occurs with some frequency in domestic animals, particularly in high-producing dairy cattle at the onset of lactation. In cattle the serum calcium concentration normally decreases to <8 mg/dL (<2 mmol/L) with the stress of parturition and onset of lactation (Box 22.7). Failure to mobilize sufficient calcium to maintain serum calcium results in the clinical syndrome of parturient paresis (see Chapter 41 for a more detailed discussion of this syndrome). Most animals are recumbent with a calcium level of 6 mg/dL (≤1.5 mmol/L) or less, and fatalities may occur if the level drops below 4 mg/dL(<1 mmol/L). Parturient paresis is associated with hypocalcemia, hypophosphatemia, and a normal to increased serum magnesium level. Change in the cation-anion balance in the diet (increased proportion of strong anions) of dairy cattle during the periparturient period has modest effects on the acid-base balance and enhances calcium mobilization from storage sites, thus reducing the incidence of milk fever in cows at high risk. Grass tetany is associated with marked hypomagnesemia and modest hypocalcemia, whereas the inorganic phosphorus level remains within the normal range.

Systemic diseases resulting in anorexia (e.g., traumatic reticuloperitonitis, ketosis, and displaced abomasum) or acute toxemic conditions (e.g., coliform mastitis, septicemia, or aspiration pneumonia) that produce anorexia in lactating cattle frequently result in hypocalcemia. Hypocalcemia is also seen in sheep on marginal rations if stressed by inclement weather or when being moved and during late pregnancy as well. Hypocalcemia is seen in cattle with fat necrosis, presumably as the result of incorporation of calcium with the fat as a form of soap. Horses sweating or with exhaustive disease syndrome or transit tetany often develop decreases in ionized calcium with resultant muscle cramps and synchronous diaphragmatic flutter, which generally respond to intravenous calcium and electrolyte fluid administration. Horses, cattle, and sheep usually respond initially to acute renal tubular damage with mild hypocalcemia and hyperphosphatemia. Idiopathic hypocalcemia, which may exist in foals 4 to 5 days old, has poor prognosis, and a cause is not established.[23] Transport tetany and lactation tetany of horses are associated with hypocalcemia. In lactation tetany of mares, this is correlated with high milk production.

HYPERCALCEMIA. Marked hypercalcemia, with a serum calcium level ranging from 14 to 20 mg/dL (3.5 to 5 mmol/L), and modest hypophosphatemia are frequently observed in horses with chronic renal failure (CRF) that are fed a high-calcium diet such as alfalfa hay (Box 22.8). In these horses, blood samples collected in standard EDTA tubes may actually clot. This occurs because the serum calcium concentration is so high that there is insufficient EDTA to bind all the calcium, and some free calcium is available to complete the clotting process. Vitamin D intoxication can develop as a result of excessive dietary supplementation or the ingestion of certain plants such as *Cestrum diurnum* (day blooming jasmine), *Solanum malacoxylon*, Solanum *sodomaeum*, and *Trisetum flavescens*, which contain toxic quantities of vitamin D analogs. Primary hyperparathyroidism is exceedingly rare in large animals, but pseudohyperparathyroidism with hypercalcemia occasionally can develop in animals with tumors that produce protein substances with parathormone-like biologic activity. This has been reported in a few horses with lymphosarcoma, squamous cell carcinoma, adrenocortical carcinoma, multiple myeloma, and ameloblastoma. Hypercalcemia has also been reported in idiopathic systemic granulomatous disease and some foals with neonatal asphyxia.[24]

Serum Phosphorus

Phosphorus is found primarily in the skeleton and teeth in close association with calcium in the intricate and dynamic crystalline structure of bone. Intracellularly, phosphate plays an essential role in the degradation and synthesis of many compounds. Also, in the forms of adenosine triphosphate (ATP), adenosine diphosphate (ADP), and adenosine monophosphate

Uncommon Causes

Acute rhabdomyolysis
Vitamin D toxicity

(AMP), it is the primary form of energy storage and transfer required for almost all of life's processes. Phosphorus in the ECF exists primarily in the organic and inorganic form, specifically as the "buffer" pair H_2PO^{-3} and HPO^{-4}, and plays a role in acid-base balance. Like calcium, phosphorus is regulated by dietary factors, the active metabolites of vitamin D, and the hormones parathormone and calcitonin. Imbalances of calcium and phosphorus or the presence of compounds that bind these substances in the gut can produce serious imbalances that are not always evident on analysis of serum samples. Measurement of urinary output or creatinine clearance ratios for calcium and phosphate are simple and helpful procedures. They provide an indication of an imbalance while more definitive procedures such as ration analysis are contemplated.

HYPOPHOSPHATEMIA. Serum phosphorus concentrations are not always an accurate guide to phosphate balance, but dietary deficiencies of phosphorus are frequently manifested by hypophosphatemia. Hypophosphatemia is a common feature in cattle with parturient paresis (see also Chapter 41) and horses with CRF (Box 22.9). It has been reported in animals with experimental oxalate toxicity, in chronic wasting states, or with starvation. Postparturient hemoglobinuria is a disorder of cattle, primarily lactating dairy cattle, that often is associated with diets low in phosphorus. Although marked hypophosphatemia is often reported, it is not an invariable feature of this disorder. Hypophosphatemia has also been seen in cattle on acidogenic diets as a consequence of increased excretion and can also be observed due to compartmental phosphorus shifts as in hypertonic dextrose administration.[25] Hypophosphatemia in horses has also been observed in renal failure, sepsis, malignancies, hyperinsulinism, metabolic alkalosis, and parenteral nutrition.[24]

HYPERPHOSPHATEMIA. Age-related differences exist in the normal range of serum phosphorus concentration. Young animals have much higher values than adults, with values for neonates commonly up to 7 to 9 mg/dL (2.3 to 3.0 mmol/L). The serum phosphate concentration declines progressively with age. Hyperphosphatemia is seen in animals with vitamin D toxicity, transiently in horses after long-distance endurance rides, and initially in horses with ARF (Box 22.10). It has also been observed in hypothyroidism, marked tissue necrosis (e.g., rhabdomyolysis, intestinal infarction, tumor lysis syndrome, hemolysis), hypoparathyroidism, and in foals treated with phosphate-containing enemas. In ruminants, hyperphosphatemia is more commonly seen in dehydration and ensuing hemoconcentration as in abomasal displacement and volvulus, where it has been shown to be closely associated with dehydration.[26]

Serum Magnesium

Between 20% and 30% of magnesium is bound to mostly albumin, 10% is bound to weak acids, and 60% is free (ionized).[27] Free magnesium can be measured with ion-selective electrodes.

BOX 22.11

Causes of Hypomagnesemia

BOX 22.12

Causes of Hypermagnesemia[a]

Epsom salt ($MgSO_4$) overdose given orally or as an enema
Intravenous administration of magnesium in excessive amounts
Use of $MgSO_4$ IV

[a]Hypermagnesemia is an uncommon condition in large animals.

Disturbances of magnesium metabolism occur principally in cattle and sheep. Complex nutritional and environmental interactions contribute to a variety of clinical syndromes attributed to magnesium deficiency and the onset of tetany in grazing animals.

HYPOMAGNESEMIA. Hypomagnesemia is reported in cattle with grass tetany, transport tetany, winter tetany, and in sheep with grass staggers (Box 22.11) (see also Chapter 41). A serum magnesium level below 1.8 mg/dL (0.75 mmol/L) is considered low; values <1 mg/dL (0.4 mmol/L) are considered severe and are likely to be associated with clinical signs. However, there is better association with magnesium levels in the CSF.[28] Hypomagnesemia caused by dietary magnesium deficiency has been reported in calves reared in confinement and fed a milk diet exclusively (milk tetany). In chemistry panels of normal horses, hypomagnesemia (total serum magnesium) is often reported to be close to or below 1 mg/dL (0.4 mmol/L) without clinical signs and is mostly rightly or wrongly considered irrelevant by the clinician. However, a study found that 48.7% of hospitalized horses had hypomagnesemia and that horses with colic and hypomagnesemia were less likely to die.[29]

HYPERMAGNESEMIA. Hypermagnesemia occurs infrequently but may be seen with overzealous administration of Epsom salts ($MgSO_4$), either orally as a drench by means of nasogastric intubation or as an enema for the treatment of digestive disorders (Box 22.12). Intravenous administration of magnesium

produces muscle relaxation but does not alter consciousness, and hypertonic $MgSO_4$ solutions are not considered a humane means of euthanasia.

Acid-Base Imbalance (Traditional Approach or Hydrogen Ions-Centered Approach)

Using the traditional approach to acid-base balance, the four primary acid-base imbalances and their compensating responses are presented in Table 22.5. Acidosis is associated with an increase in the hydrogen ion concentration (decreasing pH), whereas alkalosis is caused by a decrease in the hydrogen ion concentration (increasing pH). When the primary imbalance is associated with a change in the bicarbonate concentration, the acid-base imbalance is called a *metabolic disorder*. The compensating response for a metabolic acid-base imbalance is mediated by the respiratory tract, which alters the partial pressure of carbon dioxide (P_{CO_2}) to counterbalance the primary imbalance and to partly restore the pH toward normal, but this mechanism has a limited capacity quantitatively to correct bicarbonate concentrations back to normal values (maximum only about 2 mEq/L) (Fig. 22.2). Primary respiratory imbalances are related to changes in alveolar ventilation, which result in an increased P_{CO_2} in respiratory acidosis and a decreased P_{CO_2} in respiratory alkalosis. The compensating response for these primary respiratory acid-base imbalances is mediated by the kidneys through presumed alterations in the excretion or retention of hydrogen ions and bicarbonate. Heparinized blood samples for acid-base evaluation must be drawn anaerobically and sealed immediately. Arterial blood samples should be submitted for evaluation of primary respiratory disorders and for evaluation of ventilation in patients under general anesthesia. Venous blood samples are easier to obtain and provide reliable data for most primary metabolic acid-base abnormalities.

Blood gas analysis should be performed as soon after collection as possible. However, appropriately collected blood samples yield reliable results for as long as 4 hours if held in ice water. The patient's rectal temperature should be provided to the laboratory so that corrections can be made for variation in body temperature. Changes in body temperature have a major impact on the partial pressure of oxygen (P_{O_2}) as well as the P_{CO_2}, but relatively little effect on estimations of bicarbonate or base balance. During brief exercise at maximal intensity, the temperature of the central venous blood may exceed the rectal temperature by as much as 3° C. In these circumstances, the central blood temperature is more appropriate than the rectal temperature for correcting blood gas determinations. The blood sampling site (arterial, venous, or capillary blood) has a significant impact on the blood gas values obtained.[30] Arterial blood samples yield higher values for pH and lower values for

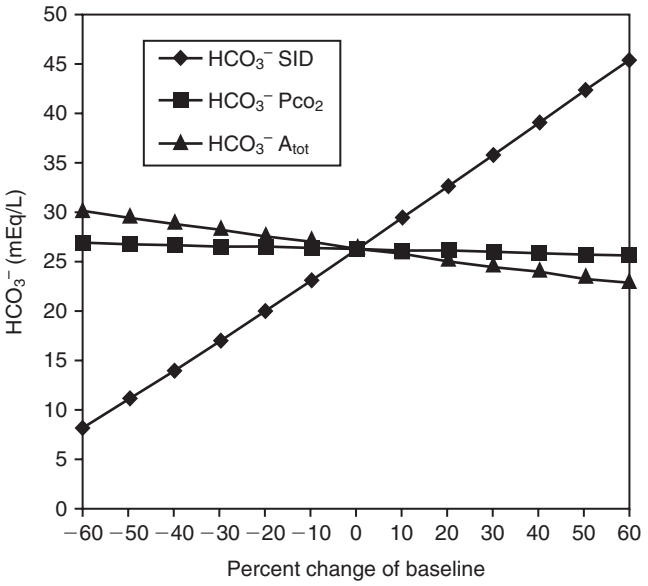

FIG. 22.2 Spider plot graphically showing the dependence of plasma bicarbonate (HCO_3^-) concentration on changes in the three independent variables (SID, P_{CO_2}, and A_{tot}). The spider plot was obtained by systematically varying one independent variable while holding the other two independent variables at their reference values (y axis values at 0 on the x axis) for plasma. Please note how little changes in P_{CO_2} affect concentrations of HCO_3^-.

P_{CO_2} than venous blood, but the bicarbonate is higher in venous blood. The use of blood gas data for evaluation of acid-base imbalances in animals has been reviewed.[31,32] In addition, a review of the traditional and nontraditional approaches to evaluation of acid-base balance as related to fluid therapy in small animals has application to many large animal situations and is well worth reading.[33]

Metabolic Acidosis

Metabolic acidosis is characterized by a decrease in pH and bicarbonate concentration. Metabolic acidosis is traditionally thought to be produced by the addition of hydrogen ions or the loss of bicarbonate ions. The most common causes include the lactic acidosis of ruminal overload, D-Lactic acidosis in neonates ruminants, hypovolemia associated with loss or compartmentalization of sodium-containing fluid, ketoacidosis in ketosis (rare in large animals) and pregnancy toxemia, loss of sodium bicarbonate–rich saliva with oral diseases or esophagostomy in cattle, gastrointestinal loss of sodium bicarbonate as a result of diarrhea, and renal failure, which may result in decreased ability to excrete hydrogen and thus to retain bicarbonate (Box 22.13). Other causes include ingestion of certain drugs or toxic compounds such as salicylate, methanol, ethylene glycol, or paraldehyde (rare in large animals). Increased ventilation provides a respiratory response for metabolic acidosis, and a decline in the P_{CO_2} generally begins within minutes. This temporarily minimizes the fall in blood pH, but long-term correction of metabolic acidosis requires classically explained renal bicarbonate retention and enhanced acid excretion. Complete correction of metabolic acidosis may be difficult in patients with intrinsic renal disease or those with diseases such as renal tubular acidosis that impair the ability of the kidneys to excrete acid or retain bicarbonate, or both.

Metabolic Alkalosis

Metabolic alkalosis is characterized by an increase in pH and bicarbonate. It occurs fairly commonly in domestic animals,

Methanol toxicity
Paraldehyde toxicity
Ethylene glycol toxicity

BOX 22.14

Causes of Metabolic Alkalosis

Common Causes

Sequestration of fluid in the abomasum and forestomach in ruminants (internal vomiting for abomasal reflux)
Gastric reflux in horses with ileus
Massive sweat loss in horses (endurance horses)
Chloride depletion
Potassium depletion
Contraction alkalosis (extracellular fluid volume contraction without bicarbonate loss)
Salivary loss of chloride in horses with esophagostomy
Use of diuretics (especially furosemide)
Functional pyloric stenosis

Uncommon Causes

Excessive bicarbonate supplementation or therapy
Mineralocorticoid excess

particularly in association with digestive disturbances in ruminants. An initiating process capable of generating alkalosis is necessary and must be coupled with additional factors to maintain metabolic alkalosis. Generation of metabolic alkalosis is traditionally thought to be caused by excessive hydrogen loss, bicarbonate retention, or contraction alkalosis (Box 22.14). Contraction alkalosis occurs when the ECF volume is reduced because of loss or sequestration of fluids high in sodium and chloride but without proportionate loss of bicarbonate, which really contradicts electroneutrality of watery solutions. This is thought to be traditionally a contributing mechanism for the generation of the metabolic alkalosis reported in heavily sweating endurance horses and in response to the diuretic furosemide in the horse. The most common causes of increased hydrogen ion loss are the gastrointestinal losses caused by salivary secretions in ponies after surgical esophagostomy[34]; massive gastric reflux associated with anterior enteritis, ileus, or small bowel obstruction in horses; and sequestration of fluid in the abomasum and forestomach associated with a variety of gastrointestinal displacements or functional disturbances (vagal indigestion, functional pyloric stenosis) of ruminants. Continuous salivary losses in horses after surgical esophagostomy result in transient metabolic acidosis followed by progressive metabolic alkalosis. Most of these disorders cause significant dehydration and sodium, chloride, and potassium deficits.

The factors responsible for maintaining metabolic alkalosis involve classically explained impaired renal bicarbonate excretion. These factors are associated with the renal response to decreases in the effective circulating fluid volume, chloride depletion, or potassium depletion. Renal tubular sodium resorption is enhanced in response to hypovolemia. Maintenance of electroneutrality requires that sodium resorption in the proximal tubule be accompanied by a resorbable anion, whereas in the distal tubule sodium resorption is associated with the secretion of another cation, usually hydrogen or, to a lesser extent, potassium. Chloride is the only resorbable anion normally present in appreciable quantities in the proximal tubular fluid. In metabolic alkalosis, plasma bicarbonate is increased and the chloride concentration is generally decreased as a result of disproportionate chloride losses. The relative lack of the resorbable anion chloride in the proximal tubule thus allows a larger amount of sodium to reach the distal tubule, where aldosterone and other factors enhance hydrogen or potassium loss into the tubular lumen in exchange for sodium. Potassium depletion reduces or eliminates potassium exchange as a means of sodium retention, thus classically explained placing greater emphasis on hydrogen ion exchange, which stoichiometrically and quantitatively is difficult to explain. Because renal hydrogen excretion is linked with bicarbonate resorption, the excess bicarbonate cannot be eliminated and metabolic alkalosis is maintained. Thus the traditional explanation is the reason for the paradoxic aciduria seen in some patients with metabolic alkalosis, and it is the reason these patients respond when given intravenous fluids containing sodium, chloride, and potassium. The compensating respiratory response to metabolic alkalosis is hypoventilation, resulting in an increase in the P_{CO_2}. Excessive sodium bicarbonate administration is an additional potential cause of metabolic alkalosis. Most normal animals can tolerate large doses of sodium bicarbonate, and excesses are rapidly eliminated by renal excretion.[35] However, patients with decreases in effective circulating fluid volume, particularly when coupled with potassium or chloride deficits, may not tolerate a bicarbonate load because renal clearance of excess bicarbonate is likely to be impaired. Attempts to alter the acid-base balance, and thereby affect the athletic performance of racing horses, by prerace administration of high doses of sodium bicarbonate–containing "milkshakes" have become a major concern around the world. This has stimulated substantial research on the acid-base balance of horses before and after racing. In many racing jurisdictions, stringent prerace or postrace standards for blood pH or bicarbonate or T_{CO_2} levels (or both) have been enacted to control this practice. The prerace administration of the diuretic furosemide is allowed in several racing jurisdictions of North America. This drug results in a mild metabolic alkalosis with increased bicarbonate, and allowances for this may be included in some regulations. Racing supplements (which may contain sodium bicarbonate), bicarbonate precursors, and diets that supply a high positive cation-anion balance also have the potential to produce a significant metabolic alkalosis.

Respiratory Acidosis

Respiratory acidosis is characterized by a decrease in pH and an increase in P_{CO_2}, which develop because of decreased effective alveolar ventilation. CO_2 diffuses through the lungs much more readily than oxygen; thus diseases that compromise ventilation normally result in decreases in PO_2 before significant increases in P_{CO_2} develop. The most common causes are acute upper respiratory obstruction and primary pulmonary diseases including pneumonia, pneumothorax, pulmonary edema, and severe equine asthma (Box 22.15). Diseases or drugs that affect

Causes of Respiratory Alkalosis

Common Causes

Hypoxemia
Pulmonary diseases
Congestive heart failure
Severe anemia
Stimulation of the respiratory center of the central nervous system
Psychogenic hyperventilation
Excitement, fear, transport, pain
Gram-negative septicemia
Neurologic disorders

Uncommon Causes

After correction of metabolic acidosis
Inappropriate mechanical ventilation
Salicylate toxicity

the respiratory center of the central nervous system may also produce respiratory acidosis, as can general anesthesia. The compensating response for respiratory acidosis is classically thought to be renal retention of bicarbonate. This response requires days to develop and is seen only in chronic respiratory acidosis. Exogenous sodium bicarbonate does not correct respiratory acidosis and should not be administered to affected patients. It should be treated by improving ventilation and alveolar gas exchange.

Respiratory Alkalosis

Respiratory alkalosis is caused by hyperventilation, which may be stimulated by hypoxemia associated with pulmonary disease, congestive heart failure, severe anemia, or neurologic disorders (Box 22.16) or residence or extended stay at high altitudes. The initial compensating response to acute respiratory alkalosis is a modest decline in the ECF bicarbonate concentration—the result of cellular buffering. Subsequent renal responses result in a decrease in the ECF bicarbonate concentration through reduced renal bicarbonate resorption. The decline in bicarbonate may be offset by chloride retention; thus hyperchloremia and decreased P_{CO_2} may be associated with compensated respiratory alkalosis, as well as with compensated metabolic acidosis. Compensating renal responses for chronic respiratory alkalosis that lasts several weeks actually may be sufficient to return pH to normal.[36]

Mixed Acid-Base Imbalances

Mixed acid-base disorders occur when several primary acid-base imbalances coexist. Metabolic acidosis and alkalosis can coexist, and either or sometimes both may occur with either respiratory acidosis or respiratory alkalosis. The following factors should be considered when evaluating possible mixed acid-base disorders:

- Compensating responses to primary acid-base disturbances do not result in overcompensation.
- Compensating responses, except for long-term renal compensation, rarely correct pH to normal. A normal pH in a patient with an acid-base imbalance is an indicator of a mixed acid-base disturbance.
- A change in pH in the opposite direction to that predicted for a known primary disorder indicates a mixed disturbance.
- Bicarbonate and P_{CO_2} always deviate in the same direction with primary acid-base disturbances. If these parameters deviate in opposite directions, a mixed abnormality exists.
- If the change in the anion gap does not approximate the change in bicarbonate, a mixed acid-base imbalance should be suspected.

Mixed acid-base abnormalities occur with some frequency in domestic animals and often are overlooked. The practitioner must be aware of the potential for mixed acid-base imbalances to correctly interpret blood gas data in complex clinical situations.

Anion Gap

The anion gap can be an extremely helpful tool for categorizing causal factors in acid-base imbalances and may prove a useful prognostic guide in animals with serious digestive disorders. The anion gap can be calculated as the difference between the major cations (sodium plus potassium) and measured anions (chloride plus bicarbonate). The anion gap normally is 12 to 17 mmol/L and provides an approximation of the so-called unmeasured anions. These are anions that are not measured routinely in the clinical laboratory; they include "physically" the anionic equivalents of plasma proteins (debatably albumin in particular) which comprises about 95% of total anion gap in normal adult animals, and sulfate, phosphate, lactate, and ketones, with a variety of inorganic anions. Significant differences exist in the normal range of the anion gap among species, and there may also be age-related differences. Foals are reported to have a larger anion gap than do adult horses.

Hypoproteinemia and hyperchloremic metabolic acidosis are the most common causes of a decrease in the anion gap. The cause of normal to low anion gap hyperchloremic metabolic acidosis often can be differentiated on the basis of the serum potassium concentration. Animals with hyperchloremic metabolic acidosis associated with gastrointestinal fluid losses or renal tubular acidosis most often manifest hypokalemia, whereas hyperkalemia generally is seen in patients with decreased mineralocorticoid secretion (Addison disease) or renal failure with renal shutdown. Decreases in the anion gap also result from overhydration caused by decreases in the protein concentration and changes in the relative concentration of plasma sodium and chloride.

Most commonly, high anion gap acidosis is associated with accumulation of a metabolizable acid, most commonly L and D lactic acid associated with anaerobic exercise, grain

VetBooks.ir

overload, acute gastrointestinal accidents, or hypovolemic shock (e.g., diarrhea in young calves). The commonly used laboratory procedures (mostly automated blood gas machines; point of care equipment) for the determination of lactate only measure the L form of lactate. Microbial fermentation in the gastrointestinal tract may result in the production of both the D and L forms of lactate. Recent studies have shown in milk-fed calves and kids that accumulation of D-lactate is a major factor in the profound acidosis associated with certain digestive disorders.[37,38] Unfortunately, at present, determination of D-lactate requires special procedures, which are now available only in special diagnostic commercial kits. Ketoacidosis, uremic acidosis, and poisoning with a variety of anionic poisons result in increases in nonmetabolizable acids that are also causes of an increased anion gap (rare in large animals). When a high anion gap metabolic acidosis is found, a thorough search for the potential causes of the accumulated unmeasured anions is indicated. The anion gap is also useful for identifying mixed acid-base imbalances. A mixed metabolic acid-base imbalance should be suspected when the change in the anion gap does not approximate the change in bicarbonate. Increases in the anion gap can also be associated with dehydration and contraction alkalosis caused by changes in the protein concentration and the relative concentration of plasma sodium and chloride.

Bicarbonate and Total Carbon Dioxide

Bicarbonate accounts for approximately 95% of the measured CO_2; thus TCO_2 or "CO_2 content" of serum or plasma provides a measure of metabolic changes in the acid-base balance. Most automated chemistry profiles now provide the TCO_2 level. Bicarbonate or TCO_2 is decreased in metabolic acidosis and increased in metabolic alkalosis. However, the bicarbonate or TCO_2 values provide only a crude indication of acid-base status. When acid-base abnormalities are suspected, appropriate samples should be submitted for blood gas and electrolyte determination run on the same analyzer. It should be pointed out that bicarbonate levels are always calculated on automated measuring systems.

Buffer Base, Standard Bicarbonate, and Base Excess or Base Deficit

The terms *buffer base*, *standard bicarbonate*, and *base excess* (or *base deficit*) represent derived calculated estimates of the metabolic component of acid-base balance and do not really physically exist. The buffer base indicates the sum of all the buffer anions in blood under standardized conditions. The standard bicarbonate is the plasma bicarbonate concentration that would be found under specific conditions that eliminate respiratory influences on the values obtained. The base excess or base deficit is often supplied in routine assessment of acid-base balance; it indicates the deviation of bicarbonate from normal, usually the stored "normal" for humans in blood gas machines, and thus not directly applicable to large animal blood gas interpretations. The calculated base deficit provides a means of estimating the amount of bicarbonate required to correct metabolic acidosis. The conundrum is that bicarbonate cannot be given without a cation (mostly Na). The bicarbonate estimate is calculated by multiplying the base deficit by the probable sodium bicarbonate space (about 30% [adults] to 50% [neonates and young animals] of body weight), as in the following equation:

$$\text{mEq } NaHCO_3^- \text{ needed} = \text{mEq base deficit} \times \text{kg body weight} \times 0.3 \text{ or } 0.5$$

It should be pointed out that normal ranges of plasma bicarbonate concentrations are different in humans and large animals, with normal large animals being an average of 4 to 5 mEq/L higher compared with normal humans. Modern blood gas machines providing base excess calculations most commonly will use human equations with normal bicarbonate concentrations of 24 mEq/L. When given clinical interpretations of values of base excess, this should be taken into consideration when applying the above equation to calculate $NaHCO_3^-$ deficits. The factor of 0.3 to 0.5 actually represents the sodium space in adult and young animals encompassing the ECF compartment.

STRONG ION-CENTERED APPROACH TO ACID-BASE BALANCE. In the strong ion-centered approach (also known as the Stewart approach or physicochemical approach), acid-base balance is determined by three independent variables: strong ion difference (SID), the partial pressure of CO_2, and the total concentration (mass) of nonvolatile weak acids (A_{tot}), the principal components of which are plasma proteins and, to a lesser extent, inorganic phosphate.[33,39] Bicarbonate and pH are dependent variables determined by these three independent variables. Briefly, this approach is a quantitative approach applying physical laws of chemistry of watery solutions to calculate parameters involved in determining acid-base equilibria and disequilibria. These laws include electroneutrality (Σ cations = Σ of anions), dissociation equilibria (proteins, bicarbonate system, water), and mass conservation. If one of the independent variables (strong electrolytes, proteins, or PCO_2) changes the other dependent variables, pH, bicarbonate, and weak electrolytes adjust. Several studies have adapted the physicochemical approach for practical application in human and veterinary medicine.[32,39-44] Experimentally determined species-specific A_{tot} and Ka data are now available for horses, cattle, dogs, and humans.[45-48]

Strong Ion Difference

Strong electrolytes are completely dissociated in aqueous solution and chemically nonreactive. The SID is simply the difference between the total concentration of strong cations (sodium, potassium, calcium, and magnesium) and total concentration of strong anions (chloride, sulfate, lactate, acetoacetate, and β-hydroxybutyrate) with sodium, potassium, and chloride normally being quantitatively the principal determinants of SID. In fluids with little or no protein, such as cerebrospinal fluid (CSF), bicarbonate concentration is the same as the SID, but it should be noted that the chloride concentration is higher (≈10 to 11 mEq/L) and SID is lower compared with blood; thus normal acid-base equilibria in such fluids are different from acid-base equilibria of blood. Abnormalities in PCO_2 are viewed in essentially the same manner in both the traditional and nontraditional approaches to acid-base balance. Plasma albumin debatably makes up the majority of A_{tot}. The A_{tot} (total mass of proteins) exists physically in blood in both dissociated (A^-) and undissociated forms (HA). A decrease in A_{tot} (A^-) resulting from hypoalbuminemia/hypoproteinemia causes an alkalosis with an increase in bicarbonate, whereas hyperalbuminemia has the opposite effect. Increases in A^- can cause an increase in anion gap, whereas decreases in A^- result in a decrease in anion gap. A change in protein concentration has effects on acid-base balance. The literature describes hyperproteinemic acidosis or hypoproteinemic alkalosis.[40] Details are outlined in Figs. 22.2 and 22.3.

When protein and inorganic phosphate remain within the normal range, acid-base balance is controlled by changes in PCO_2 mediated by the respiratory system and changes in SID, which are largely under the control of the kidneys. Heavy sweat loss in an endurance horse, displaced abomasum in a cow (trapping of chloride in abomasum), or the prerace administration of the diuretic furosemide (chloruresis) in a racehorse produces metabolic alkalosis (mainly observed abnormalities are decreases in serum chloride concentrations). In each case the alkalosis is the result of a disproportionate loss of chloride relative to sodium, yielding hypochloremia and an increase in SID. The

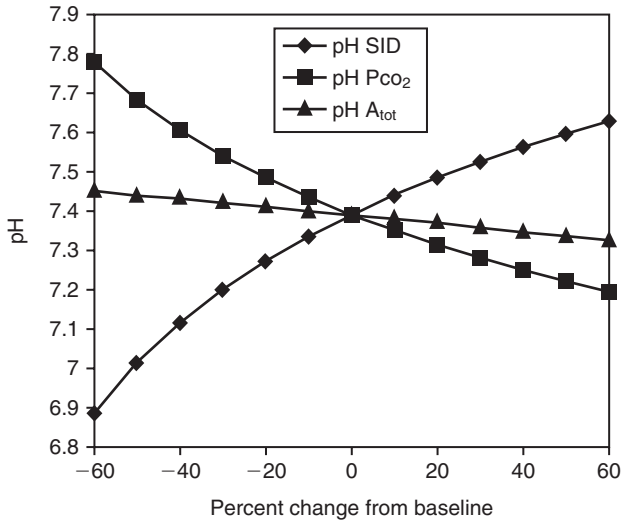

FIG. 22.3 Spider plot graphically showing quantitatively the dependence of plasma pH concentration on changes in the three independent variables (SID, P_{CO_2}, and A_{tot}). The spider plot was generated by systematically varying one independent variable while holding the other two independent variables at their reference values (y axis values at 0 on x axis) for plasma.

dissociation equilibrium of serum bicarbonate concentrations will adjust to fulfill electroneutrality requirements of watery biologic solutions. Correction of the alkalosis is brought about by the provision of relatively more chloride relative to sodium, generally as sodium chloride or potassium chloride. This results in changing SID to more normal concentrations and thus a return of bicarbonate and pH toward normal. Metabolic acidosis with a large base deficit is generally treated with sodium bicarbonate, with sodium being the strong cation added to the ECF and bicarbonate adjusting according to its dissociation equilibrium and sodium added without a strong anion. Other metabolizable anions (short-chain fatty acids such as lactate, acetate, gluconate, and propionate, added with Na as the cation) could be substituted for bicarbonate and achieve similar effects. Short-chain fatty acids are quickly metabolized to glucose and ATP as sources of energy for the body; in physicochemistry, this will result in a relative increase of the SID.

Calculation of SID is simple and provides useful insight in patients with metabolic acid-base disturbances. Factors that influence SID range from changes in free water, to sodium-chloride imbalances that result from excessive losses or disproportionate retention of sodium or chloride, to the accumulation of strong organic anions (most commonly L and D lactate). Organic acidosis can be produced by the accumulation of exogenous and endogenous anions. The anion gap does not always accurately predict the presence of unmeasured strong anions. Mathematic methods have been developed as a means for the detection of unmeasured anions[49,50] and for the calculation of the simplified strong ion gap.[51]

Both the traditional and nontraditional or strong ion approaches to acid-base balance have proven useful to address practical problems in both research and medical settings. The traditional approach to acid-base balance is more widely accepted and user-friendly. The strong ion approach may provide a better understanding as to why the bicarbonate concentration is changing as it integrates acid-base and electrolyte disorders. The strong ion approach has recently gained wider acceptance from members of the human critical care community, who have found it useful for the analysis of the complex fluid, electrolyte, and acid-base problems of patients in intensive care units. Several easy-to-use computer or calculator programs have been developed for the mathematically challenged that facilitate implementation of the strong ion approach to acid-base balance.

Serum Enzymes

Serum enzyme levels are proportional to their cell or tissue concentrations and activity. A number of variables affect the appearance in serum or plasma. The amount of any single enzyme in serum depends on concentration in the cell, total tissue mass, magnitude of cell/organ damage, normal death of the cell, apoptosis, degradation rate of the enzyme in serum or its half-life, and whether the injury is single or continuous.[2] Some of the common and less common causes of elevated serum enzyme activity are listed in Box 22.17.

Sorbitol Dehydrogenase

Sorbitol dehydrogenase (SDH) is a cytoplasmic enzyme that reversibly oxidizes D-sorbitol to D-fructose with the cofactor NAD. It is a liver-specific enzyme in all large animal species. Increases in this enzyme indicate hepatocellular damage and leakage of enzymes. Increases in SDH are also seen with obstructive or strangulating gastrointestinal lesions and with acute toxic enteritis as a result of liver damage associated with absorption of bacteria or their toxins (or both) from the damaged bowel into the portal circulation. This enzyme is a sensitive indicator of liver damage, and modest increases may be seen with anoxia, acute anemia, or general anesthesia. The half-life of SDH in the circulation is short (a matter of hours), and elevations indicate active and ongoing liver damage. This enzyme is not stable when stored at room temperature (only for 5 hours), but refrigerated samples may yield useful results up to 24 to 72 hours if frozen. SDH activity has also been observed increased in horses and cattle with intestinal diseases and in foals with sepsis indicating hepatic involvement in these circumstances.[52,53]

Creatine Kinase

Creatine kinase (CK) is present in high concentrations in the cytoplasm of myocytes; it catalyzes the reversible phosphorylation of creatinine to form creatinine phosphate, which is a major storage of high-energy phosphate in the muscle. It is a "leakage" enzyme and a highly sensitive and specific indicator of muscle damage in domestic animals. Normal values of CK activity vary according to physical activity, restraint, age, and sex. There are four important CK isoenzymes. CK-1 is a BB isoenzyme found mostly in brain. CK-2 MB isoenzyme is found mainly in cardiac muscle and small proportions in skeletal muscle. CK-3 MM isoenzyme is found mainly in skeletal muscle and lesser levels in heart muscle and is responsible for the serum CK levels in large animals. CK-Mt is found mainly in mitochondria and is 15% of cardiac activity.[54] Although CK is found in both cardiac and skeletal muscle, elevations of this enzyme most commonly are associated with exertional myopathies (rhabdomyolysis) and are seen as musculoskeletal manifestations of systemic disease. Intramuscular injections, vigorous exercise, or prolonged shipping may result in modest releases (up to a fourfold increase over resting values) of CK into the circulation without producing histologic evidence of muscle damage. Endurance exercise may lead to moderate elevation of CK (2000 to 15,000 IU/L) in some horses that show no recognizable sign of exertional myopathy. Experimentally it has been shown in horses that when administered IV, the half-life of this enzyme in the circulation is short, 2 hours, but if given IM the half-life is 12 hours.[55] In cattle the half-life is 8 to 9 hours[56]; its activity peaks at 6 to 12 hours, and even marked elevations in CK may return to normal within 24 hours after a single muscle insult. Although marked elevation of CK can be a guide to the extent of muscle damage, the short half-life and the potential for continuing myonecrosis have a marked influence on the enzyme activity observed at any point in time. A persistent elevation of CK suggests a process resulting in active and continuing muscle damage and provides grounds for

BOX 22.17

Causes of Elevated Serum Enzymes

Elevation of Sorbitol Dehydrogenase (SDH)

Common Causes

Severe anoxia
Acute liver failure
Liver abscess
Secondary to damaged bowel
  Strangulating intestinal lesion
  Acute toxic enteritis
Chronic liver failure

Less Common Causes

Acute and severe anemia
General anesthesia
Anoxia

Elevation of γ-Glutamyltransferase (GGT)

Common Causes

Acute liver failure
Chronic liver failure
Pyrrolizidine alkaloid toxicity
Aflatoxicosis
Cholangiohepatitis
Cholelithiasis
Liver flukes

Uncommon Causes

Higher normal range in young animals
Fatty liver

Elevation of Alkaline Phosphatase (ALP)

Common Causes

Acute liver failure
Chronic liver failure
Pyrrolizidine alkaloid toxicity
Cholangiohepatitis
Cholelithiasis
Liver flukes

Uncommon Causes

Higher normal range in young animals
Fatty liver

Elevation of Creatine Kinase (CK)

Common Causes

Exertional rhabdomyolysis (azoturia, myositis, tying-up)
Polysaccharide storage myopathy
Streptococcus equi–associated myopathy
Nutritional myodegeneration (selenium, vitamin E deficiency)
Post-endurance ride multisystemic disorder
Alert downer cow syndrome (muscle crush syndrome)
Malignant hyperthermia
Malignant edema
Prolonged recumbency with inability to rise

Uncommon Causes

Normal postexercise modest increase
Acute cardiomyopathy
Purpura hemorrhagica
Equine influenza
Sarcosporidiosis
Local irritation from intramuscular injections

Elevation of Lactate Dehydrogenase (LDH)

Common Causes

Muscle disease
  Exertional rhabdomyolysis (azoturia, myositis, tying-up)
  Polysaccharide storage myopathy
Streptococcus Equi–Associated Myopathy
Nutritional myodegeneration (selenium, vitamin E deficiency)
Post-endurance ride multisystemic disorder
Alert downer cow syndrome (muscle crush syndrome)
Malignant hyperthermia
Malignant edema
Liver disease
  Acute liver failure
  Chronic liver failure
  Cholangiohepatitis
  Cholelithiasis
In vitro hemolysis

Uncommon Causes

Hemolytic anemia
Acute cardiomyopathy
Purpura hemorrhagica
Equine influenza
Sarcosporidiosis
Local irritation from intramuscular injections
Fatty liver

Elevation of Aspartate Aminotransferase (AST)

Common Causes

Muscle disease
  Exertional rhabdomyolysis (azoturia, myositis, tying-up)
  Polysaccharide storage myopathy
Streptococcus equi–associated myopathy
Nutritional myodegeneration (selenium, vitamin E deficiency)
Post-endurance ride multisystemic disorder
Alert downer cow syndrome (muscle crush syndrome)
Malignant hyperthermia
Malignant edema
Liver disease
  Acute liver failure
  Chronic liver failure
  Cholangiohepatitis
  Cholelithiasis
  Liver flukes
  In vitro hemolysis

Uncommon Causes

Hemolytic anemia
Acute cardiomyopathy
Purpura hemorrhagica
Equine influenza
Sarcosporidiosis
Local irritation from intramuscular injections
Fatty liver

resting athletic horses; it can also be used as a prognosticator in downer cows (>3500 IU/L carries a guarded prognosis). Elevated CK provides no information on the factors responsible for the rhabdomyolysis; more precise information regarding the etiology can be obtained by muscle biopsy and its histologic and histochemical examination. Hemolysis or delayed separation of serum from clot may produce falsely high values for CK as a result of inadvertent muscle penetration during venipuncture.

Aspartate Aminotransferase

Aspartate aminotransferase (AST) is found in high concentrations in a variety of tissues, including skeletal and cardiac

muscles, the erythrocytes and kidneys, and the liver. AST enzyme catalyzes the transfer of the α-amino group of aspartic acid to α-ketoglutaric acid, resulting in formation of oxaloacetic acid and glutamic acid. This enzyme is a nonspecific indicator of tissue damage and tends to be less sensitive to mild insults than the tissue-specific enzymes SDH and CK. The half-life of AST in the circulation is relatively long (it has been reported in horses to be between 7 and 8 days by some and 3 to 4 days by others[57] and around 1 day in cattle[58]), and elevations may persist for as long as 10 days after an episode of myonecrosis or liver damage. As a general rule, extensive muscle necrosis tends to produce much higher elevations of AST than severe liver necrosis. This enzyme is most useful when compared with the tissue-specific enzymes as determined sequentially over the time course of a disease process. Elevations of CK and AST indicate muscle damage, whereas elevations of SDH and AST indicate liver damage. Marked but transient elevations of CK and SDH are associated with a single insult to the muscles and liver, respectively, whereas AST increases gradually and remains elevated for a much longer time. Thus a moderate to marked increase in AST in an animal with progressively declining SDH or CK indicates that some tissue damage occurred within the past 7 to 10 days, but also that the process may no longer be active. This is often a favorable prognostic indicator. Persistent elevation of or a progressive increase in CK or SDH and AST over time indicates an active, continuing process of tissue damage, and the prognosis is more guarded. AST is relatively stable at room temperature, but hemolysis, icterus, or lipemia may interfere with the assay.

γ-Glutamyltransferase

γ-Glutamyltransferase (GGT) is a membrane-bound enzyme that functions in the γ-glutamyl cycle, where it catalyzes the transfer of γ-glutamyl groups from γ-glutamyl peptides. It is important in glutathione metabolism, amino acid absorption, and protection against oxidant injury. This enzyme is found in the biliary tract from where it derives the serum activity in health and disease, therefore making it an important marker of hepatobiliary disorders and cholestasis in large animals. GGT is also found in the pancreas, gastrointestinal tract, urinary tract, mammary gland, and reproductive tract; it does not increase in serum in disorders involving these organs. GGT is quite stable, and reliable results can be obtained from samples submitted several days after blood samples have been drawn, provided the serum is refrigerated. The half-life of GGT activity in blood is not known, but it has been suggested to have a half-life of 3 days in horses. The activity of this enzyme is highest in the cells of the periportal region of the liver, in the pancreas, and in the renal tubular cells. Pancreatic diseases resulting in inflammation and necrosis are relatively rare in large animal species. Damage to the renal tubular cells leads to a release of GGT into the tubular lumen and urine. Because this enzyme is a relatively large molecule, it is not resorbed into the systemic circulation and renal tubular damage does not result in elevated serum GGT activity. Increases in GGT relative to creatinine in the urine have been used as an index of acute renal tubular damage. However, the validity of the normal range for this ratio in horses has been questioned.

In large animal species, an elevation in serum GGT is one of the more reliable indicators of damage to the liver and biliary obstruction. Disease processes such as pyrrolizidine alkaloid intoxication (in subclinical liver diseases showed a 75% sensitivity and 90% specificity); chronic active hepatitis, cholangiohepatitis, and cholelithiasis produce liver damage, primarily in the periportal region, leading to marked and persistent elevation of GGT activity in the serum.[59] In these instances, elevations in serum ALP activity are generally associated with the increase in GGT. Two syndromes—fatty liver syndrome in dairy cows and hyperlipemia syndrome of periparturient mares of pony and miniature horse breeds—are associated with liver damage, which is often reflected by elevation of GGT.

Most suckling neonatal large animals, except horses, have high levels of GGT activity in their serum. This is the result of absorption of maternal GGT, which is present in relatively high levels in the colostrum, making its serum levels a sensitive indicator of passive transfer. Elevation of GGT in neonates should be regarded as a normal finding unless it is associated with other evidence of liver disease. Serum GGT concentrations are relatively higher in foals than in adults.[60] The normal range of serum GGT activity for burros, donkeys, and asses may be substantially higher (two to three times) than the normal range of serum GGT activity for horses. Caution should therefore be used when evaluating this enzyme in these species. Elevation in serum GGT activity has been reported in Thoroughbred racehorses that are performing below expectations. The reasons for the increase in GGT are not known, but horses often respond to a period of rest or reduction in workload. These horses show little histologic evidence of liver damage, and other indices of liver damage and dysfunction usually are within normal limits. The stress of training may be associated with an elevated GGT. Certain trainers, often highly successful ones, appear to have a disproportionately large number of horses with elevations of this enzyme. The normal range for GGT of Thoroughbreds in race training may be slightly higher than that of normal sedentary horses.

Alkaline Phosphatase

Alkaline phosphatase (ALP) is used in most species as a marker for intrahepatic or extrahepatic obstruction of the biliary system. The enzyme is also released by osteoblasts from metabolically active bone. This may be the reason that young, rapidly growing animals normally have high levels of serum ALP, which accounts for the 100-fold higher levels in foals than in adults. Serum ALP in adult horses is 80% liver ALP and 20% bone ALP. Elevations in ALP are also reported in cases of rickets and healing fractures. The intestinal isoenzyme of ALP is similar to the ALP isoenzyme found in neutrophils. Elevations in the ALP activity of abdominal fluid in horses with intraabdominal disease may reflect the release of this enzyme from the neutrophils rather than being a specific marker of damage to the bowel.

ALP has been useful for evaluating liver disease in large animals, particularly in horses with pyrrolizidine alkaloid intoxication, chronic active hepatitis, and cholangiohepatitis, and in some patients with cholelithiasis. A profound elevation in ALP activity is thought to reflect periportal liver damage and biliary obstruction in these patients. A moderate to marked elevation in ALP may be observed in a wide range of disorders resulting in hepatic necrosis and intrahepatic cholestasis. Because this enzyme is not organ specific in large animals, elevations in ALP activity must be interpreted in relation to more organ-specific enzymes such as SDH and GGT.

Other Enzymes

LDH is a metalloenzyme that hydrolyzes many types of phosphate esters at an alkaline pH in the presence of zinc and magnesium ions. It is found in relatively high concentrations in a variety of organs and tissues of the body from the heart, liver, muscle, and kidney to the erythrocytes and leukocytes. An elevation in serum LDH enzyme activity must be evaluated in relation to other, more organ-specific enzymes. LDH isoenzyme analysis can be helpful in differentiating organ system damage, but the analysis is time consuming and not always available. An elevation in LDH activity is expected in hepatic necrosis and serves as an indicator of an active disease process. Extensive muscle damage and rhabdomyolysis tend to result in a more massive release of enzyme and much higher serum

VetBooks.ir

enzyme activity. A modest elevation in LDH may be seen in some hemolytic disorders and some cases of leukemia. Blood samples must be handled with care because hemolysis results in falsely elevated serum LDH activity.

Glutamic dehydrogenase (GLDH) and ornithine carbamoyltransferase (OTC) are two enzymes that are reported to be sensitive indicators of hepatic necrosis in ruminants. GLDH is a mitochondrial enzyme that catalyzes the conversion of glutamate to 2-oxoglutarate. Injury to the hepatocyte has to be severe enough to damage the mitochondria. It is suggestive of either hepatocyte death or sublethal hepatocyte injury. In large animals, it is more liver specific than AST and has better storage stability than SDH. OTC is a hepatic-sensitive enzyme that catalyzes the reaction between ornithine and carbamoylphosphate-forming citrulline and inorganic phosphate. OTC has been used mostly to evaluate fatty liver in cattle and as a prognostic indicator in abomasal displacement and fatty liver.[61] ALT is an important liver-specific enzyme that has wide application in small animals and is often included in automated chemistry profiles. This enzyme has not been useful for evaluation of liver disease in large animal species, and occasionally horses with marked rhabdomyolysis and no other evidence of liver disease show an elevation in serum ALT activity.

Bilirubin

Bilirubin is a breakdown product of the heme component of the hemoglobin molecule and to a lesser extent of the breakdown of other porphyrin-containing compounds (e.g., myoglobulin, cytochrome P_{450}, peroxidase, catalase). Bilirubin exists in the serum in three forms (unconjugated bilirubin, conjugated bilirubin α, and bilirubin δ) and is responsible for the yellow color known as *icterus*, or *jaundice*, of the mucous membranes. Unconjugated, prehepatic, albumin-bound bilirubin is also known as *indirect-reacting bilirubin*, which used to be determined by the van den Bergh reaction; currently total bilirubin is measured by the 2,5-dichlorophenyldiazonium (DPD) method, and direct bilirubin is determined by the method of Jendrassik and Grof.[62] Indirect-reacting bilirubin must be taken up by the liver cells, where it is conjugated and then excreted in the bile. Conjugated bilirubin is known as *direct-reacting bilirubin*, as determined by the van den Bergh reaction. Horses normally have a much higher serum bilirubin level than ruminants, and hot-blooded horses have a higher bilirubin level than cold-blooded horses of the pony and draft breeds. The horse also differs from ruminants in that horses often develop moderate icterus in response to fasting or anorexia associated with many systemic diseases. The increase in the bilirubin concentration in these horses is caused almost entirely by an increase in unconjugated (indirect-reacting) bilirubin, and within a few days the bilirubin can increase from the normal range up to 6 to 8 mg/dL (103 to 137 µmol/L). Therefore the total serum bilirubin concentration is of little diagnostic value in the ill horse unless both the direct- and indirect-reacting bilirubin values are determined. However, in general terms unconjugated hyperbilirubinemia occurs when there is increased production of bilirubin or when either hepatic uptake or conjugation of bilirubin is diminished. Conjugated hyperbilirubinemia is caused by either intrahepatic cholestasis or extrahepatic bile duct obstruction.

Total serum bilirubin is elevated in animals with hemolytic anemia, and this increase is caused largely by an increase in indirect-reacting bilirubin (Box 22.18). The degree to which bilirubin is elevated in hemolytic anemia is a function of the rate of RBC destruction and the capacity of the liver to excrete the newly formed bilirubin. The total bilirubin rarely exceeds 10 mg/dL (170 µmol/L) in hemolytic anemia. An exception is the hemolytic anemia of neonatal isoerythrolysis in newborn foals, which is often associated with marked clinical icterus. In these foals the serum bilirubin may exceed 25 mg/dL (428 µmol/L), a variable but substantial proportion of which (40% to 60%) is likely to be direct-reacting bilirubin causing kernicterus in some cases.

BOX 22.18

Causes of Elevated Serum Bilirubin

Elevation of Total Serum Bilirubin

Common Causes

Hemolytic anemia
Liver failure
Secondary to systemic disease or anorexia in horses

Uncommon Cause

Chronic liver failure in cattle

Elevation of Indirect-Reacting Bilirubin

Common Causes

Secondary to systemic disease or anorexia in horses
Liver failure
Hemolytic anemia

Uncommon Cause

Chronic liver failure in cattle

Elevation of Direct-Reacting Bilirubin

Common Causes

Liver failure
Cholelithiasis
Cholangiohepatitis
Neonatal isoerythrolysis

Uncommon Cause

Hemolytic anemia

The second major cause of clinical icterus and increased serum bilirubin is liver failure. Liver failure results in impaired uptake and excretion of bilirubin. Acute liver failure caused by hepatic necrosis results in marked to moderate increases in both direct- and indirect-reacting bilirubin. In horses with acute liver failure, bilirubin often exceeds 10 mg/dL (170 µmol/L), and this increase is caused primarily by increases in indirect-reacting bilirubin. Direct-reacting bilirubin rarely exceeds 25% of the total bilirubin in the horse, and increases of this magnitude suggest an intrahepatic or extrahepatic biliary obstruction. With chronic liver failure, icterus is more variable and total bilirubin rarely exceeds 10 mg/dL (170 µmol/L). Liver failure in ruminants, particularly chronic liver failure, is associated with a much less striking elevation in serum bilirubin than occurs in horses. In the absence of hemolytic anemia, a bilirubin value above 2 mg/dL (34 µmol/L) indicates impaired hepatic function in ruminants. Hyperbilirubinemia without clinical icterus may be observed in cattle and in sheep with fatty liver associated with ketosis/acetonemia; in such cases, the predominant pigment is unconjugated bilirubin. In horses, unconjugated hyperbilirubinemia can occur a few days after prolonged halothane anesthesia.[63]

Glucose

Blood glucose concentration represents an equilibrium among dietary intake, hormonal interactions (insulin, glucagon, glucocorticoids, catecholamines, and growth hormone), and biochemical pathways (glycogenolysis, gluconeogenesis, and glycolysis). Glucose is an essential substrate for brain cells and erythrocytes. Major storage sites for glucose in the body are skeletal muscles and liver in the form of glycogen.

VetBooks.ir

VetBooks.ir

Hypoglycemia

Hypoglycemia is either the result of poor sample handling, pathologic states, or fasting. Delayed separation of serum from the blood cells may allow time for these cells to consume glucose, thus causing false low glucose levels. Fasting usually does not result in hypoglycemia except in neonatal animals (Box 22.19). Newborns have limited energy reserves, and any disease (mainly septicemia and diarrhea), injury, congenital defect, maternal rejection, agalactia, or management error that limits energy intake can result in marked hypoglycemia associated with profound depression, even coma. In calves with acute severe diarrhea, blood glucose may fall below 40 mg/dL (2.2 mmol/L) in 30% to 50% of cases.[64] One study has shown that 34% of critically ill foals are hypoglycemic.[65] Hypoglycemia may also be seen in animals with acute toxic enteritis, coliform mastitis, septicemia, and colic associated with strangulated bowel, as well as in the later stages of endotoxemia and in some horses with exhaustion after prolonged exercise, hepatic insufficiency, islet B cell neoplasia, hepatocellular carcinoma, and surreptitious injections of insulin. Hypoglycemia is a reasonably consistent feature with primary ketosis and fat cow syndrome in cattle, with pregnancy toxemia in sheep and goats, and in hyperlipemia syndrome, which is seen primarily in pregnant or lactating ponies. Rapid, semiquantitative field tests for blood glucose (Dextrostix, Boehringer Mannheim Diagnostics, Inc., Indianapolis, Ind.) or handheld human glucometers provide a practical means of early recognition of this problem. It should be pointed out that this method reads glucose concentrations slightly low compared with standard laboratory procedures by 10% to 15%.[66]

Hyperglycemia

Hyperglycemia may be seen with excitement, transportation, or stress and probably is mediated by increases in catecholamine and glucocorticoid hormones (Box 22.20). The stress and pain of acute severe colic in horses frequently results in hyperglycemia occurring in approximately 50% of the colic cases, and elevations of blood glucose above 250 mg/dL(14 mmol/L) are associated with a poor prognosis in such cases. In one study all the animals with colic that did not survive had a mean glucose level of 234 mg/dL (13 mmol/L).[67] Endotoxemia initially results in a transient hyperglycemia that may be followed by marked hypoglycemia in the terminal stages of toxemia. The later stages of Cushing syndrome in horses are generally associated with a non–insulin-responsive hyperglycemia and glycosuria. Similar changes can be induced transiently when exogenous glucocorticoid hormones are administered at a high dose rate. Insulin-responsive diabetes mellitus rarely occurs in large animals but has been reported in association with destructive pancreatic lesions. Hyperglycemia in large animals has also been associated with iatrogenic hyperadrenocorticism, pheochromocytomas, after strenuous exercise, after prolonged halothane anesthesia, administration of xylazine or detomidine, during administration of glucose, endotoxemia, proximal duodenal obstruction in cattle, and pituitary pars intermedia dysfunction in horses. Hyperglycemia is rarely encountered in equine metabolic syndrome (EMS).

BOX 22.19

Causes of Hypoglycemia

Common Causes

Inappetence in newborns
Sepsis
Pregnancy toxemia
Endotoxic shock (late stages)
Hepatic failure

Uncommon Causes

In vitro glycolysis by red blood cells
In vitro glycolysis by eperythrozoonosis

BOX 22.20

Causes of Hyperglycemia

Common Causes

Acute severe colic in horses
Stress and excitement
Cushing syndrome
Glucocorticoid administration
Xylazine administration

Uncommon Causes

Overly rapid administration of dextrose
Diabetes mellitus

Creatinine

Creatinine is generated by muscle metabolism and derived from the cyclic use of phosphocreatine—the muscle energy store—resulting in the production of inorganic phosphate and creatine that degrades into creatinine. In the resting animal, this process occurs at a relatively constant rate. The absolute muscle mass and level of physical activity may influence the rate of creatinine production and thus the serum concentration. Starvation, with loss of muscle mass, may result in a slightly reduced serum creatinine level, whereas serum creatinine may be slightly higher in muscular, athletic individuals compared with sedentary animals. Creatinine is distributed throughout the body water and is not reused. Creatinine is normally excreted by the kidneys, primarily by glomerular filtration, and is not normally reabsorbed in the tubules. In azotemic patients a substantial part of creatinine is metabolized and excreted by nonrenal routes. Serum or urine creatinine concentrations determined by the standard alkaline picrate reaction may be falsely elevated by the presence of noncreatinine chromogenic compounds in the serum. These chromogens include glucose, fructose, ascorbic acid, hippuric acid, urea, ketones, cephalosporins, amino acids, and several other compounds. The contribution of these compounds can be reduced or eliminated, and most automated chemical laboratories use such methodology. However, if inappropriately high creatinine is reported in patients without other evidence of renal failure, the method of creatinine measurement should be ascertained.

The serum creatinine concentration provides a crude measure of the glomerular filtration rate. However, serum creatinine, like BUN, is not a sensitive or early indicator of changes in renal function. Alterations in renal blood flow caused by decreases in effective circulating fluid volume (hypovolemia) produce an elevation in serum creatinine and BUN; this can be considered a prerenal azotemia (Box 22.21). It occurs with some frequency in animals with acute enteritis, peritonitis, acute heart failure, massive blood loss, and some forms of colic and in horses with exhaustive disease syndrome. An important point is that many of these disorders initiate the release of inflammatory mediators, which may cause renal damage and impaired renal function above and beyond that associated with impaired renal blood flow and hypovolemia. Prerenal azotemia is usually seen in animals that are dehydrated and volume depleted and that have a history of loss or compartmentalization of sodium-containing fluid. Prerenal azotemia often can be marked (creatinine level above 6 mg/dL; 530 µmol/L), but if uncomplicated, it generally responds rapidly to fluid replacement therapy. Urine production, the urine sodium concentration, and the fractional excretion of

VetBooks.ir

BOX 22.21

Causes of Elevated Creatinine

Common Causes

Prerenal azotemia
- Reduced renal perfusion
- Hypovolemia
- Congestive heart failure
- Dehydration after endurance exercise

Renal azotemia
- Acute renal failure
- Chronic renal failure

Postrenal azotemia
- Urolithiasis
- Renal calculi
- Ureteral calculi
- Urethral calculi

Ruptured bladder

Uncommon Causes

False azotemia
- Noncreatinine chromogens in serum or plasma

Perirenal abscess
Renal carcinoma
Renal dysgenesis
Carcinoma of the bladder
Postexhaustion multisystemic syndrome in horses
Severe exertional rhabdomyolysis with myoglobinuria
Severe intravascular hemolysis with hemoglobinuria
Intoxication or poisoning
- Heavy metal poisoning
- Nonsteroidal antiinflammatory drug intoxication
- Aminoglycoside intoxication

sodium are usually low, and the urine specific gravity is usually elevated. The ratio of urine to plasma urea or creatinine, as well as the urine-to-plasma ratio of osmolality, is reported to be higher in horses with prerenal azotemia compared with renal azotemia.[31] In ruminants, creatinine is a more reliable indicator of renal failure than is BUN. Urea nitrogen can be secreted in saliva and metabolized by the ruminal microflora; this frequently results in a disparity between BUN and creatinine levels in ruminants with renal failure.

Although small increases in creatinine may be seen with progressively compromised renal function, nearly two thirds to three fourths of the nephrons must be nonfunctional before the serum creatinine level clearly exceeds the normal range. Both ARF and CRF are usually associated with elevated creatinine. ARF, especially in animals with anuria or oliguria, is usually associated with progressive daily changes in blood parameters. In contrast, blood parameters of animals with CRF tend to remain relatively constant. A transient but markedly elevated serum creatinine has been observed in some newborn foals that have no other evidence of compromised renal function. Many of these foals are born to mares that had medical problems before parturition. Alterations in placental function may allow the accumulation of creatinine in the foal's circulation. This is called *spurious hypercreatinemia* in foals, and the exact mechanism for this to date is not elucidated. In most of these otherwise normal foals, this marked elevation in serum creatinine resolves within the first few days of life; but usually fluid therapy has been used to help resolve it. There is no clinical significance to decreased serum creatinine levels.

Blood Urea Nitrogen

The term *blood urea nitrogen* (BUN) is ingrained in the veterinary literature, despite the fact that urea nitrogen determinations usually are performed on serum (SUN) or plasma samples.

BOX 22.22

Causes of Decreased Blood Urea Nitrogen

Common Causes

Liver failure
Neonatal animals (blood urea nitrogen is normally lower than in adults)

Uncommon Causes

Low-protein diet
Anabolic steroid administration

This is of little consequence because the actual difference in urea concentrations of whole blood and serum or plasma is relatively small; instead of urea nitrogen, in some parts of the world, urea is measured as the whole molecule. Urea concentration in serum is approximately twice that of the BUN. Urea provides a nontoxic means of excreting ammonia generated by amino acid catabolism and the intestinal microflora. It is distributed throughout the body water. In the intestine, urea is broken down by urease, which is produced by the intestinal microflora, and the nitrogen, as ammonium ion, is recycled to the liver. Urea is excreted by the kidneys, primarily by glomerular filtration, intestine (in high concentration in horses), saliva, and sweat. Ruminants excrete urea into the gastrointestinal tract, where it is converted to ammonia and amino acids that result in protein production.

Urea production occurs almost exclusively in the liver and is synthesized by hepatocytes from ammonia derived from amino acid catabolism. Blood or serum urea is dependent on hepatic urea production and renal tubular flow rate. Urea excretion is not solely determined by GFR because once in the tubules, at rapid flow rates, 40% of the urea is reabsorbed. However, at slow flow rates, as occurs in hypovolemia, 60% is reabsorbed, thus increasing urea levels in serum or blood. Liver failure is frequently associated with a decrease in BUN (Box 22.22). Urea nitrogen tends to be low in nursing animals because of their high fluid intake and urine output and their anabolic state of rapid growth. Urea nitrogen may be reduced slightly in animals given anabolic steroids or fed diets low in protein but of adequate calorie content.

Starvation or other processes that result in rapid tissue catabolism such as fever, burns, exercise, and increased protein digestion (e.g., hemorrhage in the gastrointestinal tract) decrease GFR, or corticosteroid administration may result in modest increases in BUN (Box 22.23). BUN, along with creatinine, provides a crude index of altered renal function in most animal species. BUN is influenced more directly by dietary factors than is creatinine, and creatinine is generally a better guide to renal failure. This is particularly true in ruminants, in which BUN may remain within normal limits in animals with marked impairment of renal function.

The BUN-to-creatinine ratio has been used to try to aid in differentiating prerenal azotemia and intrinsic renal azotemia based on the proportion of increases of each substance in the ratio. However, given the wide variation in BUN and creatinine concentration along with the differences of species, it is not a reliable indicator. In the horse a BUN-to-creatinine ratio of less than 10:1 is expected with ARF; when it exceeds 15:1, CRF is more likely. With these considerations in mind, the discussion of prerenal, renal, and obstructive causes of azotemia in the creatinine section apply to BUN.

Serum Protein

The serum or plasma proteins consist of albumin and globulin fractions. These are discussed in detail in Chapter 26.

Urinalysis

Urinalysis can be an extremely useful diagnostic tool, providing information on many systemic disorders. Ideally urine is collected at the same time as blood for clinical chemistry and before any treatment is administered. The interpretation of certain abnormalities in urine (e.g., glucosuria, ketonuria) is facilitated by concurrent knowledge of chemistry results. Urinalysis is essential in the evaluation of primary renal disease. Urine normally is collected as a voided sample or after catheterization. Voided urine samples are safe and easy to collect but are easily contaminated. Catheterization is preferred for bacteriologic evaluation, but the resultant mild trauma may result in a slight increase in urine RBCs and protein. Because of the urethral diverticulum at the level of the pelvis, it is difficult to successfully catheterize male ruminants. Urethral obstruction is common in male small ruminants, and percutaneous aspiration may be the only way to obtain a urine sample in affected animals. Urinalysis should be performed as soon after collection as possible (within 30 minutes) to avoid degeneration of cellular elements, changes in pH, or bacterial overgrowth (cytolysis, crystallization). If this is not possible, samples should be refrigerated but brought back to room temperature before tests. Urine volume and composition are influenced by feed and water intake, salt supplementation, environmental factors, exercise, stress, systemic disease, and drug administration. Urine samples collected after administration of a diuretic are dilute and unsuitable for routine urinalysis. The tranquilizer xylazine, which is often used to assist in the catheterization of male horses, may alter the results of the urinalysis because it produces diuresis as a result of glycosuria and specifically also kaliuresis.

When urinalysis is performed, the color should be noted along with the organoleptic characteristics of the urine such as the fact that an adult horse's urine has a lot of mucus and becomes cloudier at the end of urination.

Specific Gravity

Specific gravity is defined as the weight of urine relative to the weight of distilled water (=1 at 4° C [60° F]). The normal specific gravity of serum is approximately 1.008 to 1.012. The urine specific gravity is an indicator of renal function because it reflects the action of the renal tubules and collecting ducts on the glomerular filtrate by providing an estimation of the number of particles dissolved in the urine (e.g., whether the urine is concentrated or diluted via serum). It is usually measured by refractometry on urine supernatant. Urine dipsticks with reagent pads for estimating the urine-specific gravity in humans should not be used for this purpose in domestic animals because a poor correlation has been reported compared with refractometry in large animals.[68] Normal animals have the capacity to dilute their urine specific gravity to less than 1.010 and to concentrate greater than 1.050. The normal range reported for most adult large animals is 1.020 to 1.050. Suckling neonatal animals normally produce very dilute urine with a specific gravity below 1.010. Although this could represent immature renal function, it more likely reflects their high-volume fluid intake, because normal neonates can concentrate their urine if fluids are withheld.

Failure to produce concentrated urine, as reflected by a specific gravity below 1.020, in the face of dehydration is an indication of altered renal function, which may be caused by primary renal disease, diabetes insipidus, medullary washout, or nephrogenic diabetes insipidus. With severe and chronic sodium depletion, tubular sodium may be insufficient to sustain normal countercurrent mechanisms for water resorption. This process is called *medullary washout* and has been reported as a cause of polyuria in lactating dairy cattle on a salt-deficient diet. At least 50% of renal function must remain for highly concentrated urine to be produced. Isosthenuria, a urine-specific gravity that remains around 1.010 despite variation in hydration, occurs when renal disease progresses to the point at which renal function is reduced to less than a third of normal. Altered renal function in these animals is usually reflected by a moderate to marked elevation in BUN and creatinine levels and by other changes in the urinalysis. Hyposthenuria occurs when the specific gravity remains below 1.010; this indicates altered release of or response to antidiuretic hormone, which occurs with diabetes insipidus, medullary washout with chronic sodium depletion, nephrogenic diabetes insipidus, psychogenic polydipsia, and chronic liver failure in some horses. Hypersthenuric urine occurs when SG is greater than 1.030 to 1.035, and it occurs commonly in states of dehydration. It is also common in horses fed a high percentage diet of hay and in those living in hot environments.

pH

The normal range of urine pH for adult herbivores is alkaline, with values ranging from 7 to 9. Neonatal foals tend to have slightly acidic urine with a pH below 7. Aciduria in adults may be seen in postrace samples collected from racehorses, after prolonged fasting, with ketosis in ruminants, or in response to metabolic acidosis. A paradoxic aciduria is seen in ruminants with hypochloremic, hypokalemic metabolic alkalosis and has been recently attributed to K concentration changes in the urine.[69] Urine pH is also influenced by the cation-anion balance of the diet. The SID of urine, specifically the potassium concentration, has the strongest influence on urinary pH in dairy cattle and most likely in horses as well.[69]

Protein

Protein is not normally detected in urine, although a false-positive protein reaction may be noted on urine dipsticks as

VetBooks.ir

the sample of herbivores is normally strongly alkaline. Urine with a positive reaction for protein on dipsticks should be checked for protein by a chemical method (urine protein sulfosalicylic acid precipitation test). Proteinuria should be evaluated in relation to the other findings in the urinalysis. Persistent and strongly positive reactions for protein in the absence of leukocytes, RBCs, bacteria, or casts suggest glomerular protein loss, as in glomerulonephritis or amyloidosis. The presence of bacteria and leukocytes with proteinuria suggests sepsis in the urinary tract, whereas hemorrhage or inflammation in the urogenital tract is often associated with proteinuria. A transient postexercise proteinuria is observed in performance horses at submaximal or maximal levels of exertion.

Mild proteinuria is associated with tubular diseases, whereas severe proteinuria is more commonly related to glomerular damage. Urine urea to protein ratio has been used in horses to evaluate more accurately the protein concentration in urine. In horses this ratio is < 1.0 in normal animals.[70]

Glucose

Glucose is not found in the urine of normal large domestic animals unless the blood glucose level increases above the renal threshold, which is thought to be approximately 100 to 140 mg/dL (5.5 to 7.7 mmol/L) in ruminants and approximately 160 to 180 mg/dL (8.8 to 10 mmol/L) in horses. The causes of hyperglycemia and glycosuria were described in a previous section; they include Cushing syndrome, stress, and catecholamine or glucocorticoid hormone release. Hyperglycemia and glycosuria can be created iatrogenically when glucose-containing fluids are administered at an excessive rate. Glycosuria is a fairly consistent finding in sheep with enterotoxemia type D (pulpy kidney). The presence of glycosuria without hyperglycemia strongly suggests renal tubular damage resulting from a toxic or ischemic insult.

KETONE BODIES. The presence of ketone bodies in urine is abnormal in large animals. In horses, ketonuria is uncommon because they are poorly ketogenic; however, it is common in ruminants that are in negative energy balance, early-lactation cows, and pregnant ewes (pregnancy toxemia). Measurement of these ketone bodies in blood, milk, and urine has been used to diagnose and monitor clinical and subclinical ketosis in cattle.

Occult Blood

Both myoglobin and hemoglobin give a positive reaction on urine occult blood dipsticks. In most instances proteinuria shows a positive result as well. A tentative clinical impression sometimes can be formed to differentiate myoglobin from hemoglobin in dark urine if the sample is shaken vigorously in a closed, transparent container. Myoglobin tends to produce a brown foam, whereas hemoglobin produces a reddish foam. Hemoglobinuria caused by intravascular hemolysis is generally associated with clinical and hematologic evidence of hemolytic anemia. Hematuria may result in a positive occult blood reaction if lysis of some of the intact RBCs has occurred. This is likely to happen if the urine is very dilute or if it is held at room temperature for an extended period before analysis. False-positive reactions can occur if microbial peroxidase or oxidizing contaminants are present. Hematuria should be confirmed by cytologic examination of the urine sediment.

Myoglobin

Myoglobinuria should be associated with clear clinical and clinicopathologic evidence of extensive muscle damage. The ammonium sulfate precipitation method of differentiating hemoglobin from myoglobin is imprecise and frequently fails to detect myoglobin in the dark, coffee-colored urine of horses with severe rhabdomyolysis. Accurate differentiation of these compounds in urine requires more sophisticated procedures.

Cells

Cytologic evaluation of urine is deemed essential in cases of unexplained fever, hyperfibrinogenemia, weight loss, and complicated neurologic disease. The normal range for cells is generally considered to be up to five RBCs or leukocytes per high-power field. An increased number of erythrocytes indicates hematuria, which may be caused by neoplasia, trauma, inflammation, or coagulopathy. Pyuria, an increase in urine leukocytes, indicates an inflammatory process; when associated with bacteriuria, it indicates a septic process in the urinary tract. The presence of sheets or rafts of transitional cells suggests neoplasia. Foals' urine has relatively more epithelial cells compared with urine of adult animals.

Casts

Casts are accumulations of protein (Tamm-Horsfall glycoprotein) and cellular material that form in the renal tubules, and when present in the urine, they indicate renal damage or tubular disease. Casts can consist of erythrocytes, leukocytes, or renal tubular cells. As cellular degeneration proceeds, the cell type is more difficult to determine and the casts become granular and then waxy. Hyaline casts are noncellular and are formed from mucoprotein. They may be seen with glomerulonephritis, fever with passive congestion, or severe dehydration with altered renal blood flow. However, casts are soluble in alkaline pH, which is the usual urine pH of large animals, thus making their documentation in urine sediment difficult. If present, they indicate tubular involvement.

Crystals

The crystalline structures in the urine of large animals are those usually associated with an alkaline urine. Calcium carbonate crystals normally are found in abundance in horse urine, particularly if the horse has been fed alfalfa hay. Triple phosphate and calcium oxalate crystals are frequently observed in relatively small numbers. In foals calcium oxalate crystals are more prevalent. The major crystals involved in urolithiasis of feedlot cattle is struvite ($MgNH_4PO_4 \bullet 6H_2O$). In the western United States, silicate stones are most common in livestock under range conditions. Carbonate and oxalate stones are common causes of urolithiasis in small flocks of backyard sheep and goats fed alfalfa hay.

Bacteria

Bacteria are sometimes seen in small numbers in voided urine samples and may represent surface contaminants. Bacterial infections of the urinary tract are usually associated with significant pyuria. When this is noted, a catheterized sample (horse) or clean midstream catch (ruminant) should be obtained for Gram stain, culture, and sensitivity testing. Results from ruminant samples must be carefully interpreted because male ruminants routinely urinate within the prepuce, thus heavily contaminating samples. Fortunately, urinary tract infections in male ruminants and horses are rare.

Urine Creatinine Clearance Ratio[71]

Urinary electrolyte excretion is affected by a variety of factors, including dietary intake, alterations in renal function, and specific hormones that regulate renal electrolyte excretion. Determination of electrolyte concentrations from randomly collected urine samples is easily done and can be clinically useful when these concentrations are compared with serum concentrations. The presence of substantial amounts of sodium in the urine of an animal with hyponatremia suggests excessive renal sodium loss caused by altered renal function

VetBooks.ir

or hormonal control. However, marked variation in the rate of urine production can lead to serious problems in the interpretation of urine electrolyte concentrations. The standard physiologic methods of determining renal electrolyte clearance are complicated by the need for quantitative urine collection and are not well suited to most practical clinical situations. One means of overcoming these difficulties is expression of the renal electrolyte clearance relative to the endogenous creatinine clearance. Expression of the renal clearance as a ratio eliminates the need for quantitative urine collection. This derived value is known as the *creatinine clearance ratio* or the *fractional excretion* (FE), and it is calculated by the following formula:

$$FE = Urine/(X)Serum/(X) \times Serum/(C)Urine/(C) \times 100$$

where *X* represents the electrolyte concentration and *C* represents the creatinine concentration.

The FE fluctuates somewhat during the day in relation to physical activity and feed and water intake. However, under standardized conditions, there is close agreement between the FE determined from single random samples of blood and urine and that based on samples quantitatively collected during a 12- to 24-hour period.[31] The FE of electrolytes has a wide range of normal values. The principal sources of this variation are differences in dietary intake and environmental or experimental conditions. The FE of electrolytes has been useful for detecting specific dietary deficiencies or imbalances. Dietary salt deficiency is associated with an extremely low FE of sodium and chloride, whereas the plasma concentration of these ions generally remains within normal limits. In a similar fashion, dietary calcium and phosphorus imbalances seldom are reflected by the serum concentrations of these ions. Calcium deficiency and phosphorus excess are relatively common dietary problems in large animals and result in a low FE for calcium and a high FE for phosphorus. There are technical problems with the determination of the urine calcium concentration in horses because of their normally alkaline urine and the resultant precipitation of calcium carbonate in the urine. Mixed urine samples from horses must be acidified (hydrochloric acid can be used) to solubilize the calcium. It has favored the use of fractional excretion of phosphorus to diagnose nutritional secondary hyperparathyroidism in horses.

Increases in the FE of sodium are noted with renal tubular damage and impaired sodium resorption. The sodium FE increase has been a useful indicator for the differential diagnosis of prerenal azotemia, which almost invariably results in a low sodium FE, from the azotemia caused by primary renal disease, in which the FE for sodium often is markedly increased. Specific criteria of interpretation in horses have been suggested. In the case of the FE_{Na+}, the reference range varies between 0.01% and 1.0%. A level lower than 0.02% indicates Na^+ conservation by the kidney; an increase may result from excess of dietary intake, Addison disease, and more commonly tubular insufficiency. FE_{K+} normal values are considered between 15% and 80%; values below 15% have been associated with potentially recurrent myositis and chronic laminitis. FE_{Cl^-} has not been reported with a diagnostic value. FE_{Ca++} normal values are between 0% and 33% when used in association with FE_P. The reference values for FE_P have been reported up to 0.5% and as a sensitive diagnostic indicator of calcium and phosphorus balance in horses. An increase above 0.5% is mainly considered an indicator of possible nutritional secondary hyperparathyroidism, renal tubular disease, or pseudohyperparathyroidism.

Collection and Submission of Samples for Hematologic and Cytologic Evaluation*

CATHERINE J. BENSON, *Consulting Editor*

Proper test choice and sample acquisition, preparation, and submission of specimens to a reference laboratory are crucial to making diagnostic decisions to aid in patient care and treatment. Numerous preanalytic factors such as incorrect labeling of samples, presence of interfering substances, use of incorrect collection tubes for a certain test, sampling the wrong tissue for cytologic evaluation, and samples with low cellularity can all impact data results and interpretation. Hematologic and cytologic sample quality can also be affected by the ambient storage temperature and the time interval between collection and evaluation. Care should be taken to eliminate or minimize sources of preanalytic errors to ensure high-quality laboratory results. Hematologic data and cytologic results should always be interpreted in light of the clinical history, physical examination findings, and other diagnostic testing such as imaging or histopathology results. If there are questions regarding sample collection, submission, or handling, contact the reference laboratory.

Venipuncture Site and Technique

Venipuncture site should be based on where it is safe to access a vein that will not collapse when blood is withdrawn.[1] In horses and goats, the jugular vein is most commonly used for blood collection. Alternative but often less recommended sites for venipuncture in horses resulting from safety concerns include the facial sinus, cephalic vein dorsal to carpus, and saphenous veins. In cattle, the jugular and coccygeal (tail) vein can be accessed. Less often, the mammary vein is used due to the risk of personal injury and of hematoma formation at the blood draw site. Depending on the venipuncture site, species, and size of the animal, an 18- to 22-gauge needle and syringe or a double-ended needle and sheath or Vacutainer system (Becton Dickinson and Co., Franklin Lakes, N.J.) with a collection tube can be used to collect blood after the site of the venipuncture is cleaned with an absorbent and 70% isopropyl alcohol and the vein is digitally occluded. After venipuncture, digital pressure should be applied over the site where the needle is removed to prevent hematoma formation.[2] Good technique is important because traumatic venipuncture can result in platelet activation and clumping of platelets. This can falsely decrease the measured platelet count generated by hematology analyzers. Clotted samples will necessitate a recollection.

Handling and Transportation of Samples

Samples for complete blood cell counts (CBCs) should be submitted in ethylenediaminetetraacetic acid (EDTA) tubes, filled to the proper amount indicated on the container, and inverted several times to ensure proper mixing of the blood with the anticoagulant. Too little blood may result in a falsely decreased packed cell volume (PCV) caused by shrinkage of red blood cells (RBCs). When collecting for both a CBC and serum biochemical profile, blood should first be put in an EDTA tube and then in a serum tube that does not contain anticoagulant. Care must be taken to avoid contaminating the blood remaining in the syringe with retrograde flow of EDTA blood because this can alter calcium and potassium values on the serum biochemistry.[1] Samples for coagulation testing (prothrombin time and activated partial thromboplastin time) should be placed in a sodium citrate tube at a proportion of 1:9 with blood. Concurrently sending blood from a clinically healthy animal can serve as a control to help assess artifacts if there is a delay in sample transit. Samples for plasma fibrinogen concentration can be submitted as whole blood in either EDTA tubes or in sodium citrate tubes.[3] Consultation with the reference laboratory is advised because the technique used by a specific laboratory will dictate how the sample should be submitted.

Blood smears for microscopic evaluation should be made immediately to minimize artifacts from deterioration of cells. Blood smears should also routinely be made for manual differential counting, to check for platelet clumps that may be artificially decreasing the platelet count and to evaluate for hemoparasites and atypical cells that would otherwise not be detected. Hematologic results are affected by the ambient storage temperature and the time interval between collection and evaluation. If samples cannot be run immediately on a hematology analyzer, they should be refrigerated. In cattle and goats, if blood samples are handled appropriately, hemoglobin concentration, RBC count, and total white blood cell (WBC) count are stable for the first 24 hours after collection. PCV is stable for up to 12 hours with mild increases at 24 hours.[4]

*Contributions to previous editions by Jed A. Overmann and Debra Deem Morris are acknowledged.

Blood should not be frozen because this will rupture the cells.[1] Shipping and packaging of samples for hematologic and cytologic evaluation should follow guidelines from the reference laboratory.

General Principles for Submitting Cytology Samples

Proper labeling of slides with patient name and sample site will help ensure accurate record keeping and minimize error. Slides that have one edge that is frosted should be labeled with a pencil with the patient identification and sample site before the sample is put on the slides. This is preferred to "permanent" ink marking pens because the preparation stains and fixatives used in the staining process will often wash off the ink.[5] When submitting samples to a diagnostic laboratory, it is important to fill out a complete history including the patient signalment; tissue sampled; location; duration of the mass or illness; a description of the mass or lesion (color, three-dimensional size for masses, shape, texture, consistency, etc.); other important clinical findings (bloodwork, surgical, imaging results); and differential diagnoses. Minimizing the amount of blood present on slides is also important, especially in cases in which inflammation is suspected. In these cases, cytologic findings may need to be interpreted in conjunction with CBC data to aid in determining if inflammation is present or if leukocytes are blood associated. Samples can be obtained by fine-needle aspirate, impression smears, scrapings, and swabs of lesions. Depending on the sample, blood smear, squash, or roll preparations can be made to spread cells on the slide. Once air-dried samples are made, they can be stained with Romanowsky type stains (Wright-Giemsa, Diff-Quik, etc.). Although stained slides may be submitted, it is also important to include some unstained slides when submitting samples to a diagnostic laboratory. Keep unstained cytology slides/samples away from formalin during surgery and when biopsy samples are also being prepared and submitted because the formalin fumes can render cytology samples nondiagnostic.[5]

Bone Marrow Aspirates and Core Biopsy Samples

Please refer to Chapter 28.

Lymph Node Aspirates

Lymph nodes should be manually stabilized, and aspiration or nonaspiration techniques as have been described elsewhere can be used to collect cells.[6] In both techniques, the needle should be maintained within the lymph node and it can be redirected to obtain cells from multiple areas. Peripheral lymph node samples tend to be highly cellular because the lymphocytes tend to exfoliate well and blood contamination is often mild. As a result, it is important to spread the cells out well, which can be done by the squash preparation or blood smear technique. Evaluation of poorly stained thick areas should be avoided. Lymphocytes are often fragile and are prone to lysis; it is therefore important to be gentle when making the preparations. Evaluate only intact lymphocytes because ruptured lymphocytes can appear larger than normal, leading to the misdiagnosis of lymphoma.

The main differential diagnoses for lymph node aspirates include normal lymph node, reactive lymph node, various inflammations (lymphadenitis), lymphoma, and metastatic neoplasia.[6] Normal lymph nodes are composed of mostly small lymphocytes with fewer medium and large lymphocytes. Low numbers of plasma cells, macrophages, eosinophils, nondegenerate neutrophils, and rare mast cells can also be seen. In reactive lymph nodes, small lymphocytes still predominate, but there are increased numbers of medium and large lymphocytes and plasma cells. Reactive lymph nodes are a relatively nonspecific finding in animals with antigenic stimulation, inflammation, or neoplasia. Increased numbers of degenerate or nondegenerate neutrophils, macrophages, or a combination of these 2 cell populations should prompt evaluation for an underlying infectious organism (bacteria or fungus) and for metastatic neoplasia. Eosinophilic inflammation can be seen with parasitic disease, some fungal diseases, and allergic conditions.[6]

General Principles for Various Body Fluids

Fluid should be collected in both EDTA tubes and tubes without anticoagulant. EDTA tubes are best for cell counts, cytologic examination, and total protein measurement, whereas tubes lacking anticoagulant are used for biochemical and microbiological analysis. At least 1 mL of fluid should be collected in each tube if possible.[7] It is recommended to consult with a reference laboratory for the most current guidelines regarding sample collection, storage, and transport for culturing abdominal, pericardial, thoracic, cerebrospinal, and synovial fluids. Direct preparations of highly cellular turbid fluid or concentrated preparations of low cellularity clear fluid should be made as soon as possible, especially when a delay in transportation cannot be avoided. Cytologic findings that may be seen with delayed processing of fluid samples include erythrophagocytosis, vacuolization of large mononuclear cells, and pyknosis. Bacterial overgrowth can also impair interpretation.[8]

Body Fluid Analysis

Abdominocentesis, thoracocentesis, and pericardiocentesis techniques have been previously described in horses[2,7,9,10] and cattle.[2,11] Gross impressions such as the amount of fluid, color, and consistency/turbidity should be evaluated. Normal fluid should be light straw-colored and clear.[11] Samples from thoracic, abdominal, and pericardial fluid should be evaluated on the basis of total nucleated cell counts (TNCC) and total protein concentration (TP). The TNCC and TP together aid the clinician in classification of the fluids into the broad categories of transudate, modified transudate, and exudate. However, microscopic analysis should always be performed to evaluate the cellular differential and to assess for neoplastic cells, organisms, or evidence of chronic hemorrhage. In adult horses, samples from the thoracic cavity are generally transudates if they have fewer than 5000 cells/μL and a total protein of less than 2.5 g/dL, are modified transudates with 5000 to 15,000 cells/μL and a total protein of 2.0 to 5.0 g/dL, and are exudates if the TNCC is greater than 10,000 to 15,000 cells/μL and the TP is greater than 3.0 to 3.5 g/dL.[12] Samples from the peritoneal cavity are similar except that modified transudates can have a TNCC of 1500 to 10,000 cells/μL and a TP of 2.5 to 3.5 g/dL.[8] TNCC and TP interpretations vary widely in cattle, and appropriate references should be consulted.[11] Further information can be obtained in Chapters 30–32.

Synovial Fluid Analysis

Collection of synovial fluid should be aseptic, and a full description of techniques is found in other sources.[13,14] Synovial fluid should be placed in an EDTA tube for cytologic analysis, as well as in a serum tube if a mucin clot test or cultures are desired.[13] The gross and microscopic appearance of the synovial fluid, total nucleated cell count, protein concentration, viscosity, and mucin quality (assessed via the mucin clot test) are all important features to analyze when making interpretations of joint fluid.[14] Normal joint fluid is clear to pale yellow, does not clot, and is highly viscous. Although there is some variability in the TNCC obtained from normal joints from various locations, generally synovial fluid samples are of low cellularity (often < 1000 cells/μL). Hemarthrosis should be distinguished from blood contamination, and the overall differential cell count should be interpreted in light of the degree of blood contamination. Overall, the percentage of neutrophils in normal

joint fluid should not be greater than 10% in the absence of significant blood contamination. Large mononuclear cells and small lymphocytes predominate in normal joint fluid. Neutrophilic inflammation can be due to septic inflammation, immune-mediated disease, or acute trauma. Bacterial cultures and sensitivities are recommended to rule out infectious organisms. Immune-mediated diseases affecting joints are relatively uncommon in the horse.[13]

Alterations in the Erythron

LESLIE C. SHARKEY and ERIN N. BURTON, *Consulting Editors*

MAJOR ALTERATIONS

Hematocrit, 424
Packed cell volume, 424
Hemoglobin, 424
Red blood cell count, 424
Mean cell volume, 424
Mean cell hemoglobin concentration and mean cell hemoglobin, 424
Erythrocyte morphology, 425
Agglutination of RBCs, 426
Coombs test, 426
Anemia, 426
Blood loss, 427
Hemolysis, 427
Decreased erythrocyte production, 427
Erythrocytosis (polycythemia), 427

The *erythron* is defined as the total mass of circulating erythrocytes and their precursors within the bone marrow. Alterations in the erythron are common in clinical practice, and developing an approach to interpreting these abnormalities is important. Initial assessment of the erythron is generally accomplished through evaluation of a complete blood cell count (CBC). Major alterations include anemia and erythrocytosis. On the basis of CBC results, clinical history, and physical examination, additional diagnostic tests can then be selected to further characterize these abnormalities in an attempt to identify a specific underlying pathophysiologic process.

Erythropoiesis

Erythrocytes are produced in the bone marrow, largely under the influence of erythropoietin (EPO), with increased erythropoiesis occurring in response to blood loss or hemolysis. Horses are unique in that equine erythrocytes generally remain in the bone marrow until fully mature before they are released into circulation. As a result, peripheral indicators of regeneration used in other species such as polychromasia and reticulocytosis are typically absent or unreliable in the horse. Detection of relatively low numbers of reticulocytes in the peripheral blood of anemic horses, however, has been described using an automated hematology analyzer, which may be a more sensitive means of detecting these cells than the manual methods used previously.[1-5]

Laboratory Evaluation of Erythrocytes

General reference intervals are presented for common erythrocyte parameters in large animals (Table 24.1); however, laboratory- or instrument-specific reference intervals should be used whenever possible. A complete discussion of age- and breed-related influences on erythrocyte parameters is found elsewhere.[6-8] What follows is a brief review of common laboratory evaluators of the erythron.

Hematocrit, Packed Cell Volume, Hemoglobin Concentration, and RBC Count

Hematocrit (HCT), packed cell volume (PCV), hemoglobin (Hgb) concentration, and red blood cell (RBC) count are all ways of quantifying the erythrocytes in peripheral blood, and these measures tend to increase (erythrocytosis) or decrease (anemia) together. HCT and PCV are similar in that they describe the percentage volume of whole blood occupied by erythrocytes. The HCT is a calculated value and is a function of the mean cell volume and RBC count, whereas the PCV is determined by centrifugation of whole blood in a microhematocrit tube. The Hgb concentration and RBC count are measured values generated by hematology analyzers.

Mean Cell Volume

The mean cell volume (MCV) is directly measured by most hematology analyzers and represents the average erythrocyte volume. An increased MCV can be the result of a regenerative anemia in the ruminant and occasionally in the horse. Decreased MCV is seen with iron-deficiency anemia (also copper) and can also be seen in healthy calves and foals.[3,4,7,8]

Mean Cell Hemoglobin Concentration and Mean Cell Hemoglobin

The mean cell hemoglobin concentration (MCHC) is the cellular Hgb concentration per average erythrocyte and is calculated from the Hgb concentration and HCT. A decreased MCHC can be seen in ruminants with regenerative anemias, but this would not be expected in the horse. Both horses and ruminants can have decreased MCHC as the result of iron-deficiency anemia. A low MCHC has also been reported in

VetBooks.ir

TABLE 24.1

Reference Intervals for Ruminants and Horses

	Cattle[a]	Sheep[b]	Goats[b]	Horses (Hot-Blooded Breeds)[b]	Horses (Cold-Blooded Breeds)[b]
PCV/HCT (%)	22-33	27-45	22-38	32-53	24-44
Erythrocytes ($\times 10^6/\mu L$)	5.1-7.6	9-15	8-18	6.8-12.9	5.5-9.5
Hemoglobin (g/dL)	8.5-12.2	9-15	8-12	11-19	8-14
MCV (fL)	38-50	28-40	16-25	37-58.5	—
MCHC (g/dL)	36-39	31-34	30-36	31-38.6	—
Reticulocytes	—	0	0	—	—

PCV, Packed cell volume; *HCT,* hematocrit; *MCV,* mean cell volume; *MCHC,* mean cell hemoglobin concentration.

calves (<5 weeks) as an age-related change.[5,9] Increased MCHC values are almost always false increases and can be seen with hemolyzed, severely icteric, or lipemic samples or those with large numbers of Heinz bodies present.

Mean cell hemoglobin (MCH) is the amount of hemoglobin per average erythrocyte (in picograms). This is a calculated value based on the Hgb concentration and the RBC count. In general, MCH is affected in a similar manner to MCHC. MCHC, however, is considered more useful since it takes into account cell volume and is thus preferred over MCH when evaluating the erythron.

Erythrocyte Morphology

ANISOCYTOSIS. Anisocytosis is variation in erythrocyte size. A mild to moderate degree of anisocytosis can be seen in healthy ruminants, whereas mild anisocytosis can be seen in healthy horses. Increased anisocytosis can be the result of a regenerative anemia in ruminants and occasionally in horses. The RBC distribution width (RDW) provides an index of the variation in erythrocyte size.

POLYCHROMASIA. Polychromatophilic erythrocytes are slightly immature, macrocytic cells that appear blue-gray on a Wright-stained blood smear because of their retained cytoplasmic ribonucleic acid. An increase in these cells in the peripheral blood is indicative of a regenerative response in ruminants. Increased polychromasia is not expected in horses because in this species erythrocytes complete maturation in the bone marrow before release into circulation. Polychromatophilic erythrocytes are relatively analogous to reticulocytes; however, not all reticulocytes will be viewed as polychromatophilic erythrocytes on a peripheral blood smear. Thus a reticulocyte count is considered a more objective and sensitive means of detecting a regenerative response, particularly if performed by an automated hematology analyzer. If a reticulocyte count is not available, a moderate to large degree of polychromasia observed on a peripheral blood smear is a good indicator of a regenerative response in ruminants.

HOWELL-JOLLY BODIES. Howell-Jolly bodies are small, dark, circular structures consisting of nuclear material within erythrocytes. These can be present in small numbers in healthy horses. Increased numbers can be associated with regenerative anemias and splenic dysfunction. Note that in cattle Howell-Jolly bodies can appear similar to *Anaplasma marginale* and can be difficult to differentiate from these organisms in some cases.

NUCLEATED ERYTHROCYTES. Nucleated erythrocytes (nRBCs) are not normally seen in the peripheral blood of healthy horses or ruminants. In ruminants, small numbers associated with regenerative anemias can sometimes be present but should be accompanied by a significant degree of polychromasia. Bone marrow damage (e.g., toxic damage, hypoxia, neoplasia) can also result in circulating nRBCs. The presence of nRBCs and basophilic stippling in the absence of significant anemia should prompt consideration of lead toxicity (more common in ruminants).

BASOPHILIC STIPPLING. Basophilic stippling is seen as multiple small basophilic inclusions within erythrocytes and is the result of staining of ribosomal aggregates. Basophilic stippling is often seen in association with regenerative anemias in ruminants. As described previously, it can also be seen in cases of lead toxicity.

HEINZ BODIES. Heinz bodies form in erythrocytes as a result of oxidative damage that leads to precipitation of Hgb. They are recognized on Wright-stained blood smears as rounded, pale pink staining structures that protrude from the edge of erythrocytes. Heinz bodies can be confirmed by visualizing them with use of a new methylene blue stain that stains Heinz bodies as dark, rounded structures associated with the erythrocyte membrane. Ingestion of oxidants such as wilted red maple leaves, onions, and garlic; phenothiazine; *Brassica* spp.; and copper toxicity can result in Heinz body formation in large animals. Heinz body formation causes affected erythrocytes to be more susceptible to both intravascular and extravascular hemolysis.

ECCENTROCYTES. Eccentrocytes also form as a result of oxidative damage. In the case of eccentrocytes, oxidative damage results in partial fusion of the erythrocyte membrane causing displacement of Hgb contents to one side of the erythrocyte. Oxidants listed as causes of Heinz bodies can also result in eccentrocyte formation. Eccentrocytes have also been reported in horses with glucose-6-phosphate dehydrogenase deficiency and flavin adenine dinucleotide deficiency. Both are rare erythrocyte enzyme deficiencies that result in the affected animal's erythrocytes being more susceptible to oxidative damage by endogenous or exogenous sources.[10]

ROULEAUX. Rouleaux formation is seen as linear stacking of erythrocytes on a peripheral blood smear. Rouleaux formation is common in healthy horses. A consequence of rouleaux formation is that equine blood samples tend to have a relatively high erythrocyte sedimentation rate, and as a result whole blood samples should be thoroughly mixed before evaluation. Rouleaux formation is uncommon in healthy ruminants but can be seen with increased plasma proteins such as fibrinogen and immunoglobulins. Increases in these plasma proteins can also enhance rouleaux formation in horses. In any species, care should be taken to differentiate rouleaux from erythrocyte agglutination.

VetBooks.ir

AGGLUTINATION. Agglutination is the result of surface-associated antibody on erythrocytes causing clumping. When viewed microscopically on a peripheral blood smear, aggregation produces clumps of erythrocytes that are described as having the appearance of "clusters of grapes." Agglutination is significant in that it is indicative of immune-mediated hemolytic anemia (IMHA). In some cases, it may be difficult to differentiate prominent rouleaux from agglutination. A saline dilution test can be done to confirm true agglutination. This test is accomplished by diluting whole blood with saline and evaluating a wet preparation. Rouleaux will disperse with dilution, whereas true agglutination will persist. Generally a 1:2 to 1:4 dilution will disperse rouleaux; however, occasionally higher dilutions are needed. Agglutination confirmed by a saline dilution test is generally considered to preclude the need for Coombs testing. Agglutination in the horse has also been described as a result of treatment with unfractionated heparin.[11]

Erythrocyte Parasites

A variety of erythrocyte parasites can be detected by review of peripheral blood smears. Examples include *Mycoplasma* spp., *Anaplasma* spp., *Theileria* spp., and *Babesia* spp.[12]

Coombs Test

The Coombs test or direct antiglobulin test is used to detect erythrocyte surface-associated antibody. Positive Coombs test results support a diagnosis of IMHA (including neonatal isoerythrolysis). A negative Coombs test result, however, does not rule out IMHA because this test is known to have a relatively low sensitivity (i.e., many false negatives).

Evaluation of the Anemic Patient

Anemia develops from one or more of three main pathophysiologic mechanisms: blood loss, hemolysis, and Decreased erythrocyte production. More specific causes are often categorized in terms of these three main mechanisms (Boxes 24.1 and 24.2). Specific causes of anemia are also sometimes grouped in terms of whether they cause regenerative or nonregenerative anemia. Anemias that are the result of blood loss or hemolysis are typically regenerative, whereas those that are the result of decreased erythrocyte production will be nonregenerative.

A regenerative response in the ruminant is best identified by a moderate to marked degree of polychromasia or a reticulocytosis. Note that following an acute episode of hemorrhage or hemolysis in ruminants, it takes 2 to 4 days for the bone marrow to respond by beginning to release increased numbers of polychromatophilic cells/reticulocytes into circulation. Peak bone marrow response generally occurs within 7 days. This time frame must be kept in mind when assessing peripheral blood for indicators of regeneration. Other findings that can support the regenerative nature of an anemia would be an increased MCV, a decreased MCHC, basophilic stippling, nRBCs, increased numbers of Howell-Jolly bodies, and increased anisocytosis. It may take 2 to 4 weeks or more in ruminants for the HCT to return to normal after an episode of hemorrhage or hemolysis.

As noted previously, classifying an anemia as regenerative or nonregenerative is more difficult in the horse because of the relative absence of peripheral indicators of regeneration (e.g., polychromasia, reticulocytosis). In these patients, serial CBCs can be performed to detect increasing HCT over time. Similar to ruminants, it takes about 4 days for the bone marrow to begin to respond to an episode of hemorrhage or hemolysis. Mild increases in the MCV can be seen in some horses with regenerative anemias. The bone marrow response to anemia in horses is relatively sluggish compared with other species, and it may take up to 1 to 2 months following severe hemolysis or 2 to 3 months following severe hemorrhage for HCT values to return to normal.[13] In both horses and ruminants, the regenerative response to hemolysis is generally considered to be somewhat more vigorous than the response to hemorrhage. It is suggested that this may be in part due to the fact that in hemolysis, iron (from Hgb) is not lost from that body and is then made available for production of new erythrocytes. Evaluation of bone marrow can also be performed in horses to evaluate for a regenerative response. Enumeration of polychromatophilic cells and reticulocytes in the bone marrow, assessment of overall cellularity, and calculation of the myeloid-to-erythroid ratio (M:E) are used to determine if a regenerative response is present. Excessive hemodilution of the bone marrow sample and the variable M:E ratios present in normal animals, however, can complicate interpretation in some cases.

BOX 24.1

Causes of Anemia in the Horse

Common Causes

Blood Loss

Trauma
Surgery
Ectoparasites (lice, ticks)
Endoparasites (strongyles)
Gastrointestinal bleeding (ulcers, neoplasia)
Immune-mediated thrombocytopenia
Equine purpura hemorrhagica

Hemolysis

Neonatal isoerythrolysis
Red maple leaf toxicosis
Equine infectious anemia

Decreased Erythrocyte Production

Anemia of inflammatory disease (chronic inflammation, neoplasia)
- Chronic abscessation
- Chronic pneumonia or pleuritis
- Lymphoma

Less Common Causes

Blood Loss

Bleeding diathesis associated with disseminated intravascular coagulation (DIC)
Guttural pouch mycosis
Hematuria
Hemoabdomen
Moldy sweet clover toxicosis
Rodenticide toxicity (brodifacoum)
Congenital coagulation factor deficiencies (hemophilia A)
Platelet function disorders (von Willebrand disease, Glanzmann thrombasthenia)

Hemolysis

Fragmentation (DIC, vasculitis)
Immune-mediated hemolytic anemia (idiopathic)
Immune-mediated hemolytic anemia (secondary)
- Clostridial infections
- Penicillin therapy
- Lymphoma

Theileriosis/Babesiosis
Onion toxicosis
Phenothiazine toxicosis
Glucose-6-phosphate dehydrogenase deficiency

Decreased Erythrocyte Production

Anemia of chronic renal failure
Bone marrow neoplasia (leukemia, metastatic neoplasia)
Myelofibrosis
Aplastic anemia (idiopathic, drugs including phenylbutazone)

VetBooks.ir

BOX 24.2

Causes of Anemia in Ruminants

Common Causes

Blood Loss

Trauma
Endoparasites (*Haemonchus* sp. and liver flukes[14])
Ectoparasites (lice, ticks)
Abomasal ulcers, bleeding
Acute severe Salmonella hemorrhagic diarrhea
Oak toxicosis with hemorrhagic diarrhea
Hemorrhagic bowel syndrome (jejunal hemorrhage syndrome)

Hemolysis

Bovine viral diarrhea virus vaccine
Anaplasmosis
Brassica spp. toxicosis
Leptospirosis
Onion toxicosis
Clostridial infections
Chronic copper toxicosis
Water deprivation or salt poisoning followed by ingestion of fresh water

Decreased Erythrocyte Production

Anemia of inflammatory disease (chronic inflammation, neoplasia)
Chronic pneumonia
Chronic abscessation
Johne's disease
Chronic bovine virus diarrhea infection
Lymphoma

Less Common Causes

Blood Loss

Hemorrhagic enteritis
Hemoabdomen
Bleeding diathesis associated with disseminated intravascular coagulation
Moldy sweet clover toxicosis
Caudal vena cava syndrome
Severe acute pyelonephritis
Bovine viral diarrhea and mucosal disease complex[22]

Hemolysis

Babesiosis/theileriosis
Mycoplasma spp. infection
Postparturient hemoglobinuria
Immune-mediated hemolytic anemia

Decreased Erythrocyte Production

Anemia of chronic renal failure
Bracken fern toxicosis (also hemorrhage in enzootic hematuria)
Radiation toxicosis
Myelofibrosis (pygmy goats)
Myelophthisis

Blood Loss

Immediately following an episode of acute blood loss, the HCT and plasma protein concentration are generally within the reference interval. The HCT in horses can actually increase mildly above baseline in some cases as a result of splenic contraction. It is only after fluid shifts have occurred from the interstitial space into the vasculature that the HCT and plasma protein concentration begin to decrease. Increased thirst and renal conservation of free water contribute to the fluid shifts that will continue to occur over a 24- to 48-hour period as vascular volume is restored. Hypoproteinemia concurrent with anemia is supportive of hemorrhage as the cause, assuming there are no other significant sources of protein loss (e.g., gastrointestinal [GI] or renal). Evidence of regeneration should also be present if sufficient time has passed since the episode of blood loss. In some cases, the source of blood loss is obvious (e.g., trauma, surgery, severe epistaxis), whereas in other cases more abstruse sources of blood loss must be investigated. Evaluation of the patient for endoparasites, ectoparasites, hematuria, GI blood loss (e.g., ulcers, neoplasia), and hemoabdomen is warranted in these instances. Chronic blood loss, commonly from parasitic causes,[14] GI ulcers, or GI neoplasia, can result in an iron deficiency anemia. Supportive findings for iron deficiency anemia are decreased MCV, decreased MCHC, hypochromic erythrocytes, and a mild degree of erythrocyte fragmentation (i.e., schistocytes and keratocytes). Iron-deficiency anemia is initially regenerative but, if ongoing, can become poorly regenerative to nonregenerative. Hypoproteinemia may be present; however, protein concentration is within the reference interval in some animals because protein loss is compensated by increased production by the liver. Iron deficiency anemia can also occur in young foals and calves as a result of low dietary intake.[15] An iron panel can be performed to confirm iron deficiency.

Hemolysis

Hemolysis results in a regenerative anemia often with a normal to increased plasma protein concentration. Erythrocyte morphology should be assessed for evidence of Heinz bodies, eccentrocytes, schistocytes, erythrocyte parasites, and agglutination. Hemolyzed plasma and hemoglobinuria are supportive of an intravascular hemolytic process, whereas icterus and hyperbilirubinemia support extravascular hemolysis. Hemoglobinuria, however, should be differentiated from hematuria and myoglobinuria, and liver disease and anorexia (in the horse) should be ruled out as causes of the icterus and hyperbilirubinemia. Feed and/or pasture should be evaluated if ingestion of an oxidant is suspected. Additional diagnostics to consider in cases of hemolytic anemia are Coombs testing (IMHA) and Coggin's testing (equine infectious anemia).

Decreased Erythrocyte Production

Anemia of inflammatory disease, often the result of infection, inflammation, or neoplasia, is the most common cause of a mild to moderate nonregenerative anemia. An inflammatory leukogram and hyperfibrinogenemia would be supportive of the presence of a systemic inflammatory response. Chronic renal failure can also result in a nonregenerative anemia of variable severity (moderate to severe) and can initially be assessed by a serum biochemical profile and urinalysis. Feed and/or pasture conditions and drug history should be determined to prioritize other causes of anemia resulting from decreased erythrocyte production. Bone marrow evaluation is indicated to investigate unexplained nonregenerative anemias, especially when other cytopenias are present.

Erythrocytosis

Erythrocytosis (polycythemia) refers to an increased RBC count, Hgb concentration, and HCT. Erythrocytosis can be either relative or absolute in nature (Box 24.3). In general, relative erythrocytosis is far more common than absolute and these causes should be considered or ruled out first. With relative erythrocytosis, there is no actual increase in total body erythrocyte mass; however, hemoconcentration or splenic contraction causes apparent increases in these measures in the peripheral blood. Hemoconcentration is most often due to dehydration and loss of plasma volume (e.g., diarrhea, excessive sweating, water deprivation, diuresis). Endotoxic shock can also result in hemoconcentration because of increased vascular permeability and subsequent fluid shifts from the intravascular to extravascular space. In both cases, plasma volume is decreased, effectively concentrating the erythrocytes in circulation. With dehydration,

Secondary Inappropriate

Erythropoietin-secreting neoplasms
Renal pathology causing local hypoxia

increased plasma protein concentration and clinical evidence of dehydration (e.g., skin tent, tacky mucous membranes, sunken eyes) would be supportive. Epinephrine-mediated splenic contraction as the result of excitement, pain, fright, or vigorous exercise can also cause a relative erythrocytosis as a result of redistribution of relatively high HCT splenic blood into the peripheral circulation. This is most often seen in the horse. Plasma protein concentration is not expected to increase with splenic contraction as compared with dehydration. Erythrocytosis caused by splenic contraction is a transient change and typically normalizes within a few hours if the inciting stimulus has been removed.

Absolute erythrocytosis occurs when there is a true increase in total erythrocyte mass as a result of increased erythropoiesis and can be primary or secondary in nature. Absolute erythrocytosis is considered secondary when it is in response to increased erythropoietin (EPO) levels or activity. This can be an appropriate physiologic response to chronic hypoxemia (e.g., chronic pulmonary disease, right-to-left cardiovascular shunting, or animals living at high altitude); however, tumor production of EPO or EPO-like substances or renal pathology causing local tissue hypoxia can result in a secondary erythrocytosis in the absence of systemic hypoxemia. Primary absolute erythrocytosis is considered a chronic myeloproliferative disease (primary erythrocytosis or polycythemia vera) where erythropoiesis occurs independent of EPO. There are rare reports of primary erythrocytosis in the horse.[16] Absolute erythrocytosis of unknown cause has also been described in a herd of Jersey calves and in a Japanese black heifer.[17]

Clinical evaluation of animals with an erythrocytosis should first begin by considering causes of relative erythrocytosis because these are much more common. If dehydration, shock, and splenic contraction are ruled out and if the increased HCT persists over time without response to fluid therapy, then the erythrocytosis may be considered absolute. Arterial blood gas, thoracic radiographs, and echocardiography can help to identify decreased cardiorespiratory function and systemic hypoxia as the cause. Neoplasia (e.g., lymphoma, hepatoblastoma, hepatocellular carcinoma) and renal disease should also be ruled out before considering the erythrocytosis primary in nature.[18-21] Bone marrow aspiration and biopsy are generally not helpful in differentiating causes of absolute erythrocytosis (i.e., primary vs. secondary) because erythroid hyperplasia would be expected in both cases. Serum EPO concentrations would be expected to be normal to low in primary absolute erythrocytosis and increased in secondary absolute erythrocytosis. This assay, however, is not widely available, and there is likely some overlap in EPO levels among patients with primary and secondary absolute erythrocytosis, making interpretation difficult in some cases.

Alterations in the Leukogram*

LESLIE C. SHARKEY and DANIEL A. HEINRICH, *Consulting Editors*

MAJOR ALTERATIONS

Neutrophilia, 431
Neutropenia, 432
Eosinophilia, 432
Basophilia, 432
Lymphocytosis, 432
Lymphopenia, 433
Monocytosis, 433

Interpretation of the leukogram in the context of the clinical history, the physical examination, and the rest of the minimum laboratory database (complete blood cell count, serum biochemical data, and urinalysis) can provide valuable insights into the diagnostic process in large animal species. Often leukogram data are used to evaluate patients for the presence of inflammation or hematopoietic neoplasia. Careful attention to sample collection and handling (see Chapter 23) will help to ensure high-quality results. Key components of the leukogram include the total white blood cell (WBC) count, differential cell counts including the absolute numbers of each leukocyte type, and a microscopic evaluation of the blood film. Blood film evaluation is necessary to visually verify the WBC count, to generate the differential, and to evaluate the leukocytes for important morphologic abnormalities that contribute to the diagnostic interpretation of the quantitative data. Although the newer automated hematology analyzers will generate leukocyte differentials for numerous species, the Clinical and Laboratory Standards Institute still considers the manual differential cell count to be the reference standard.[1] Microscopic examination of the blood film for the presence of toxic change, band neutrophils, reactive changes in lymphocytes, neoplastic and atypical cells, and organisms as well as for validation of the total leukocyte count is required for a full characterization of the leukogram. For instance, in cases of equine acute lymphoid and myeloid leukemia, only small numbers of circulating atypical cells may be present, highlighting the importance of peripheral blood film review.[2]

The concurrent measurement of acute phase proteins such as fibrinogen can augment the diagnostic interpretation of leukogram data.

When evaluating the leukogram, clinicians should remember that each data set is a snapshot in time of a dynamic system in which the numbers of cells in the circulation reflect a balance between the release of cells from the bone marrow and egress of cells into the tissues. Serial monitoring of patients often provides more information than a single time point. It is also important to keep in mind that the numbers of cells trafficking in the circulation may not be reflective of the tissue content of cells; therefore cytology or biopsy of tissues may be necessary to confirm the presence of inflammation or hematopoietic neoplasia.

Leukocytes

Leukocytes are partitioned into granulocytes (neutrophils, eosinophils, basophils) and mononuclear cells (lymphocytes, monocytes). In postnatal life the main source of hematopoiesis is the bone marrow, except for lymphocytes, which migrate from the bone marrow to tissues such as the lymph nodes, spleen, and mucosal-associated lymphoid tissue after birth. The following sections briefly describe the biology of each type of leukocyte as well as the interpretation of high and low values and common morphologic abnormalities. Note that the reference intervals for some leukocyte subtypes encompass zero, making the detection of low values difficult and therefore the interpretation of questionable clinical significance (Table 25.1). Although reference intervals are provided here for guidance, clinicians should use laboratory-specific reference intervals because of the potential effect of instrumentation and geographic variation on leukocyte parameters. Other factors that influence reference intervals in large animal species include age, reproductive and lactation status, and husbandry issues that are explored in further detail elsewhere.[3-5]

Neutrophils

Neutrophils develop from hematopoietic stem cells in a process that usually takes about 6 days under the influence of an array of cytokines. Some species can accelerate the process in situations of increased demand, but that capacity appears to be limited in cattle.[6] There is a storage pool of neutrophils in the marrow; however, once that is depleted, earlier precursors, including band neutrophils and sometimes metamyelocytes or

TABLE 25.1

Normal Values for Leukogram Data (Adult Animals)

	Cattle	Sheep	Goats	Horses
White blood cells (1×10^3/μL)	4.9-12	4-12	4-13	5.4-14.3

even myelocytes, may be observed in the peripheral circulation in a phenomenon known as a "left shift." Neutrophils circulate for only a few hours after release, existing either in the circulating pool where they can be measured or in the marginal pool along the endothelial surface where they are not recovered during blood sample collection. Shifts between the circulating and marginal pools in response to hormonal mediators can result in rapid changes in neutrophil numbers measured in the leukogram.

Neutrophils migrate into tissues, especially the gastrointestinal and respiratory tracts and the skin, through selectin-mediated rolling followed by integrin-mediated adhesion of neutrophils to the endothelium. Transmigration between or through endothelial cells allows neutrophils to enter the tissues, where they will bind to chemokines that direct them toward targets in the tissue. Receptor-mediated phagocytosis of bacteria and other particulate matter is followed by proteolytic digestion and/or the respiratory burst using granule contents. Neutrophils also amplify local inflammation and interact with cells of the adaptive immune response.[7] These mechanisms can result in damage to normal tissues in addition to the killing of infectious agents, contributing to acute respiratory distress syndrome and multiple organ failure. Senescent neutrophils undergo apoptosis in tissues and are cleared by tissue macrophages.

Some of the morphologic abnormalities that can be relevant to the interpretation of the leukogram in large animals include toxic change, Pelger-Huët and pseudo–Pelger-Huët anomalies, and the presence of intracellular organisms, including *Anaplasma phagocytophilum*. The common components of toxic change include cytoplasmic basophilia and vacuolization and the presence of Döhle bodies in the cytoplasm of neutrophils; rarer manifestations include nuclear abnormalities, toxic granulation, and increased cell size (both larger neutrophils and giant neutrophils). Larger and giant neutrophils can be induced by endotoxin infusion and can be misclassified as monocytes by automated hematology analyzers and potentially by inexperienced microscopists, indicating the benefit of slide review by an experienced hematologist.[8] It is important to be aware that normal foals can have intracytoplasmic purple granules (staining primary granules) for as long as 30 days after birth and that these should not be confused with toxic granules.[9] Toxic change is subjectively evaluated during the blood film evaluation and graded as 1+ to 4+. These changes occur in the neutrophil cytoplasm during the development in the marrow and signal the likelihood of inflammation; toxic change may be accompanied by a left shift. To further support the importance of blood film review when evaluating the overall leukogram, the presence of band neutrophils and more severe toxic change is associated with the presence of systemic inflammatory response syndrome (SIRS) and poorer outcome in horses admitted for emergency care,[10] and higher band neutrophil counts are associated with nonsurvival in equine neorickettsiosis.[11] Pelger-Huët anomaly is an incidental asymptomatic congenital condition in which a defect occurs in the segmentation of leukocyte nuclei, giving the impression of a severe left shift in the absence of toxic change or other signs of inflammation.[12,13] In contrast, pseudo–Pelger-Huët is pathologic hyposegmentation that occurs as a result of severe inflammation and is accompanied by toxic change and inflammatory disease. *A. phagocytophilum* is a tick-borne bacterium common to humans as well as small and large animal species that survives in neutrophils by avoiding the bactericidal mechanisms.[14] Organisms are most likely to be identified microscopically in acute infection, when serologic methods for detection may still be negative.

Eosinophils

Eosinophil development in the marrow is very similar to that of neutrophils, although it occurs under the influence of distinctive cytokines. Normally eosinophils spend a short time in the circulation before entering the tissues using similar mechanisms to neutrophils, although the numbers in the peripheral blood are usually quite small. The tissue survival time of eosinophils is usually short; however, eosinophils may persist in tissues for longer periods if appropriate survival factors are present. Recirculation is even possible under some conditions. Although eosinophils have the capacity for phagocytosis, more prominent functions include defense against parasites by externalization of granule contents and modulation of inflammation, particularly allergic and hypersensitivity disorders. Eosinophils are primarily tissue dwelling cells, so numbers of cells in the circulation may not accurately reflect tissue eosinophilia.

Basophils

Basophil development largely parallels that of eosinophils, although it is associated with a specific growth factor repertoire. Basophils are the least numerous leukocyte in the peripheral blood under most conditions, where, like other granulocytes, they circulate briefly before entering tissues through similar mechanisms. With even less phagocytic and bactericidal potential than eosinophils, basophils are important in hypersensitivity responses and allergic conditions, which they mediate through release of their granule contents into the local environment. The accuracy of basophil counts by automated analyzers has been questioned.

Lymphocytes

Lymphocytes encompass a heterogeneous group of mononuclear leukocytes fundamental to the adaptive immune response, although some, like natural killer cells, are aligned with innate immunity. Circulating lymphoid cells are generally divided into natural killer cells, B cells, and T cells, with an expanding number of T-cell varieties being characterized, each with a specific function. Advanced diagnostic techniques such as flow cytometry are required to identify cells from different lymphocyte subsets, which are not routinely distinguished during blood film evaluation. All originally derive from bone marrow stem cells; however, T cells complete maturation

VetBooks.ir

in the thymus and participate in cell-mediated immunity, whereas B cells develop in the marrow and other peripheral tissues to eventually disperse throughout the body to effect humoral immunity. Unlike most leukocytes in the peripheral blood, lymphocytes have significant potential for proliferation. Lymphocytes continually recirculate among tissues in a process called "trafficking," which is most relevant for T cells because B cells release antibodies that are carried by the circulation to relevant sites. At any given time, only a tiny fraction of an animal's lymphocytes is present in the circulation, so the peripheral blood lymphocyte count is not reflective of total body lymphoid activity. Likewise, advanced diagnostic techniques are required to characterize the lymphocyte subsets in circulation, which may change with different pathologic processes. In many large animal species, it is not uncommon to see circulating lymphocytes with small, eosinophilic cytoplasmic granules.

Monocytes

Monocytes develop in the bone marrow and enter the circulation, where they persist longer than other leukocytes. Like other leukocytes, monocytes migrate into tissues; however, they have the potential to differentiate into a variety of macrophage subtypes (e.g., Kupffer cells, alveolar macrophages, microglial cells) depending on the local microenvironment. Monocytes can reenter the circulation from the tissues. Unlike mature granulocytes that are postmitotic, monocytes have a limited capacity for replication in tissues. The major functions of macrophages once in the tissues include inhibiting the growth of intracellular pathogens, antigen processing, removal of dead cells and debris, control of iron metabolism, and complex regulation of the inflammatory response. Depending on the stimuli, macrophages can develop into proinflammatory M1 macrophages or antiinflammatory M2 cells.[15]

Principles of Leukogram Interpretation

As noted previously, the absolute numbers of leukocyte subtypes are interpreted in the context of appropriate reference intervals. If there are questions about the validity of available reference intervals, clinicians should consider the option of submission of samples for comparison from one or more age- and sex-matched unaffected individuals sharing the husbandry conditions and genetics of the patient of interest. Although individual abnormalities are discussed in the following sections, integration of all leukogram data to identify diagnostic patterns is often the best approach.

Neutrophilia

Although bacterial infection is the most common cause of neutrophilia in large animal species, nonbacterial infectious agents such as *Blastomyces dermatitidis* infection in alpaca,[16] noninfectious inflammatory processes such as traumatic tissue damage, surgery, foaling in horses,[17] and immune-mediated hemolytic anemia can also cause increased neutrophil concentrations (Boxes 25.1 and 25.2).[18] A left shift and toxic change provide additional evidence of an inflammatory cause for neutrophilia, but they may not always be present, especially with mild or chronic compensated inflammation. In fact, normal neutrophil numbers do not exclude infectious or inflammatory diseases because the numbers of circulating cells do not reflect tissue activity in all conditions. Neutrophilia can signal the presence of otherwise difficult-to-detect processes such as extrapulmonary *Rhodococcus equi* infection in foals,[19] musculoskeletal *Corynebacterium pseudotuberculosis* infection,[20] meningitis or meningoencephalomyelitis in horses,[21] liver abscesses and cholangiohepatitis in dairy cattle,[22,23] leukoencephalomalacia and eosinophilic myocarditis in horses,[24,25] and endocarditis in rams.[26] Stress resulting from causes such as transport and changes in housing can be another important cause of neutrophilia in cattle.[27] Marked neutrophilia occasionally follows a period of neutropenia induced by inflammation (overshoot effect), and very rare genetic causes such as bovine leukocyte adhesion deficiency have been documented. Some authors advocate the use of a neutrophil/lymphocyte ratio to augment the interpretation of absolute neutrophil and lymphocyte numbers on the basis that ruminants have been described to have greater numbers of lymphocytes than neutrophils in the circulation under normal circumstances. Recent information on bovine leukocyte reference intervals suggests that clinicians should exercise caution with that approach and consider laboratory- and herd-specific information when interpreting the ratio.[28]

BOX 25.1

Causes of Neutrophilia in Horses

Common Causes

Excitement, exercise
Stress, exogenous corticosteroid administration
Chronic pneumonia, pleuritis
Strangles (*Streptococcus equi* infection)
Chronic peritonitis, abdominal abscess
Other internal abscessation
Chronic salmonellosis or colitis
Thrombophlebitis
Purpura hemorrhagica (vasculitis)

Less Common Causes

Bacterial endocarditis
Cellulitis
Pyelonephritis
Chronic hepatitis, cholangiohepatitis
Cholelithiasis
Lymphosarcoma
Meningitis, meningoencephalitis
Other internal neoplasia
Pituitary adenoma (equine Cushing's syndrome)
Autoimmune hemolytic anemia
Granulocytic leukemia
Systemic fungal infections

BOX 25.2

Causes of Neutrophilia in Ruminants

Common Causes

Stress, exogenous corticosteroid administration
Chronic pneumonia
Chronic traumatic reticuloperitonitis
Peritonitis
Internal abscessation
Caseous lymphadenitis (O, C)
Mycoplasmal or chlamydial polyarthritis (O, C)
Chronic pyelonephritis
Chronic metritis
Liver abscesses
Enteritis
Umbilical abscessation
Chronic salmonellosis
Septic arthritis

Uncommon Causes

Autoimmune hemolytic anemia
Toxins
Pregnancy toxemia (O, C)
Bovine granulocytopathy syndrome

C, Caprine; *O*, ovine.

VetBooks.ir

Neutropenia

Endotoxemia results in rapid redistribution of neutrophils from the circulating pool to marginal pool and tissues, resulting in neutropenia followed by fast-onset neutrophilia.[8] Neutropenia resulting from bone marrow depletion is often observed in large animal species during the first 24 to 48 hours of an acute inflammatory episode, especially in cattle (Boxes 25.3 and 25.4).[29] Persistent neutropenia is a poor prognostic sign or may indicate bone marrow pathology if other peripheral cytopenias are present. Neutropenia at a single time point may also have prognostic significance; for example, neutropenia in foals 2 weeks of age or younger when admitted to an intensive care unit (ICU) was associated with nonsurvival.[30] Transient viral infections in cattle, such as bovine viral diarrhea virus and bluetongue virus, can cause neutropenia, as can some tick-borne diseases. As for any species, toxic damage to the marrow or bone marrow necrosis, fibrosis, or neoplasia can result in generalized peripheral cytopenias, including neutropenia. Recent work identified neutropenia without toxic change in 10 of 12 horses with acute leukemia in conjunction with at least one other cytopenia and circulating blasts.[2] Alloimmune neonatal neutropenia has been reported in horses.[31]

BOX 25.3

Causes of Neutropenia in Horses

Common Causes

Acute salmonellosis
Acute toxic colitis
Acute peritonitis (ruptured viscus)
Gram-negative septicemia, endotoxemia
Neonatal septicemia
Acute pleuritis
Acute metritis
Proximal enteritis (duodenitis, proximal jejunitis)
Equine influenza
Equine herpesvirus type 1 infection

Less Common Causes

Equine ehrlichial colitis (Potomac fever, *Ehrlichia risticii* infection)
Equine ehrlichiosis (*Anaplasma phagocytophilum* infection)
Idiopathic aplastic anemia
Equine viral arteritis
Radiation toxicosis
Myelophthisic disease (e.g., leukemia)
Alloimmune neonatal neutropenia

BOX 25.4

Causes of Neutropenia in Ruminants

Common Causes

Gram-negative septicemia, endotoxemia
Septic metritis
Septic (coliform) mastitis
Diffuse peritonitis
Ruptured uterus with peritonitis
Ruptured abomasal ulcer
Acute salmonellosis
Acute pneumonia
Toxemia- or toxin-induced bone marrow suppression
Fat cow syndrome (fatty liver)
Clostridial infection

Uncommon Causes

Bovine virus diarrhea
Bracken fern toxicosis
Trichloroethylene toxicosis
Radiation toxicosis
Idiopathic aplastic anemia

Eosinophilia

Eosinophilia is not common in large animal species, even when parasitism can be demonstrated (Boxes 25.5 and 25.6). This may be related to the tissue predilection of eosinophils and the relatively short transit time from marrow to target tissue. However, marked eosinophilia has been reported, such as secondary to *Sarcocystis fayeri* infection in horses[32] and demodicosis in cattle.[33] Rare hypereosinophilic syndromes that are accompanied by peripheral eosinophilia have been described; an example is idiopathic chronic eosinophilic pneumonia in horses.[34] Paraneoplastic eosinophilia resulting from lymphoma has been reported in multiple species. Although eosinopenia may characterize the corticosteroid response in most species, it is difficult to recognize because the lower limit of the reference interval is often zero.

Basophilia

Basophilia is rare in large animal species and is often attributed to hypersensitivity responses. It has been reported in association with certain snake envenomation in horses,[35] and acute basophilic leukemia was recently reported in a calf; however, circulating cells in peripheral blood were blasts and not terminally differentiated basophils.[36] Basopenia is not recognized as clinically significant.

Lymphocytosis

Lymphocytosis characterizes an epinephrine response (especially in young horses) as well as antigenic exposure (Boxes 25.7 and 25.8). The lymphocytosis caused by antigenic stimulation may be accompanied by morphologic changes in lymphocytes, including reactive lymphocytes that have increased amounts of cytoplasm, cytoplasmic basophilia, increased azurophilic granules, or larger cell size. Spontaneous lymphoid leukemias, both acute and chronic in nature, are described sporadically

BOX 25.5

Causes of Eosinophilia in Horses

Uncommon Causes

Internal parasitism
Cutaneous habronemiasis
Systemic hypersensitivity reaction
Lymphosarcoma
Eosinophilic leukemia

BOX 25.6

Causes of Eosinophilia in Ruminants

Uncommon Causes

Milk allergy
Atypical interstitial pneumonia
Acute bovine pulmonary emphysema
Sarcocystosis
Toxoplasmosis
Migrating parasite larvae, such as:
- Lungworms
- Ascarids
- Flukes
- *Trichostrongylus* spp.
- *Hypoderma* spp.
- *Parelaphostrongylus* spp.

Causes of Lymphopenia in Ruminants

Common Causes

Stress, exogenous corticosteroid administration
Gram-negative septicemia, endotoxemia
Septic mastitis
Diffuse peritonitis
Ruptured abomasal ulcer
Acute pneumonia
Infectious bovine rhinotracheitis

Uncommon Causes

Bovine virus diarrhea
Immunodeficiency

in horses, with chronic forms potentially lacking cytopenias[37] and bovine leukemia virus causing persistent lymphocytosis in a third of infected cattle and leukemia in approximately 4%.[29]

Lymphopenia

The most common cause of lymphopenia in large animal species is corticosteroid effects, although the acute phase of systemic infectious diseases may also be associated with a transient period of lymphopenia (Boxes 25.9 and 25.10). Rarely, congenital combined immunodeficiency syndromes, especially in Arabian and Arabian-cross foals, cause severe lymphopenia and global depletion of lymphoid tissues.

BOX 25.11

Causes of Monocytosis in Large Animals

Uncommon Causes

Granulomatous disease
Chronic bacterial infections

Monocytosis

Monocytosis can be seen with inflammation or tissue necrosis, or occasionally as part of a stress leukogram. Because the reference intervals for monocytes approach or include zero, monocytopenia is not a diagnostically useful observation (Box 25.11).

Approach to Interpretation of the Leukogram in Horses

Reference intervals for equine patients are often wide due to the inclusion of a range of ages and breeds; the benefits of using breed- or age-specific reference intervals must be balanced against the preference for reference intervals generated by the laboratory performing the testing.[38] As an approximation, 20,000 leukocytes/μL indicates moderate leukocytosis, 30,000/μL indicates marked leukocytosis, and greater than 30,000/μL is considered extreme. Marked rebound neutrophilia can be observed after an episode of neutropenia resulting from neutrophil depletion caused by acute inflammation or endotoxemia. Foals often have greater absolute numbers of neutrophils and lower numbers of lymphocytes than adult horses for the first several months of life. Variable effects of training on leukocyte counts have been reported.

Epinephrine-mediated (physiologic) leukocytosis is observed more frequently in horses than in many other species, particularly in young warm and hot bloods and horses that are not habituated to transport or handling. This type of leukocytosis is typically characterized by a mild mature neutrophilia and a moderate lymphocytosis that persists for about 20 to 30 minutes. In contrast, the corticosteroid leukogram is less age or breed specific and includes a moderate mature neutrophilia with no left shift or toxic change, lymphopenia, eosinopenia, and inconsistent monocytosis. Corticosteroid leukograms are more persistent than physiologic leukocytosis and frequently can be superimposed on inflammatory leukograms because of the stress of illness.

Leukemias are rare but have been reported in horses. Lymphocytic leukemia is the most common, frequently associated with high lymphocyte counts and/or immature lymphocytes. Other forms of myeloid leukemia may present with large numbers of atypical cells originating from any myeloid lineage or relatively small numbers of circulating atypical cells. The presence of multiple cytopenias may indicate further assessment of bone marrow in patients with small numbers of circulating atypical cells.[2] Disruption of the hematopoietic microenvironment by proliferating neoplastic cells often suppresses the production of other cell lines.

Approach to Interpretation of the Leukogram in Ruminants

Most sources report that neutrophils predominate in neonatal calves and lambs, with a reversal of this ratio about a week after birth.[29] One study examining reference interval data in Holstein cows longitudinally from 1957 through 2010 suggests that, over time, mean neutrophil counts have increased while other leukocyte counts have dropped.[28] A survey of other laboratories suggested that this observation had been made elsewhere but was not universal. Potential causes hypothesized include genetic

VetBooks.ir

selection, changes in management practices, and decreased prevalence of viral pathogens such as bovine viral diarrhea and bovine leukosis virus. Because a predominance of neutrophils compared with lymphocytes regardless of whether absolute cell counts deviate from the reference intervals has been used as an indicator of inflammatory disease in cattle, these findings may be significant to ruminant leukogram interpretation. In light of these findings, clinicians should be especially attentive to the source of reference intervals provided by laboratories.

Corticosteroid leukograms are relatively common in ruminants, as opposed to the changes associated with excitement, which are rare. Stress leukograms are commonly observed in cattle, sheep, and goats in the periparturient period. Stress leukogram changes are often superimposed on inflammation. As described previously, cattle have a sluggish marrow response to increased demand for neutrophils, resulting in the frequent observation of neutropenia in the first 24 to 48 hours after an acute inflammatory stimulus. Persistent neutropenia of more than 3 to 4 days indicates marrow suppression or inability of the marrow to respond to excessive tissue demands. As in the horse, rebound neutrophilia may ensue, often accompanied by a significant left shift that may include myelocytes and metamyelocytes in addition to band neutrophils. The left shift will resolve as neutrophil numbers increase with marrow compensation for increased demand. In chronic or low-grade inflammation, there may be no abnormalities in the leukogram, in which case evaluation of acute phase proteins may be helpful. The leukogram responses of sheep to inflammation generally mirror those of the bovine, whereas goats tend to respond more like small animal species with less frequent periods of leukopenia in response to inflammation.

Alterations in Blood Proteins

JENNIFER L. JOHNS, *Consulting Editor*
MEERA HELLER

■ MAJOR ALTERATIONS

Hyperproteinemia, 436
Panhyperproteinemia, 436
Hyperglobulinemia and the acute phase response, 438, 439
Hypoproteinemia, 440
Hypoalbuminemia, 440
Panhypoproteinemia, 441

Serum or plasma protein measurements constitute a vital component of laboratory diagnostic evaluations. Globulin and total protein measurements will be higher in plasma than serum due to the presence of coagulation proteins, particularly fibrinogen. It is vital to use appropriate reference intervals for the sample type. The following measurement techniques are widely used (units for the following serum or protein measurements are g/dL or the SI unit: g/L):

Refractometry: The total protein concentration of serum, plasma, or body fluids can be determined via refractometry. The principle of measurement is that the degree of light refraction by a solution is proportionate to the concentration of solids. Refractometers are calibrated under the assumption that the solids are largely proteins and that other substances are present in constant concentrations.[1] Increases in other substances can increase the refractive index of a solution and falsely increase the total protein reading; for example, marked hyperglycemia with glucose concentration of 700 mg/dL or azotemia with blood urea nitrogen (BUN) concentration of 300 mg/dL can falsely increase the protein reading by 0.6 g/dL.[2] Hemolysis does not alter refractometer protein readings. The effect of marked icterus is unclear.[3] Use of the urine specific gravity scale for direct measurement of serum, plasma, or body fluid protein concentration is inappropriate, as calibration differs for these different fluid types.[1] Conversion tables are available for translation of specific gravity values into protein concentration values.[4]

Biuret reaction: Serum total protein is commonly measured via modified biuret testing on automated analyzers. The principle involves basic spectrophotometry measuring color change following copper binding to peptide bonds. Depending on the specific assay, hemolysis can cause a positive interference (e.g., hemoglobin of 400 mg/dL can cause a 12% positive bias).[5] This method is not sensitive to very low protein concentrations (e.g., in cerebrospinal fluid).

Bromcresol green (BCG) albumin binding: Albumin concentration in serum or plasma is usually measured via the BCG reaction. The principle involves basic spectrophotometry measuring color change when BCG binds to albumin. Nonspecific BCG binding to globulins can artifactually inflate the albumin value, particularly with a very low albumin concentration.[6] Plasma albumin values can be increased over serum values because of nonspecific plasma globulin binding. Also, heparin interference can increase or decrease an albumin reading depending on the assay.[7] Globulins are typically calculated by subtracting the albumin value from the total protein value.

Protein electrophoresis (PE): Serum or plasma proteins can be separated into albumin and globulin fractions electrophoretically. The principle of measurement is that an electrical charge is applied to a cellulose acetate or agarose gel matrix, allowing serum and plasma proteins to migrate through the matrix and separate into bands based on their charge and size. The acetate or gel is stained to detect the protein bands and read via densitometry to generate a tracing. Albumin has a low molecular weight (roughly 66 kDa), is highly anionic, and migrates the furthest to form a band near the anode. The identical nature of all albumin molecules and therefore their migration to a single band generates a single sharp, narrow-based peak on the tracing. Globulins are divided into α-, β-, and γ-globulin regions in ruminants. In horses, globulins are further divided into α_1, α_2, β_1, β_2, and γ-globulin regions (Fig. 26.1). The heterogeneity of globulin fractions results in broad-based peaks for each, as the diverse proteins in each region migrate slightly differently. Rarely, a narrow-based peak will be seen in the γ-globulin region (see the Hyperglobulinemia section later). The presence of coagulation proteins will cause higher globulin peaks on plasma protein electrophoresis (PPE) than serum protein electrophoresis (SPE). In particular, fibrinogen will migrate into either the "late-beta" peak or the β-γ junction and in rare cases might obscure the presence of a monoclonal peak.[8,9] α- and β-globulins include many acute phase proteins (see the Acute Phase Response section later), whereas immunoglobulins (antibodies), primarily immunoglobulin G (IgG), comprise the γ-globulins. IgA and IgM are immunoglobulins that migrate in the β_2 or β-γ junction regions but are not detected in health via PE testing.

Immunoelectrophoresis: Immunoelectrophoresis is a specialized technique for quantifying each immunoglobulin subtype (e.g., IgG, IgM) via electrophoresis followed by immunoprecipitation using subtype-specific antibodies. Units are usually mg/dL. Other immunoglobulin measurements are designed specifically for detection of IgG in neonatal samples and are discussed under failure of passive transfer (Chapter 53).

Reference values for proteins vary by species (Table 26.1): When evaluating protein concentrations in a patient, some clinicians use the ratio of albumin to globulins (A/G ratio). However, it is often simpler to evaluate albumin and globulins separately, as the A/G ratio can change with alterations in one or both parameters.

Biological variation with life stage: Transfer of immunoglobulins from the dam to the neonate via colostral ingestion is a key process that determines the neonate's subsequent immunocompetence and is often reflected in serum globulin levels in the first few weeks of life. In addition, neonates generally have lower serum albumin levels; for example, calves had decreased albumin values in the first 8 days of life.[10] Total protein levels in calves are decreased at birth, rise immediately following colostrum intake, then fall below the reference interval again at about 2 weeks of age and remain subnormal for some time.[10] IgG measurement also reflects the combined presence of maternal and neonatal proteins (Fig. 26.2). Studies in cows found gradually increasing plasma globulin levels during pregnancy until 4 weeks preparturition, then a steady drop until parturition.[11] IgG1 production is greatly increased at parturition, and the half-life is decreased, corresponding with transfer to colostrum.[12] Serum total protein steadily increased during lactation in Danish Landrace goats.[13] In pregnant and lactating mares, no significant differences in albumin, globulins, and total protein were found at any stage.[14] Aging can be associated with alterations in some laboratory parameters. However, no significant differences in biochemical parameters or specific concentrations of IgG, IgA, or IgM were found in aged horses, despite alterations in lymphocyte populations.[15,16]

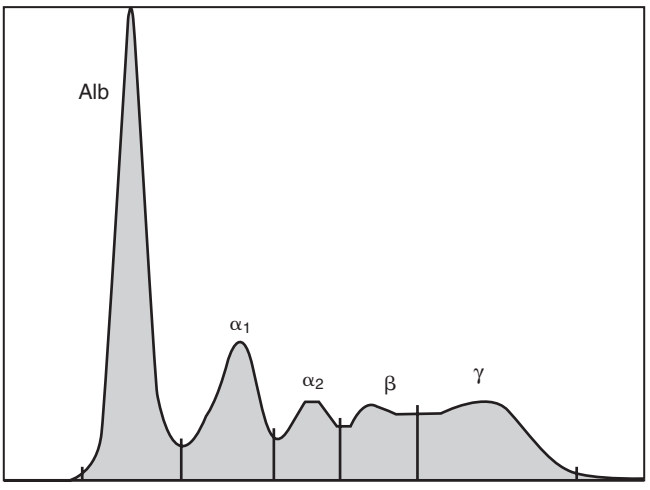

FIG. 26.1 Normal equine serum protein electrophoresis. *Alb*, Albumin.

Hyperproteinemia

Hyperproteinemia can result from an increase in both albumin and globulins (panhyperproteinemia) or an increase in only globulins (hyperglobulinemia) (Boxes 26.1 and 26.2).

Panhyperproteinemia

An increase in the concentration of all blood proteins results from hemoconcentration. Dehydration (due to decreased fluid intake, excessive fluid loss, or both) causes panhyperproteinemia

BOX 26.1

Causes of Hyperproteinemia in Horses

Panhyperproteinemia-Dehydration

Common Causes

Acute toxic colitis of unknown cause
Acute salmonellosis
Potomac horse fever
Intestinal clostridiosis
Intestinal strangulating obstruction
Proximal enteritis
Gram-negative sepsis, endotoxemia
Botulism
Choking (esophageal obstruction)

Less Common Causes

Chronic renal failure
Chronic hepatic disease
Guttural pouch mycosis with dysphagia
Equine protozoal myelitis
Salt toxicity
Toxins, poisonous plants
Lead toxicity
Yellow star thistle poisoning (dysphagia)
Dysphagia of unknown cause

Hyperglobulinemia

Common Causes

Abdominal (mesenteric) abscess (including "bastard" strangles)
Pulmonary abscess
Chronic pleuritis
Purpura haemorrhagica
Equine infectious anemia

Less Common Causes

Chronic hepatic disease
Strongylosis

BOX 26.2

Causes of Hyperproteinemia in Ruminants

Panhyperproteinemia-Dehydration

Common Causes

Ruminal acidosis (grain overload)
Abomasal torsion
Acute salmonellosis
Peritonitis
Sepsis, toxemia (mastitis, metritis)
Intussusception
Vagal indigestion
Oral or pharyngeal foreign body with dysphagia
Coccidiosis
Diarrhea, undifferentiated
Salt toxicity
Toxins, poisonous plants

Less Common Causes

Renal amyloidosis
Lymphoma
Pregnancy toxemia
Rabies

Hyperglobulinemia

Common Causes

Abdominal abscess (traumatic reticuloperitonitis, uterine tear, other)
Chronic pneumonia
Umbilical abscess
Lymphoma
Caseous lymphadenitis (sheep and goats)
Other abscess

Less Common Causes

Parasitism
Pregnancy

with an associated increase in packed cell volume (PCV). This is due to a relative increase in protein and red blood cell (RBC) concentrations in blood. True hyperalbuminemia (i.e., increased albumin synthesis) does not occur. Hyperalbuminemia is an insensitive indicator of dehydration. If the true albumin level is decreased, a dehydrated patient may have a normal albumin result that masks both hemoconcentration and hypoalbuminemia. Similarly a dehydrated, anemic animal may have hyperproteinemia with a normal or decreased PCV. In an animal with a plasma protein concentration of 7.0 g/dL in health, a 10% decrease in plasma volume (severe dehydration) will result in a plasma protein concentration of 7.8 g/dL.[3] As with albumin measurement, the total plasma protein measurement will underestimate degree of dehydration if the patient is losing protein along with fluid. This is relatively common in renal disease, in protein-losing enteropathy with diarrhea, and in third-space loss when fluid and protein accumulate in the thoracic and/or abdominal cavity. Dehydration alone can result from gastrointestinal (GI) fluid sequestration, including intestinal obstruction, vagal indigestion with internal vomiting, and grain engorgement. Less common causes of dehydration include polyuria with renal failure, exudation from extensive skin wounds, and excessive sweating. Physiologic responses to dehydration include increased urine concentration and decreased urine output, increased fluid absorption from the GI tract, and increased thirst.

Hyperglobulinemia

The most common cause of hyperglobulinemia with normal hydration status (i.e., without hemoconcentration) is inflammation resulting in increased production of numerous globulins, including many acute phase proteins (see the Acute Phase Response section later). Chronic inflammation frequently results in a nonspecific increase in γ-globulins *(polyclonal gammopathy)* due to production of different immunoglobulins by plasma cells in response to chronic antigenic stimulation. A broad-based peak will be seen on SPE in the γ region and can extend into the β region due to production of IgM and/or acute phase β-globulins. An increase in both β- and γ-globulin fractions (β-bridging) can occur with intense antigenic stimulation, chronic active hepatitis, or lymphoma. Increased IgG in the γ-globulin fraction is termed *hypergammaglobulinemia* and can be seen in a range of chronic inflammatory diseases, including internal abscessation, chronic hepatitis, immune-mediated diseases (e.g., immune-mediated hemolytic anemia or thrombocytopenia), and lymphoma. Infection with the agent of epizootic bovine abortion triggered significant increases in IgG in clinically affected heifers.[17]

Increased production of a single immunoglobulin by a clonal population of B lymphocytes/plasma cells is known as a *monoclonal gammopathy*. On SPE, the monoclonal peak is as narrow-based and sharp as the albumin peak due to the identical migration of the monoclonal immunoglobulins (also known as *paraproteins*). Monoclonal gammopathies are usually secondary to neoplasia of B lymphocytes or plasma cells, including B-cell lymphoma, multiple myeloma, and B-cell lymphocytic leukemia. Increased susceptibility to hemorrhage can occur

with monoclonal gammopathy due to impaired platelet function caused by immunoglobulin coating and can be exacerbated by hyperviscosity syndrome.

The Acute Phase Response

Acute inflammatory processes can trigger an acute phase response. Infectious causes are common, but many noninfectious causes (e.g., trauma, strenuous exercise) are documented. The body's response to the inflammatory insult is altered liver production of many proteins, termed *acute phase proteins* (APPs). A few proteins are negative APPs, and their production decreases with acute inflammation. Albumin is the most prominent negative APP, and levels will decrease in circulation proportionate to its half-life in each species. For example, the albumin half-life is 19.4 days in horses and 16.5 days in cattle, so hypoalbuminemia due to inflammation will take several weeks to develop in these species.[6,18] Transferrin and transthyretin (prealbumin) are other negative APPs, as is apolipoprotein A1 (see the Apolipoprotein A1 section later). The presumed role of decreased production of certain proteins is to shift available amino acids to the synthesis of proteins that are useful in host defense.[19]

Most acute phase reactants are positive APPs, meaning production increases with inflammation. These proteins will migrate into the α and β regions on SPE or PPE. The positive APPs are a diverse group, including proteins involved in coagulation, opsonization, iron regulation, and limiting tissue injury. Protein electrophoresis can reveal increased globulin fractions that are composed largely of APPs. Some diseases cause fairly specific alterations; for example, internal parasitism in diarrheic horses caused increased β_1 globulin levels that were significantly higher than those in diarrheic horses with other disorders.[20] Nonprotein assays are also used to diagnose an acute phase response; for example, serum iron outperformed plasma fibrinogen as an indicator of acute inflammation in horses.[21]

Measurement of individual APPs can be useful diagnostically and is not limited to blood; assays for APPs in milk and saliva have also proven useful.[22-24] The following is a list of major APPs in large animals.

Fibrinogen

Fibrinogen is a useful marker of inflammatory disease in large animals. Increased plasma fibrinogen, termed *hyperfibrinogenemia*, can occur in a myriad of conditions. Fibrinogen is semiquantitatively measured via the heat precipitation method, along with total plasma protein, as part of the routine complete blood cell count (CBC). Serum samples cannot be used to measure fibrinogen. The heat precipitation method cannot be used to detect hypofibrinogenemia (see Chapter 27).

As for other proteins, fibrinogen concentration can be increased due to dehydration. Calculating the plasma protein/fibrinogen (PP/F) ratio is useful when fibrinogen is increased. If the PP/F ratio is greater than 15, hyperfibrinogenemia is likely due to dehydration. If the PP/F ratio is less than 10, the patient has true hyperfibrinogenemia (due to inflammation).[25] Severe inflammatory disease in horses and ruminants consistently causes hyperfibrinogenemia, although the increase in fibrinogen may not be proportionate to the degree of inflammation. Increased fibrinogen often precedes development of an inflammatory leukogram in ruminants, particularly in cattle.[25] Hyperfibrinogenemia can persist for a period of time postoperatively. In one study more than half of horses undergoing subchondral bone cyst removal still had hyperfibrinogenemia 15 days post operation; in another study fibrinogen remained increased through day 11 following laparotomy and other procedures.[26,27]

In adult horses a number of conditions, including colic, sterile inflammation, surgical intervention, and chronic internal abscessation, are associated with hyperfibrinogenemia (Box 26.3).[26,28-30] Vaccination of horses induces an acute phase response including increases in both fibrinogen and serum amyloid A.[31] Fibrinogen response in foals is more variable. In healthy neonatal foals fibrinogen levels are initially lower than adult values and then equilibrate within a few weeks of age.[32,33] Hyperfibrinogenemia lags behind leukocytosis as an indicator of inflammation in foals.[32,34] Fibrinogen was an unreliable marker of foal sepsis in one study,[35] although marked hyperfibrinogenemia of 900 to 1500 mg/dL had utility as a diagnostic marker of foal osteomyelitis.[36] Fibrinogen may be useful as an indicator of foal pneumonia due to *Rhodococcus equi*: One study found that hyperfibrinogenemia had greater specificity than leukocytosis, but another reported better diagnostic performance (encompassing both sensitivity and specificity) of leukocytosis over hyperfibrinogenemia.[37,38] Late pregnancy correlates with increased fibrinogen concentration in mares. In one study fibrinogen concentration progressively increased roughly 1 week prior to foaling, peaked at the time of foaling, then gradually decreased but remained increased over control values for several weeks post foaling.[39]

Fibrinogen is a particularly useful indicator of inflammation in cattle and other ruminants, as they develop substantial hyperfibrinogenemia in response to inflammation (Box 26.4).[40] A number of inflammatory diseases in cattle are associated with hyperfibrinogenemia, including peritonitis, mastitis, and pneumonia. Lymphoma and uncomplicated displaced abomasum (without peritonitis) did not present with hyperfibrinogenemia.[40] Progressive increase in fibrinogen concentration occurs with pregnancy in cattle, with a significant increase just prior to parturition compared to the 2 days prior to calving.[41] Fibrinogen is reportedly low to undetectable in neonatal calves.[42] One

Ferritin	Horses[103]
α1-Acid glycoprotein (α1-AG)	Cattle[75]; Goats[89]; Sheep[94]

study of healthy calves reported a peak in fibrinogen at postnatal day 6 (mean value 400 mg/dL), then a gradual decline until reaching a mean nadir of 250 mg/dL at day 50 followed by a slight rise; values always remained within the reference interval for adult cattle.[8] Fibrinogen was significantly increased in calves with suspected septic shock.[43]

Other APPs

The usefulness of individual APP measurement in diagnosis of inflammatory disease varies by species (Table 26.2). The following APPs have proven utility in one or more large animal species.

HAPTOGLOBIN. When haptoglobin enters the circulation, it immediately binds hemoglobin to form a complex that is then internalized by hepatic Kupffer cells.[44] Increased haptoglobin during the acute phase response occurs due to transcriptional activation. Haptoglobin may regulate and modulate the immune response during inflammation.[45] Serum haptoglobin concentration increased in experimentally induced bacterial placentitis in mares and experimentally induced strongyle infections of young horses.[46,47] Both acute and chronic heaves correlated with increased serum haptoglobin following allergen challenge.[48] Interestingly, in one study haptoglobin concentration decreased in serum but increased in peritoneal fluid in horses with colic.[49] Serum haptoglobin concentration increases in the first week postpartum in dairy cows.[50] Measurement of haptoglobin in milk is superior to measurement in serum for diagnosis of mastitis, although serum measurement is also useful.[22,51] Haptoglobin performs well as an acute phase marker in sheep, with increases found during inflammatory diseases including bacterial metritis and pneumonia.[52,53] Serum haptoglobin concentration varies with reproductive status in goats: Pregnant does in the second trimester have decreased values, and lactating does have increased values when compared to open, nonlactating does.[54]

C-REACTIVE PROTEIN (CRP). In health, CRP is present in trace amounts in circulation. Inflammation and tissue necrosis can markedly upregulate CRP levels.[55] The role of CRP in the acute phase response may be clearance of endogenous or exogenous substances (e.g., microorganisms, cellular debris), but CRP may also worsen inflammatory tissue damage via complement activation.[56] Dairy cattle had increased serum CRP levels during lactation that were highest at peak lactation and declined thereafter; mastitis and other inflammatory diseases caused further increases (e.g., a threefold increase in CRP levels in mastitic cows compared to healthy lactating cows).[57] Increased CRP has been associated with pneumonitis, enteritis, and arthritis in horses.[58]

SERUM AMYLOID A (SAA). The SAA protein family of apolipoproteins includes both constitutively expressed proteins and acute phase reactants that are markedly upregulated during inflammation.[59] The induced proteins chemotactically recruit leukocytes and are implicated in the pathogenesis of chronic inflammation, as they are precursors of the amyloid A protein in amyloidosis. SAA testing via point-of-care handheld devices has become standard practice in some equine facilities. Studies support the use of SAA measurement as an indicator of acute inflammation (including septic inflammation and heaves) and a useful monitoring tool for clinically ill horses, with diagnostic accuracy often superior to that of total white blood cell (WBC) count, fibrinogen, and/or A/G ratio.[46,48,60-62] In one study systemic inflammation in horses caused substantial increases in SAA compared to local inflammation, and a cutoff value of greater than 10 mg/L yielded sensitivity of 82% and specificity of 71% in differentiating inflammatory from noninflammatory disease in horses.[62] SAA concentration in both serum and peritoneal fluid increased in horses with colic.[49] In contrast, experimental strongyle infection failed to elicit an increase in serum SAA concentration.[47] SAA has demonstrated prognostic value in horses with colic but was not useful as a prognostic marker in general inflammatory disease when used as a single measurement.[63,64] As with haptoglobin, SAA increases in the first postpartum week in dairy cows, and measurement of milk SAA levels is superior to serum levels to diagnose mastitis, although both are useful.[22,50,51]

APOLIPOPROTEIN A1 (APO A1). Apo A1 is a negative acute phase reactant in humans and domestic animals. Apo A1 is associated with high-density lipoproteins. A role as a constitutive antiinflammatory factor has been posited for Apo A1.[65]

CERULOPLASMIN (CP). CP plays a key role in iron metabolism, and CP-bound copper accounts for 95% of plasma copper concentration. CP interacts with several proteins, including ferritin, neutrophil myeloperoxidase, and lactoferrin.[66] Equine serum CP concentration increases with sterile inflammation and surgical manipulation. Transient changes in serum CP concentration occur in mares immediately before and after foaling.[67]

α2-ANTIPLASMIN (α2-AP). α2-AP is a fibrinolytic inhibitor via its specific inactivation of plasmin. Measurement of increased plasmin α2-AP complexes is one indicator of fibrinolysis. α2-AP increases in horses with colic, as does plasminogen, and therefore may have utility as an acute phase biomarker.[30,68]

PIG MAJOR ACUTE PHASE PROTEIN (PIG-MAP, ALSO ITIH4). Pig-MAP is the porcine homolog of a human kallikrein-sensitive protein and is a useful indicator of inflammatory diseases.[69,70] The related proteins in humans, pigs, and rats have been designated collectively as ITIH4, a new member of the inter-alpha-trypsin inhibitor (ITI) protein family with unknown biological function. The utility of ITIH4 as an acute phase reactant in cattle is also described.[71]

FERRITIN. Ferritin is an iron storage and transport protein. Ferritin levels can markedly increase during infectious and other inflammatory disorders, presumably to sequester iron and limit availability to microbes.[72] Species-specific assays are generally needed to measure ferritin. An equine-specific assay is available and has some cross-reactivity with other species.[73] Ferritin has

shown usefulness as a biomarker in horses. Strenuous exercise also causes an increase in ferritin that persists for up to 2 days.[74]

α1-ACID GLYCOPROTEIN (α1-AG). Also known as orosomucoid, α1-AG is a carrier of basic substances, including therapeutic drugs and steroids. Increased α1-AG values have been found in cattle with various inflammatory disorders, including mastitis and traumatic pericarditis.[75]

Hypoproteinemia

Hypoalbuminemia

Albumin is the most abundant of the plasma proteins. It accounts for approximately 75% of plasma colloidal oncotic pressure (COP), and its synthesis is primarily regulated by COP. Albumin is a nonspecific transport protein for a number of substances, including calcium, lipids, and hormones, and serves as an amino acid source for body tissues. Hypoalbuminemia is caused by a decrease in albumin production and/or an increase in albumin loss, most commonly renal or GI loss (Boxes 26.5 and 26.6). As described above, decreased albumin synthesis is a common component of the acute phase inflammatory response. Overall hypoproteinemia generally does not occur, partly because the decrease in albumin is usually mild and partly because of the corresponding increase in globulins.

Albumin production can decrease with chronic insufficient intake of amino acids. In particular, protein-energy malnutrition can lead to hypoalbuminemia more quickly than total starvation.[76] Hypoalbuminemia is an indicator of chronic malnutrition given albumin's relatively long half-life, and clinical signs relating to hypoalbuminemia develop over a prolonged period. GI disorders that disrupt normal protein digestion and absorption can lead to decreased protein synthesis and are discussed below under protein-losing enteropathy (PLE).

Although albumin is produced by the liver, synthesis generally does not decrease in acute liver disease. Chronic, diffuse liver diseases such as chronic hepatitis, fibrosis, and hepatic neoplasia may cause hypoalbuminemia. Because the half-life of albumin is longer in horses and cattle than in dogs and humans, hypoalbuminemia is uncommon in large animal hepatic disease but can occur in conditions such as chronic hepatic lipidosis or chronic pyrrolizidine alkaloid toxicosis. In one study 6% of horses with acute liver disease and 18% of those with chronic liver disease were hypoalbuminemic; increased globulins were found in 64% of all horses with liver disease.[77] Decreased albumin and increased globulins can indicate a poorer prognosis in horses with liver disease.[78] A potentially more useful indicator of liver disease in horses than hypoalbuminemia is a postalbumin shoulder (a small hump on the right [cathodal] side of the albumin peak) on SPE; this shoulder can also appear with acute inflammatory disease or severe hypoalbuminemia.[25,79]

Excessive albumin loss usually occurs through the urinary and/or GI tracts. Less common causes include chronic blood loss (acute substantial blood loss is associated with panhypoproteinemia) and burns or other exudative skin disease. Normal urine contains little or no protein due to resorption of filtered small proteins in the proximal tubule. Transient physiologic proteinuria, sometimes referred to as *functional proteinuria*, can occur with exercise, stress, seizures, and excessive protein intake, and following colostrum ingestion in neonates. These are (mostly) prerenal sources of proteinuria and do not cause hypoproteinemia.[80]

Renal proteinuria arises due to diseases of the glomeruli and/or proximal tubules; hemorrhage or inflammation within the kidney is another cause but is often categorized under "postrenal" proteinuria. Albumin is readily filtered through defects in the glomerular basement membrane due to its low molecular weight. Proteinuria due to glomerular lesions consists largely of albumin and can result in hypoalbuminemia and overall hypoproteinemia, whereas tubular proteinurias do not produce hypoalbuminemia.[80] Glomerulonephritis, amyloidosis, and less commonly pyelonephritis are top differentials for glomerular disease leading to proteinuria and hypoalbuminemia.[81]

PLE is a GI condition resulting in net loss of protein from the body, due to abnormal loss of protein from the GI tract and/or inability of the GI tract to absorb proteins. PLE is not a disease itself; it is a manifestation of numerous GI disorders. The diagnosis of PLE includes ruling out urinary protein loss, body cavity effusion, increased protein catabolism, and decreased synthesis due to liver disease. The clinically important mechanisms of PLE are defective lymphatic transport, increased mucosal permeability, GI parasitism, exudative inflammation, and/or ulcerative blood loss. Hypoalbuminemia can be useful both diagnostically and prognostically in PLE. In a study of

BOX 26.5

Causes of Hypoproteinemia in Horses

Hypoalbuminemia

Common Causes

Parasitism
Glomerulonephritis
Pyelonephritis
Idiopathic granulomatous enteritis
Intestinal lymphoma (lymphosarcoma)
Parasitism
Salmonellosis
Equine ehrlichial enterocolitis (Potomac horse fever)
Colitis
Clostridiosis
Nonsteroidal antiinflammatory drug toxicosis

Less Common Causes

Chronic hepatic fibrosis (pyrrolizidine alkaloid toxicity and other causes)
Hepatic neoplasia
Chronic hepatitis
Amyloidosis
Tuberculosis
Histoplasmosis
Chronic eosinophilic gastroenteritis
Starvation, malnutrition

Panhypoproteinemia

Common Causes

Excessive fluid therapy or water intake
Acute blood loss
Gastrointestinal ulceration
Strangulating gastrointestinal obstruction, infarction
Protein-losing enteropathy (chronic granulomatous bowel disease)
Acute severe peritonitis
Nonsteroidal antiinflammatory drug toxicity
Glomerulonephritis

Less Common Causes

Blood-sucking gastrointestinal or external parasites
Intestinal lymphoma (lymphosarcoma)
Urinary tract blood loss
Congenital vascular disorders: renal trauma
Renal calculi
Pyelonephritis
Neoplasia
Cystic calculi
Disseminated intravascular coagulation
Immune-mediated thrombocytopenia
Congestive heart failure

Congestive heart failure
Pyelonephritis
Urinary tract blood loss

horses with diarrhea, albumin was lower in horses that died than in those that survived, likely reflecting albumin leakage across inflamed intestinal mucosa.[20]

In horses the most common cause of PLE is idiopathic granulomatous enteritis, one of the chronic inflammatory bowel diseases of the horse.[14] Other causes of equine PLE are acute enterocolitis, including bacteria-associated disease; GI lymphoma and other GI neoplasia; nonsteroidal antiinflammatory drug (NSAID) toxicity, including phenylbutazone toxicity; GI parasitism; and other conditions in the chronic inflammatory bowel disease group, including intestinal tuberculosis, histoplasmosis, and eosinophilic gastroenteritis. Proliferative enteritis of foals or yearlings due to *Lawsonia intracellularis* infection often presents with hypoalbuminemia or panhypoproteinemia.[82,83]

The most common cause of chronic PLE in ruminants is infection with *Mycobacterium avium* subsp. *paratuberculosis*, also known as *Johne's disease*. Intestinal protein loss in Johne's disease arises from both mucosal lesions and secondary intestinal lymphangiectasia.[84] Other differentials include parasitism such as *Trichostrongylus* infection, intestinal lymphangiectasia, and GI lymphoma.

In addition to the above causes of decreased albumin production and increased albumin loss from the body, hypoalbuminemia can arise from dilution within the body. Redistribution of albumin into subcutaneous tissues and higher-protein body cavity effusions can result in hypoalbumemia. Edema and peritoneal effusions may contribute to the severe acute hypoalbuminemia described in fescue toxicity in horses.[85] Some edematous and effusive disorders such as congestive heart failure (see the Panhypoproteinemia section later) can cause either hypoalbuminemia or panhypoproteinemia.

The clinical sequelae of hypoalbuminemia relate to the decrease in COP and subsequent fluid shift. Severe hypoalbuminemia (e.g., from protein-losing nephropathy or chronic liver disease) can cause a very low-protein effusion called a pure transudate. Other clinical signs of hypoalbuminemia include edema of the limbs, head, and ventrum. The albumin level generally must be below 1.5 g/dL in horses and below 1 g/dL in ruminants before clinical signs occur. A correlate of the longer albumin half-life in large animals is that albumin replacement by synthesis is also slower, resulting in more clinically significant edema due to hypoalbuminemia.[79]

Panhypoproteinemia

Vigorous fluid therapy or excess water intake can cause dilution of plasma proteins and subsequent relative panhypoproteinemia. Panhypoproteinemia due to both dilution and increased GI protein loss occurs frequently in patients with acute GI disease receiving intravenous fluid therapy.

Acute blood loss with subsequent interstitial fluid shift into the vasculature, and volume expansion during pregnancy, can also cause relative panhypoproteinemia. Acute blood loss results in loss of all plasma proteins, and then interstitial fluid rapidly shifts into the intravascular space to help maintain volume. This dilution effect is intensified by increased water intake that commonly occurs after acute blood loss. Acute hemorrhage resulting from trauma, severe epistaxis, or internal vascular rupture should be ruled out in a hypoproteinemic, anemic animal.

GI disorders can lead to panhypoproteinemia via loss of either blood or protein alone. Differentials for GI blood loss include abomasal or gastric ulcers, blood-sucking parasites (e.g., *Haemonchus contortus* in ruminants), viral or bacterial infection, azotemia, neoplastic invasion, or exposure to caustic chemicals. NSAID toxicosis and strangulating GI obstructions or infarctions can result in mucosal necrosis and leakage of plasma proteins into the gut lumen. Although protein-losing enteropathy usually initially causes hypoalbuminemia, panhypoproteinemia often develops over time. Proliferative enteropathy of young horses (described above) often results in panhypoproteinemia. Acute severe peritonitis with massive protein exudation due to GI rupture can also quickly lead to hypoproteinemia.

Other conditions resulting in clinically significant blood loss include urinary tract disorders due to congenital vascular disorders, renal trauma, renal or cystic calculi, pyelonephritis, and renal neoplasia. Coagulopathies, including disseminated intravascular coagulation (DIC) or immune-mediated thrombocytopenia, may cause either external blood loss via the GI or urinary tract or internal bleeding into body cavities.

Congestive heart failure may cause either hypoalbuminemia or panhypoproteinemia via several mechanisms, including dilutional effects from plasma volume expansion, protein loss into ascitic fluid and the interstitium, and decreased albumin synthesis due to hepatic congestion and/or concurrent inflammation.[86]

Alterations in Hemostasis

JENNIFER L. JOHNS, *Consulting Editor*
MEERA HELLER

MAJOR ALTERATIONS

Thrombocytopenia, 442
Thrombocytosis, 444
Platelet function defects and von Willebrand disease, 444
Prolonged prothrombin time, 444
Prolonged partial thromboplastin time, 445
Increased fibrin/fibrinogen degradation products, 446
Decreased plasma antithrombin III, 446
Hypofibrinogenemia, 447
Thromboelastography, 448
Abnormalities in other tests of hemostatic function, 448

The diagnostic test panel to evaluate coagulation in large animals can include platelet count, plasma semiquantitative fibrinogen to assess for increased fibrinogen concentration, prothrombin time (PT), partial thromboplastin time (PTT), and serum fibrin and fibrinogen degradation products (FDPs). Alternatively, thromboelastography (TEG) may be substituted for (or performed in addition to) the combination of PT, PTT, and FDPs. Proper collection and preparation of blood samples are paramount in obtaining accurate results (see Chapter 23). Platelet counts are routinely performed as part of the complete blood cell count (CBC). Citrated blood is required for coagulation testing including PT, PTT, FDPs, and TEG, and can also be used for platelet analysis including platelet count. It is critical to have a 1:9 ratio of citrate to whole blood. The patient's hematocrit can affect coagulation results when whole blood is used. When the hematocrit is more than 55%, correction to a lower citrate volume is recommended to prevent overcitration and prolonged coagulation times.[1] If the laboratory does not have reference intervals for a particular species, plasma from two or more healthy animals should be collected and assayed in a similar manner for comparison. Table 27.1 shows reference values for platelets and fibrinogen, but laboratory-specific values are preferable for these analytes and are necessary for other coagulation parameters.

Platelet Parameters

The platelet count is technically the platelet concentration in whole blood. Units = [platelets] × 10^3/μL; SI units = [platelets] × 10^9/L. Automated analyzers are routinely used to generate a platelet count. A rough estimate can be made via manual smear review: at 100× oil objective, the total number of platelets in 10 fields is counted. This count is then divided by 10 to yield an average number. This average is multiplied by a 15,000 to 20,000 conversion factor to yield [platelets]/μL.[2] Both this estimate and the automated platelet count will be artifactually decreased if platelet clumps are present. Cattle normally average around 8 to 10 platelets per 100× oil field, and horses normally have 5 or more platelets per field.[2]

Mean Platelet Volume (MPV)

The mean platelet volume (MPV) is the mean or average platelet volume and is measured in femtoliters (fL). This value is an average and does not represent the range of platelet volumes. Increased MPV is consistent with increased release of large or giant platelets and usually indicates a platelet regenerative response. The measurement of reticulated platelets (analogous to reticulocytes for red blood cells) is used diagnostically in human medicine and is likely to become an accepted index of platelet regeneration in veterinary medicine as well.

Platelet Distribution Width (PDW)

The platelet distribution width (PDW) is a calculated range of platelet volumes (representing anisocytosis), analogous to the red cell distribution width. The PDW is expressed as a percentage. A higher percentage indicates a greater variation in platelet volume. The PDW in combination with the MPV value can indicate whether there are increased numbers of smaller and/or larger platelets.

Thrombocrit

Also called the *plateletcrit*, the thrombocrit value is a function of the platelet count and the MPV. It is a better indicator of the total platelet functional potential than the platelet count, due to the greater functional capacity of larger platelets.[3]

Thrombocytopenia

A decrease in the circulating platelet count is termed *thrombocytopenia*. Thrombocytopenia is caused by one of three basic mechanisms: platelet sequestration, decreased platelet production, and decreased platelet life span due to consumption or

TABLE 27.1

Normal Values for Hemostatic Data in Ruminants and Horses

	Horses	Cattle	Sheep	Goats	Llamas	Pigs
Platelet count (1×10^{-3}/L)	100-600	100-800	250-750	300-600	[a]	200-500
Fibrinogen (mg/dL)	200-400	200-700	200-500	200-300	100-400	200-400

[a]Insufficient data available.

Modified from Duncan JR, Prasse KW, Mahaffey EA, eds: *Veterinary laboratory medicine*, ed 3, Ames, IA, 1994, Iowa State University Press; and Kaneko JJ, Harvey JW, Bruss ML, eds: *Clinical biochemistry of domestic animals*, ed 5, San Diego, 1997, Academic Press.

BOX 27.1

Causes of Thrombocytopenia in Horses

Common Causes

Disseminated intravascular coagulation (DIC)
Immune-mediated thrombocytopenia (IMT) (drugs: penicillin, trimethoprim-sulfadoxine)
Endotoxemia, septicemia (e.g., acute toxic colitis, intestinal strangulating obstruction, neonatal septicemia)
Equine infectious anemia
Equine anaplasmosis *(Anaplasma phagocytophilum)*
Lymphoma

Less Common Causes

Salmonellosis
Equine viral arteritis
Equine influenza
Myeloproliferative disease (myelogenous leukemia)
Plasma cell myeloma
Aplastic anemia
Stachybotryotoxicosis
Neonatal alloimmune thrombocytopenia

BOX 27.2

Causes of Thrombocytopenia in Ruminants

Common Causes

Disseminated intravascular coagulation (DIC)
Bracken fern *(Pteridium aquilinum)* toxicosis
Septic mastitis or metritis (endotoxemia)

Less Common Causes

Salmonellosis
Gram-negative sepsis
Trichloroethylene-extracted soybean meal
Lymphoma
Plasma cell myeloma
Immune-mediated thrombocytopenia (IMT)
Stachybotryotoxicosis
Myelofibrosis (pygmy goats)

destruction (Boxes 27.1 and 27.2). Spurious thrombocytopenia occurs occasionally in horses when blood is collected into ethylenediaminetetraacetic acid (EDTA) anticoagulant, causing in vitro platelet clumping.[4] Platelet clumps are visible in the stained blood smear and may be indicated by error messages on an analyzer. Collection of a second sample into sodium citrate can yield an accurate platelet count and confirm a suspicion of spurious thrombocytopenia. Heparinized samples are not recommended for platelet counts, as heparin-induced clumping can occur in any species. If citrated samples are used for platelet counts, the count must be corrected for citrate dilution (i.e., multiplied by 1.1).

Splenic platelet sequestration can occur as a result of splenomegaly. Splenomegaly occurs due to various disorders, including infiltrative diseases such as lymphoma, leukemia, and multiple myeloma; infectious and other inflammatory diseases such as immune-mediated hemolytic anemia that result in splenitis; lymphoid hyperplasia; and/or splenic extramedullary hematopoiesis. In addition, congestive splenomegaly occurs when venous outflow is occluded by torsion, intestinal displacements, or congestive heart failure. Platelet sequestration is a relative thrombocytopenia due to redistribution (versus an absolute thrombocytopenia), is reversible, and does not result in increased bleeding tendency.

Decreased platelet production can occur with various bone marrow disorders, including myelophthisis (replacement of normal marrow). Myelophthisis is often due to marrow infiltration with neoplastic cells (e.g., plasma cells in multiple myeloma) and can result in pancytopenia. Familial myelofibrosis was reported in pygmy goats and resulted in marked pancytopenia, including thrombocytopenia with myelophthisis.[5] Toxic damage to the marrow (e.g., from bracken fern toxicosis or nonsteroidal antiinflammatory drug administration) can result in myelosuppression and potentially aplastic anemia. Immune-mediated destruction of megakaryocytes, a variant of immune-mediated thrombocytopenia (IMT), causes decreased platelet production and release. Infectious agents can cause decreased platelet production via either indirect effects on megakaryocytes (e.g., equine infectious anemia virus) or direct infection of megakaryocytes (e.g., acute bovine viral diarrhea infection).[6,7] Evaluation of a bone marrow aspirate and core biopsy is indicated to evaluate megakaryocyte numbers and assess for dysplasia in a patient that is either pancytopenic or persistently thrombocytopenic without evidence of peripheral consumption or destruction.

Blood loss is a rare cause of thrombocytopenia; it is more likely that any concurrent bleeding is the result rather than the cause of severe thrombocytopenia. Studies in dogs found that acute severe blood loss induces a mild to moderate thrombocytopenia, with up to 50% reduction in platelet count.[2] Rapid dilution of the blood volume with aggressive fluid therapy can decrease the platelet count as well as other hemostatic elements. This decrease is generally mild to moderate.

Platelet life span can be reduced by destruction of platelets or by platelet consumption in widespread coagulation. Immune-mediated platelet destruction is a common cause of thrombocytopenia in horses. IMT can be either idiopathic or secondary to various etiologies, including viral and bacterial infections, drug administration, and hemic neoplasia.[7-10] Thrombocytopenia due to idiopathic IMT is often marked, in contrast to thrombocytopenia due to other causes. The thrombocytopenia of equine anaplasmosis due to infection with *Anaplasma phagocytophilum* is apparently multifactorial; an element of IMT is possible but not supported by experimental studies, and splenic sequestration is also a potential contributor.[11,12] Neonatal alloimmune thrombocytopenia has been reported in horses, mule foals, and pigs and is caused by colostral antibodies against foreign (paternal) epitopes on the neonate's platelets.[2]

VetBooks.ir

Excessive consumption of platelets occurs with disseminated intravascular coagulation (DIC). DIC is a clinical condition of disordered hemostasis that arises secondary to severe trauma, infectious diseases, or other inflammatory diseases, including septicemia and disseminated neoplasia.[13] Examples include DIC in horses with colic, calves with septic shock, and pigs with spontaneous heatstroke.[14-17] The diagnosis of DIC in most species relies on finding evidence of both platelet and coagulation factor consumption (thrombocytopenia with one or more coagulation test abnormalities, described later) along with evidence of increased fibrinolysis (see the Increased Fibrin and Fibrinogen Degradation Products section later). Snake envenomation directly causes platelet destruction in the absence of typical DIC, as some snake venoms contain platelet-activating factors. Endothelial damage or necrosis (e.g., due to equine viral arteritis infection) can also result in platelet destruction with or without concurrent DIC.[18]

Clinical Signs of Thrombocytopenia

Thrombocytopenia is characterized by petechial or ecchymotic hemorrhages on the oral, nasal, and/or vaginal mucous membranes and the nictitans, sclerae, pinnae, and ventral abdomen. Epistaxis, melena, hyphema, and/or hematuria may occur, although spontaneous hemorrhage is rare unless the platelet count drops below 10,000 to 20,000/μL. Concurrent inflammation can increase a thrombocytopenic patient's propensity for spontaneous hemorrhage.[19] Prolonged bleeding from injections or wounds and a propensity to form hematomas with minor trauma are relatively common with a platelet count below 40,000/μL.

Thrombocytosis

Thrombocytosis is an increase in platelet count over the reference interval. A physiologic increase in platelet count can occur at high altitude.[2] Relative thrombocytosis due to redistribution from splenic and other tissues stores can occur with exercise or epinephrine release. Splenectomy can result in thrombocytosis for several weeks due to both increased production and decreased platelet sequestration and destruction in the absence of the spleen.

Absolute thrombocytosis can occur as a secondary reactive change in a number of conditions. Thrombocytosis due to any cause other than myeloproliferative disease does not generally result in increased risk of thrombosis or other clinical abnormalities; it is a reflection of the underlying disease(s). Many infectious and other inflammatory disorders, including immune-mediated diseases, can cause "reactive thrombocytosis," as can surgery, neoplasia, and other inflammatory disorders. A less common cause of thrombocytosis is iron deficiency, and this may be true in large animal species as well. Chronic blood loss can be associated with thrombocytosis, and iron deficiency may be one factor. Administration of vincristine or vinblastine can result in thrombocytosis. Thrombocytosis can also occur as a rebound effect following prior thrombocytopenia with an appropriate bone marrow response. A very rare cause of persistent severe thrombocytosis is primary thrombocythemia or other chronic myeloproliferative disease; bone marrow evaluation is indicated in this situation.

Platelet Function Defects and Von Willebrand Disease

Defects in platelet function have been described in large animals, but diagnosis can be challenging. The template bleeding test is routinely performed in small animals to assess primary hemostasis (e.g., platelet number/function and von Willebrand factor [vWF] function) but is criticized for poor reproducibility in both humans and animals, including horses.[20] Template bleeding tests have been useful for monitoring effects of aspirin therapy on hemostasis in horses and may be suitable for serial monitoring of a patient if other factors such as platelet count remain constant. Aggregometry is considered a gold standard assay for platelet function but can be cumbersome; automated platelet function analysis with the PFA-100 device has become a standard platelet function assay in human medicine and is emerging as a valuable assay in veterinary medicine. More specific assessment of platelet function can require specialized assays.

Glanzmann's thrombasthenia is a disorder resulting in poor platelet aggregation and clot retraction in humans and animals and is caused by one or more defects in quantity or quality of platelet surface glycoprotein IIb/IIIa. Hereditary Glanzmann's thrombasthenia has been diagnosed in a few adult horses of various breeds.[21-24] Other hereditary thrombopathias are infrequently described in animals, including a novel disorder that is termed *atypical equine thrombasthenia*.[25] Chédiak-Higashi syndrome is reported in Hereford, Japanese Black, and Brangus cattle. The bleeding diathesis associated with this syndrome is defined by substantial impairment of platelet aggregation in response to collagen.[26] A hereditary thrombopathy in Simmental cattle is characterized by impaired platelet aggregation, with clinical signs including periodic epistaxis and severe hemorrhage following surgical procedures.[27] Inheritance of this thrombopathy appears to be multigenetic, and aggregometry was not useful in differentiating carrier versus clear animals. A variant form of von Willebrand disease has also been described in a Simmental calf.[28] Von Willebrand disease has been reported in Quarter Horses and consisted of a deficiency in high molecular weight multimers of vWF, consistent with type 2 von Willebrand disease in other species.[29]

Acquired defects in platelet function are common secondary to drug administration. Drugs that impair platelet function include aspirin, phenylbutazone, sulfonamides, estrogens, and phenothiazines.[14] Several underlying medical conditions can also negatively affect platelet function, including uremia and liver disease. Production of high levels of immunoglobulins, particularly immunoglobulin M (IgM), in monoclonal gammopathies hinders platelet function via protein coating of platelet surfaces.

Prolonged Prothrombin Time

The PT, or one-stage prothrombin time, is a measure of the extrinsic (tissue factor) and common pathways of coagulation (Fig. 27.1). The assay tests the time after the calcium-thromboplastin reagent is added to the plasma sample until formation of a fibrin clot. The PT is prolonged when the fibrinogen level drops below 100 mg/dL or with a marked deficiency of one or more coagulation factors in the common pathway (factors II [prothrombin], V, and/or X) or the tissue factor pathway (factor VII). The sensitivity of PT testing is variable and generally insensitive to mild coagulation factor deficiencies; a study in horses found that standard PT testing is reasonably sensitive to an overall decrease greater than 20% in coagulation factor activity.[30] As with other basic coagulation time assays, a common approach is to interpret the coagulation time as prolonged if it is more than 25% above the upper end of the reference interval.

Acquired defects in coagulation factors are much more common than inherited defects and generally involve deficiencies in multiple rather than single coagulation factors. Causes of acquired defects include hepatic disease, vitamin K antagonism (e.g., moldy sweet clover poisoning), and increased consumption via DIC (Boxes 27.3 and 27.4). The PT is usually the first abnormal coagulation test with decreased coagulation factor production in chronic liver disease.[14] Widespread coagulation and consumption in DIC also causes a prolonged PTT and thrombocytopenia, along with increased fibrinolysis. In

BOX 27.3

Causes of Prolonged Prothrombin Time in Horses

Common Causes

Disseminated intravascular coagulation (DIC)
Anticoagulant or rodenticide toxicosis
Acute hepatic necrosis
Pyrrolizidine alkaloid toxicosis
Aflatoxicosis
Chronic hepatic fibrosis

Less Common Cause

Moldy sweet clover

BOX 27.4

Causes of Prolonged Prothrombin Time in Ruminants

Common Causes

Moldy sweet clover (*Melilotus* species) toxicosis
Disseminated intravascular coagulation (DIC)

Less Common Causes

Anticoagulant or rodenticide toxicosis
Pyrrolizidine alkaloid toxicosis
Rubratoxicosis
Aflatoxicosis
Bitterweed *(Hymenoxys odorata)* toxicosis
Chronic hepatic fibrosis
Hereditary fibrinogen deficiency

addition to quantitative deficiencies, coagulation factors may be functionally impaired by increased FDPs or circulating anti-factor antibodies.

Vitamin K is necessary for hepatic production of functional coagulation factors II, VII, IX, and X as well as anticoagulant proteins C and S. The action of vitamin K is inhibited by coumarin compounds acquired via moldy sweet clover hay or anticoagulant rodenticide ingestion or by therapeutic adminstration (e.g., warfarin in horses). Vitamin K inhibition results in deficient carboxylation of coagulation factors and a resulting inability to bind endothelium stably. These incompletely carboxylated factors are termed *PIVKAs* (*p*roteins *i*nduced by *v*itamin *K a*ntagonism/absence). A modified PT assay called the Thrombotest PT is specific for defects in factors II, VII, and/or X and can be used in cases of suspected coumarin toxicosis; specific tests for PIVKAs are not available for domestic animals.

Clinical signs of coagulation factor deficiencies include spontaneous hemorrhage (e.g., epistaxis, melena, hematuria) or prolonged bleeding after trauma, diagnostic procedures, or surgery. Hematomas or hemarthroses are common after minor trauma or normal exercise, and bleeding into body cavities can occur. Coagulation times are designed primarily for screening purposes and are very insensitive to minor defects of one or more factors (e.g., the PT was prolonged with factor VII levels ranging from 16% to 39% of normal in one study).[1] Less severe coagulation defects may require specific factor assays for diagnosis.

Prolonged Activated Partial Thromboplastin Time

The PTT is a measure of the intrinsic (contact activation) and common coagulation pathways (see Fig. 27.1). The activated PTT is now the only test used, and it measures time from the addition of calcium to plasma with partial thromboplastin reagent and a surface activator until clot formation. The PTT is prolonged with deficiencies or defects in factors XII, XI, IX, and VIII coagulant (VIII:C) as well as prekallikrein (PK). Most PTT assays detect PK deficiency, and the assay can be corrected to prove that a PK abnormality is the cause of prolonged PTT. The activated coagulation time (ACT) is a simplified variation of the PTT that can be tested by mixing whole blood with activator and calcium. It is less sensitive to factor defects, as prolonged ACT may not occur until a single factor is at 5% to 10% of normal function, and can be prolonged

Hemophilia A (deficient factor VIII coagulant [VIII:C])
Congenital deficiencies of factor IX, factor XI, prekallikrein, or high molecular weight kininogen
Hepatotoxins (pyrrolizidine alkaloids, rubratoxins, aflatoxins, bitterweed)

BOX 27.6

Causes of Prolonged Activated Partial Thromboplastin Time in Ruminants

Common Causes

Moldy sweet clover toxicosis
Disseminated intravascular coagulation (DIC)

Less Common Causes

Congenital deficiency of factor XI
Anticoagulant or rodenticide toxicosis
Hepatotoxins (pyrrolizidine alkaloids, rubratoxins, aflatoxins, bitterweed)
Hereditary fibrinogen deficiency

also with severe thrombocytopenia.[1] As with all tests, reference values vary by species; for example, alpacas have substantially shorter PTTs normally than horses or cattle.[31] Age may also play a role, as healthy newborn foals have PTTs and PTs that are longer than adult reference values.

The most common cause of a prolonged PTT is increased consumption of clotting factors induced by DIC (Boxes 27.5 and 27.6). Liver failure and vitamin K antagonism prolong both PTT and PT. Single factor defects will prolong the PTT and not affect the PT. Inherited deficiencies of factors VIIIa (the precursor form of VIII:C) and XI and PK have been described in horses.[32-36] Congenital factor VIIIa deficiency (hemophilia A) is sex-linked, and males are clinically affected; carriers cannot be detected via PTT, as factor levels are insufficiently decreased. The level of factor VIIIa must drop below 5% of normal before spontaneous bleeding occurs. Clinical signs of coagulation factor deficiencies are those of hemorrhagic diathesis, as described in the previous section. Inherited factor XI deficiency is transmitted in Holstein cattle by an autosomal recessive trait.[37] Cattle deficient in factor XI rarely demonstrate bleeding tendencies.

Although both PT and PTT can be prolonged during DIC, it is not uncommon for only one test to be abnormal initially. Serial analyses should reveal a trend toward prolongation of both tests along with decreasing platelet count. When a persistently prolonged PTT is the only laboratory abnormality, hereditary factor deficiency should be suspected. As with PT, the PTT is a relatively insensitive screening test. The assays generally have prolonged times when at least one factor is decreased to 30% or less of normal function or when combined factor activity is at least mildly decreased. Both PT and PTT can be shortened (times will be below reference interval) with increased fibrinogen, factor V, and/or factor VIII (PTT only). Shortened coagulation times are not traditionally used as indicators of clinical hypercoagulability, as other causes of shortened coagulation times include traumatic venipuncture and insufficient anticoagulation. However, there is evidence in other species that shortened PT and/or PTT can correlate with evidence of hypercoagulability via thromboelastography and/or clinical thromboembolic disease.[38-40] Hypercoagulability should therefore be considered a differential for shortened PT and/or PTT in a large animal patient.

BOX 27.7

Causes of Elevated Fibrin and Fibrinogen Degradation Products in Large Animals

Common Causes

Disseminated intravascular coagulation (DIC)
Thrombophlebitis
Postoperative state
Severe inflammation
Immune-mediated thrombocytopenia (IMT)

Uncommon Causes

Massive internal hemorrhage
Primary hyperfibrinolysis

Increased Fibrin and Fibrinogen Degradation Products

FDPs can be composed of fragments of fibrin and/or fibrinogen. Assays are either serum or plasma specific, as fibrinogen present in plasma can react to the polyclonal antibody of the serum assays, and are relatively species specific. A study in horses found that two FDP assays, one serum-based and one plasma-based, had low sensitivity for FDPs in horses with colic.[41] At the same time, a plasma D-dimer assay was a useful adjunct test. Commercial D-dimer assays have also been used in cattle; in one study peritoneal fluid D-dimer was a useful indicator of peritonitis.[42] D-dimer (one form of FDP) is a cross-linked fibrin fragment and is therefore specific for fibrinolysis, whereas FDPs as a group are less specific. When measurable, increased levels of FDPs and/or D-dimer generally indicate increased fibrinolysis in response to excessive coagulation (Box 27.7). In addition to DIC, localized intravascular fibrin deposition following surgery, internal hemorrhage, sepsis, and other severe inflammatory processes may cause increased FDP levels. Plasmin perturbations may occur with snake envenomation, heatstroke, surgery, or administration of plasminogen activators and can lead to fibrinogenolysis and increased FDPs.[1] Decreased FDP clearance due to hepatic or renal disease can also lead to increased FDP levels.

Increased serum FDPs can contribute in turn to hemorrhagic clinical manifestations of DIC by interfering with thrombin activity, fibrin polymerization, and platelet aggregation. Interpretation of FDP or D-dimer tests depends on evaluation of the other components of the hemostasis profile (platelet count, PT, PTT) in concert with the patient's history and clinical signs. Serum FDP levels greater than 40 µg/mL or plasma levels greater than 20 µg/mL most often occur with DIC; lower values do not exclude DIC. Horses have measurable D-dimer concentrations in health, so an upper cutoff value must be used to report abnormal values.[41] In one study horses with clinical evidence of DIC secondary to colic had decreased D-dimer levels consistent with hypofibrinolysis during hypercoagulation.[17]

Decreased Plasma Antithrombin III

The physiologically most important inhibitor of coagulation is antithrombin or antithrombin III (ATIII). This low molecular

VetBooks.ir

weight glycoprotein primarily neutralizes activated factors IX, X, and II (thrombin) along with other coagulation proteins. Heparin is a necessary cofactor to potentiate ATIII and enable its rapid inhibitor activity. ATIII is measured via chromogenic assays to evaluate functional activity; activity is expressed as the percent relative to a species-specific plasma pool from healthy animals. Plasma ATIII levels may be reduced by decreased liver production, excessive use, loss from the intravascular compartment, or increased catabolism. Inherited ATIII deficiency is not reported in animals. Newborn foals have lower ATIII levels than adult horses normally.[43]

Chronic liver disease may result in failure to produce ATIII and a number of other important plasma proteins. However, horses with chronic liver disease were shown to have increased plasma ATIII levels.[44] These findings suggest that ATIII may behave as an acute phase protein in horses, as some horses also had increased fibrinogen levels. A second group of horses in the study with acute diarrhea or colitis had decreased ATIII levels. ATIII is variably reported as a positive or negative acute phase protein in animals.[1,44] Estrogens may contribute to ATIII deficiency due to negative effects on synthesis.[1]

In conditions such as DIC, ATIII is consumed and can be decreased as a result of binding to activated coagulation factors and subsequent hepatic clearance of the ATIII-factor complexes. Any pathologic activator of coagulation, including trauma, neoplasia, or sepsis, may cause reduction of plasma ATIII (Boxes 27.8 and 27.9). ATIII can be reduced as a component of coagulopathy secondary to endotoxemia in foals.[45] Administration of unfractionated or low molecular weight heparin leads to decreased ATIII levels via increased activity and subsequent clearance of ATIII.[46]

Diseases that cause massive proteinuria or protein-losing enteropathy result in loss of ATIII in addition to other plasma proteins. Because of the small size of ATIII, it is lost in approximately the same proportion as albumin. Nephrotic syndrome in humans and animals may lead to secondary hypercoagulability and thrombotic disease due to urinary ATIII loss and other complicating factors; hypoalbuminemia can be a useful predictor of thrombotic risk given concurrent loss of ATIII and albumin and may also play a contributory role.[47,48]

The major clinical sequela of ATIII deficiency is a tendency to develop venous thrombosis. Thrombosis in nephrotic syndrome was discussed earlier. Venous thrombosis is commonly recognized in horses with severe toxic colitis or endotoxemia, but the potential role of ATIII deficiency is unknown. Decreased ATIII has been documented in nonsurviving horses with colic and in horses with strangulating obstructions.[49] The contribution of ATIII consumption in DIC to the clinical manifestations is complex and difficult to evaluate; however, use of ATIII concentrates in human patients with acute DIC has improved survival in some instances.[44] As with all components of the hemostatic system, plasma ATIII must be evaluated in combination with other hemostasis values.

Hypofibrinogenemia

Decreased fibrinogen concentration, termed *hypofibrinogenemia*, can be detected via a modified thrombin time test, the Clauss TT, or via immunoassay using anti-fibrinogen antibodies. Heat precipitation is useful to detect increased fibrinogen but is too insensitive to detect hypofibrinogenemia. Plasma fibrinogen levels represent the balance between fibrinogen production and degradation, an important concept in large animals since fibrinogen production is often increased due to inflammation (see Chapter 26) and increased consumption may potentially be masked. Pregnancy also can cause increased fibrinogen.[50]

Hypofibrinogenemia may result from impaired hepatic synthesis, increased consumption with DIC, or uncompensated loss during massive hemorrhage (Boxes 27.10 and 27.11). Decreased plasma fibrinogen is uncommon in liver disease of large animals; increased production due to concurrent inflammation appears to be more common. With DIC and fibrinolysis, decreased fibrinogen concentration due to consumption is expected in most species. However, hypofibrinogenemia is not common in horses with DIC. Horses with colic in one study had evidence of increased coagulation postoperatively, including decreased ATIII and increased D-dimer, with concurrent hyperfibrinogenemia.[51] Hypofibrinolysis has also been shown in horses with DIC.[17]

Hereditary afibrinogenemia has been described in a family of Saanen dairy goats with a hemorrhagic diathesis in newborn kids that included umbilical bleeding and recurrent hemarthroses.[14] Fibrinogen was undetectable in the affected animals, while heterozygotes had hypofibrinogenemia.

BOX 27.8

Causes of Reduced Antithrombin III in Horses

Common Causes

Disseminated intravascular coagulation (DIC)

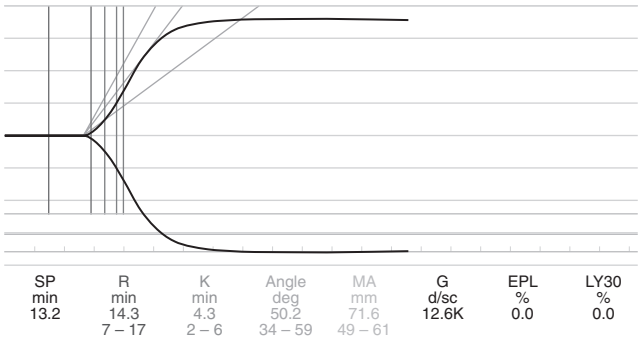

FIG. 27.2 Thromboelastograph (TEG) tracing from a horse demonstrating increased maximum amplitude *(MA)*, suggestive of platelet hyperresponsiveness and/or other potential causes of hypercoagulable tendency. Other values including the R (reaction) time and K (kinetics) time are within reference intervals.

Thromboelastography

Thromboelastography (TEG) analysis is a viscoelastic measurement technique used to assess global clot formation and lysis in whole blood. It is sometimes termed *rotational TEG;* a similar measurement technique is ROTEM (rotational thromboelastometry). The advantage of TEG analysis over traditional minimum coagulation panels consisting of platelet count, PT, and activated PTT testing is that TEG can detect hypercoagulable states and increased fibrinolysis (Fig. 27.2). TEG is therefore the only readily available test of hypercoagulability in veterinary medicine. Fibrinolysis can be assessed by D-dimer in horses or by FDPs in other large animal species, but with the specificity issues inherent to FDP testing as described earlier. Disadvantages of TEG or ROTEM testing include the need for analysis within 2 hours of blood collection and the impact of marked anemia on testing.[52,53] Substantial thrombocytopenia can alter TEG results, but the results may be useful as a potential index of bleeding tendency in the patient and may be superior to platelet count alone for this use because TEG also accounts for platelet function.[54,55] A concurrent CBC is vital for interpretation of TEG results.

Studies have shown some diagnostic and prognostic utility of TEG in evaluating coagulation in horses with gastrointestinal disease.[56-58] Using TEG and other viscoelastic testing, studies in neonatal foals have determined both that coagulation parameters in normal neonatal foals can differ from those in adult horses and that septic foals can have evidence of coagulation abnormalities, including hypercoagulability.[59,60] Other common uses of TEG or ROTEM in large animal research studies include evaluation of the effects of plasma or artificial colloid transfusion on coagulation and assessment of the effects of dexamethasone treatment in healthy adult horses (no differences seen) and in veal calves (treated calves had evidence of hypercoagulability).[61-65]

Other Tests of Hemostatic Function

Other tests of hemostasis may be indicated in specific disease situations; they include the following.

Thrombin Time

The standard thrombin time test measures the rate of fibrinogen to fibrin conversion and can be a useful assay for the effects of FDPs, heparin, and paraproteins; for example, a prolonged thrombin time can indicate the presence of FDPs that interfere with fibrin polymerization. This test also evaluates for the presence of hypofibrinogenemia, but the Clauss TT (described earlier) is a better assay for that purpose, as any interference effect from FDPs, heparin, and other factors is largely eliminated.

Specific Factor Assays

Specific factor analyses are generally indicated for the diagnosis of hereditary factor deficiencies. Prolonged PTT values along with the signalment, history, and clinical picture may indicate that specific factor assays are needed. In DIC, specific factor analysis is unlikely to be useful.

α_2-Antiplasmin

α_2-Antiplasmin (α_2-AP) binds plasmin to cleave and inactivate it, and then the complexes are cleared from circulation. In humans, α_2-AP is decreased by severe liver disease (reduced production) and with DIC (consumption). Experimental studies in ponies suggest that α_2-AP may be reduced with chronic or subclinical DIC.[66] Conversely, increased α_2-AP is reported in horses with colic as part of the acute phase response (see Chapter 26).

Protein C

The protein C pathway provides the second major anticoagulant mechanism that regulates hemostasis. Protein C is activated by thrombin complexed to thrombomodulin and subsequently inactivates factors Va and VIIIa via proteolysis and using the cofactor protein S. In humans, decreased protein C can occur in liver failure or DIC, increasing the risk of thrombotic disease, and decreased protein C is reported in horses with severe colic.[49]

Collection and Analysis of Bone Marrow

ANDREA A. BOHN, *Consulting Editor*
PABLO ESPINOSA-MUR

Bone marrow is composed of hematopoietic cells as well as structural components, including trabecular bone, adipose tissue, a sinusoidal system, supporting reticular cells, and an extracellular matrix. The hematopoietic system is composed of erythrocytes, leukocytes, and platelets; their precursor cells; and the tissues that support the continuous cycles of cell differentiation required for maintenance of oxygen delivery, protection from infectious agents, and hemostasis. A single multipotent stem cell is the precursor for all hematopoietic cells. From this cell arise progenitor cells directed toward various cell lineages. Postnatally, hematopoiesis to replenish circulating erythrocytes, granulocytes, monocytes, and platelets predominantly occurs in the bone marrow. Although lymphocytic precursor cells continue to travel from the bone marrow to the thymic cortex and enteric mucosa for differentiation postnatally, most circulating lymphocytes are associated with the extramedullary lymphoid organs.

Constantly replenishing blood cells, the bone marrow is one of the most active tissues in the body. Blood cell turnover is rapid; for example, neutrophils have a circulatory half-life of approximately 10 hours. The life span of platelets, on average, is approximately 7 to 10 days, and the life span of large animal erythrocytes is approximately 5 months, with slightly shorter half-lives reported in some breeds.[1-3] Readers are referred to a veterinary hematology textbook for more in-depth information on the hematopoietic system.[4]

Multipotent mesenchymal stromal cells are progenitor cells that give rise to the structural components of bone marrow and show great promise in regenerative medicine. Bone marrow–derived mesenchymal stem cells (BMSCs) have shown higher osteogenic capacity compared to mesenchymal stem cells (MSCs) from adipose tissue, umbilical cord tissue, and cord blood,[5] although they seem to proliferate at a slower rate than MSCs originating from other tissue types.[6] Bone marrow aspirates are routinely performed in equine practice to obtain bone marrow concentrates and BMSCs. Bone marrow aspirates without processing, concentrates, and BMSCs are frequently used to treat tendon, ligament, and meniscal injuries. Intra-articular administration is also used to enhance healing of cartilage defects and treat subchondral bone cystic lesions in horses.[7,8]

Diagnostic Indications for Bone Marrow Aspiration or Biopsy

Bone marrow evaluation provides important diagnostic information on the hematopoietic status of an animal; it is typically performed to evaluate hematopoiesis and to detect evidence of neoplastic or infectious disease (Box 28.1). The complete blood cell count (CBC) is the most common method used to evaluate the hematopoietic system, but a more comprehensive evaluation includes bone marrow aspiration and/or biopsy. Bone marrow aspiration is commonly used to evaluate the cause of cytopenia. Unexplained nonregenerative anemia, neutropenia, thrombocytopenia, and pancytopenia are indications for bone marrow aspiration. In these cases, bone marrow evaluation is used to determine if the cytopenia is more likely a result of lack of production or of consumption or destruction of the cell in question. If an animal's clinical presentation and other laboratory data provide a reasonable explanation for cytopenia, a decision to perform the procedure may not be justified. For example, if another disease process is present that could explain nonregenerative anemia, such as a chronic inflammatory disease or chronic renal failure, bone marrow aspiration is not indicated in most cases.

Another common reason for bone marrow aspiration is the observation of atypical cells, unexplained immature cells, or abnormal blood cell morphology on a peripheral blood film. In these cases bone marrow is evaluated for the diagnosis of leukemia, myelodysplastic syndromes, and infiltrative disease. Potential infiltrative disease is sometimes detected radiographically, and the presence of lytic or proliferative bone lesions can also be an indication for bone marrow aspiration. Because abnormalities within the bone marrow are not always reflected in the peripheral blood, it may be prudent to perform bone marrow aspiration if a neoplastic or infectious process is clinically suspected but cannot be found elsewhere. This suspicion may arise from finding cytopenias or detecting an unexplained hypercalcemia or monoclonal gammopathy, conditions that are often associated with neoplasia; identifying a fever of unknown origin; or recognizing the probability of an infectious agent that may have bone marrow involvement.

Even though complication rates are low, bone marrow aspiration should not be performed indiscriminately, and, as for all testing, the clinician should consider what question is being asked and if bone marrow evaluation is the appropriate diagnostic test for answering that question. Examination of a peripheral blood film often provides clues as to the necessity of bone marrow evaluation. In general, cytopenia should be persistent and confirmed before bone marrow evaluation is performed. Rechecking a low cell count by drawing a new blood sample, especially if initial results do not fit with the clinical presentation of the animal, is recommended. An ethylenediaminetetraacetic acid (EDTA)–associated pseudothrombocytopenia

BOX 28.1

Indications for Bone Marrow Evaluation

To assess regeneration in anemic horses
To investigate cause of cytopenia
- Unexplained nonregenerative anemia
- Unexplained neutropenia
- Unexplained thrombocytopenia
- Pancytopenia

To investigate for neoplasia
- Atypical cells in peripheral blood
- Lytic or proliferative bone lesions
- Hypercalcemia
- Monoclonal gammopathy

To investigate for infectious disease
- Fever of unknown origin

Lytic or proliferative bone lesions

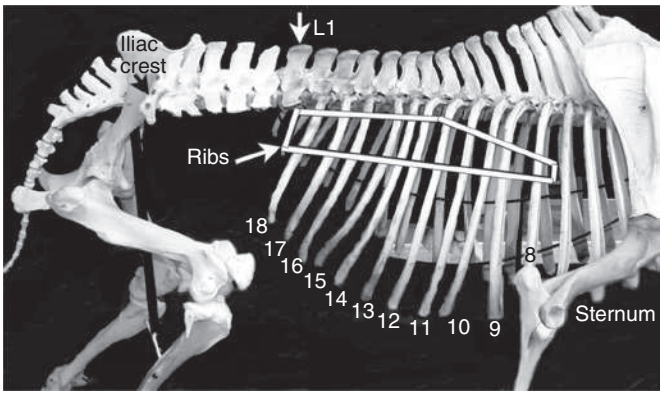

FIG. 28.1 Equine skeleton depicting sites for bone marrow aspiration: the sternum, iliac crest, vertebral ends of ribs *8* to *18*, and first lumbar vertebra *(L1)*.

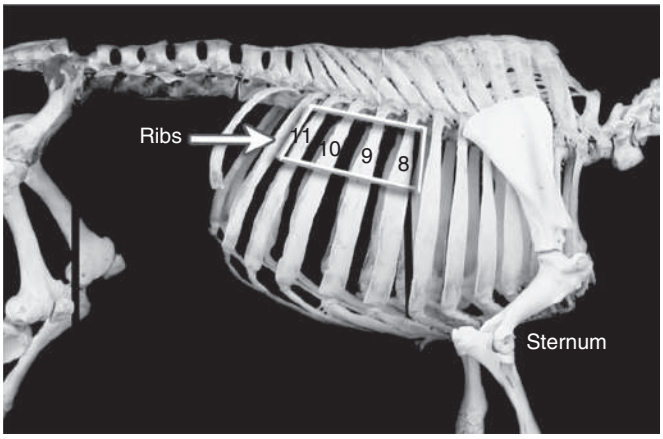

FIG. 28.2 Bovine skeleton depicting sites for bone marrow aspiration: the sternum and vertebral ends of ribs *8* to *11*.

has been reported in horses,[9] which can be ruled out by drawing blood into a heparin or sodium citrate tube for platelet counts. A low platelet count can also be artefactual if platelet aggregation occurs during blood collection. The presence of clumped platelets on a peripheral blood film is an indication that platelet aggregation has occurred and that a low platelet count should be viewed with skepticism. Repeated CBCs can also be used to assess persistence of an abnormality. It can take up to 5 days for the bone marrow to respond to acute anemia and for regeneration to be evident in the peripheral blood. Bone marrow aspiration is typically not indicated when there is evidence of regeneration in the peripheral blood. Evidence of erythroid regeneration in the peripheral blood includes an increase in the number of reticulocytes or polychromatophilic cells, basophilic stippling, and macrocytosis. Because the changes typically associated with regenerative anemia are rarely seen in horses, bone marrow aspiration is often the only way to assess erythropoiesis in this species. [See Color Plates 28.1 to 28.4 for an example of erythroid hyperplasia in a horse.] Evidence of regeneration in granulocytes includes the presence of a left shift and toxic changes.

Cytologic evaluation of bone marrow aspirate is more commonly performed than core biopsy because results can be attained more quickly and the morphology of the cells is superior, allowing a more accurate assessment of cell types. The disadvantage of aspiration versus biopsy is that architecture cannot be assessed with an aspirate, and it can be impossible to confirm whether a poor cellular sample is a result of a pathologic process or an unsatisfactory sampling. The core biopsy provides a better assessment of bone marrow cellularity and is necessary for the confirmation of myelofibrosis, generalized bone marrow suppression, or necrosis. [See Color Plates 28.5 to 28.8 for core biopsy samples of generalized bone marrow hypoplasia from a bovine.] The core biopsy also provides a more accurate assessment of metastatic neoplasia because architecture can be assessed. It is generally recommended to submit both aspirates and biopsy for evaluation or, at least, collect a core biopsy to be stored in formalin for later evaluation, if needed.

If a bone marrow sample is being submitted for evaluation, a CBC should be submitted concurrently because interpretation of the bone marrow is dependent on CBC results and changes can occur quickly in the blood.

Bone Marrow Collection

Sites

Hematopoietically active bone marrow is most consistently found in the flat bones (sternum, ribs, pelvis, vertebrae) and proximal ends of long bones (humerus, femur). The most commonly described sites for bone marrow aspiration in large animals are the sternum, ribs, and iliac crest (Figs. 28.1 and 28.2). Which location is chosen may depend on species, age, and temperament of the animal as well as on available facilities.

The ventral sternum is the preferred site in adult horses, small ruminants, and camelids (Figs. 28.3 to 28.6). It is one of the preferred sites in cattle. The advantages of the sternum are that it is covered by only a thin layer of bone, it has areas not covered by thick muscles, and samples can be reliably obtained from the site. The disadvantages of the sternum are that it is near vital organs and that the operator is in an awkward position when working on a standing animal. A procedure for sampling the cranial aspect of the sternum has also been described in horses[10] (see Fig. 28.3). There is more muscle to go through with this approach.

The ribs are one of the preferred sites for bone marrow aspirates in cattle. The dorsal ends of ribs 8 to 11 can be accessed for sequential aspirations[11] (see Fig. 28.2). Ribs can also be used in the horse, but the needle slips off the bone more easily. In calves, sheep, and goats the marrow cavity of the rib is small and more difficult to hit,[12] and in camelids the rib marrow is less consistent in location than the sternum.[13] Successful collection from ribs has been described in camels, with the fifth to eighth ribs as the best sites.[14]

The iliac crest is the site often used for bone marrow sampling in foals, and it can also be used in young adult horses up to a couple of years in age[15] (Fig. 28.7). Samples can also be obtained from older horses at this site, but the needle must

VetBooks.ir

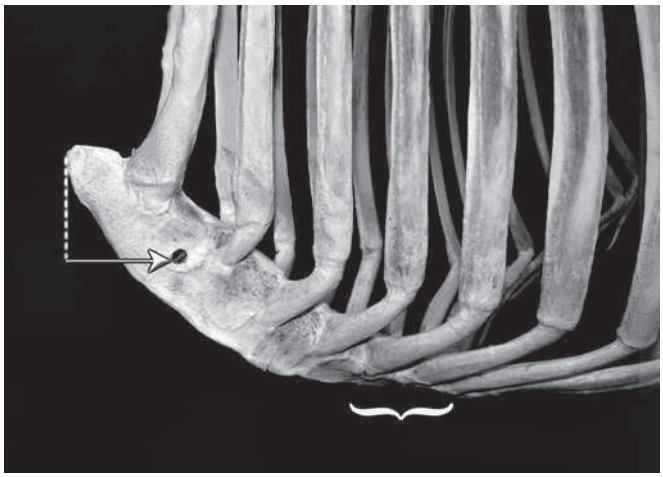

FIG. 28.3 Lateral view of equine sternum. The ventral sternum is the most popular site for sampling bone marrow in the adult horse *(bracket)*, but the cranial sternum can also be used. The aspirate site of the cranial sternum is reached by going one hand width below *(dotted line)* and one hand width lateral to its cranial tip. From there, the needle is advanced in a horizontal plane at a 45-degree angle to the longitudinal axis of the horse *(arrow)*.

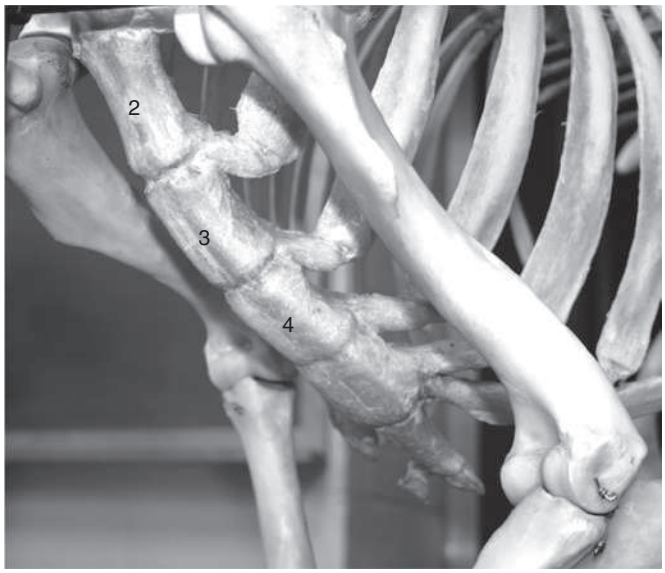

FIG. 28.6 Llama sternum. The llama sternum can be sampled at ventral midline, inserting the needle vertically through the callosity, or from a lateral approach, inserting the needle dorsal to the callosity.

FIG. 28.4 Equine sternum sectioned on midline. The bone marrow aspiration needle is anchored in the center of the fifth sternebra. The arrowhead indicates the first sternocostal joint; left and right joints are usually fused together in horses. The black arrow indicates the first sternebra.

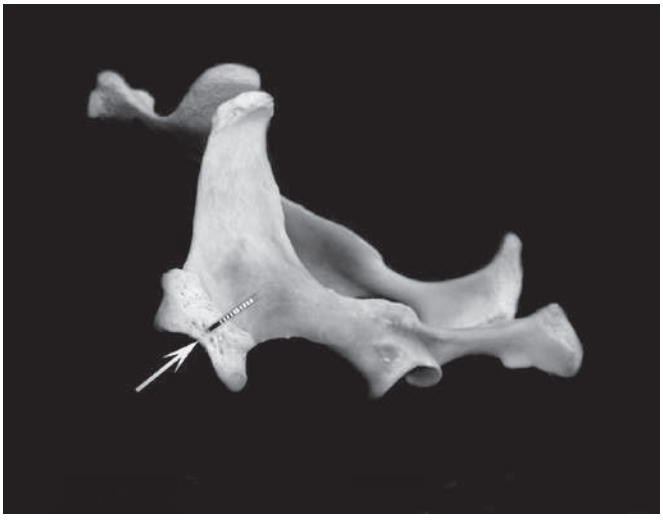

FIG. 28.7 Equine pelvis. To obtain bone marrow, the needle should be placed near the center of the tuber coxae *(arrow)* and advanced toward the opposite coxofemoral joint *(dotted line)*.

FIG. 28.5 Cross-section of sheep sternum. The needle is entering the second sternebra. The second through fourth sternebrae are recommended as optimal sites for bone marrow collection.

be inserted more deeply, needle placement is more critical, and it becomes difficult to obtain a successful sample in horses more than 9 years old.[16] The wing of the ilium is generally considered too thin for bone marrow aspiration in camelids,[13] although successful bone marrow aspiration from the iliac crest of a 2-year-old alpaca has been reported[17] (Fig. 28.8). The iliac crest can also be used in sheep (Fig. 28.9).

Another site informally described for horses is the spinal process of the first lumbar vertebra (Fig. 28.10). It is usually vertical, whereas the adjacent processes tend to be more angled. The tip of the process is wider than the shaft and has a thin layer of bone. The needle is advanced straight down into the marrow cavity, which is narrow, but if the needle is close to correct placement the walls of the process help guide the needle into the marrow cavity. The advantage of this site is that the operator is not working under the horse. The spinal process is reported to be a poor site to sample in the cow.[18]

VetBooks.ir

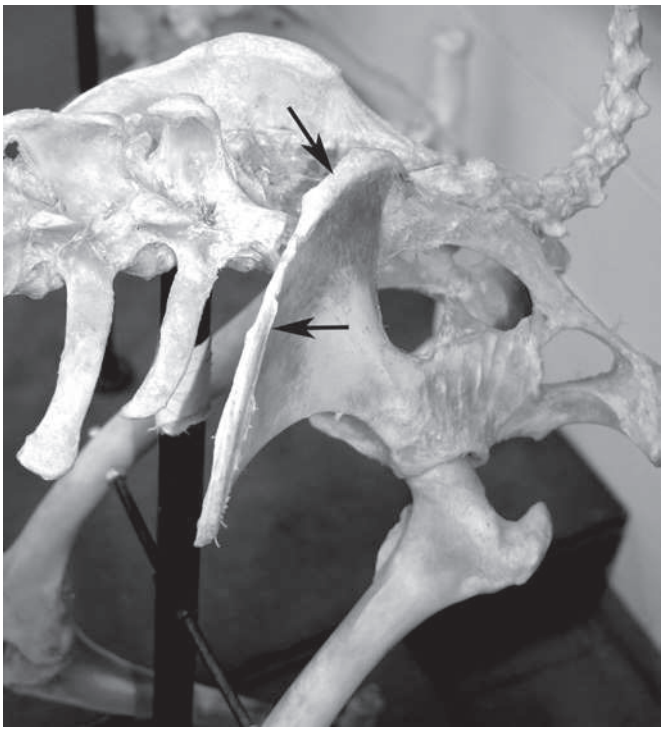

FIG. 28.8 Llama pelvis. The wing of the ilium *(arrows)* is generally considered too thin for easy bone marrow collection in camelids.

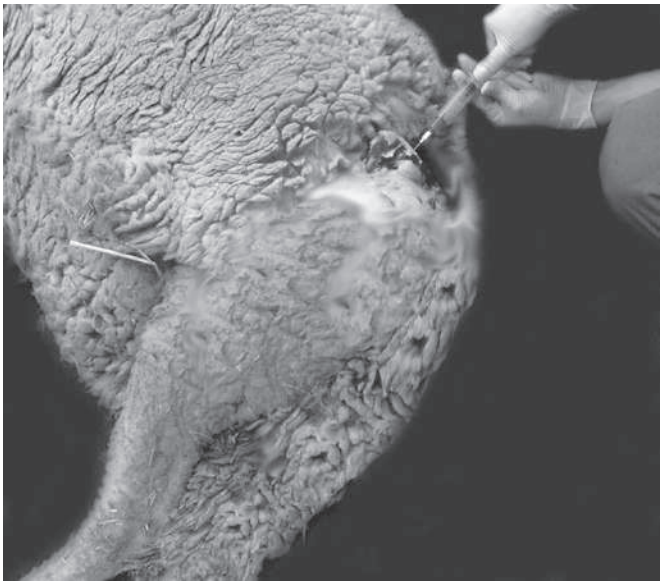

FIG. 28.9 Bone marrow aspirate from the ileum of a sheep. This sheep was undergoing necropsy, and the wing of the ileum has been dissected out.

Preferred collection sites to obtain equine bone marrow for regenerative therapeutic purposes include the sternum and tuber coxae. For young horses either site can be elected. However, in older animals aspirates from the tuber coxae yield significantly lower numbers of BMSCs.[19] Complication rates associated with the procedure are generally low for both sites[20]; nevertheless, severe complications have been reported following sternal aspirates.[21] In vitro, BMSCs from ileal aspirates showed higher chondrogenesis properties (glycosaminoglycan accumulation) than cells isolated from the sternum[22]; however, in vivo studies to validate this potential advantage are lacking.

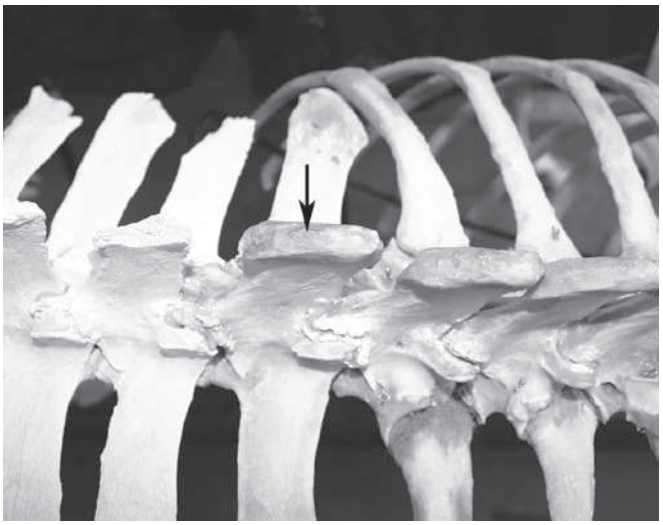

FIG. 28.10 First lumbar vertebra of a horse. Although not widely used, the spinal process of L1 *(arrow)* is another site from which bone marrow can be obtained in the horse.

APPROACH TO THE STERNUM. In the horse, bone marrow aspiration is typically performed in the standing animal. Sedation or a twitch may be used if necessary. The preferred site is on the ventral midline. A recent study performed in horses revealed that the fifth sternebra is the most consistent and safe site for aspiration of bone marrow.[23] Ultrasound can be used to select the desired sternebra and provide guidance for the optimal puncture site (Fig. 28.11). If ultrasound is not available, the optimal insertion site is exactly on the ventral midline in the cleavage between the deep pectoral muscles where a line connecting the points of the elbows would cross[24] (Fig. 28.12).

The manubrium of the sternum can also be sampled in horses by finding the cranial end of the sternum and going one hand width below and one hand width laterally from the end (see Fig. 28.3). From this spot the needle is advanced through the muscle in a horizontal plane at a 45-degree angle to the longitudinal axis of the horse.[10]

Sternal bone marrow can be sampled from adult cattle standing in stocks or a squeeze chute. It may be necessary to use techniques to prevent kicking, such as jacking the tail, or sedation. Unruly adult cattle and large calves can be cast and held in lateral recumbency. The upper front leg of the cast animal is held extended along the neck, exposing the sternum, after the other legs are secured with a rope.[25] Calves that weigh less than 300 lb can be placed in dorsal recumbency and secured by assistants or with ropes.[12] The needle should be placed on the midline and inserted perpendicular to the third or fourth sternebra. The appropriate sternebra is located by palpating the third or fourth rib and following it to the sternum.

For the sternum of a small ruminant to be sampled, the animal is placed in dorsal recumbency with legs secured, or it can be restrained in a sitting position with an assistant standing behind, supporting the animal and holding a foreleg in each hand.[12] The location of the appropriate site is midline, between the front legs. The second through fourth sternebrae can be used in sheep (see Fig. 28.5). A prominence may be felt between the first and second sternebrae. The appropriate sternebrae can also be located by palpating ribs and following them to their articulations.[26] In sheep, the needle will advance approximately 0.5 cm into the bone (2.5 to 3.8 cm from the skin) before entering the marrow cavity.[26]

The sternum of llamas can be sampled with the animal either standing in a chute or in left lateral recumbency, usually sedated[27] (see Fig. 28.6). The sample can be taken by inserting

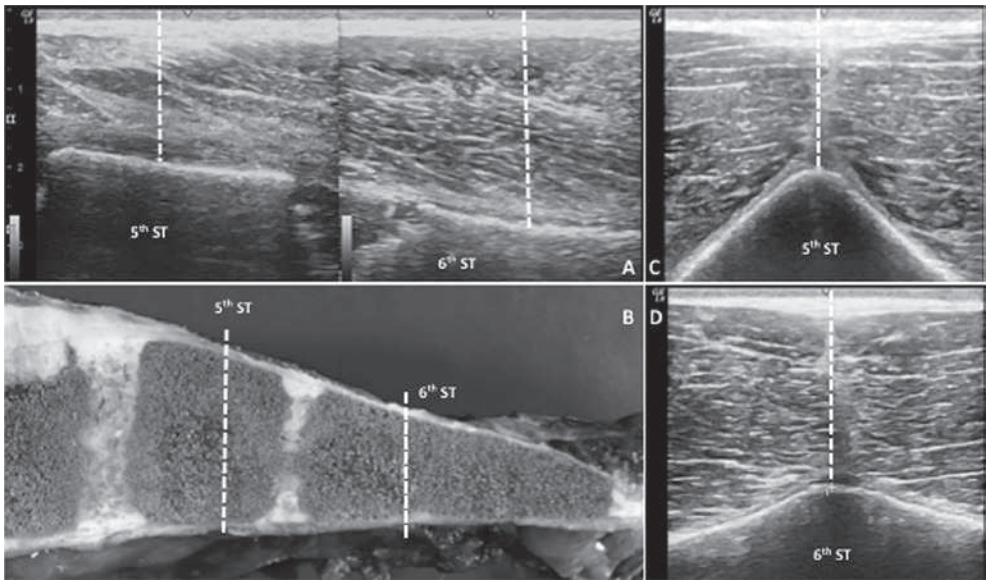

FIG. 28.11 Equine sternum. **A,** Longitudinal ultrasound of the fifth and sixth sternebrae. Cranial is to the left and ventral to the top of the image. The fifth sternebra is more superficial *(dotted line*, 1.88 cm) than the sixth sternebra *(dotted line*, 2.71 cm). **B,** Longitudinal section of equine sternum with the same orientation as in A. The fifth sternebra is more cuboidal and shorter longitudinally than the sixth sternebra. White dotted lines correspond to the position of the measuring lines in image A. Transverse ultrasound of the fifth **(C)** and sixth **(D)** sternebrae: the more conical shape of the fifth sternebra compared to the flat shape of the sixth sternebra might make it more difficult to anchor the aspiration needle in the center.

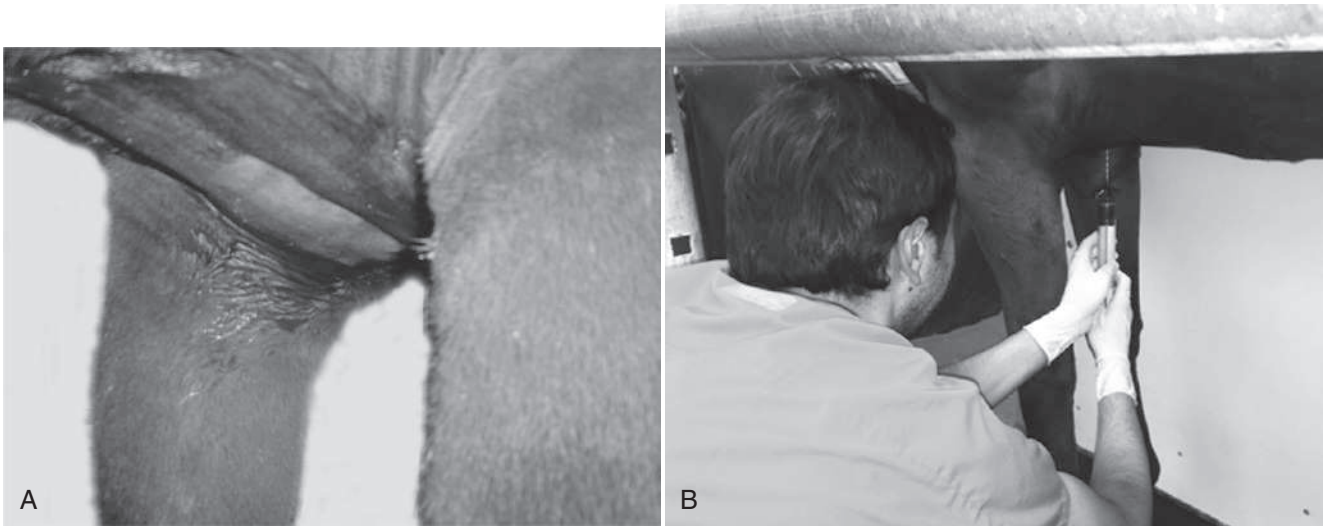

FIG. 28.12 Bone marrow aspiration in a standing, sedated horse. **A,** The ventral sternum between the horse's elbows is clipped and surgically scrubbed. **B,** After local anesthetic and stab incision, a spinal needle is inserted at the intersection of the ventral midline with a parallel line between the points of both elbows. A heparin-primed 60-mL syringe is used for therapeutic bone marrow collection.

the needle vertically through the callosity on the ventrum of the sternum or with a lateral approach, approximately 3 to 4 cm dorsal to the callosity with the needle directed medially and slightly dorsally to engage bone.[13] Marrow will be approximately 2.5 cm deep in an adult. The sample is normally more dilute with blood than in other species.[13]

When the ventral sternum is sampled, unless a lateral approach is used, the needle should be placed on the midline, as near to the center of the bone as possible, and advanced perpendicular to the bone. A sudden reduction of resistance may be felt when the marrow cavity is entered; because the sternal cortex is so thin, especially in horses; however, there may be no obvious change. Care needs to be taken to not enter the thoracic cavity. Because a change in resistance may not be felt, once the tip of the needle is firmly seated in the bone an aspiration attempt should be made.

APPROACH TO THE RIB. The vertebral end of the rib more consistently contains marrow than does the sternal end of the bone[28,29] (Fig. 28.13). Palpation can be used to find the rib that has the least amount of fascia covering it. In the horse, the eighth to eighteenth ribs can be used, going as high as possible but below the latissimus dorsi and serratus posticus muscles[28] (see Fig. 28.1). In cattle, place the needle approximately 3 inches ventral to the ninth or tenth costovertebral junction[18] (Figs. 28.2 and 28.14). The needle should be inserted perpendicularly at the middle of the rib, midway between the anterior and posterior borders (see Fig. 28.14, A). To help keep the needle from sliding off the bone, a scalpel can be first inserted until it touches the bone to be used as a guide.[15]

APPROACH TO THE ILIAC CREST. The iliac crest is often used in foals (see Fig. 28.7). The needle should be placed

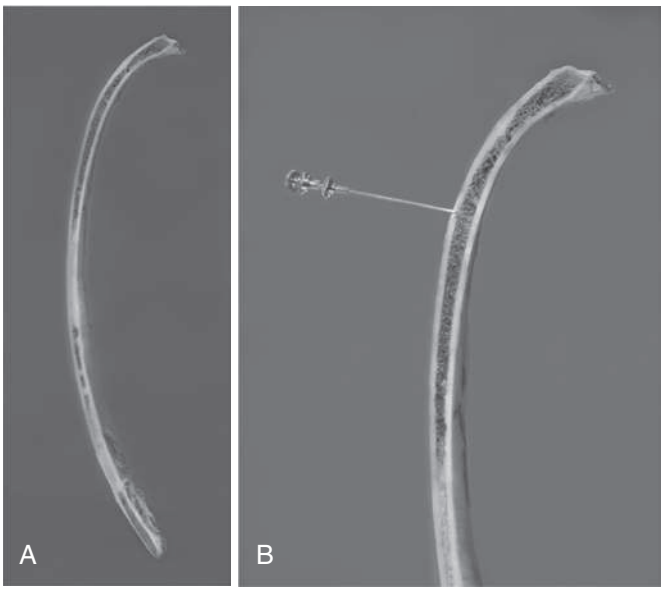

FIG. 28.13 Cross-section of bovine rib 10. **A,** Bone marrow is more consistently present in the vertebral end. **B,** Rosenthal bone marrow needle is inserted into the rib approximately 3 inches below the costovertebral junction.

BOX 28.2

Supply Checklist for Bone Marrow Collection

General

Clippers
Surgical scrub
Lidocaine
Syringe and needle
Sterile gloves
Scalpel blade (No. 15 adequate)
Bone marrow needle

Therapeutic

13-gauge bone marrow needle
Heparin
60-mL sterile syringes

Diagnostic

Bone marrow needle: ≥16 gauge, 1½ inches
10- to 20-mL sterile syringe
Glass slides
Jar of formalin for core biopsy
Optional:
- Anticoagulant
- EDTA blood tubes
- Petri dish or watch glass

EDTA, Ethylenediaminetetraacetic acid.

midway between the two tuberosities of the tuber coxae and somewhat toward its posterior border. With regard to angle, the needle should be pointing at the coxofemoral joint of the opposite side.

Bone marrow will be hit when the needle is inserted approximately ⅛ inch for foals, whereas in adult horses bone marrow may be more than 2 inches deep. The main benefit of using this method is that there is no risk of inadvertently entering the thoracic cavity.[16]

Preparation for Bone Marrow Aspiration or Biopsy

Bone marrow aspiration should be performed as a sterile procedure. After the animal has been restrained and the site of approach has been identified, hair should be clipped and the area surgically scrubbed (see Fig. 28.12, A). Local anesthetic is injected at the site where the needle will be inserted, from the skin to the periosteum (Figs. 28.14, B and 28.15, A). A small stab incision is typically made with a scalpel to aid the needle's approach to the bone. If the rib is to be sampled, the scalpel blade can be held in place to act as a guide for the needle. It is important to be organized and have all supplies ready so that the procedure will flow smoothly and the sample will not clot before it can be processed (Box 28.2; Fig. 28.16).

How the sample ultimately will be handled will dictate some of the available supplies needed: syringes, glass slides, Petri dish, EDTA blood tubes, and/or anticoagulant. One option is to prime the syringe that will be used for aspirating the sample with anticoagulant. Syringes are primed with heparin for therapeutic bone marrow harvesting. To prevent clotting in diagnostic samples, 1 to 2 mg of EDTA is recommended per milliliter of blood. One to two drops of a 3% to 15% EDTA solution should be adequate. The EDTA solution can be aspirated from a purple-topped blood tube. Priming the syringe with anticoagulant, although it adds a preparatory step, decreases the worry that the sample will coagulate and allows more time for processing the sample. If the syringe is not primed, as soon as the sample is seen in the syringe hub, the syringe needs to immediately be disconnected from the needle and the sample quickly processed before it has a chance to clot. If a reticulocyte count is to be performed to assess erythroid regeneration, supravital stains, such as new methylene blue and brilliant cresyl blue, require mixing with a portion of anticoagulated, liquid sample before slides are made; therefore placing at least some of the bone marrow sample in an EDTA tube is recommended.

The diagnostic sample in the syringe may be processed by expressing it directly onto several clean glass slides, into an EDTA blood tube, or into a Petri dish or watch glass. The Petri dish or watch glass must contain anticoagulant if no anticoagulant was used in the syringe. The anticoagulant commonly used is EDTA, which can be used in solution or as a salt, but other anticoagulants such as sodium citrate are also effective. Samples placed in an anticoagulant should be gently mixed immediately.

Collecting the Sample

The goal of bone marrow aspiration is to obtain a good sample of hematopoietic cells with minimal blood contamination. Anatomically, within the bone marrow, hematopoietic cells are extravascular and found in spaces dissected by venous sinuses and a central vein.[30] To collect the sample, a bone marrow or spinal needle with stylet should be used. Commonly used needles include Rosenthal, Illinois sternal-iliac, and Jamshidi bone marrow needles (Fig. 28.17). Some needles come with a guard that can be adjusted to prevent deeper penetration than desired. The needle used should be 16 gauge or larger and at least 1½ inches long. Larger needles may be needed, depending on the site of aspiration and the age and size of the animal. For therapeutic collection, a 13-gauge bone marrow aspiration needle is recommended.

After an animal has been properly prepared, the bone marrow needle is inserted through the skin, perpendicular to the bone. Once the needle contacts bone, it can be advanced using manual pressure and a clockwise-counterclockwise twisting motion (see Fig. 28.14, C). One hand can be used to stabilize the needle angle and placement while the other hand is on the needle hub pushing and turning the needle.[24] If the needle is

FIG. 28.14 Bone marrow aspirate of a cow. The animal was placed in a head gate and sedated, and a tail jack was applied. **A,** The area over the vertebral end of rib 11 has been clipped and surgically scrubbed. The cranial and caudal edges of the rib are palpated approximately 3 inches down from the costovertebral junction, and the midpoint of the rib is identified for aspiration location. **B,** At the chosen aspiration site, lidocaine is injected from skin to periosteum. **C,** After a stab incision has been made and the Jamshidi-type bone marrow needle has been inserted through the skin, the needle is forcibly pushed forward through cortical bone as it is rotated in a clockwise-counterclockwise motion. **D,** After a decrease in resistance is felt, the stylet is removed. **E,** A syringe is attached to the needle, and a few sharp pulls on the plunger are needed before sample is noted in the hub of the syringe.

VetBooks.ir

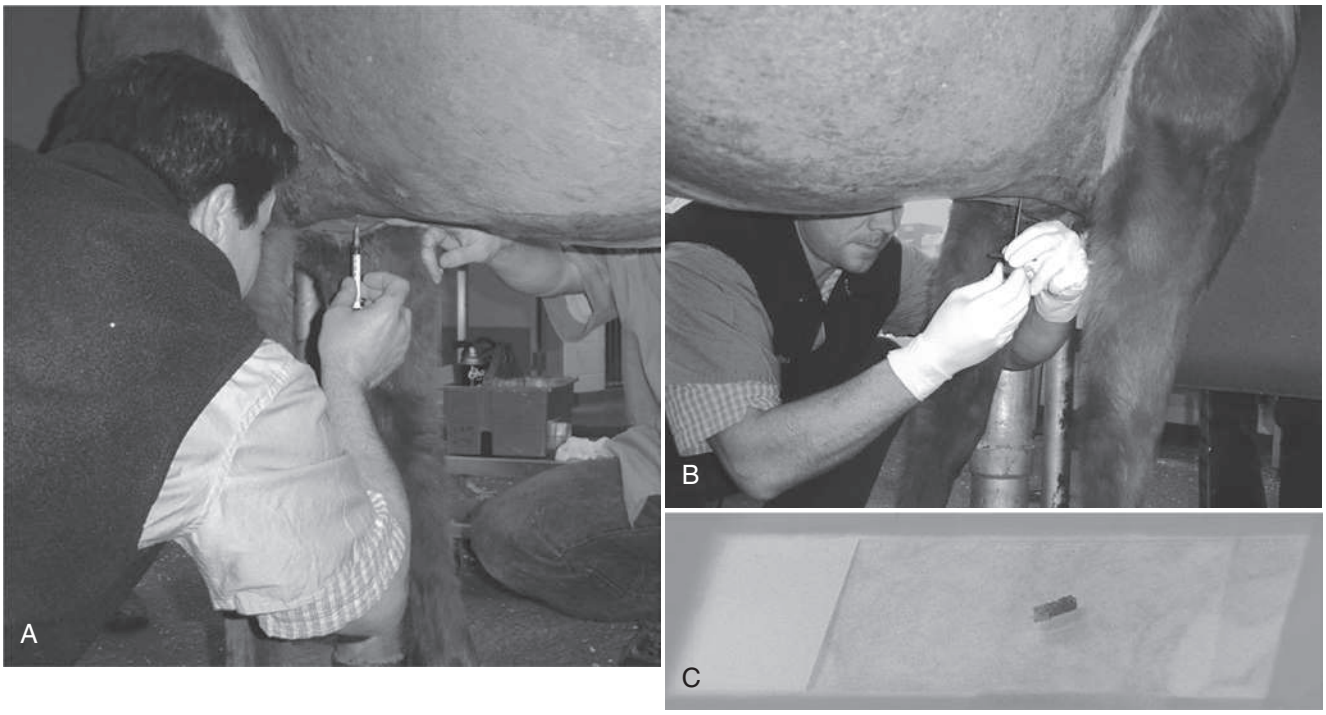

FIG. 28.15 Core bone marrow biopsy of a horse. The animal was placed in a stock and sedated; the ventral sternum between the elbows was clipped and surgically scrubbed. **A,** Lidocaine is injected from the skin to the periosteum. **B,** After a stab incision, the Jamshidi bone marrow biopsy needle is advanced into cortical bone. Here, the stylet is about to be removed before the needle is advanced further. **C,** Core biopsy sample.

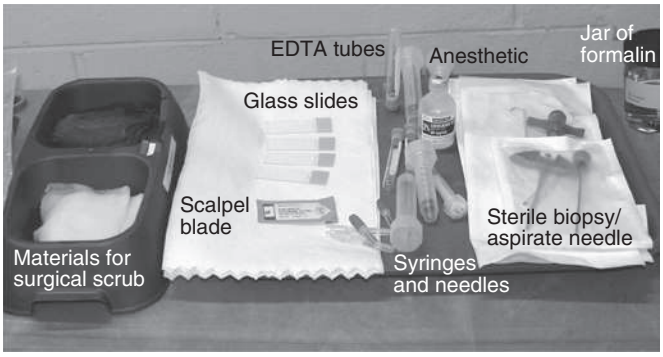

FIG. 28.16 Supply table is set up and ready for bone marrow aspiration. Sterile gloves were opened on an adjacent table. *EDTA*, Ethylenediaminetetraacetic acid

FIG. 28.17 Bone marrow needles with stylets separated. On the *left* is a 14-gauge, 2¾-inch Rosenthal needle. On the *right* is an 11-gauge, 4-inch Jamshidi needle.

going through dense bone, a wood mallet can also be used to advance it.

For a diagnostic sample, once it is suspected that the needle has entered the marrow cavity, either because of detection of a sudden reduction in resistance or because of needle depth, the stylet should be removed and an aspiration attempted (see Fig. 28.14, D). In dense bone, pliers may be helpful in removing the stylet.[12] After the stylet is removed, a 10- to 20-mL sterile syringe is securely attached to the needle, and the plunger of the syringe is pulled back quickly and sharply, creating negative pressure in order to dislodge bone marrow particles (see Fig. 28.14, E). Suction can be repeated two or three times. As soon as blood is seen in the hub of the syringe, suction should be discontinued, the needle and syringe removed from the animal, and the sample processed promptly. Additional suction will likely result in only dilution of the sample with peripheral blood. The first drop of blood is the most cellular, and further aspiration results in lower cellularity of the sample.[31]

For collection of equine therapeutic bone marrow, the needle is seated firmly into the center of the medullary cavity of the fifth sternebra (see Fig. 28.4). Once the needle is inserted approximately 3 to 5 mm into the bone, the stylet is removed and aspiration can begin (see Fig. 28.12, *B*). One or two 60-mL syringes with 10 mL each of heparin (1000 IU/mL) are used for aspiration. The syringe is then capped, and the sample is

mixed thoroughly by rocking the syringe gently back and forth. Studies have shown that the first 5 mL of an aspirate contain the highest proportion of BMSCs.[22,23] Furthermore, for sequential aspirates (two aspirates of 50 mL each), the second aspirate yields few to no BMSCs.[22]

If the initial aspiration does not obtain any material, remove the syringe, replace the stylet, and carefully advance the needle a little further. If still no sample is obtained after additional advancement of the needle and repeated suction, slowly withdraw the needle while applying suction to the syringe. Ultimately, repositioning the needle to a different site, such as moving a couple of centimeters cranially or caudally, may result in a successful aspiration.[13] It has been reported that the use of a multidirectional bone marrow aspiration needle improves the colony-forming unit fibroblast counts in a bone marrow aspirate.[32]

Processing the Sample for Diagnostic Purposes

Whether the bone marrow sample is directly applied to glass slides or expressed into a Petri dish or watch glass, processing needs to proceed rapidly to prevent clotting or drying out of the sample. When on the slide, if the sample contains a lot of excess blood, the slide can be briefly tilted so that the fluid portion can run off into an absorbent surface, leaving behind adherent particles for spreading (Fig. 28.18, C and Fig. 28.19, A). If the sample is placed into an EDTA tube or Petri dish with anticoagulant, spicules (small grayish particles) can be transferred out of the bloody sample using a pipette and placed on a glass slide[20] (see Fig. 28.18).

To spread the sample on a slide, place a second glass slide flat on top of the sample, allowing the sample to form a thin layer between the slides (Fig. 28.19, B). Without additional pressure other than the weight of the slide, gently pull the slides apart from each other horizontally and without vertical separation, which can create suction and rupture cells (Fig. 28.19, C). This typically results in a nicely spread sample with intact particles and nice monocellular layers for evaluation. Several slides should be made. After slides are made, they should be allowed to air dry, kept away from formalin fumes, and stored at room temperature until staining.

Some bone marrow slides are stained with a Romanowsky-type stain (Wright, Giemsa, Diff-Quik) for cytologic examination, and some should be left unstained in the event that special staining procedures are wanted. It is highly recommended that at least one slide be stained right away for microscopic examination in order to determine sample quality and to ensure that bone marrow elements are present while the animal is still available and prepped, in the event that the first aspiration is nondiagnostic and additional attempts will be needed (Fig. 28.20). If a sample containing mostly peripheral blood without spicules is obtained, it may be possible to acquire diagnostic information by centrifuging the sample in Wintrobe hematocrit tubes and making smears from the buffy coat. Staining for reticulocytes requires that an anticoagulated, liquid bone marrow sample be mixed and incubated with a supravital stain before slides are made.

If a core biopsy sample is obtained, the tissue can be gently rolled on a slide to make an impression smear for cytologic evaluation. The biopsy tissue should then be placed in 10% neutral buffered formalin for preservation. A larger gauge needle (10 to 13 gauge) is generally recommended for core biopsy. The Jamshidi needle, designed so that the distal tip tapers to help retain the sample, is the most popular needle for biopsy. The needle and stylet are initially inserted as for

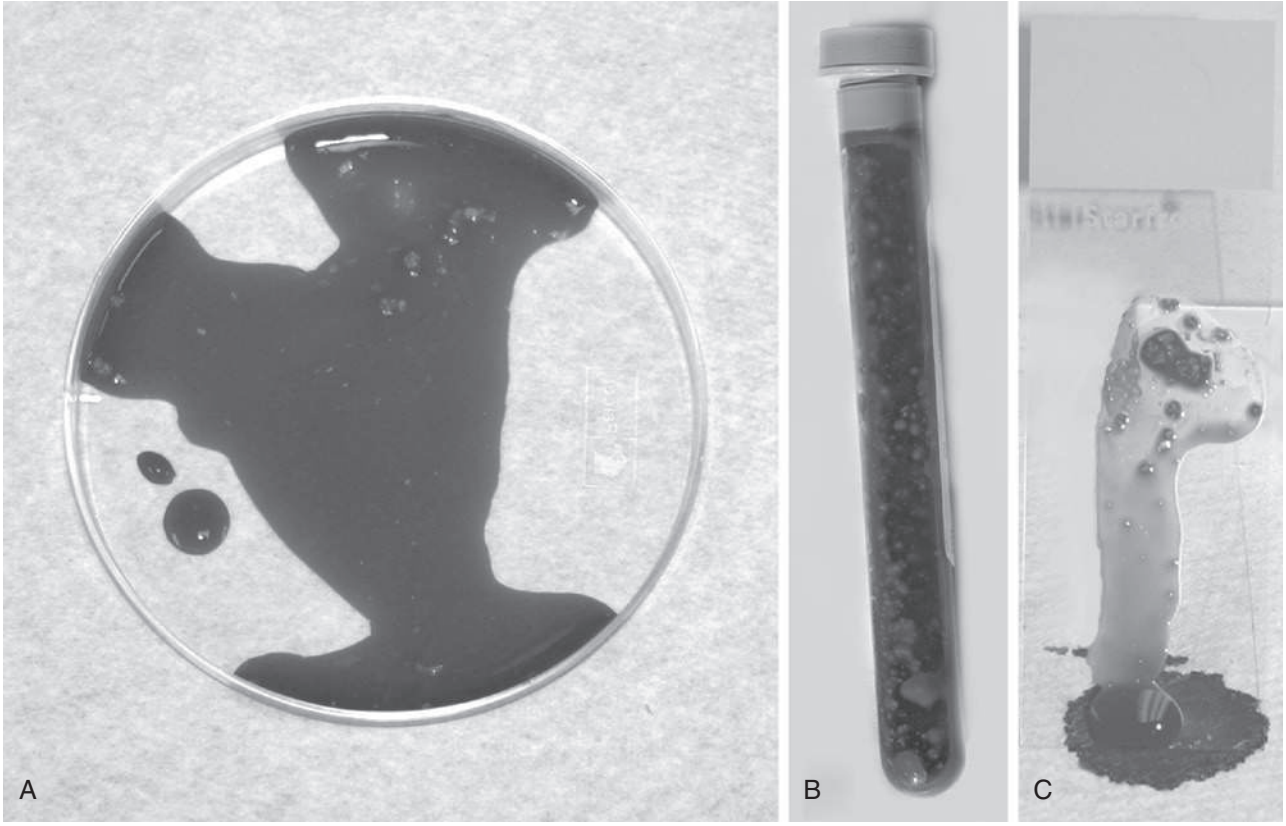

FIG. 28.18 Bone marrow spicules (small grayish particles) should be seen in the aspirated sample. **A,** Particles can be picked out of background blood from a Petri dish. **B,** Particles can be seen adhering to the sides of an ethylenediaminetetraacetic acid (EDTA) blood tube. **C,** Particles will adhere to a glass slide while excess blood runs off.

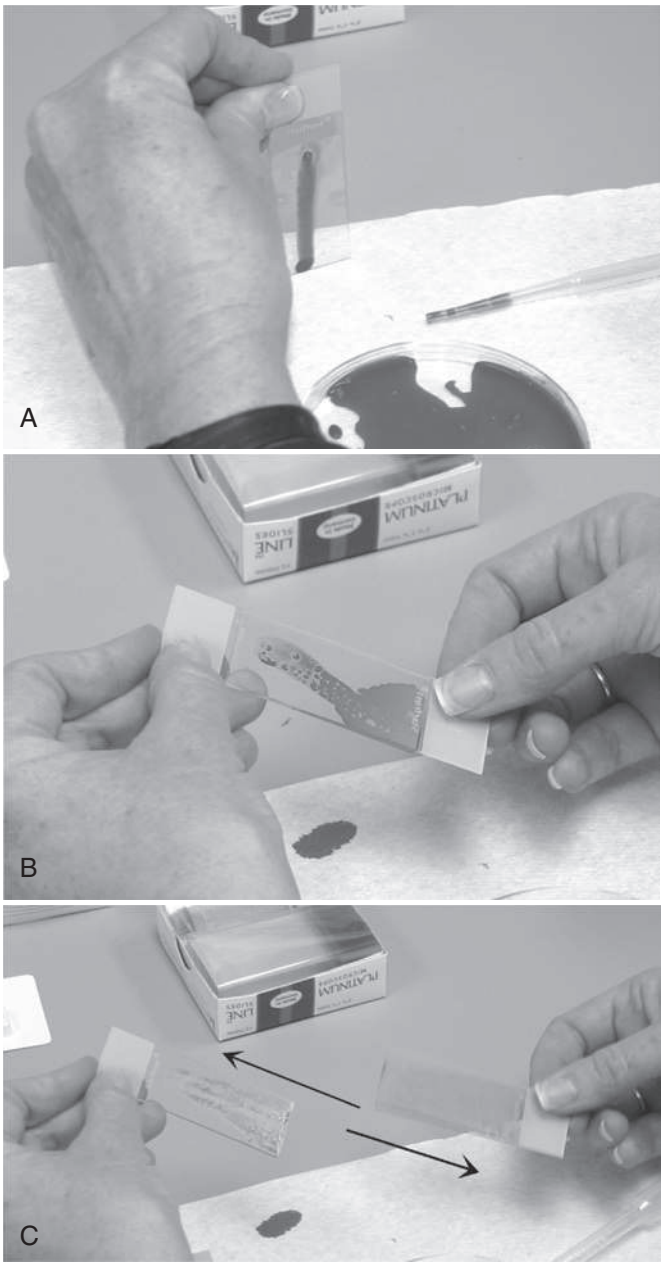

FIG. 28.19 Making slides of a bone marrow sample. **A,** Excess blood is allowed to run off the slide onto an absorbent surface while the spicule remains adhered to the slide. **B,** A second slide is laid on top of the sample, causing the sample to spread out between the slides. **C,** The slides are horizontally pulled apart, then allowed to air dry.

aspiration (see Fig. 28.15, B). Once the needle enters the bone marrow, the stylet is removed and the needle is advanced further with the same twisting motion. Ideally, the needle is inserted at least an additional 1 to 2 cm, but this may be limited by location. After the needle is advanced to obtain the core, it is rotated and rocked forcibly to help break the core at its base for successful removal. Once the needle is removed from the animal, a probe is inserted into its lumen at the distal tip, pushing the sample out the hub end (see Fig. 28.15, C).

Often bone marrow aspirates are placed into an EDTA blood tube for submission to an outside laboratory. In this case it is still recommended to make slides of the sample to submit along with the fluid sample. If the sample is left in the fluid phase, cells can deteriorate during transit, and it is always helpful for the cytologist to have a freshly prepared sample to

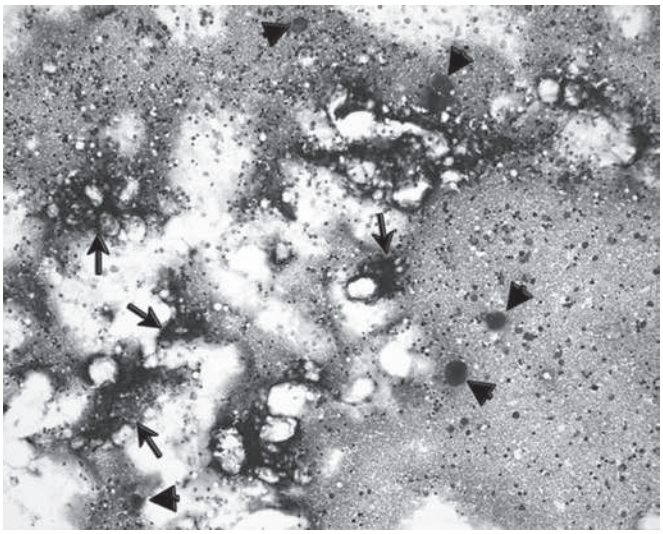

FIG. 28.20 Stained slide of adequate bone marrow aspirate sample. Megakaryocytes *(arrowheads)* and particles *(arrows)* are present. There is also increased cellularity compared with peripheral blood. (Wright-Giemsa stain, 10× objective.)

examine (of both bone marrow and peripheral blood). In addition, a slide can be stained and evaluated for diagnostic quality before the sample is shipped.

If repeated aspirates all result in samples of low cellularity, a core biopsy is typically indicated. Cytologically, it can be impossible to differentiate low cellularity caused by a pathologic process from that resulting from poor sampling; therefore a biopsy is used to evaluate cellularity.

Processing the Sample for Therapeutic Purposes

Bone marrow aspirates and concentrates have the advantage of being immediately available for injection after collection with minimal processing. However, multipotent stromal cells represent a minor fraction of the total population of nucleated cells in these samples. The other cells that comprise the aspirate include hematopoietic cells, monocytes and macrophages, and low numbers of lymphoid cells and endothelial progenitors. Studies suggest that after density centrifugation, which removes granulocytes and immature myeloid precursors, BMSCs are only 0.001% to 0.01% of the mononuclear cells remaining.[33,34] Concentrated bone marrow is made by centrifuging the heparinized bone marrow aspirate sample at 1500 revolutions per minute (rpm) for 10 minutes and removing the supernatant. In concentrated bone marrow, platelet and leukocyte concentrations increase (~8 times), but erythrocyte concentration decreases.[35]

Because BMSCs comprise such a small proportion of bone marrow, techniques have been developed for their selection and isolation. Commercial closed systems are available to separate MSCs. These kits can optimize cell viability after collection and reduce the risk of contamination[36] (PrepaCyte-CB, U.S. Patents 6,933,148 and 7,160,723). Studies in humans have shown that these closed systems provide a fast and reliable separation of human cord blood, with higher recovery rates of nucleated cells compared to other methods. Although this method removes most red blood cells, the addition of ammonium chloride solution to lyse the remaining red blood cells is recommended. The remaining nucleated cells are washed with a buffered isotonic media (Dulbecco's phosphate-buffered saline [DPBS]) and spun at 2100 rpm for 5 minutes. After the supernatant is discarded, the cells are resuspended in growth media. Another commonly performed open isolation method

VetBooks.ir

for enriching nucleated cells is to place the bone marrow aspirate in a density gradient solution for separation of the mononuclear fraction by centrifugation, prior to culture in growth media. Two density gradient solutions, Percoll and Ficoll, are commonly used for this method. A study performed with equine bone marrow showed that Percoll solution may have a higher yield of BMSCs and earlier self-renewal (14 days) than Ficoll solution.[37] This same study also compared both density gradient solutions to a classic isolation method based on MSCs from bone marrow concentrates adhering to plastic culture dishes, and no significant difference in cell viability or in osteogenic or chondrogenic differentiation was identified between the protocols.[37]

Bone Marrow Evaluation

Bone marrow evaluation requires expertise (advanced training and experience), and in most cases it is anticipated that samples will be sent to a trained cytologist for evaluation. To obtain the most information from a bone marrow aspirate, it is important to have a good-quality sample. Even if not reading the sample oneself, it is recommended that one stain a slide to confirm that a diagnostic sample was obtained (stain the worst slide; if it is acceptable, one can expect the others to be acceptable, too). Recent CBC results and freshly made blood films are also essential for full interpretation of a bone marrow sample. Relative changes among different cell lines are assessed in the evaluation of hematopoiesis because absolute cell counts are unreliable in bone marrow aspirates.[31] Knowledge of the peripheral blood picture is necessary to assess whether changes (or lack of changes) in the bone marrow are consistent with normal hematopoiesis. Freshly made blood films are important to have when comparing the morphology of cells in the bone marrow with the morphology of those in the peripheral blood. Results from cytologic evaluation of bone marrow should ultimately be correlated with history, clinical presentation, and other laboratory data.

Cytologic Examination

In general, the evaluation of bone marrow includes assessment of the following parameters. On low magnification the cellularity and quality of the sample as a whole are assessed, as well as the cellular density of bone marrow particles. Iron stores are evaluated within the particles. Megakaryocyte numbers are also best assessed at low magnification. On high magnification the sample is evaluated for the presence of myeloid and erythroid cell lines. The cell lines are evaluated for orderly maturation, and cell morphology is assessed for evidence of dysplastic changes. The relative proportion of myeloid to erythroid cells is determined by subjective assessment or by counting cells to derive a myeloid/erythroid (M/E) ratio. The sample is also evaluated for the presence of other cell types or infectious organisms. Results from the bone marrow evaluation are then interpreted in accordance with peripheral blood abnormalities.

Cellularity of bone marrow spicules is subjectively determined by assessing how much area of a particle is composed of cells versus fat. Cellularity of normal marrow can vary according to the age of an animal, with higher cellularity in younger animals and lower cellularity in older animals. Examples of differing cellularities are depicted in Fig. 28.21. Iron stores are assessed within spicules and typically described as *present*, *decreased*, or *increased* (Fig. 28.22).

Maturation of bone marrow cell lines follows somewhat of a pyramidal pattern, with cells dividing as they mature, resulting in higher numbers of cells in the more mature cell stages (Color Plates 28.9 and 28.10). In bone marrow of healthy animals, rubriblasts and myeloblasts typically comprise at most a small percentage of the total cell population. Twice as many prorubricytes and promyelocytes may be seen. Numbers of cells in each stage increase up to polychromatophilic rubricytes and metamyelocytes, after which there are relatively stable numbers between the subsequent maturational phases. In general, for each blast there are 16 mature granulocytes or erythrocytes. Mitotic figures are normally present in low numbers.

The M/E ratio is most accurately determined by counting a minimum of 500 cells. Nucleated cells of all maturational stages are included in the count and categorized as myeloid or erythroid. The ratio is calculated by simply dividing the total number of myeloid cells by the total number of erythroid cells. It is important to include several different areas of the sample to make it as representative of the whole sample as possible. Blood contamination can also affect the M/E ratio, especially if leukocytosis is present. Reported M/E ratio ranges for healthy animals of different species have varied. In some sources the M/E ratio in cattle is listed as less than 1, although ranges from 0.27 to 2.59 have been reported.[11,29,38-40] The range of M/E ratios in ten 3- to 6-year-old pregnant sheep was reported as 0.77 to 1.68.[26] The reported range for the M/E

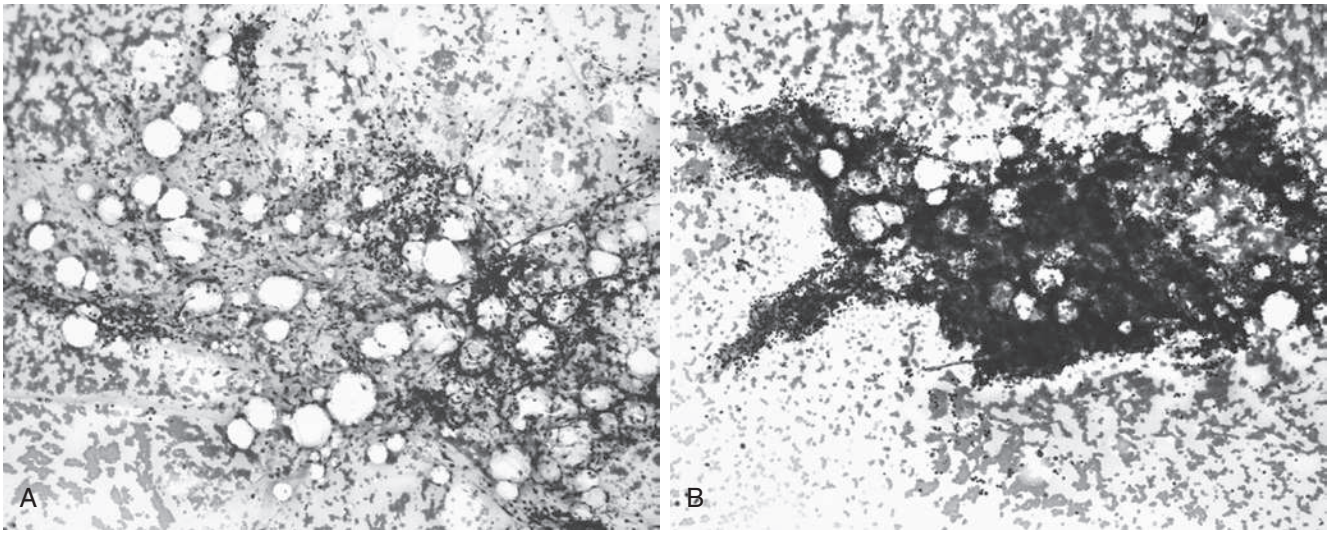

FIG. 28.21 Bone marrow particles. The particle in **A** is of low cellularity. Only a small proportion of the particle is composed of nucleated cells. The particle in **B** is of high cellularity. At least 75% of the particle is composed of nucleated cells. (Wright-Giemsa stain, 10× objective.)

VetBooks.ir

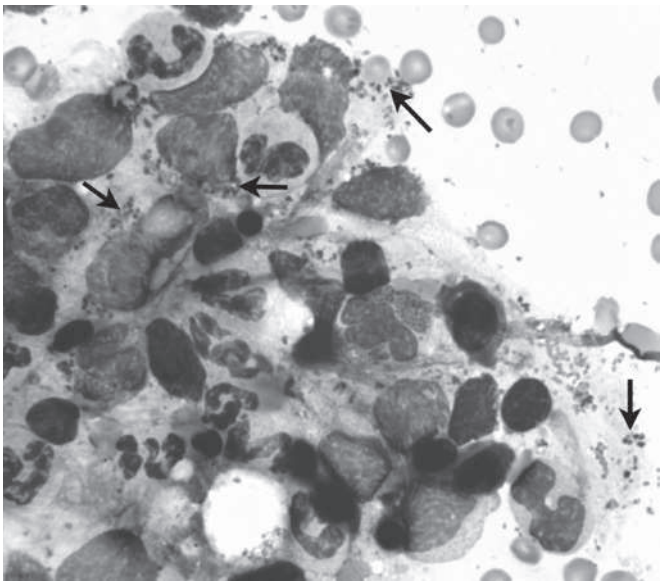

FIG. 28.22 Bone marrow aspirate. The blue-black granules visible extracellularly and within macrophages represent iron stores *(arrows)*. Iron stores can also be seen as brown crystalline material within particles. (Wright-Giemsa stain, 100× objective.)

ratio in a low number of llamas is 0.9 to 2.9.[27] Llama, alpaca, and vicuna have a lower M/E ratio at high elevation (4200 m) versus low elevation.[2] M/E ratios in horses generally range from 0.5 to slightly greater than 1, with 1.5 sometimes reported as the upper value.[10,41-43]

Evidence of dysplastic changes in hematopoietic cells includes asynchronous maturation between the cytoplasm and nucleus, large cell forms, and abnormal nuclei, such as ring-shaped nuclei. Cell types other than hematopoietic cells should be evaluated as to their presence and proportion of the total cell population. Low numbers of macrophages (<1%), plasma cells (<2%), and small lymphocytes (<10%) are commonly seen in bone marrow samples.

Interpretation

It is easy to make a conclusion about bone marrow cellularity if the sample is highly cellular, but a poorly cellular sample is more difficult to interpret if adequate particles are not present. A core biopsy may be needed to differentiate between a poorly cellular marrow and a nonrepresentative sample. In general the bone marrow will become more cellular in a hyperplastic or regenerative response.

In many cases it is adequate to describe iron stores as being present without quantification. When assessing the cause of anemia, an abnormality in iron stores may provide useful diagnostic information. Lack of iron stores would suggest iron deficiency, whereas abundant iron stores are associated with anemia of chronic inflammation. Perls' iron stain (Prussian blue reaction) can be used on bone marrow slides to confirm low iron stores. Llama bone marrows normally contain abundant iron.[27]

No definitive criteria for megakaryocyte numbers have been determined. If thrombocytopenia is not present, any number of megakaryocytes is acceptable. Many megakaryocytes are expected to be seen within individual particles when there is regeneration associated with thrombocytopenia. Higher numbers of immature megakaryocytes may also be seen; these will be smaller cells (still larger than other bone marrow cells) with a higher nuclear/cytoplasmic ratio, deeper basophilic cytoplasm, and fewer lobes to the nucleus. If megakaryocytes are not frequently seen in the bone marrow from an animal with thrombocytopenia, this suggests hypoplasia or destruction of megakaryocytes.

When assessing bone marrow for normal, progressive maturation of cell lines, it is expected that all developmental stages will be present, with greater numbers of the more mature cells. Variation from normal can be seen for many reasons, often reflected by a shift to the left or what appears to be a maturation arrest. A shift to the left is the situation in which all maturation stages are represented but there is a higher proportion of the less mature cells (the proliferating pool) than normal. *Apparent maturation arrest* is a term used when maturation appears to terminate at a particular stage; the earlier maturation stages are present, but later stages are poorly represented. Suppression of hematopoiesis can result in abnormalities in maturation progression but often is reflected by a decrease in all stages of maturation. If the number of cells within a cell line is too low, progression of maturation can be difficult to evaluate. Destruction of cells, such as with immune-mediated disease, at a particular maturation stage will result in decreased numbers of cells of the affected type as well as cells at all later stages, which can appear as a maturational arrest. If a disease process results in large demand or rapid mobilization of cells out of the bone marrow, depletion of the more mature cell stages can appear as a maturational arrest. In such cases a left shift also is often associated with the increased demand. Acute leukemia is typically reflected as an apparent maturational arrest or left shift. Therefore it can be difficult to differentiate between hyperplastic marrow in which there has been rapid mobilization of mature cells out of the marrow and a myeloproliferative disorder on cytologic examination alone. In some instances sequential bone marrow aspirations can be useful in helping to determine disease pathogenesis. Abnormalities in maturational progression may also be reflected by the presence of dysplastic changes.

The M/E ratio is used to help determine if the erythrocyte or myeloid cell lines are hypoplastic or hyperplastic. An equal number of nucleated erythroid and myeloid cells will result in an M/E ratio of 1. An M/E ratio greater than 1 (or greater than the reference interval) often indicates that granulocytic production exceeds erythroid production, but it could also indicate a decrease in erythropoiesis. Likewise, an M/E ratio less than 1 (or less than the reference interval) often indicates that erythropoiesis exceeds granulopoiesis, but it could also indicate suppression of the latter. Determining which interpretation is appropriate requires knowledge of concurrent CBC results. An increase in the M/E ratio would be appropriate in an animal with neutrophilia, but if the neutrophil count is normal and anemia is present, it would indicate erythroid hypoplasia. In the face of anemia, a decrease in the M/E ratio would indicate erythroid hyperplasia and regeneration, but a decrease in a neutropenic animal that is not anemic would indicate myeloid hypoplasia. In some disease states both the myeloid and the erythroid series may be affected, which could potentially exacerbate or mask alterations.

Whereas most species readily reflect an erythroid regenerative response in the peripheral blood, horses do not. Reticulocytes are rarely seen in equine peripheral blood, and in one investigation it took several days of severe anemia (packed cell volume [PCV] of 13% to 14%) in horses before a reticulocytosis of 1% to 2% was seen.[44] An increase in mean corpuscular volume (MCV) may be detected in the peripheral blood of horses with chronic anemia or acute, massive hemolytic or hemorrhagic anemias,[43-46] but the best way to assess erythropoiesis in horses is to examine the bone marrow. The number of reticulocytes significantly increases in the bone marrow of horses with regenerative anemia. In the study of acute blood loss in which only 1% to 2% of reticulocytes were seen in peripheral blood, bone marrow reticulocytes went from 4.1% (pre–blood loss) to as high as 66.5%.[44] Reticulocytes typically comprise less than

VetBooks.ir

2% of erythrocytes in normal bone marrow, and a regenerative response is considered present if reticulocytes comprise greater than 5%.[15] Determining the number of reticulocytes per 1000 erythrocytes after staining with a supravital stain such as new methylene blue is the most reliable method, but an estimate can be made by counting the number of polychromatophils per 100× oil objective field in a Wright-stained smear (assuming the field of view includes approximately 100 cells; this can vary with the microscope). In the face of anemia, greater than 5 polychromatophils/oil field is considered a good regenerative response, and less than 2 polychromatophils/oil field is indicative of erythropoietic suppression.[47] Care should be taken not to dilute the sample with peripheral blood, as this will dilute the number of reticulocytes from the bone marrow.

Other bone marrow parameters that indicate erythrocyte regeneration in horses include a decreased M/E ratio (<0.5) and a left shift of erythroid precursors.[43,47] Depending on the type of blood loss, it could take several weeks to reduce the M/E ratio below the reference interval.[48] With regeneration, a doubling of the proliferating pool of erythrocyte precursors can occur within 3 days of an acute severe hemorrhage, with maximal response at 9 days.[49] The proportion of basophilic and polychromic rubricytes can reach 39% to 55% of all cells in the regenerative equine bone marrow.[43]

Atypical cell populations in the bone marrow can represent a myeloproliferative disorder, an infiltrative neoplastic process, inflammation, or antigenic stimulation. Atypical cell populations can be a result of significant increases in cell numbers of types normally seen in the marrow. Blast cells normally constitute only a small percentage of total cells in the bone marrow. A diagnosis of acute leukemia is typically associated with blast cells that constitute more than 20% to 30% of cells within the bone marrow. Cytologic results need to be correlated with other clinical data because granulopoiesis characterized by a marked left shift in bone marrow precursor cells with rapid mobilization of more mature cells from the bone marrow can resemble a myeloproliferative disorder.

Another cause of increased numbers of cells normally residing in the bone marrow is inflammation. Suppurative inflammation can be seen, typically associated with septicemia. Histiocytic or granulomatous inflammation is characterized by increased numbers of macrophages. Both suppurative and histiocytic inflammation can be associated with infectious or noninfectious disease processes. If inflammation is present, the sample should be thoroughly inspected for organisms, and culture may be indicated.

Increased numbers of lymphocytes and plasma cells can be seen with antigenic stimulation or with neoplasia. In general, it is rare to see the proportion of lymphocytes or plasma cells exceed 20% with antigenic stimulation. The morphology of lymphocytes and plasma cells should be well differentiated if they are associated with nonneoplastic processes. Cells associated with neoplasia can also appear well differentiated; therefore cell morphology alone may not be useful in establishing a diagnosis. Clinical presentation and ancillary testing (e.g., serum protein electrophoresis, flow cytometry) can be helpful in interpreting lymphocytoses and plasmacytoses.

The presence of cells not typically seen in the bone marrow or cells exhibiting a high degree of pleomorphism or other criteria of malignancy should raise suspicion of a neoplastic process. Neoplasia can arise from within the bone marrow or can metastasize to the bone marrow from other sites.

Degenerative cells or amorphous proteinaceous debris suggests bone marrow necrosis. This can occur secondary to infarction, neoplasia, or inflammation. Degenerative cells are often unidentifiable.

After cytologic evaluation of bone marrow and correlation with CBC results, a determination can be made as to whether any of the cell lines are hypoplastic or hyperplastic and whether there is evidence of maturational arrest, dysplasia, neoplasia, or inflammation. This information can then be correlated with the clinical information to determine appropriate differential diagnoses and likely disease pathogenesis.

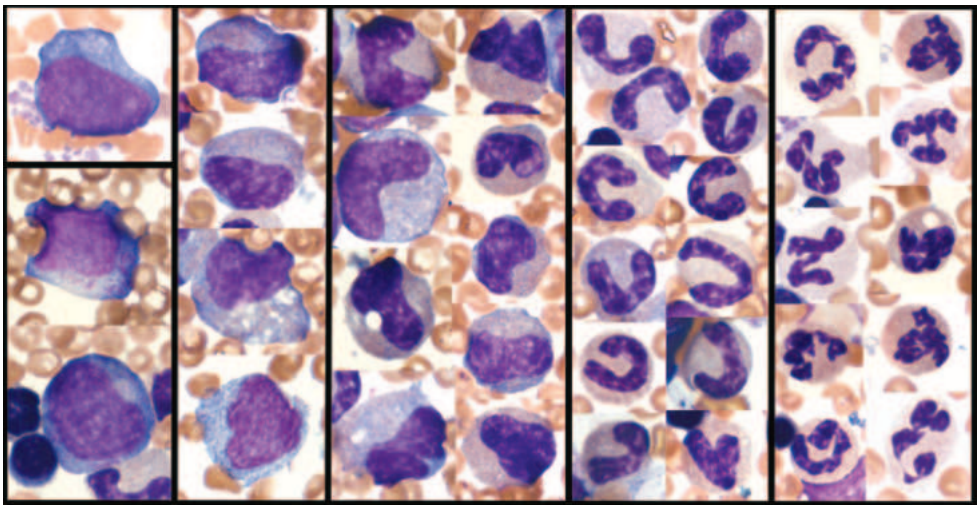
Color Plates 28.1 to 28.4 Bone marrow biopsy and aspirate from a 5-year-old female Quarter Horse with marked anemia (packed cell volume [PCV] = 9%; 31%-47%) and thrombocytopenia (42,000 platelets/µL; 125,000-300,000/µL). The bone marrow is highly cellular as seen in Color Plates 28.1 (H&E) and 28.2 (Wright-Geimsa); arrows point to megakaryocytes, 10× objectives. The myeloid/erythroid (M/E) ratio is decreased at 0.3, and polychromatophils comprise 30% of red blood cells (RBCs). Color Plate 28.3 shows a large erythroid population (unmarked cells and b = erythroblast) with fewer myeloid cells *(m)* and lymphocytes *(L)*; many polychromatophils *(P)* can be seen in Color Plate 28.4 (Wright-Geimsa, 100× objective). This is representative of regeneration and consistent with either chronic blood loss or immune-mediated destruction of erythrocytes, which could both be occurring in this horse. The horse was diagnosed with intramuscular hemangiosarcoma.



Color Plates 28.5 to 28.8 Bone marrow biopsy from a 2-year-old mixed-breed steer with mild anemia (packed cell volume [PCV] = 23%; 24%-46%), severe neutropenia (0/µL; 600-4000/µL), and thrombocytopenia (3000 platelets/µL; 100,000-800,000/µL) (Color Plates 28.5 and 28.6), compared to a normal age-matched control (Color Plates 28.7 and 28.8). Severe generalized bone marrow hypoplasia is apparent. The marked bone marrow suppression in this case is due to bracken fern toxicity. H&E; 10× (Color Plates 28.5 and 28.7) and 40× (Color Plates 28.6 and 28.8) objectives.

VetBooks.ir

Color Plate 28.9 Maturational stages of erythrocytes within the bone marrow. The *left panel* contains rubriblasts in the upper square with prorubricytes below. Rubriblasts are large cells with large nuclei containing coarse-grained chromatin and nucleoli; a perinuclear halo is present within scant, deeply basophilic cytoplasm. Prorubricytes have a more mature nucleus; chromatin condensation begins, and no nucleoli are present. The *middle panel* contains basophilic and polychromatophilic rubricytes; chromatin condensation is distinct, and the cytoplasm is paler, grayer, or polychromatic. The *right panel* contains metarubricytes with dark, intense chromatin condensation and pink cytoplasm. (Wright-Giemsa stain, 100× objective.)

VetBooks.ir

Color Plate 28.10 Maturational stages of granulocytes within the bone marrow. The *left panel* contains a myeloblast in the upper square with promyelocytes below. Myeloblasts are large cells with large nuclei containing fine reticular chromatin and nucleoli; the cytoplasm is basophilic and agranular. Promyelocytes contain coarse cytoplasmic granulation; nuclear chromatin is beginning to condense, and nucleoli are present. *Subsequent panels*, *moving to the right*, contain myelocytes, metamyelocytes, band neutrophils, and segmented neutrophils. Myelocytes have a lower nuclear/cytoplasmic ratio and contain fewer and finer cytoplasmic granules; the nucleus is round to kidney-shaped and contains no nucleoli. As maturation progresses, the cells become smaller, the cytoplasm becomes more eosinophilic, the chromatin becomes more condensed, and the nucleus indents and segments.

Molecular Diagnostics in Large Animals

Christian M. Leutenegger • Nicola Pusterla

Of the four classes of organic molecules that compose the basic physical structure of all living beings, nucleic acids are the only molecules that carry replicable instructive information. Nucleic acids differentiate themselves from lipids, carbohydrates, and even proteins in their ability to organize the basic unit of life, the cell. Even minor alterations in deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) molecules can disrupt the fine balance between health and disease. The field of molecular diagnostics seeks to elucidate the variations and mutations in genetic material that can cause disorder in the otherwise intricately organized body.

The amplified era of molecular diagnostics for infectious diseases began in 1983 when Dr. Kary Mullis of Cetus Corporation first conceptualized the polymerase chain reaction (PCR). He went on to win the Nobel Prize in Chemistry for this revolutionizing technology 10 years later.[1,2] Since the inception of PCR technology, infectious disease diagnostics have been at the forefront of molecular medicine, with the promise of detecting contagious pathogens in a safer and more sensitive way to aid in controlling their spread. Infectious disease testing is expected to continue to dominate the molecular diagnostic market for large animals in the foreseeable future. The use of amplified and nonamplified tests to assay the molecular makeup of the host rather than the pathogen is growing. Whereas cancer diagnostics is in its infancy for large animal testing, parentage and forensic testing together with single-nucleotide polymorphism (SNP) detection using in situ hybridization (ISH), fluorescent in situ hybridization (FISH), and sequencing technologies is gaining importance in assessing the presence and prognosis of genetic diseases.

The ability of molecular diagnostic assays to sensitively and specifically detect the primary cause of a disease, with short turnaround time, is giving significant advantages to disease diagnostics. Molecular tests are able to detect a specific unknown. Such tests are binary by nature; they provide a yes-or-no answer. However, certain tests when used quantitatively provide more insight into the medical manifestation induced by *Clostridium perfringens* toxins, for example. The clinically valuable information rests in determining the presence or absence of a specific pathogen in a biological sample derived from an animal. Because detection of viral, bacterial, rickettsial, fungal, or parasitic nuclear material in a biological sample gives clinically important information, molecular tests have direct clinical utility. However, the clinical context is always important to consider when making an interpretation on a molecular test. Determining the presence of a gene sequence per se without the clinical context does not necessarily correlate with a given clinical action, since diseases are generally multifactorial. In contrast, establishing the presence of the neuropathogenic form of equine herpesvirus (EHV)-1 in an equine patient's blood sample has direct association with EHV-1 infection, whether this translates into a symptomatic stage or not. The binary nature of molecular tests, which establishes the presence or absence of genetic material in a sample with a high degree of accuracy, has an accepted clinical value for infectious disease diagnostics because of its correlation with clinical signs.

Rapid results have tremendous clinical value in curtailing infection. Molecular methods can provide results in hours compared with days for culture-based or alternative technologies. The high sensitivity and specificity of molecular testing are

VetBooks.ir

particularly valuable in early determination of infection and make it advantageous compared with antibody and antigen testing without amplification techniques. In most cases pathogens enter the host and replicate exponentially; early detection provided by the higher sensitivity allows for earlier clinical intervention and a better prognostic outlook. Molecular tests have been shown to produce fewer false-positive and false-negative results compared with other test platforms. Therefore molecular tests are becoming the gold standard in the laboratory in terms of sensitivity and specificity. Key features for the adoption of molecular diagnostics for infectious agents are as follows:

- Superior sensitivity and specificity compared with most immunoassays
- Automated platforms that significantly increase throughput
- Quantitative assessment of viral load, which is clinically useful
- Fast turnaround time that speeds detection and reduces overall costs
- Simultaneous analysis of multiple analytes
- Standardized environment with the potential for full comparability across laboratory systems
- Ability to tightly quality control and monitor all aspects of the test workflow, including sample quality, DNA and RNA quantity, contamination situation during extraction and in the laboratory in general, presence of inhibition, and performance of the PCR test and reagents

Technologic Superiority of Molecular Tests

The relative technologic superiority of molecular methods makes them likely to partially replace other types of more conventional methods, such as culture-based tests or certain direct antigen and antibody tests to determine the presence of an infectious pathogen in a sick animal. Whereas antibody testing is more of a broad screening tool, molecular diagnostics allow accurate detection of the genome of a pathogen in a clinically sick animal. Culture-based tests have a turnaround time of days and are labor intensive. In addition, certain infectious agents are difficult to culture or are biohazardous for laboratory personnel (e.g., *Mycobacteria* species, fungi, *Mycoplasma* species, *Lawsonia intracellularis*). In such instances, molecular detection of selected pathogens has already supplanted conventional culture.

Rapid and High-Throughput Applications Promote Molecular Tests

Rapid and specific detection of infectious disease agents is crucial for the prevention or containment of outbreaks. In the case of avian flu, the rapid detection of H5N1 strains of that virus is critical for containment. The avian flu pandemic concerns necessitate rapid and high-throughput molecular tests to maintain the well-being of animal and human community health. Similarly, West Nile virus (WNV) screening of mosquito pools and birds, as well as screening for exotic Newcastle disease, are additional examples of high-throughput applications with predominance for molecular tests.

Increasing Adoption of Molecular Tests by University and Commercial Laboratories

Since the advent of molecular platforms in the diagnostic laboratory, most molecular tests in veterinary medicine are performed by several commercial and public laboratories. Unlike the market in human molecular diagnostics, which is dominated by four large players (Roche, Bayer, Gen-Probe, and Abbott), veterinary molecular diagnostics show significant fragmentation in particular with many university diagnostic laboratories. However, the transition to the more advanced real-time PCR platform within the past 5 to 7 years and the abandonment of conventional PCR tests by many laboratories has led somewhat to a concentration process in the veterinary diagnostic landscape for a good reason: real-time PCR is the more advanced method and is considered a fully matured technologic platform with great incentives for automation, operational efficiency, and affordability.

Simultaneous Testing of Multiple Pathogens

Parallel testing of multiple infectious agents in highly standardized platforms is a central advantage of molecular assays; it essentially allows several tests for both DNA and RNA pathogen targets to be performed simultaneously on a single sample, therefore condensing the medical message obtained on a given diagnostic sample. This development is a noteworthy driver for molecular diagnostics because it allows acquisition of more meaningful data from a single sample. This so-called panel strategy allows an efficient workup of complex clinical syndromes with general symptomatology that do not allow an etiologic diagnosis based on clinical signs. These clinical cases are complex for the decision-making process for the veterinarian dealing with patients unable to communicate the pain matrix. In complex organ-related problems with general or unspecific symptomatology, multiple infectious agents can be responsible for a clinical picture or aggravate other primary events in the differential workup. Even though veterinarians tend to make a single-pathogen diagnosis, it has become more evident in recent years that many syndromes are caused by multiple infections present at a given time. Panel testing on a large scale will uncover unknown co-infections in animals, which can diffuse the clinical picture. It has long been speculated, for example, that seemingly clinically irrelevant EHV-2 infections in horses may be a predisposing factor for *Rhodococcus equi* pneumonia in foals. More characteristic examples include respiratory infections in companion animals, often initiated by subclinical viral or bacterial infections that lead the way to secondary infections. In addition, many vectorborne pathogens have a high tendency to persist in infected animals and therefore may facilitate viral infections or aggravate preexisting conditions such as feline immunodeficiency virus or feline leukemia virus infection. Sepsis caused by infectious agents is expected to become an important segment for equine molecular diagnostics, especially in neonatal medicine. Molecular diagnostics enable fast turnaround time with rapid initiation of treatment. In the future, panel testing for the most important sepsis-inducing agents could be complemented by the addition of assays targeting antimicrobial resistance genes. This would allow the modification of treatment regimens in case antimicrobial resistance is detected.

Indications for Use of Polymerase Chain Reaction Assays for Infectious Diseases

Diagnostic tests such as PCR assays offer the potential for fast and accurate determination of the presence of an infectious agent, which can lead to an improved clinical outcome because of the faster initiation of more etiologic-based treatment and the possibility for quantitative treatment monitoring. Even if molecular-based tests are more expensive than more traditional diagnostic assays, their overall impact will lead to reduction in treatment costs.

Key indications for use of a molecular test are the speed and accuracy of molecular assays. In comparison with traditional culture for bacteria, rickettsial organisms, fungi, and viruses, molecular testing offers direct detection of the target pathogen within a fraction of the time. Owing to its speed, PCR assays have the potential to replace traditional culture methods for infectious agents that are difficult to culture or are not cultivable at all.

Compared with serology testing, molecular tests offer the advantage of detecting an infectious agent before an immune response occurs and a detectable antibody titer is developed. Immunoglobulin M (IgM) analysis in certain applications (such as WNV) can alleviate this problem; however, molecular testing methods are more reliable in picking up early virus replication

VetBooks.ir

and allow a faster epidemiologic assessment and earlier patient treatment.

In certain instances, for the discrimination of a clinically relevant EHV-4 infection from a latent infection, the detection of viral DNA is not informative. In such cases the quantitative assessment of viral loads is necessary.[3] Similarly, the choice of RNA or DNA affects the ability to distinguish disease (active virus replication and production of viral transcribed RNA) from nondisease (viral DNA of latently infected cells) status.

Molecular Biology Technologies

The main methodologies used for molecular diagnostics include the following:

- Nucleic acid capture, probe hybridization
- ISH, FISH
- Isothermal amplification of nucleic acids[4]
- Transcription-based amplification methods
- Signal amplification by branched-chain DNA
- Qualitative pathogen identification using nucleic acid amplification
- Quantitative assays
- Genotyping assays
- Genotype sequencing assays
- Multianalyte testing panels

Genotyping assays are typically used to test for known mutations associated with inherited genetic conditions such as hyperkalemic periodic paralysis (HYPP) in horses, an autosomal dominant condition that causes potassium-induced attacks of skeletal muscle paralysis. Many of these assays depend on sequence-specific probes designed to hybridize with known genetic variations. For infectious agents, genotyping or speciation is achieved by using highly specific PCR- or hybridization-based assays or by restriction enzyme fragment length polymorphism (RFLP) assays. In these assays, amplified material is digested with a certain restriction enzyme that characterizes the difference between two target sequences.

Polymerase Chain Reaction in Veterinary Molecular Diagnostics

Because of its predominance in research and diagnostic applications, PCR assays will be discussed in more detail in later chapters. To give practitioners guidance about what to look for when PCR-based molecular diagnostic assays are offered, we will discuss some aspects such as design guidelines, differences between traditional and real-time PCR assays, sampling, controls, and interpretation of results in greater depth.

PCR testing in its pure form is a three-cycle event: denaturation of double-stranded target (or, in later cycles, PCR products), annealing of target and primers, and extension of the DNA strand from the primer.

COMPARING REAL-TIME POLYMERASE CHAIN REACTION WITH TRADITIONAL POLYMERASE CHAIN REACTION TESTING FOR DIAGNOSTIC APPLICATIONS. Real-time PCR testing was introduced into the marketplace in 1996 and replaced the tedious gel electrophoresis step to detect PCR products after amplification. In one survey, 98% of equine veterinarians knew about PCR testing, and 79% of equine veterinarians at universities knew the difference between conventional and real-time PCR testing.[5] During gel electrophoresis, the PCR products are separated by size and visualized using a dye (ethidium bromide) that intercalates with the double-stranded DNA. Real-time PCR detects the PCR products by using an internal probe that is labeled with two fluorescent dyes: a reporter dye and a quencher dye. The fluorescent activity of the reporter dye is absorbed (quenched) by the quencher dye. The probe binds to the PCR products between the two PCR primers. If the primers are extended by the DNA polymerase, the 5′ nuclease activity of the DNA polymerase digests the internal probe (hence hydrolysis probe) and releases the quenched fluorescence. Alternatively, hybridization probes that are not digested during amplification and that allow melting curve analysis can be used. This single change in the protocol regarding how to detect the PCR products revolutionized the use of PCR testing for both research and diagnostic applications. Most of the advantages resulting from this principle originate from the fact that the PCR tube does not have to be opened after a PCR assay for analysis. This principle is called *closed-tube detection*. The advantages are as follows:

1. Because of the closed-tube detection format, PCR products cannot escape from the PCR reaction containers. If escape occurs, it leads to the contamination of the PCR laboratory and subsequently the next PCR reactions. The consequence is false-positive PCR results. Real-time PCR efficiently eliminates this risk of PCR product carryover. There is also a second safety system called AmpErase UNG (Invitrogen, Grand Island, N.Y.),[6] which eliminates contaminating PCR products.
2. Real-time PCR is a kinetic PCR principle, underlining the fact that PCR product accumulation is measured during every single PCR cycle in real time. Because of this fact, real-time PCR is a quantitative method.
3. The real-time PCR platform introduced in 1996 consisted of a laser-based thermocycler, software to design real-time PCR assays, reagents, disposables, and protocols. Because of its integrated design, PCR assays generated with the new system were highly standardized.
4. Data analysis is run on an attached computer that collects fluorescent data points. This principle eliminates all laboratory steps after the real-time PCR cycling is finished. Because of the computer-formatted end analysis, results can be fed directly into the information and management systems of diagnostic laboratories. Real-time PCR has also enabled rapid cycling to finish the PCR process in less than 1 hour. Real-time PCR results therefore can be turned around significantly faster than with traditional PCR testing (normally within a 24-hour period).
5. Because of the probe used to detect the PCR products, real-time PCR is also a more specific assay than single-round traditional PCR. Only specific PCR products are detected by the probe. Real-time PCR testing, essentially a liquid-based hybridization method, is considered as specific as Southern blotting, which is a solid-based hybridization method.
6. Because real-time PCR incorporates hot-start enzymes, the specificity is even greater than with regular non–hot-start DNA polymerases. Hot-start enzymes are inactive at ambient temperatures and have to be heated to 95° C for 20 seconds to 10 minutes in order for the DNA polymerase activity to begin. Because of the hot-start nature, nonspecific binding of primers does not lead to unspecific PCR products and results in an overall increased specificity of the assay.
7. In combination, real-time PCR is described to be as sensitive as or more sensitive than double-round (nested) traditional PCR. Analytic sensitivity and limit of detection using real-time PCR testing is normally in the single molecule range, whereas the limit of quantitation with traditional PCR testing is in the range of 10 to 20 molecules.

Preanalytic Variables

In general, molecular diagnostic laboratories provide strict recommendations for sample collection, including shipping instructions. These instructions include specimen type, volume, and anticoagulant and specimen transport, storage, and handling. The sample type is largely influenced by the pathogenesis of the disease and plays a key role in the performance and interpretation of the test results. Veterinarians are advised to adhere to these recommendations, because the quality of the

VetBooks.ir

result is directly correlated to the quality of the sample and preservation of the nucleic acid content. Molecular assays often offer the convenience of using a small specimen acquired with a minimally invasive procedure. The diagnosis of herpesviruses is a classic example in which culture and neutralization assays have been largely replaced by PCR testing on a small volume of aspirate or swabs from mucosal surfaces. Molecular tests can detect the presence of small numbers of organisms, and the probability of detection increases when a larger volume of specimen is added to the amplification reaction. Because molecular assays do not need viable organisms for testing, more flexibility in specimen transport is possible than with culture methods.

Appropriate specimen collection and transport conditions are important to ensure successful extraction of intact nucleic acid and to prevent cross-contamination. Specimen transport and storage conditions are likely to vary among specimen types and between RNA and DNA tests. RNA is more susceptible to degradation, but in general molecular diagnostic samples should be cooled in order to slow the nucleic acid degradation within the sample. Because of the difficulty of maintaining a freeze chain, molecular diagnostic samples should only be cooled throughout the collection, storage, and transportation process in order to minimize sample deterioration. Detailed storage and shipping instructions are crucial for a successful molecular diagnostic workup. Practitioners should be aware of these recommendations and consider using appropriate cooling containers when samples are collected in the field. Such samples maintain stability if stored appropriately in a cooled environment. Freezing and in particular the thawing process often adversely affect the quality and should be avoided if not otherwise instructed by the laboratory.

Sampling errors are among the many preanalytic variables that can affect the outcome of the results. It is therefore recommended that the laboratory have the appropriate labeling material available for blood containers or other sample types. Blood or body liquid contamination on the outside of the containers is an obvious cause of sample cross-contamination before the samples are manipulated in the laboratory. Proper collection procedures are essential to prevent these kinds of artifacts.

NUCLEIC ACID EXTRACTION. Many commercially available manual and automated methods have been successfully applied to infectious disease testing using a variety of clinical materials. Especially in veterinary molecular diagnostics, the variety of sample types can be challenging for processing through a single platform but can be achieved by validating sample type–specific pretreatment procedures in order to create a lysate of similar viscosity and nucleic acid concentration, which maximizes the extraction efficiency. Automated or semiautomated platforms are rapid and usually require only a small volume of specimen. In general, these systems are total nucleic acid extraction systems and support the parallel analysis of DNA and RNA pathogens from the same sample in a panel configuration. In addition, commercially available automated systems can reduce hands-on labor requirements and speed up the process significantly, leading to even shorter turnaround times. Most systems can accommodate sample volumes ranging from 100 to 500 μL and even 1 mL of specimen lysate. Nucleic acid binding capacity varies and can be as high as 200 μg per individual extraction position, which allows the maintenance of a good limit of detection even when many infectious agent targets are analyzed in parallel for a given panel.

INTERPRETATION OF RESULTS. Interpretation of results obtained with molecular assays for infectious diseases requires understanding of the pathogenesis and biology of the target organisms. Some challenges are unique to molecular tests and are different from considerations in interpreting other microbiological tests. Such differences are related to the distinction of viable from nonviable organisms and the correlation of nucleic acid detection with presence of disease or disease association.

Interpretation of a negative result includes information about the sensitivity and nucleic acid extraction efficiency. A false-negative result may be caused by a degraded or unstable sample. Insufficient volume or inappropriate sample type, inadequate sampling procedures, and transport problems are additional sources for potentially false-negative results. Sample-specific internal positive controls targeting endogenous genes such as the universal 18S rRNA (ssrRNA) or glyceraldehyde-3-phosphate dehydrogenase *(GAPDH)* gene help to identify these problems. These so-called internal positive controls allow quantification of the sample-specific nucleic acid (both DNA and RNA) and allow validation of a diagnostic sample for its use in PCR; samples below a certain quantity of DNA are at risk of being called false negative; therefore repeat collection can be recommended. In addition, inhibition phenomena originating from difficult sample matrixes such as feces, urine, or environmental samples contaminated with trace amounts of soil (humic acid) have to be controlled with internal positive controls to assess the inhibitory effects.

The factors requiring consideration for the interpretation of positive results include assay specificity and contamination issues. PCR testing or any other target amplification method is subject to these considerations. Real-time PCR testing using closed-tube detection procedures reduces the risk of PCR product carryover as a source of false-positive results and the availability of systems, which mark the PCR products when produced with certain types of nucleotides (uracil instead of thymidine), allows the specific degradation of contaminating PCR products before the next PCR amplification occurs (AmpErase UNG system). Combined with air movement control in the molecular diagnostics laboratory (overpressurized clean laboratory and negative-pressurized sample preparation laboratory) and limited access to trained laboratory technicians, great safety can be achieved, leading to valid results.

In general, molecular assays do not provide information about the viability of an infectious agent. Exceptions to this are DNA viruses, bacteria, and parasites analyzed for transcribed genes instead of their genomic DNA. This approach allows the assessment of the replication competence of a target and therefore is highly correlated with viability. Examples are toxin quantification, differentiation of vaccination versus infection, and herpesvirus quantification in order to differentiate between lytic (acute) and chronic (latent) infection, which has immediate implications to the ability of the virus to cause or contribute to clinical signs. In addition, spliced RNA occurs only if viral genes are actively transcribed and provides a means for obtaining information about the replication activity of a virus and the stage of infection. In other cases, targeting the ribosomal RNA of parasites such as *Toxoplasma* and *Cryptosporidium* is a means for obtaining viability information and also may increase the analytic sensitivity.[7]

Detection of the nucleic acid of a pathogen does not necessarily ensure that the organism is the cause of the disease. A primary example is herpesvirus infections (EHV-1 and EHV-4), in which the detection of DNA may indicate the presence of lytic, nonreplicating, or latent virus. Studies indicated that high viral loads of EHV-4 DNA allow the formulation of a cutoff value to differentiate between lytic and latent infection.[8] In this particular case, high viral loads were associated with the presence of clinical signs and viral RNA transcripts. Therefore quantitative real-time PCR testing can provide a means to obtain much improved disease association and invalidates the notion that PCR "just detects dead DNA."

REPORTING OF MOLECULAR RESULTS. Reporting results for qualitative assays in infectious disease monitoring is simple: a sample either does or does not contain the nucleic acid of

VetBooks.ir

a target organism. Further relevant information includes the nucleic acid extraction efficiency, nucleic acid stability, and sample integrity determined with the various quality controls.

Reporting results for quantitative molecular infections is more complex. For veterinary medicine, some quantitative applications have been established and are progressively phased into diagnostic routine analysis. Such quantitative PCR (qPCR) tests combined with fully standardized protocols will continue to expand within the veterinary diagnostic market as our understanding of the biology and pathology of infectious agents grows.

Regulatory Considerations of Molecular Laboratories

Veterinary molecular diagnostics is an emerging market with a growing level of regulation. Standards such as those defined by the American Association of Veterinary Laboratory Diagnosticians (http://www.aavld.org), Molecular Methods (CLSI; http://clsi.org/), or MIQE (minimum standard guidelines for fluorescence-based quantitative real-time PCR experiments) are adopted by commercial laboratories aiming to provide a comprehensive diagnostic service. Other sources for guidelines are U.S. Food and Drug Administration guidelines (www.fda.gov) for the detection of nucleic acids; ASTM guidelines (*Standard Guide for Detection of Nucleic Acid Sequences by the Polymerase Chain Reaction Technique;* www.astm.org); and the Association for Molecular Pathology (*Recommendations for In-House Development and Operation of Molecular Diagnostic Tests;* www.ampweb.org).

Guidelines for Clinicians to Select Molecular Diagnostic Laboratories

Veterinarians can use a variety of guidelines to select laboratories for molecular diagnostics. However, there are some major factors worth considering before samples are submitted. First, it is worthwhile to obtain information about the nature of the PCR test (traditional vs. real-time). Second, questions addressing the quality control and quality assurance system within a particular laboratory should be asked. Third, turnaround time, pricing, and the level of guidance with result interpretation and availability of consulting resources are additional factors worth investigating before samples are submitted.

Summary

As with any methodologies, qPCR is a work in continuous progress, development, and improvement. Although all of the methods described in this review use the Nobel Prize–awarded PCR process, the advantages and disadvantages of subtle differences in assay format, accuracy, and reliability of quantitation have to be rigorously compared. The next generation of quantitative real-time PCR processes will be increasingly automated, standardized, and miniaturized. The time for nucleic acid preparation and PCR amplification will be further reduced by using small microtiter-formatted microfluidic cards or silicon-based chip technology.[9-11] Amplification time has been brought down to several minutes by using an advanced nucleic acid analyzer (ANAA) consisting of a battery-powered array of silicon-based PCR microchips with thin-filmed resistive heaters, thus enabling ultrafast amplification, further pushing the technologic possibilities in order to improve the diagnostic results output.[10]

How will these new systems be incorporated in routine veterinary diagnostics? Veterinary medicine will experience a broad adoption of many quantitative assays for infectious agents and genetic abnormalities in the near future. The ability to standardize assays will allow high-throughput applications that have not been possible with traditional molecular methods. For this reason, applications for veterinary medicine may experience not only quantitative but also qualitative growth. These assays will help improve patient management and client satisfaction.

Molecular Testing for Infectious Diseases in Horses

Nicola Pusterla • Christian M. Leutenegger

The ready availability of a correct etiologic diagnosis, particularly in contagious infections, enables the veterinarian to make early decisions regarding the patient's care and management, address appropriate treatment, and allow timely notification and discussion of management issues pertaining to the prevention of disease spread. The past 2 decades have seen a revolution in the understanding, management, diagnosis, control, and prevention of infectious diseases.[1,2] This period has encompassed the discovery of emerging equine agents, antimicrobials, and vaccines, as well as a wealth of improved diagnostic tests for equine practitioners. Despite these advances, infectious diseases remain a leading cause of equine morbidity and mortality, with resurgence of certain infections (e.g., West Nile virus); an increasing population of elderly, more susceptible horses; and an increasing international equine commerce, expanding the geographic distribution of pathogens.[3,4] The focus of rapid diagnosis of infectious diseases has also shifted during this time. The most obvious change has been the appearance and increasing importance of nucleic acid (NA) amplification-based techniques, primarily the polymerase chain reaction (PCR), at the expense of traditional methods of clinical microbiology.[5] PCR has become an increasingly important tool in microbial diagnosis in recent years, mainly because of its rapidity, high sensitivity, and high specificity. These superior characteristics have propelled the field of PCR-based molecular diagnostics into the arena of applied diagnostics for infectious agents. Because the number of published and offered PCR assays is steadily rising, there is a need for critical evaluation, comparison of performance, and eventually standardization of methods to enable equine practitioners to select the optimal methodology.

Sample Submission

NA techniques to detect the presence of infectious agents in biological specimens require stringent quality guidelines. These guidelines aim to ensure the stability of NAs (both genomic DNA and total RNA), which are the target for molecular-based diagnostic methods. Whole blood samples are collected aseptically into evacuated blood tubes containing ethylenediaminetetraacetic acid; body fluids (e.g., thoracic, abdominal, joint, cerebrospinal, tracheal wash, bronchoalveolar lavage, guttural pouch lavage fluid) and tissues should be collected into serum tubes without additives; nasal or nasopharyngeal secretions should be collected with rayon- or batting (Dacron, Invista, Wichita, Kan.)-tipped swabs and are best kept in a sterile serum or conical tube (virus transport medium is recommended for the detection of viruses); and fecal material should be collected into small fecal cups or serum tubes (Fig. 29.1; Table 29.1). All samples must be sent cooled on blue ice by express mail overnight to the laboratory. Freezing of samples should be avoided. Short-term storage for a period of 2 to 3 days before shipment (over a weekend) should be done in a refrigerated compartment. Each sample should be properly labeled and accompanied by a submission form containing information pertaining to the patient, owner, veterinarian, sample, and pathogen(s) to be tested (most submission forms can be downloaded from the respective laboratory website). The laboratory should be notified in advance, and inquiry should be made about the availability of the offered tests, as well as turnaround time and associated costs. Incoming samples normally are processed the same day, and PCR results usually are available within 24 to 48 hours if the NA passes quality control.

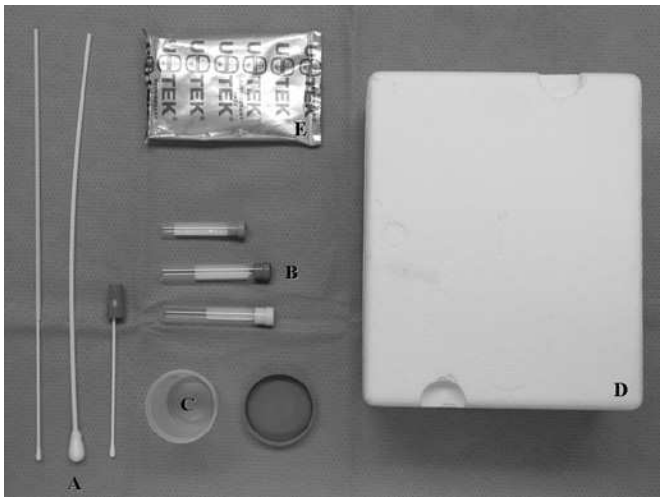

FIG. 29.1 Collection and shipping material routinely used to submit equine tissue samples for molecular detection. A, Three sterile swabs of different lengths. **B,** Three sterile, evacuated tubes with and without additives. **C,** Sterile cup with lid. **D,** Styrofoam shipping container. **E,** Cooling element to keep the samples cooled.

Clinical Applications

An array of NA amplification techniques may be offered by laboratories in order to establish an etiologic diagnosis of equine infectious diseases. Several published studies have shown the benefit of NA amplification techniques in comparison with conventional microbiological techniques. Current efforts are aimed at improvement of the diagnostic efficiency of molecular techniques, for both common and less common pathogens. To facilitate a decision on which pathogens should be evaluated for a specific case, some laboratories offer panels covering specific organ systems (e.g., respiratory, gastrointestinal, neurology, bloodborne). Such panels test several common pathogens for each organ system. Some of the diagnostic PCR applications most relevant for equine practice are presented as follows, along with their advantages and potential pitfalls.

RESPIRATORY PATHOGENS. Respiratory pathogens are often contagious, and infections must be diagnosed rapidly in order to prevent a disease outbreak and institute the appropriate management plan. The short turnaround time and reliability of PCR make this molecular technology an ideal tool for the diagnosis of respiratory pathogens.

Equine influenza is commonly diagnosed by virus isolation or detection from nasal or nasopharyngeal swabs collected from horses during the early febrile stage of the disease. Virus can be grown from nasal and nasopharyngeal swabs by inoculation and incubation of embryonated chicken eggs or passage through Madin-Darby canine kidney cells. Although isolation of the virus is essential to allow antigenic and genetic characterization of the strain, this technology is time consuming and successful isolation is, at best, to be expected in 50% of the cases. Further, since mutations have been reported to occur during the process of viral culture, recovered isolates must be viewed critically. In recent years new methods for virus detection, such as antigen-detection enzyme-linked immunosorbent assays (ELISAs) and PCR, have been described. Collectively these detection methods have shown higher sensitivity than virus isolation and antigen-capture ELISAs.[6-9] Amplification of the single-stranded RNA of equine influenza viruses is performed by reverse transcription-PCR (RT-PCR) technology, using a one-step, nested, or real-time approach. The hemagglutinin, nucleoprotein, and matrix gene are the commonly targeted genes for these molecular assays. Unfortunately, comparison of the different PCR assays is precluded by the use of different technologies, the lack of standardization among the assays, and variation in targeted genes. Nucleotide and deduced amino acid sequences of portions of the hemagglutinin gene are now routinely used for phylogenetic characterization of outbreak strains. Further, novel real-time PCR assays can be used as a viable replacement for the more traditional methods of quantifying equine influenza virus in vaccine efficacy studies. Another advantage of assays such as antigen-detection ELISAs and PCR is their ability to detect a nonviable virus, a situation that may occur when nasal or nasopharyngeal samples are frozen or not adequately stored and/or shipped to a diagnostic laboratory, allowing a rapid diagnosis in the acute phase of infection. Routine diagnostic testing for equine influenza virus does yet not allow differentiation between clade I and clade II viruses of the Florida sublineage.

EHV-1 and *EHV-4* are important and widespread equine viral pathogens that cause important economic losses in the equine industry. Both are double-stranded DNA alphaherpesviruses

TABLE 29.1

Tissue Samples Commonly Used for Molecular Detection of Common Equine Pathogens

Pathogen	Tissue Submission
Anaplasma phagocytophilum	Whole blood
Babesia caballi	Whole blood
Borrelia burgdorferi	CSF, CNS
Clostridium botulinum	Feces, gastrointestinal content, feed, wounds, and carrions
Clostridium difficile (antigen and toxin A and B)	Feces
Clostridium perfringens	Feces
Corynebacterium pseudotuberculosis	Aspirate from abscess, body fluid
Cryptosporidium spp.	Feces
Equine arteritis virus	NPS, uterine swab, placenta, aborted fetus, semen
Equine coronavirus	Feces
Equine herpesvirus 1	NPS, whole blood, TW, BAL, CSF, CNS, uterine swab, placenta, aborted fetus
Equine herpesvirus 2	NPS, whole blood, TW, BAL
Equine herpesvirus 4	NPS, TW, BAL
Equine herpesvirus 5	NPS, whole blood, TW, BAL
Equine influenza virus	NPS, TW, BAL
Equine rhinitis A virus	NPS, urine
Equine rhinitis B virus	NPS
Equine rotavirus	Feces
Lawsonia intracellularis	Feces, intestinal biopsy
Leptospira spp.	Urine, blood, uterine swab, placenta, aborted fetus
Neorickettsia risticii	Whole blood, feces
Neospora hughesi	CSF, CNS
Rhodococcus equi	TW, BAL, feces
Salmonella spp.	Feces
Sarcocystis neurona	CSF, CNS
Streptococcus equi subsp. *equi*	NPS, NPL, GPL, lymph node aspirate
Streptococcus equi subsp. *zooepidemicus*	NPS, NPL, GPL, lymph node aspirate
Theileria equi	Whole blood
West Nile virus	Whole blood, CSF, CNS

BAL, Bronchoalveolar lavage fluid; *CNS*, central nervous system tissue; *CSF*, cerebrospinal fluid; *GPL*, guttural pouch lavage; *NPL*, nasopharyngeal lavage; *NPS*, nasal/nasopharyngeal swab; *TW*, tracheal wash fluid.

VetBooks.ir

that affect the equine respiratory tract and can establish lifelong latent infection after primary exposure. Traditionally, virus isolation has been the gold standard for diagnosing EHV-1 and EHV-4 infections. The sample of choice is a nasal or nasopharyngeal swab, which should be taken early in the febrile phase of the disease. The swabs should be kept in viral transport medium and shipped on ice to a veterinary diagnostic laboratory. Because of the lymphotropism of EHV-1, virus isolation can also be attempted from citrated or heparinized whole blood. Virus isolation requires the maintenance of specific cell culture lines, making this process relatively expensive and time consuming. EHV-1 can be propagated in a broad range of cell lines; however, EHV-4 grows only in cell lines of equine origin. Virus isolation is often hampered by the fragility of the virus, intermittent viral shedding, and interference with local antibodies. PCR offers an alternative to virus isolation and has proven to be a sensitive method of detecting EHV-1 and EHV-4 in respiratory secretions, peripheral blood lymphocytes, and other tissues.[10-12] Many PCR assays have been established to study the pathophysiology and improve the diagnosis of these viruses. Conventional one-step or nested PCR assays do have inherent risks of carry-over contamination as a result of postamplification steps required to detect the PCR products. Novel molecular platforms such as real-time qPCR have strongly reduced the risk of contamination. PCR assays used in routine diagnostics are based on the detection of viral genomic DNA and are therefore unable to distinguish among lytic, nonreplicating, or latent viruses. Alternative molecular approaches have recently been established using real-time PCR to allow discrimination among the different viral states in horses naturally infected with EHVs.[13,14] Discrimination among the different viral states is now possible by 1) targeting several genes (e.g., glycoprotein, latency-associated transcripts), 2) detecting viral genomic DNA and transcriptional activity of the target genes at the messenger RNA (mRNA) level, and 3) using absolute quantification. Viral threshold loads are used in selected human infectious diseases (i.e., HIV, HCV) to determine disease stage and response to antiviral therapy. A similar concept is used diagnostically for EHV-1– or EHV-4–infected horses in order to discriminate between lytic and nonreplicating virus, to determine their infectious risk based on viral load in respiratory secretions, and to monitor their response to treatment.[13,14]

Streptococcus equi subsp. *equi* infection is rarely associated with detection difficulties when using conventional cultures in clinically affected horses. Culture, however, may be unsuccessful during the incubation, and early clinical phases of infection and the presence of other β-hemolytic streptococci, especially *S. equi* subsp. *zooepidemicus*, may complicate interpretation of cultures. Available PCR assays are designed to detect the DNA sequence of various virulence genes of *S. equi*. PCR assays can be completed in a few hours, and results may be available on the same day that samples have been submitted to the laboratory. One of the pitfalls of PCR has been its inability to distinguish between live and nonviable organisms; therefore positive results have in the past been considered presumptive until confirmed by culture. Nowadays, the viability issue can be addressed by quantitation of *S. equi* virulence genes or the detection of transcriptional activity for virulence genes at the RNA level.[15] In several studies, PCR proved to be up to three times more sensitive than culture.[16-17] PCR accompanying culture on a nasal swab or guttural pouch lavage may be used in a control program to select possible carrier animals, because PCR is capable of detecting *S. equi* DNA in guttural pouch lavages for weeks after disappearance of live organisms. Such is not the case for the nasopharynx, in which the efficient mucociliary apparatus removes organisms and DNA at the same time. PCR should be considered in order to detect asymptomatic carriers, establish the *S. equi* infection status of asymptomatic horses, and determine the success of elimination of *S. equi* from the guttural pouch. A particular problem in the management of strangles outbreaks is the lack of a suitable assay to differentiate between wild-type and vaccine *S. equi* strains. However, recent studies have shown gene variations in the N-terminal region of the SeM gene of various field isolates, allowing epidemiologic analysis of disease transmission.[18] Further, a deletion in the *aroA* gene of a live-attenuated strangles vaccine marketed in Europe (Equilis StrepE, Merck Animal Health, Walton Manor, Walton, Milton Keynes, UK) has allowed the development of a PCR assay able to differentiate between wild-type and vaccine strains.[18] Such assay has, however, not yet been developed to differentiate between the intranasally applied attenuated live vaccine marketed in North America (Pinnacle I.N., Zoetis, Overland Park, Kan.) and field isolates. However, when needed for forensic reasons, differentiation can be done via the morphology of colonies, biochemical analysis, genotyping, and restriction digest.[19] Together, these assays allow differentiating between wild-type and vaccine/ancestor strains.

Streptococcus equi subsp. *zooepidemicus (S. zooepidemicus)* is a commensal, opportunistic equine pathogen that is generally present in the upper respiratory tract and responsible for secondary bacterial bronchopneumonia in young and adult horses. The literature reports on a few outbreaks of upper respiratory disease associated with *S. zooepidemicus*.[20,21] The clinical signs are indistinguishable from *S. equi* infection and include lethargy, anorexia, elevated rectal temperature, serous to purulent nasal discharge, coughing, and lymphadenopathy with abscessation. Single clones of *S. zooepidemicus*, as determined by sequencing of the szP gene and multilocus sequence typing, have been associated with increased pathogenicity.[20] From a diagnostic standpoint, one should not test for *S. zooepidemicus* in nasal secretions from horses with upper airway disease due to the ubiquitous nature of this bacterial organism. However, *S. zooepidemicus* should be considered as the etiologic agent in respiratory cases when detected by culture or qPCR from a draining lymph node or guttural pouch empyema and other respiratory pathogens have been ruled out.

Rhodococcus equi is an important cause of chronic suppurative bronchopneumonia with extensive abscessation in foals 3 weeks to 6 months of age. Culture of the organism from tracheal wash (TW) fluid currently is considered the gold standard for diagnosis.[22] However, it can be difficult to reliably grow *R. equi* from a single TW sample, possibly because of prior antimicrobial administration or overgrowth by multiple pathogenic bacterial species.[23,24] Hillidge[25] reported that only 62% of foals with positive *R. equi* cultures at necropsy and 64% of those with radiographic evidence of lung abscessation yielded *R. equi* on culture of TW fluid. PCR has been evaluated in order to increase the diagnostic sensitivity of TW fluid samples. Strains of *R. equi* isolated from sick foals uniformly contain an 85- to 90-kb plasmid that carries the gene responsible for expression of a 15- to 17-kDa antigen (vapA) of undetermined function.[26,27] Environmental strains of *R. equi* not associated with disease do not contain this plasmid. Therefore detection of the vapA gene of *R. equi* in a TW fluid sample from a foal with pneumonia can be considered diagnostic. Both culture and PCR, however, may detect environmental contaminants of *R. equi* in TW fluid, but PCR has the ability to distinguish between virulent and avirulent strains. Foals, however, may have virulent or avirulent strains of *R. equi* present as contaminants in their airways that are not responsible for clinical signs of pneumonia. This situation may be more likely on farms in which *R. equi* problems are endemic. In a study evaluating the sensitivity of conventional culture, PCR, and serology from 53 foals with pneumonia, PCR of TW fluid was found more sensitive and specific for the diagnosis of *R. equi* pneumonia than the other two available diagnostic tests.[28] PCR should be used in conjunction with standard culture

VetBooks.ir

because of the probability of the presence of multiple bacterial pathogens and the inability of PCR to determine antimicrobial sensitivity of *R. equi*. PCR with its higher sensitivity and specificity may be useful to rule out *R. equi* pneumonia in culture-negative foals that have failed to improve with standard antimicrobial therapy and have clinical signs consistent with *R. equi* pneumonia. It may also be useful in monitoring response to therapy and deciding when to discontinue therapy in foals that are confirmed to have *R. equi* pneumonia. In clinical situations in which the severity of the respiratory signs of the patient prevents the collection of TW fluid, feces have been shown to be a sensitive surrogate specimen for the molecular detection of *R. equi*.[29,30] However, serial *R. equi* qPCR testing on feces should not be used as a screening test for clinical *R. equi* foal pneumonia.[31]

Equine rhinitis A and B virus and equine arteritis virus, although less commonly associated with infectious upper respiratory disease, should also be considered as target pathogens during respiratory outbreaks.[32-34]

EHV-2 and EHV-5 are widespread in horse populations; therefore the detection of any of these viruses can occur in healthy but also sick animals. These two viruses are optimally adapted to their host, which means that significant clinical expression of infection is rarely encountered. Recent work has shown that different genetic variants of these viruses circulate among healthy horses, hypothesizing that viral reinfections or reactivations may be the origin of clinical disease and also explaining the sporadic occurrence of such cases.[35] Another characteristic of the gammaherpesviruses is their ability to immunomodulate the immune system, potentially increasing the susceptibility of horses to various infectious pathogens.[36] A recently described atypical interstitial pneumonia named equine multinodular pulmonary fibrosis (EMPF) has been linked to the presence of EHV-5 in affected pulmonary tissue.[37] The diagnosis of this disorder is based on clinical signs, radiographic abnormalities of the lungs, lower airway fluid cytology, histopathology of pulmonary tissue, and EHV-5 detection by qPCR in bronchoalveolar fluid and/or pulmonary tissue.[37,38] Due to their high prevalence in the horse population, and in order to avoid dilemmas with the interpretation of PCR results, testing of EHV-2 and EHV-5 in horses with upper respiratory tract disease is not recommended at this time.

NEUROLOGIC PATHOGENS. Although highly sensitive and specific PCR assays have been developed for detection of viral and protozoal genomes in the cerebrospinal fluid (CSF) of neurologic patients, these methods are often of limited value in the routine diagnosis of these diseases because viremia is often short-lived or the pathogen has no affinity to the cells of the CSF. Consequently, pathogens are usually no longer detectable at the onset of systemic or central nervous system signs.

Equine protozoal myeloencephalitis (EPM), caused by the protozoal Apicomplexa parasites *Sarcocystis neurona* and *Neospora hughesi*, represents one of the greatest diagnostic challenges for equine practitioners. Detection of the parasite at necropsy is considered the gold standard. Therefore clinical diagnosis is based on clinical findings, exclusion of other neurologic diseases, and the use of serologic assays (e.g., Western immunoblot, indirect immunofluorescent assay, ELISA) on serum and CSF.[39-41] Molecular diagnostics have also been investigated, but their sensitivity was found to be low.[42]

Apparently, intact merozoites rarely enter CSF, and free parasite DNA is destroyed rapidly by enzymatic action.[43] On the basis of low sensitivity, PCR testing of CSF should not be recommended for routine diagnosis of EPM. In contrast, PCR testing of neural tissue has been shown to be useful as a postmortem test.[44] Sequence analysis is routinely used to identify *S. neurona* and *N. hughesi* isolates and to determine the heterogeneity and evolutionary relatedness within these and related species.[45,46] Detection and isolation of *S. neurona* from peripheral blood have been reported only in experimental studies.[47,48] Therefore molecular detection of *S. neurona* in blood is insensitive and should not be used in order to document or rule out EPM in a neurologic horse.

Diagnosis of WNV encephalitis in horses currently is based on observation of compatible clinical signs (e.g., ataxia, paresis, paralysis, hyperesthesia, muscle fasciculation, seizures, fever) and one or more of the following: isolation of WNV from blood, CSF, or tissue; a fourfold increase in plaque reduction neutralization test antibody titers on paired serum samples taken 2 weeks apart; or the detection of IgM antibody to WNV by IgM-capture ELISA.[49,50] Given the nonspecificity of the IgM ELISA (i.e., does not differentiate between disease and exposure) and the time required to serologically confirm WNV infection, alternative tests able to rapidly detect WNV in clinical specimens are important. RT-PCR using a one-step, nested, or real-time approach has been evaluated to investigate antemortem cases of suspected WNV encephalitis in horses and humans using blood. The diagnostic sensitivity of WNV RT-PCR using either serum or whole blood was low.[51-53] However, 57% to 70% of CSF samples from human beings with serologically confirmed WNV infection tested positive by real-time RT-PCR.[51,52] The reduced ability to detect WNV in CSF or serum from patients with serologically confirmed WNV infection is likely due to the short-lived viremia in dead-end hosts, and it emphasizes the fact that, in order to detect WNV in blood or CSF, the sample should be collected early during the disease process. Investigation of the sensitivity of RT-PCR on CSF from horses with WNV encephalitis has not yet been reported. RT-PCR has also been shown to accurately identify WNV in field-collected mosquito pools, avian tissues, and human and equine brain tissue samples with a degree of sensitivity approaching that of virus isolation in Vero cells.[52-54]

Myeloencephalopathy is an uncommon presentation of EHV-1 infection and should always be considered as a differential diagnosis when a horse develops sudden neurologic signs (e.g., ataxia, paresis, urinary incontinence), especially if multiple horses on the premises are involved or when a recent history of fever, abortion, or viral respiratory disease in the affected horse or herdmates is reported.[55] Diagnosis is often based on history, clinical signs, and xanthochromia and elevated total protein concentration in CSF resulting from vasculopathy. Attempts to isolate virus from the blood or CSF of patients are often unsuccessful because the peak of viral shedding has usually passed by the time neurologic signs appear.[56] However, affected horses can shed the virus in nasal secretions and thus represent a risk of infection for unaffected in-contact horses. This outcome has been reported in a hospital setting in which horses developed neurologic disease after having been exposed to horses with EHV-1 myeloencephalopathy.[57] Therefore it is imperative to determine the risk of shedding in a suspected horse in order to initiate appropriate infectious disease control protocols. PCR, as previously shown for viral respiratory diseases, is a fast and sensitive molecular diagnostic tool and should be performed on blood and nasal or nasopharyngeal swabs to document viremia and nasal shedding, respectively.[58,59] The dilemma as to whether the virus is in a lytic, nonreplicating, or latent state can be addressed by using absolute quantitation or transcriptional activity of the target gene similar to the approach used for EHV-4.[13] A recently identified single nucleotide polymorphism (SNP) at position 2254 in the DNA polymerase gene *(ORF 30)* correlates with neurologic disease.[60] This SNP is responsible for a single amino acid residue at position 752 of the DNA polymerase with EHV-1 strains associated with neurologic outbreaks involving a D_{752} genotype (also referred to as G_{2254}), whereas most nonneurologic outbreaks

VetBooks.ir

involve a N_{752} genotype (also referred to as A_{2254}). Rapid qPCR assays have been established to allow differentiation between neuropathogenic and nonneuropathogenic strains.[61-63] However, the genotyping of field isolates needs to be interpreted carefully as 14% to 24% of EHV-1 isolates from horses with EHM do not have this neuropathogenic marker.[64] Strain characterization may be important given that the potential of EHM development is greater in horses infected with a neuropathogenic genotype (D_{752}). Furthermore, detection of a neurotropic EHV-1 strain may influence therapy, especially in the use of antiviral drugs such as valacyclovir, used to decrease viremia and prevent the development of neurologic sequelae.

Borrelia burgdorferi, the causative agent of Lyme disease, is a helical-shaped, gram-negative, unicellular spirochete transmitted by infected *Ixodes* ticks. In general, the diagnosis of Lyme disease in horses is made on the basis of the geographic origin of the horse, ruling out other causes of clinical signs and a high antibody titer to *B. burgdorferi*.[65] qPCR for *B. burgdorferi* in CSF has been shown to be specific, but the results are often negative due to the rare occurrence of the spirochetes in the CSF.[66] However, PCR can be used to help document the presence of *B. burgdorferi* at postmortem on neurologic tissue or infected ticks.[67]

GASTROINTESTINAL PATHOGENS. The detection of equine gastrointestinal pathogens using conventional or molecular tests is often challenging because these pathogens are difficult to grow in cell culture systems or can be present in pathogenic or nonpathogenic forms, making interpretation of positive results difficult. Furthermore, the use of fecal material for molecular diagnostics has been associated with false-negative results because of the presence of inhibitory substances in the feces that can interfere with NA extraction or amplification.[68] However, development and use of specific extraction kits (DNA Stool Mini Kit, QIAGEN, Valencia, CA) have improved the yield of NA from feces.[69]

Neorickettsia risticii is the rickettsial agent responsible for equine neorickettsiosis (EN) (formerly Potomac horse fever), a serious enterocolitis of horses. Because of the nonspecific nature of the clinical signs, a provisional diagnosis of EN is often based on the presence of typical clinical signs and the seasonal and geographic occurrence of the disease. A definitive diagnosis of EN, however, should be based on isolation or detection of *N. risticii* from blood or feces of infected horses.[70] Isolation of the agent in cell culture, although possible, is time consuming and not routinely available in many diagnostic laboratories. The recent development of *N. risticii*–specific PCR assays has greatly facilitated the diagnosis of PHF.[71-72] These molecular assays have contributed to the investigation of the epidemiology of PHF, allowing the discovery of helminthic vectors and intermediate and definitive helminthic hosts, as well as determining the natural route of infection.[73-75] Nucleic acid of *N. risticii* can be detected in the blood and feces of naturally or experimentally infected horses, but the detection period does not necessarily coincide between the two sample types (Fig. 29.2). On the basis of these results, we recommend analyzing both blood and feces from suspected horses in order to enhance the chance of molecular detection of *N. risticii*.

Lawsonia intracellularis, an obligate intracellular bacterium, is the causative agent of proliferative enteropathy in a variety of domestic and wild animal species.[76] In horses, Equine proliferative enteropathy (EPE) often affects young horses. Antemortem diagnosis can be challenging and is based on interpreting clinical signs (e.g., lethargy, anorexia, fever, weight loss, subcutaneous edema, diarrhea, colic), clinicopathologic results (e.g., hypoproteinemia resulting from hypoalbuminemia), and ultrasonographic findings (e.g., thickened small intestinal walls) and excluding other causes of similar gastrointestinal findings.[77] Currently, culture of the organism is difficult and is not routinely offered by laboratories. Antemortem diagnosis relies on serology and PCR.[78] The combination of both tests and repeated fecal sampling for PCR from target animals will increase the chance of diagnosing the disease. PCR has the advantage of being fast and can yield positive results in the early stage of disease, when antibodies are not yet measurable. Prior use of antimicrobials can negatively affect the molecular detection of *L. intracellularis* in feces. Therefore in a suspected case, fecal collection for PCR testing should be performed before the institution of any antimicrobial treatment.

In recent years, PCR assays for the detection of *Salmonella* spp. in fecal samples from horses admitted to veterinary hospitals have been evaluated.[79-82] Collectively, these studies have shown an unquestioned higher analytic sensitivity for the detection of *Salmonella* spp. PCR assays when compared with conventional microbiological culture. The higher detection rate of *Salmonella* by PCR has been attributed to the detection of nonviable organisms and of previously undescribed *Salmonella*-like bacterial organisms. The use of novel virulence target genes for the molecular detection of *Salmonella* spp. has considerably improved the performance and accuracy of such assays. More and more veterinary hospitals across North America are switching from conventional microbiological culture to qPCR for the testing of *Salmonella* as part of their infectious disease control program. In such instances, qPCR is performed on fecal and environmental samples following a 24-hour selective enrichment step. The use of qPCR is cost effective and has the potential to reduce contamination risks and turnaround time, with results being available within 22 to 28 hours from sample collection (18 to 24 hours enrichment time, 4 hours for DNA purification and amplification). Further, the use of absolute quantitation allows assessment of the infectious nature of hospitalized animals and may be an excellent alternative to conventional culture methods for surveillance and research studies.[83] Although qPCR for *Salmonella* spp. is an accurate and fast screening test, one must still consider microbiological culture to confirm positive molecular results and to determine the serovar and antibiogram of the isolated *Salmonella* spp.

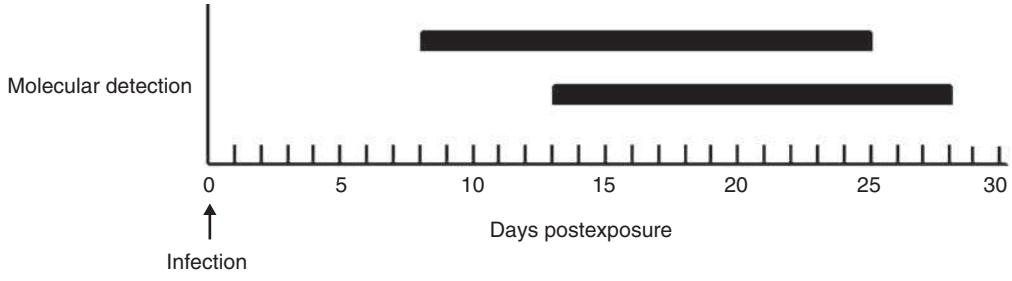

FIG. 29.2 Molecular detection period of *Neorickettsia risticii* in blood and feces of experimentally infected horses. *(From Pusterla N, Madigan JE, Leutenegger CM: Real-time polymerase chain reaction: a novel molecular diagnostic tool for equine infectious diseases. J Vet Intern Med 20:3, 2006. Reprinted with permission of the American College of Veterinary Internal Medicine.)*

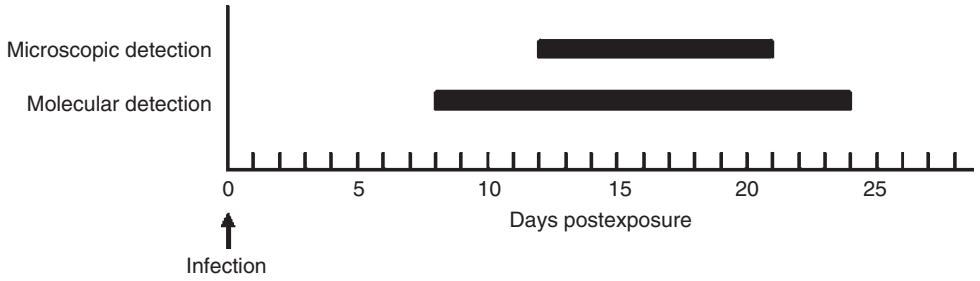

FIG. 29.3 Microscopic and molecular detection period of *Anaplasma phagocytophilum* in the blood of horses experimentally infected with *Ixodes scapularis*. *(From Pusterla N, Madigan JE, Leutenegger CM: Real-time polymerase chain reaction: a novel molecular diagnostic tool for equine infectious diseases. J Vet Intern Med 20:3, 2006. Reprinted with permission of the American College of Veterinary Internal Medicine.)*

The detection of equine coronavirus (ECoV) by qPCR in the feces of foals with fever and diarrhea is difficult to interpret because ECoV has also been detected in the feces of healthy foals.[84] Healthy foals have been found to be infected mostly by ECoV in a single infection without any other co-infecting agents, whereas ECoV was found exclusively in association with other co-infecting agents in sick foals. This is in agreement with coronaviruses in other species, where the virus may not have enough pathogenic potential to cause disease but causes local immune suppression, allowing secondary infections to take place more efficiently. In adult horses, ECoV causes a self-limiting disease characterized by lethargy, anorexia, fever, and less frequently changes in fecal character and colic.[85,86] The diagnosis of ECoV infection in adult horses should be supported by the qPCR detection of ECoV in the feces.

Equine rotavirus poses a challenge each foaling season to farm managers and veterinarians in intensive horse-breeding areas throughout the world. A quick and reliable diagnosis is essential in order to separate affected foal with diarrhea and reduce the spread of this virus. The diagnosis of rotavirus infection has in the past relied on direct virus detection using a rapid antigen-capture ELISA. Commercially available qPCR assays have shown high analytical sensitivity, specificity, and accuracy in the diagnosis of equine rotavirus infection and will likely replace the less sensitive ELISA test in the near future.[87]

Clostridium difficile is a fastidious anaerobe considered an important cause of colitis, although it can also be found in the intestinal tract of healthy horses.[88] Although the dynamics of colonization are unknown, it is likely that horses can carry *C. difficile* for long periods without ever developing disease. Carrier status is generally higher in foals and adult horses treated with antimicrobials. The diagnosis of *C. difficile* infection is generally based on the detection of toxin A or B or both in feces, gastric reflux, or colonic content, ideally using a test that has been validated in horses.[88] A variety of immunoassays are available, but only one assay has been validated in horses (*Clostridium difficile* TOX A/B II ELISA, Techlab, Blacksburg, Va.).[89] This test, which detects toxin A and B, has a reported sensitivity of 84% and specificity of 96% compared with the gold standard (cell cytotoxicity assay). qPCR targeting the toxin A and B genes of *C. difficile* has been shown to be highly sensitive with the advantage of a short turnaround time.[90] However, the clinical specificity will depend on the overall background prevalence of *C. difficile* colonization in the population of horses tested. qPCR is considered an acceptable screening tool to rule in or rule out *C. difficile* infection, allowing proper management and isolation of qPCR-positive patients.

Clostridium perfringens type A and C are important causes of enteric disease in young foals. Disease induced by *C. perfringens*, especially type C, is associated with hemorrhagic diarrhea, abdominal distention, and circulatory shock.[91] The diagnosis of *C. perfringens* infection is challenging because the microbe can be cultured from the feces of healthy foals. Therefore identification of toxins and ruling out other etiologies of diarrhea are key.[91] For toxin assays, fresh feces should be submitted to a laboratory with immunoassays for *C. perfringens* toxins including alpha, beta, and epsilon toxins. Fecal assays for *C. perfringens* enterotoxin (CPE) are readily available but lack sensitivity because only minorities of equine isolates produce CPE.[92] The alternative diagnostic avenue is to submit isolates cultured from feces for qPCR analysis. The novel pore-forming necrotizing toxin (netF) of *C. perfringens* type A is an important advance in understanding the virulence of this pathogen and potentially improves the diagnostic field.[93]

MISCELLANEOUS PATHOGENS. Equine granulocytic anaplasmosis (EGA) is caused by *Anaplasma phagocytophilum*, a rickettsial pathogen transmitted by *Ixodes* spp. ticks. Diagnosis is often based on awareness of the geographic area for infection, typical clinical signs, abnormal laboratory findings, and identification of characteristic pathogen inclusions in the cytoplasm of neutrophils and eosinophils in a peripheral blood smear.[94] qPCR has been used for many years to study several aspects of the epidemiology and pathophysiology of EGA.[95] For clinical purposes, the material of choice is whole blood. PCR has been shown to be a sensitive and specific tool, supporting the diagnosis especially during the early and late stages of the disease, at times when the number of organisms is too small to be detected via microscopy (Fig. 29.3).

Corynebacterium pseudotuberculosis is a common cause of external and internal abscesses in horses from arid regions of North America.[96] The epidemiology has been investigated with the help of qPCR, and flies have been identified as potential vectors.[97] *C. pseudotuberculosis* is easy to grow on culture, and use of qPCR on clinical samples is restricted to specific situations (e.g., culture-negative aspirates or body fluids).

Additional PCR assays for *Leptospira* spp., *Clostridium botulinum* neurotoxins, *Mycobacterium* spp., *Mycoplasma* spp., *Babesia caballi*, *Theileria equi*, *Cryptosporidium* spp., and methicillin-resistant *Staphylococcus aureus* have been developed and are being used in the research setting.[98-102] These assays will likely be offered in the near future for diagnostic purposes when additional epidemiologic information has been evaluated and accuracy of the tests has been validated using clinical samples from infected horses.

Molecular Testing for Infectious Diseases in Cattle, Sheep, and Goats

Beate M. Crossley • Sharon K. Hietala

The availability of molecular-based diagnostic technologies designed to identify infection or genetic conditions by detecting

VetBooks.ir

specific genome targets in the host or agent DNA or RNA has expanded logarithmically in the past decades. Diseases and genetic conditions affecting cattle, sheep, and goats are commonly studied and diagnosed using a variety of molecular techniques and, in particular, PCR assays and increasingly using genome sequence analysis.

Whole genome sequencing, the ability to rapidly generate the genetic sequence of an entire pathogen, is increasingly available as a diagnostic tool and provides a high level of both diagnostic sensitivity and specificity, although at the expense of rapid turn-around and high technical costs that are most often passed on to the user. PCR-based technologies and assays that target a single gene or part of a gene remain the most common of the molecular-based diagnostic assays currently available for routine diagnostic services. These services are provided by state and federal diagnostic laboratories, university laboratories, and commercial laboratories; due to the technical complexity of molecular-based diagnostics, paired with the wide range of assays available to diagnose genetic and infectious diseases of food animals; however, no single laboratory can feasibly provide comprehensive testing for all species and all diseases. Instead, laboratories tend to focus on the diseases or genetic conditions of primary significance to their allied industries and use the technologies that provide the most rapid, reproducible, and economic results for their particular group of clients. Largely based on this specialization within laboratories, molecular-based assays may be developed and put into use without significant effort toward assay standardization and validation. The list of PCR-based assays available for detection of infectious agents, in particular, has grown significantly in the past decades and continues to expand, although with no guarantee that the assays have been suitably designed, tested in the field, or clearly advertised as to their "fitness for purpose." For PCR-based assays, the selection of the genetic sequence (DNA or RNA) used as the target of the diagnostic assay is heavily dependent on the proposed use of the test and on the availability of known genomic sequence(s) for development of the assay. All genomes accumulate mutations over time, with some genes being highly mutable to allow evolutionary advantage, such as those genes that encode antimicrobic resistance or protein conformations for evading the host immune system. Other genes such as those encoding specific functions (e.g., replication) tend to remain highly conserved and stable to protect the survival of the organism. Assays used to detect a specific agent, such as bovine viral diarrhea (BVD) virus, can be designed to target a conserved region of the genome that is shared by all members of the species. Alternatively, assays used to characterize or subtype particular strains or isolates, such as BVD virus type 1b, can be designed to target regions with significantly more mutability or sequence variation. Assays designed as "fit" for surveillance testing must often sacrifice the ability to discriminate closely related pathogens, for instance, separating BVD viruses from the genetically related Border disease viruses in order to have the needed surveillance sensitivity to detect the broad range of potential BVD virus isolates. Similarly, assays designed for test and cull, or related disease control programs, must have a high diagnostic specificity for detecting only the agent or trait of interest. These assays tend to sacrifice diagnostic sensitivity or detection level in order to minimize the risk of false-positive results. Although molecular diagnostics provide a powerful and rapidly advancing tool, the clinician is advised to use molecular-based assays with appropriate awareness of their individual strengths and weaknesses, including the designated use or "fitness for purpose." Unquestionably, molecular technologies will continue to be developed and implemented in veterinary medicine. Although it can be expected that newer technologies will replace existing procedures, it should be expected that many of the molecular tools will be no more than a supplement to traditional diagnostic approaches.

Sample Submission

As with any diagnostic technology, the specimen used must be appropriate for the disease or genetic condition and take into consideration the timing and pathogenesis of the disease process and availability of the intact genetic material being targeted by the diagnostic assay. Among the important criteria in the selection and use of molecular-based assays are onset and duration of agent replication in the host, specific tissue(s) affected, and the relative abundance of target DNA or RNA over the course of the infection. In addition to tissues obtained from postmortem investigation or surgical sampling, antemortem diagnostic testing can target genetic material recovered from swabs of mucous membranes; blood, urine, milk, or skin scrapings; or fecal material as appropriate to the disease process.

Because all molecular-based diagnostics detect genomic material in one form or another, the isolation and purification of nucleic acids (DNA or RNA) from the diagnostic specimen are critical to the success of the assays. Dependent on the tissue or specimen used for diagnostic testing, recovery of sufficient quantities and quality of nucleic acid can be problematic. Common sources of assay failure include substances in the sample that can interfere with the chemistries used in detection or PCR-based amplification steps. Examples include, but are not limited to, heparin, iron, peroxidases, hemoglobin, and myoglobin, as well as the relative abundance of total DNA or RNA associated with the different specimen types. This type of assay error is controlled in an increasing number of PCR assays by the inclusion of internal controls before initiating the assay in order to monitor for specimen-based interference or related-assay failure. Another common source of assay failure is destruction of target nucleic acids in the specimen before testing, commonly as a result of enzymes associated with postmortem autolysis or those chemistries used in preserving the sample, such as formalin fixation.[1] Because of the complexities of nucleic acid recovery and target nucleic acid detection, assays developed for use with one matrix, such as whole blood, may not be suitable for use with other matrices, such as milk or feces. Appropriate sample collection buffers, storage temperatures, and shipping requirements are available from the laboratories performing the specific testing.

Molecular-Based Diagnostic Technologies

Nucleic acid fragments, either DNA or RNA, can be detected by binding to a complementary fragment of nucleic acid that has been marked with a reporter dye or enzyme. The short strands of DNA or RNA, generally chemically synthesized and referred to as *oligonucleotides*, are identified as *hybridization probes* when marked with a reporter dye or enzyme. Radioactively labeled probes, although once the standard, have almost uniformly been replaced by enzymatic tags, such as avidin-biotin, peroxidase, or chemiluminescent tags. Target nucleic acids can be detected directly in the diagnostic specimen when sufficiently abundant, or they may be detected following PCR-based amplification of the nucleic acid target.

SOUTHERN BLOTS, NORTHERN BLOTS, AND DOT-BLOTS.

Various techniques are used to immobilize genetic material before detection steps, with or without prior PCR amplification. As a group, the techniques are referred to as "blots." Dot-blots and Southern blots refer to DNA bound to nitrocellulose membranes, whereas Northern blotting is the terminology used when RNA is immobilized onto membranes. In Southern and Northern blots, nucleic acid fragments are first separated by size using an electric current running through a semisolid gel, a technique referred to as *gel electrophoresis*. The nucleic acid detection step for DNA and RNA blots may include a specific hybridization probe or may simply use the molecular weight of the DNA or RNA fragment. Related terminology

VetBooks.ir

includes Western blot, which describes protein immobilized on a membrane, and immunoblot, referring to detection of the immobilized protein using specific antibody as an immunologic marker. Variations of this approach, using proteins or capture antibodies immobilized on specialized paper strips, form the basis for lateral flow ("dip-stick") pen-side tests including those developed for the rapid field detection of foot-and-mouth disease virus.

The laboratory technique referred to as in situ hybridization allows for localization and observation of a DNA or RNA target within a histologic tissue section.[2-5] The hybridization probes are typically end-labeled with a reporter molecule. Examples of hybridization assays used in veterinary diagnostics include FISH to identify genetic abnormalities and RNA probes (riboprobes) used as assay controls or for selected infectious disease detection in tissue samples. In situ hybridization technology can be applied to frozen or formalin-fixed tissues, with best results provided when the tissue is fixed as soon as possible postmortem to avoid loss of target nucleic acids during tissue autolysis. Nucleic acids from veterinary pathogens have been shown to be stable in formalin-fixed, paraffin-embedded tissues for up to 15 years.[2,6] Because of technical complexity, in situ hybridization is not widely applied to routine diagnostics but appears to be advancing in that direction.

POLYMERASE CHAIN REACTION. PCR is the most commonly applied of the molecular technologies and can be grouped roughly into standard PCR and the more rapid real-time and quantitative PCR. Both techniques amplify minute quantities of target DNA to levels that are detectable using laboratory instrumentation or special staining procedures. The principal difference in the two approaches is that standard PCR is divided into two major processes in the laboratory: 1) amplification of the DNA target, followed by 2) detection of the amplified target DNA. Real-time PCR combines the two steps so that target detection occurs during the DNA amplification process. The advantages of PCR over standard isolation and identification techniques is the significantly reduced time required to obtain a result, with PCR results generally provided in hours instead of days. Real-time PCR results can be reported as dichotomous results (positive, negative) or on a continuous numeric scale, generally as a cycle threshold (Ct) with the lower numeric values correlating with higher concentrations of the target pathogen or genetic marker. Diagnostic caution is generally needed in interpreting "weak-positive" real-time PCR results caused by technical limitations and the nature of how real-time PCR results are captured in the laboratory. Advantages for standard PCR assays are the generally longer products (amplicons) that are more reliable for genetic sequence analysis and confirmation as compared with shorter real-time PCR amplicons. PCR-based technologies are a particularly powerful tool when designed to detect the presence of organisms that are extremely slow growing or difficult to culture, such as the *Mycobacterium avium* subsp. *paratuberculosis* (Johne's disease) bacterium, *Leptospira* spp., and bluetongue virus, among others. Because PCR-based assays detect nucleic acids, they do not require that the organism is viable in the sample. This is considered an advantage for those agents that may be easily destroyed during sample transport to the laboratory but a disadvantage where fragments of a pathogen's genome may persist for weeks or months after the animal has become noninfectious. An excellent example of this is the bluetongue virus, in which PCR can detect nonreplicating viral genome adherent to red blood cells for several weeks after live virus can be recovered from the blood. With the proliferation of PCR assays being developed in research laboratories, state diagnostic laboratories, and commercial laboratories, it is often difficult for the practitioner to know which genetic marker or gene fragment was used in the design of a particular assay. This is of particular diagnostic importance because different gene segments in an individual pathogen's genome may favor screening assays (high detection sensitivity, greater risk of cross-reactivity with lower diagnostic specificity) versus confirmatory assays (high specificity for the target but lower detection sensitivity). The number of different assays, often identified by just the name of the agent, creates confusion and frustration for those faced with selecting the appropriate assay to use. It is important when selecting and interpreting results of PCR assays to remember that not all assays targeting a specific pathogen will have the same genomic target or are even designed to have equivalent sensitivity in detecting an infection, making direct comparison of results between laboratories difficult. Quality diagnostic laboratories will be able and willing to discuss the assays performed in their laboratory including the designated diagnostic purpose of the specific assay, as well as the benefits and pitfalls identified during the assay validation process.[7,8]

Standard PCR. Standard PCR is used for detection of DNA or RNA and can be applied to mammalian, microbial, or viral genomes. The PCR technique is based on the natural cross-linking of complementary (matching) nucleic acids to form double-stranded DNA. When DNA is sufficiently heated, double-stranded DNA separates into single strands, each of which can then be used as a template for chemically (or biologically) generating an exact copy. Specific heat-stabile polymerase enzymes are used in the laboratory for the process of DNA replication. The PCR reaction amplifies DNA using multiple cycles of heating double-stranded DNA to generate a single-strand template and cooling sufficiently to allow the polymerase enzyme to generate a new double-stranded DNA made up of the original strand and its test-tube synthesized copy. For diagnostic assay purposes, it is necessary to copy only a small but diagnostically characteristic fragment of any particular genome. This fragment is generally referred to as the PCR target or target sequence. PCR primers are short chemically synthesized fragments typically 10 to 30 nucleic acids in length that are used to mark the beginning and end of the selected target sequence and, as their name implies, are used to prime or start the initial PCR amplification process. The choice of target sequence and appropriate primer design are critical to the accuracy and efficiency of PCR-based diagnostic assays. For detecting target RNA, as is needed for the PCR diagnosis of an RNA virus, the technique of reverse transcriptase PCR (RT-PCR) is used. The reverse transcriptase enzyme converts target RNA into DNA, identified as cDNA or copy DNA for use in the PCR steps. The PCR amplification process typically takes 2 to 6 hours to complete and is followed by detection steps that require additional hours to days to complete. Detection of the amplified DNA fragment, often referred to as an *amplicon*, uses techniques that identify the DNA fragment by molecular weight, by marking a specific target sequence in the amplified DNA with hybridization probes, or by a combination of both (PCR/probe). PCR amplification followed by hybridization probe detection offers increased specificity, thus less chance of a false-positive finding, and often provides a 10-fold or greater increase in detection sensitivity. Dependent on the stringency designed into the assay by balancing such measures as temperature, length of replication cycles, and enzyme concentrations, false-negative results will occur when the sequence of the primers or probe does not precisely match the sequence of the target. In some cases, PCR assays are very precise and designed to recognize a single nucleic acid polymorphism (SNP analysis) in the target sequence, and in other cases they are intentionally designed with lower stringency to allow some degree of variability among isolates or strains being detected by the assay. Because RNA viruses in general lack the proofreading enzymes found in DNA viruses, bacteria, and protozoa, they are at greater risk for appearance of random

VetBooks.ir

mutations at primer or probe sites. PCR false-negative results associated with primer or probe mismatches resulting from random genomic mutations at the primer or probe binding sites are of particular concern for RNA viruses, and they provide ample justification for a laboratory to investigate with alternative or additional technologies when negative PCR-assay results clearly do not match a clinical or epidemiologic pattern of disease.

Nested PCR. Nested PCR is a PCR technique modification generally used to increase the detection sensitivity of an assay.[9] During nested PCR, an initial PCR reaction amplifies a selected fragment of DNA, which is then used as a template in a second round of PCR. The second or nested PCR reaction targets one or more unique fragments of DNA within the initially amplified region. The two-step process has the advantages of increasing detection sensitivity and detection specificity and of diluting the impact of interference from potential PCR inhibitors found in some tissues and clinical materials. Nested PCR assays have been described for WNV, malignant catarrhal fever virus, and *Chlamydia* spp., among others. The significant disadvantage of the two-step process comes from handling the first round of amplified DNA in the laboratory. With the high concentrations of target DNA available following PCR amplification, laboratories must take rigorous precautions to mediate the risk of contaminating laboratory workspaces, equipment, and reagents with the amplified DNA. The significant risk and associated costs of laboratory contamination and resulting false-positive results are used in many diagnostic laboratories as justification for charging additional fees or not offering nested PCR techniques.

Real-time PCR. Diagnostic assays originally developed using standard PCR approaches have over the years been converted to real-time PCR and real-time qPCR technology, to take advantage of the speed, technical efficiency, and cost reduction often associated with this approach.[10] Because real-time PCR technology completes both amplification and detection in the same reaction tube or well, there is no need for the laboratory to handle amplified DNA and risk workspace contamination. Importantly, the combination of amplification and detection in a single-reaction vessel not only decreases the time required to complete the test, but importantly has allowed expansion of PCR-based assays into high-throughput, portable, and on-site formats as described for foot-and-mouth disease virus, anthrax detection, and others. Because real-time PCR targets shorter genetic sequences, the methodology is more effective than standard PCR for testing formalin fixed tissue.[1] The preservation method tends to destroy longer strands of genetic material. Real-time PCR offers an additional advantage of supporting quantitative approaches for measuring and reporting the amount of the original target in the sample tested. qPCR answers a frequent criticism of standard PCR, specifically that detection limits, potentially as low as a single cell or viral particle, may produce a positive finding that is biologically irrelevant to clinical disease. qPCR allows the relative amount of target nucleic acid to be correlated with the associated clinical presentation. Despite the significant benefits, real-time PCR is, however, less efficient than standard PCR in producing amplified genetic material that can be used for subsequent nucleic acid (genome) sequence analysis, as is often employed to confirm positive PCR findings, or further characterize a pathogen on the basis of genetic material obtained from the diagnostic case materials.

Multiplex PCR. Multiplex PCR expands the use of PCR and real-time PCR-based detection from a single target to multiple targets simultaneously from a single specimen.[11-13] The ability to include multiple genome targets for a single virus or bacteria in a PCR assay minimizes the risk of a PCR false-negative as a result of genetic diversity within the agent of interest. Technically, the inclusion of an internal control, which is rapidly becoming a standard quality practice in veterinary diagnostic laboratories, is a simple form of multiplexing. Inclusion of targets for multiple closely related viruses has been used to differentially detect related pathogens, such as the closely related sheep and wildebeest-associated forms of malignant catarrhal fever; to subtype BVD viruses; and to differentially detect virulent *Escherichia coli*. Multiplex PCR also has broad application in syndrome-based testing where several pathogens may produce similar to identical clinical pictures. A single diagnostic specimen can be used in a multiplex format to detect one or more agents associated with a particular clinical presentation, such as the multiple viral and bacterial agents in shipping fever complex. Prototypes of this approach have been developed but are not yet widely deployed, and there are technologic limits to the number of PCR assays that can be combined without significant loss of assay performance. In real-time PCR formats, three to five unique assays have been the practical limit, based on the technical limitations of commonly available equipment and detection dyes.

ISOTHERMAL AMPLIFICATION. Isothermal techniques use alternate chemistries to PCR that allow amplification of nucleic acids to be carried out at a single temperature. Among the isothermal amplification technologies that have been used for the detection of veterinary pathogens are nucleic acid–based amplification, loop-mediated isothermal amplification (LAMP), rolling circle amplification, and direct signal amplification systems.[14,15] Although there are increasing efforts, especially for the development of LAMP-type diagnostic assays, none of these technologies has seen widespread diagnostic application, largely based on the complexity in initial assay design. However, LAMP-type assays may offer future PCR alternatives that can be developed into automated portable diagnostic tools, or possibly be developed as fully integrated self-contained testing units for use in the field rather than limited to a laboratory environment.

MICROARRAYS. Arrays of DNA or RNA fragments, variously referred to as *gene chips* and *microarrays*, consist of thousands of oligonucleotides attached in a specific pattern to a solid surface, typically a glass slide or silica chip.[16-22] The sample nucleic acids compete with fluorescently labeled competitor oligonucleotides for binding to the chip. A fluorescent detector and computer software are then used to analyze the patterns of fluorescence, indicating where nucleic acids have (or have not) been bound to the chip. Microarrays have been used primarily as research tools focused on detecting and understanding gene expression. The practical application to veterinary medicine includes studies such as the evaluation of genetic resistance to naturally occurring nematode infections, including *Hemonchus*, *Trichostrongylus*, and *Ostertagia* in sheep. Microarray technology has not seen wide use in veterinary diagnostic laboratories, largely because of the large initial investment required for equipment. However, examples of diagnostic microarrays have shown promise, and it is expected that, once established, the technology will be cost effective on an individual animal basis. In human diagnostic medicine, microarrays designed with genetically conserved sequences for all major groups of microorganisms have been used to identify or "mine" for unknown pathogens. This approach was used to detect and identify the SARS virus, before it was initially recovered and characterized by virus isolation techniques. Alternately, genotyping arrays have been designed to target specific virulence-associated genes, allowing differentiation of disease-associated subtypes of organisms from other members of the same or closely related species, such as enterotoxigenic *E. coli* and multidrug-resistant *Salmonella* strains.

An alternative to gene chip technology is liquid array technology, in which the nucleic acids are captured by oligonucleotide probes bound to a microbead, rather than to a flat surface. Bead sets are internally labeled with different-colored dyes used to distinguish the specific agents being measured.

VetBooks.ir

Liquid array systems use flow cytometry, laser technology, and signal processing to recognize the internal color of the beads and measure associated surface-binding of a target-specific fluorescent hybridization probe. The bead-based modification to microarray technology allows a laboratory to create a flexible diagnostic-test panel in a single assay by adding or removing target beads on the basis of the unique clinical presentation, diseases suspected, or species' specificity of interest. In theory, 100 different targets are detectable in a single assay.

RESTRICTION FRAGMENT LENGTH POLYMORPHISM. Molecular techniques provide a valuable tool for genotypic characterization or subtyping of viral, bacterial, and parasitic agents. Subtype characterization[23-26] is essential for, among other things, taxonomic classification, differential detection of virulent strains, identification of genetic sources of antimicrobic resistance or virulence factors, recognition of vaccine escape mutants, epidemiologic investigation of disease outbreaks, and identification of interspecies transmission of specific pathogens. Restriction fragment length polymorphism (RFLP) is a technique useful for subtyping of pathogens based on genetic sequence variation within specific genes.[27] Target DNA, which may or may not previously have been PCR amplified, is digested using one or more well-characterized restriction enzymes. Characteristic profiles or patterns produced by the different-sized DNA fragments remaining after enzyme digestion are detected by gel electrophoresis. RFLP has been used to investigate interspecies transmission of enterotoxigenic *Staphylococcus aureus* associated with intramammary infections in cattle, sheep, and goats.[28] Random amplified polymorphic DNA (RAPD) analysis is a technique that has proved useful in detecting genetic variation and for strain typing.[29] Rather than amplifying a specific region of a genome, RAPD relies on random amplification of genomic DNA using short arbitrary sequences as PCR primers. RAPD does not require prior knowledge of an organism's DNA sequence for specific primer design and can be applied to small amounts of template DNA. The RAPD technique has been applied, for example, to rapid differentiation of pathogenic from nonpathogenic coccidia of sheep including *Toxoplasma gondii* and *Sarcocystis* spp. Identification of nonculturable, slow-growing, and atypical bacterial species using sequence analysis of the *16s ribosomal RNA (rRNA)* gene has become recognized as a valuable diagnostic tool in recent years. The basis of the *16s rRNA* typing technique is the highly conserved nature of the *16s rRNA* gene within bacterial species, as well as among species of the same genus.[13,30,31] Automation developed to support *16s rRNA* amplification, sequencing, and data analysis is available to and currently in place in selected veterinary diagnostic laboratories. Although the technique is not currently cost effective for routine identification of all microbial isolates in a clinical setting, the technology is used for identification of atypical, slow-growing, and rarely encountered species.[32] Because *16s rRNA* databases continue to be updated to include pathogens of veterinary and zoonotic interest, it is likely that the technology is seeing broader application.

SEQUENCE ANALYSIS. Nucleic acid sequence analysis is used to identify and compare the exact nucleic acid sequence of a gene fragment, gene, or possibly entire genome for forensic purposes; to investigate disease outbreaks; to track evolutionary changes in rapidly mutable microorganisms; or for precise phenotype or genotype analysis of animals or organisms. The technology used for sequence analysis is progressing exponentially since initially introduced in the 1970s and most recently includes "next-generation sequencing," high-throughput sequencing procedures, and metagenomics used for routine diagnostic applications, food safety, and detection and characterization of new and emerging pathogens. Equipment and computational strength used for sequence analysis were once limited to specialized research laboratories and reference centers, but they are increasingly available in well-equipped diagnostic laboratories. Next-generation, also called second-generation, sequence analysis approaches use bench-top commercialized equipment based on DNA synthesis, ligation, or ion semiconductor technology for the rapid and highly accurate genome sequencing of pathogens. The complete genomic sequence of individual pathogens can be completed within a matter of hours to days using next-generation sequencing technologies.

For diagnostic purposes genetic sequencing may be paired with PCR amplification of specific genetic markers or regions of known pathogens, or it may be used in de novo applications that determine the genetic sequence and identity of an unknown or previously uncharacterized pathogen.[20,21] Sequence analysis, using an approach known as *Sanger sequencing*, is most commonly used in diagnostic medicine to confirm the identity of a pathogen testing positive in a PCR assay, to detect genetic variants or diagnostically important mutations in a pathogen's genetic makeup, and for forensic investigation into the source of an agent or disease outbreak based on specific genetic markers in the recovered pathogens. The target for Sanger sequencing is the amplified DNA (or cDNA) generated from routine standard PCR or real-time PCR testing of diagnostic samples. Sanger sequencing is currently used by the majority of veterinary diagnostic laboratories as a supplementary diagnostic tool. Next-generation sequencing is a rapidly developing tool that, unlike Sanger sequencing, which targets small pieces of DNA such as a specific part of a single gene, targets entire genes or genomes, making it an ideal tool for discovery of novel pathogens; identification of genetic disorders, which is often done by looking for the same genetic markers in animals previously linked to human genetic diseases[1]; and genomic and phylogenetic research of both pathogens and host animals.[33,34] Next-generation sequencing is not yet a routine diagnostic tool, as the sensitivity of next-generation sequence analysis is highly dependent on the quality of the sample, the precision needed in sample processing, and the relatively complex data analysis. However, the field of study is rapidly evolving. A number of platforms including devices for field applications[35] are currently available, each of them operating with slightly different methods resulting in both advantages and limitations.[36] Sampling bias, enzymatic reaction with associated error rate and bias, and computing database bias all must be addressed before reliable results can be communicated to the client, the public, and those making animal health policy decisions.[37] Multiple guidelines addressing the importance of a rigorous data analysis have been published for human medicine and are equally applicable to veterinary medicine for ensuring the reliability of results.[38] Relevant examples of new and emerging viruses identified using next-generation sequencing approaches include the Schmallenberg virus that spread rapidly in European cattle, resulting in reproductive inefficiency and fetal abnormalities,[39] a new Bluetongue serotypes,[40] as well as a tickborne "looping-ill"–related virus in goats and novel astroviruses in both cattle and sheep associated with encephalitis and gastrointestinal diseases.[39] Importantly, next-generation sequencing continues to expand the clinically important molecular characterization of uncultured bacteria.[41] In the future, metagenomics and next-generation sequencing data are expected to allow monitoring of treatment interactions with the host's microbiome, as has already been demonstrated with poultry data.[42]

Genetic Diseases

Diseases that are linked to genetic mutations in specific breeds—such as bovine leukocyte deficiency and complex vertebral malformation in Holstein cattle, β-mannosidosis in cattle or goats, and spider-lamb syndrome in sheep—can be controlled by selective breeding using PCR-based testing to identify carriers of

VetBooks.ir

the defective gene. Similarly, susceptibility to certain diseases has been linked to specific genetic haplotypes that can be detected by molecular analysis.[43] Although at times controversial, rapid PCR-based genotyping of sheep[44] has been used for selective breeding programs targeting the genetic alleles associated with "scrapie resistance." DNA testing for genetic selection, parentage confirmation, coat color, and related management purposes is also available for cattle, sheep, and goats. For genetic testing, the appropriate sample is typically whole blood, from which genomic DNA is extracted; the gene of interest is amplified by PCR; and then mutations are detected by sequence analysis, microsatellite target testing, and restriction enzyme analysis to identify the mutations in the gene of interest.[45,46]

Summary

For molecular diagnostics, as with any new technologic advance, there was initial hesitation or mistrust of the techniques, followed by a rush to take advantage of new diagnostic tools. With routine implementation of PCR, sequence analysis, and associated molecular diagnostic techniques have come significant advantages in diagnostic sensitivity and specificity, in the speed that a laboratory diagnosis can be reached, and in the potential for in-depth genome-level investigation of disease occurrences. At the same time, molecular techniques have introduced a new level of complexity to diagnostic medicine. The use and interpretation of molecular-based diagnostic results require sufficient understanding of the techniques used in order to judge the reliability and the relevance of the findings. Molecular techniques have become, and will continue to grow as, extremely valuable diagnostic tools, but like any tools in diagnostic medicine, they must be used with caution and with a clear understanding of their strengths, limitations, and appropriate applications to specific clinical investigations.

Diseases of the Cardiovascular System*

VIRGINIA B. REEF, *Consulting Editor*

Performing the Electrocardiogram

No single electrocardiographic lead system has been universally accepted for use in large animals. Bipolar leads (I, II, III, base-apex, X, Y, and Z of the orthogonal lead system) and unipolar leads (aV_F, aV_R, aV_L, thoracic) have been described, but the amplitude, duration, and configuration of the different waveforms vary widely depending on an animal's breed, size, body type, and sex. In addition, there is lability of certain waveforms within each animal depending on its level of exercise, excitement, or organic heart disease. Large animals have a deeply penetrating Purkinje system, and depolarization from the ventricular endocardium to the epicardium occurs explosively and in many directions at once. This period of ventricular activation is responsible for the electrocardiographic criteria that indicate ventricular enlargement in small animals but contributes little to generating the QRS complex of large animals. Establishing specific diagnostic criteria for chamber enlargement in large animal species has been difficult, because changes in the QRS complex are not sensitive or specific for ventricular enlargement.

The electrocardiogram (ECG) is used primarily to detect cardiac arrhythmias. For this purpose, a single-channel machine can be used, and the lead system chosen can be any that generates distinctive P, QRS, and T complexes. If an arrhythmia is detected, other leads should be obtained to further characterize the QRS and T complexes and confirm their origin. The lead system should be easy to apply, and the tracing free of artifacts created by muscle tremors, skin movement, shifting of weight, and changes in limb position. Two such leads commonly used to obtain a rhythm strip for the diagnosis of cardiac arrhythmias are the base-apex lead[1] and the Y lead of the orthogonal lead system.[2] The base-apex lead is attached by placing the positive electrode from one of three standard bipolar leads (lead I, II, or III) on the left thorax in the fifth intercostal space at the level of the elbow or at the location where the apex beat is most readily palpable. The negative electrode is attached to the skin of the right jugular furrow two thirds of the way from the ramus of the mandible to the thoracic inlet or at the top of the right scapular spine. The ground electrode can be attached to any site remote from the heart. Electrical contact is improved by clipping hair or wetting the skin with alcohol. The base-apex lead ECG is recorded by switching the machine to the bipolar lead that has been attached to the horse and recording the ECG (Table 30.1). Lead Y is attached by placing the positive electrode over the xiphoid and the negative electrode cranially to the front of the chest. Smartphone-enabled ECGs are useful to obtain a rhythm strip by placing the microphone end of the recording device at a 30-degree angle craniodorsally over the heart in the left fifth intercostal space.[3]

Continuous electrocardiographic recording over a 24-hour or longer period (Holter monitoring) or with telemetry is also useful for evaluating horses with arrhythmias. Continuous ECG recording can be performed with high-quality sticky electrodes applied to the skin underneath the surcingle, electrode patches that are held against the skin with a surcingle, or electrode patches attached to shaved skin with a cyanoacrylate adhesive and protected underneath a surcingle.[4,5] In the latter two situations, a dry sponge may help absorb motion, yielding a cleaner tracing. With sticky electrode patches, the electrodes may be applied directly to the skin or are taped to a small square of cardboard to provide them with some support and embedded in foam to minimize motion artifacts. The best recording with a three-lead system is usually obtained with the left arm electrode placed on the sternum, the right leg electrode on the right side in the fifth intercostal space at the level of the point of the shoulder, and the right arm electrode placed on the left side in the fifth intercostal space at the level of the point of the shoulder. These electrodes are then held in position with a tight surcingle. The electrodes are connected to a digital recorder that records the animal's heart rhythm for the entire monitoring period (Holter monitor) or a telemetry device that sends the ECG signal back to the receiver to be displayed on a monitor. To obtain an exercising ECG, high-quality sticky electrodes are applied to clean, dry hair. Several ECG placements enable a more motion-free tracing. The positive electrode (left arm) is placed near the left cardiac apex, and the negative electrode (right arm) is near the left shoulder area. The right leg electrode is placed near the positive electrode (left arm), and the ground electrode (right leg) is placed near the left shoulder electrode. Positioning the electrodes so that the negative (right arm) is under the surcingle or girth on the right shoulder region enables lead three to have a larger amplitude on the three-lead telemetry system. With this configuration, the ground electrode is under the surcingle on the left dorsal thoracic region, the positive electrode is over the cardiac silhouette, and the right leg is ventral to this; both electrodes are underneath the surcingle or girth. Electrode placement will vary somewhat with the tack that is applied and whether the horse is being ridden or driven. The entire

III	Left leg	Left arm

recording or monitoring period can be stored on a smart card for subsequent analysis. The continuous 24-hour Holter ECG is useful for diagnosing arrhythmias that occur intermittently or monitoring cardiac rhythm during exercise for later analysis. Telemetry electrocardiography is useful for real-time cardiac rhythm monitoring during treatment or exercise.

In the base-apex lead, the P wave is positive in most horses and ruminants. The P wave is most frequently bifid in horses. In many horses a T_a wave, indicative of atrial repolarization, occurs as a negative deflection after the P wave (Fig. 30.1). The QRS complex begins with a small positive deflection (rS) and is followed by a large negative deflection that terminates in the ST segment. The T wave is variable and can be positive, negative, or biphasic in horses and ruminants. Frequently the appearance of the T wave is variable within one recording. Fig. 30.2 illustrates a typical base-apex ECG recorded from both a cow and a horse at a 25-mm/s paper speed with the gain set at 10 mm/mV.

A systematic approach is used to analyze the ECG. The following step-by-step approach is recommended:

1. Identify all the QRS complexes. Each QRS complex should be followed by a T wave, and the QT interval should be similar for all QRS configurations unless there is a marked change in heart rate. Identify the remaining complexes. Are P waves, "F" (flutter) waves, or "f" (fibrillation) waves present? Are there any artifacts?
2. Determine the atrial and ventricular rates. Are they identical? Is one too fast or too slow? This determines whether there is a tachycardia or bradycardia.
3. Are the P-P and R-R intervals regular? Determine whether an irregular rhythm has underlying regularity that is interrupted by irregular intervals or whether the rhythm is consistently irregular. Second-degree atrioventricular block (AVB) and atrial and ventricular premature beats are arrhythmias with underlying regularity, whereas atrial fibrillation (AF), sinus arrhythmia, and sinus arrest are truly irregular rhythms.
4. Are P waves present? If so, is there a P wave preceding every QRS complex? If not, there are premature depolarizations, ventricular tachycardia (VT), escape beats, or AF. Are all P waves followed by QRS complexes? If not, second-degree AVB may be present. Is the resultant P-R interval constant? If not, there may be a wandering pacemaker or first-degree AVB.
5. Are all P waves and QRS complexes identical or normal in contour? If not, this signifies more than one pacemaker, premature depolarizations, or escape beats.

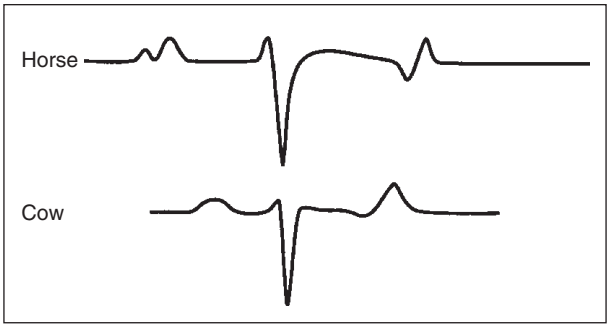

FIG. 30.2 Schematic representation of a typical base-apex lead electrocardiogram recorded from a cow and horse. In horses the P and T waves may be variable in appearance.

Use of Echocardiography in Large Animals

Echocardiography is a noninvasive diagnostic tool that uses sound waves in the range of 1.0 to 18.0 MHz to visualize the heart in motion, using either a single icepick (M-mode) or a two-dimensional (2D; B-mode) image. Noninvasive evaluation of blood flow in the heart and great vessels is performed with pulsed-wave, color-flow, and continuous-wave Doppler echocardiography. Precise localization of abnormal flow within the heart and great vessels is performed with pulsed-wave and color-flow Doppler echocardiography, whereas continuous-wave Doppler echocardiography is used to determine the peak velocity of blood flow and to noninvasively estimate pressure gradients. In contrast to M-mode and 2D echocardiography, for which the best image is obtained with the ultrasound beam perpendicular to the structures being imaged, optimal Doppler signals are obtained with the ultrasound beam parallel to the blood flow being evaluated. For accurate peak blood flow velocities to be recorded with continuous-wave Doppler echocardiography, the ultrasound beam should be as close to parallel as possible (<20-degree angle) to the direction of blood flow being measured. This alignment is difficult or impossible to achieve in most large animals with valvular heart disease, so accurate peak blood flow velocities often cannot be obtained; the peak velocity is thus underestimated. Noninvasive estimations of

pressure gradients are inaccurate in these instances. Alignment of the ultrasound beam parallel to shunt flow is possible with most ventricular septal defects (VSDs) because of the typical location of the VSD is in the membranous or perimembranous portion of the interventricular septum. A review of the theory and application of basic echocardiography in horses and cattle has been published.[6–12] There is currently a large body of literature concerning routine M-mode and 2D echocardiography in normal large animals and in those with a wide variety of cardiac diseases. Tissue Doppler imaging (TDI) and speckle tacking are now being used in horses to evaluate atrial and ventricular myocardial function.[13–20] Most recently, 4D echo (3D over time) has been used in horses to evaluate cardiac structure and function.[21]

Echocardiography is particularly useful in evaluating large animals with cardiovascular disease because the examination is noninvasive and can be performed in a timely fashion in most standing, unsedated animals. Acepromazine is the sedative of choice if sedation is needed for the examination and should be administered ahead of time if it appears that sedation will be necessary.[22,23] Diagnostic criteria for valvular, myocardial, pericardial, and congenital lesions of the heart are well established, and the information obtained assists the practitioner in confirming a diagnosis, assessing the extent of the disease, determining the severity of cardiac dysfunction, monitoring the response to treatment, and providing an accurate prognosis. Large animal echocardiographic equipment should provide satisfactory resolution of images at depths of ≥28 cm; a 30-cm depth of field is ideal for most until there is marked cardiomegaly. Portable ultrasound machines that can display depths of up to 40 cm for equine and bovine cardiology are available. These machines are available with pulsed-wave, continuous-wave, and color-flow Doppler. However, Doppler echocardiography is used primarily by specialists experienced in large animal cardiology, because performing and interpreting the echocardiogram, including Doppler, requires a significant amount of training and expertise. In addition, state-of-the-art color-flow and tissue Doppler equipment remains fairly expensive, although it has decreased in price.

Echocardiographic examination is performed in a systematic way, using standardized images to obtain information about chamber size, wall thickness, myocardial function, valve appearance, valve function, great vessels, blood flow, and presence of abnormal structures or echodensities. The standard adult equine or bovine echocardiogram is performed from the right parasternal window (right fourth intercostal space in horses and third intercostal space in ruminants) with a 2.5-MHz or lower-frequency transducer. Higher-frequency transducers should be used to examine younger or smaller animals, South American camelids, and small ruminants. Both long- and short-axis views of all cardiac structures should be evaluated. The cardiac valves should be carefully examined for any abnormalities of structure or function (dysplasia, thickening, prolapse, ruptured chordae tendineae [RCT], fenestrations, flail valve leaflet, vegetative lesion, or high-frequency vibrations). The relative size, shape, and relationship of the cardiac chambers and great vessels should be assessed, and an evaluation of myocardial function and blood flow performed. Measurements of left atrial diameter and left atrial area can be obtained from the 2D echocardiogram at end systole.[24] Standard measurements of left ventricular internal diameter, left ventricular free wall thickness, interventricular septal thickness, and right ventricular internal diameter should all be obtained at end diastole and peak systole from the M-mode echocardiogram. The diameter of the aortic root and left atrial appendage, the distance between the interventricular septum and the peak opening of the septal leaflet of the mitral valve (septal to E point separation), and the left ventricular ejection time (ET) should also be determined. End-diastolic measurements are obtained at the Q wave of the ECG, whereas peak systolic measurements are made from the peak downward deflection of the interventricular septum. Calculations of fractional shortening (FS) and ejection fraction (EF) can then be performed to assess left ventricular function using the following formulas:

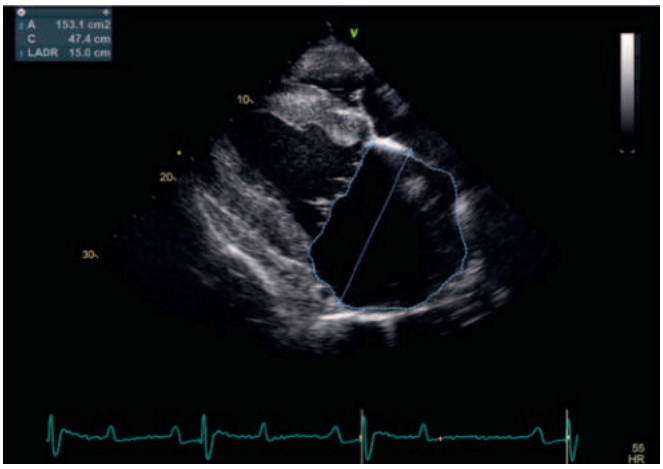

FIG. 30.3 Two-dimensional echocardiographic image of the left atrial diameter and left atrial area obtained from the right parasternal long-axis window in a horse with mild left atrial enlargement secondary to cardiomyopathy and mitral regurgitation.

$$FS = \frac{LVID_d - LVID_s}{LVID_d} \times 100$$

$$EF = \frac{LVID_d - LVID_s}{LVID_d} \times ET \times 100$$

in which $LVID_d$ is the left ventricular internal diameter at end diastole (cm), $LVID_s$ is the left ventricular internal diameter in systole (cm), and *ET* is the left ventricular ejection time (seconds).

Echocardiograms should also be performed from the left cardiac window when the entire heart cannot be successfully imaged from the right side; AF is present; abnormalities of the mitral valve, aortic valve, pulmonic valve, aorta, pulmonary artery, left atrium, left ventricle, or outflow portion of the interventricular septum are suspected or detected; or murmurs originating from the mitral, aortic, or pulmonic valves are detected or a pericardiocentesis is planned. The maximal diameter of the left atrium should be obtained at peak systole from the left cardiac window at the level of the left coronary artery, parallel to the mitral valve (Fig. 30.3), and the left atrial area can also be measured from this view.[24] The diameters of the aorta and pulmonary artery should be measured from similar locations in the vessel on the 2D echocardiogram and compared. Echocardiography should be considered a useful diagnostic test to evaluate patients with the following complaints, physical examination findings, or tentative diagnoses:

1. Cardiac murmur, to determine the etiology of the murmur
   a. Any grade 3/6 or louder holosystolic or pansystolic murmur on the left side of the thorax
   b. Any grade 4/6 (3/6 in prepurchase setting) or louder holosystolic or pansystolic murmur on the right side of the thorax
   c. Any holodiastolic decrescendo murmur
   d. Any continuous machinery murmur
2. Congenital heart defects, especially VSDs and atrial septal defects (ASDs)
3. Acquired valvular heart disease
4. Cardiac enlargement
5. Cardiac arrhythmias not associated with high resting vagal tone

6. Unexplained exercise intolerance or collapse or exercise intolerance attributed to cardiac causes
7. Muffled heart sounds, pericardial friction rubs, or pericardial effusion
8. Myocarditis or myocardial dysfunction
9. Congestive heart failure (CHF)
10. Pulmonary hypertension
11. Cardiovascular neoplasia
12. Aortic rupture or other abnormalities of the great vessels
13. Ionophore toxicity or exposure to other myocardial toxins
14. Any unexplained fever of unknown origin, with or without a cardiac murmur

Color-flow Doppler echocardiography should be used to map the size and location of a turbulent jet associated with an intracardiac or extracardiac shunt, valvular regurgitation, or stenosis (rare) and to semiquantitate its severity.[25,26] Continuous-wave Doppler echocardiography can then be used to measure the peak velocity of blood flow in the jet, estimating (noninvasively) the pressure difference between cardiac chambers using the Bernoulli equation. This can be accurately performed in most patients with a VSD, yielding information about the hemodynamic significance of the defect, but is difficult to impossible to accurately perform in many patients with valvular insufficiencies because of the limited windows available for interrogating blood flow in large animals and the inability to align the ultrasound beam to within 20 degrees of the turbulent blood flow. This poor alignment of the ultrasound beam with the regurgitant jet results in an underestimation of the peak regurgitant jet velocity. Contrast echocardiography, a technique involving microbubble-laden injections of saline, carbon dioxide, or indocyanine green, can also be used to demonstrate valve dysfunction and the direction of intracardiac and extracardiac shunts (VSDs, ASDs) but has largely been replaced by color Doppler echocardiography. TDI should be performed to look for left atrial systolic dysfunction (left atrial stunning) post conversion of AF.[27] TDI and speckle tracking are also useful in identifying ventricular myocardial dysfunction.[28–32]

Cardiac Catheterization in Large Animals

Cardiac and great vessel catheterization can be performed in standing unsedated large animals to determine the following data:
- Pressure and waveforms (shape of the pressure curve)
- Oxygen tension, oxygen saturation, oxygen content
- Cardiac output and other indicators of ventricular size and function

Cardiac catheterization is also used for special diagnostic studies such as angiocardiography, nuclear angiocardiography, and indicator dilution studies. These data are used to determine the direction and size of intracardiac and extracardiac shunts, chamber size and contractility, and valvular and myocardial function. Most of this information is now obtained noninvasively with echocardiography, minimizing the need for more invasive techniques.

Cardiac catheterization is usually reserved for specialty practices and referral institutions, owing to the equipment needed and skills required for acquiring and interpreting accurate data. Results are not always specific, but catheterization can add quantitative measurements that increase diagnostic and prognostic accuracy for certain cardiac conditions and may provide a direction for therapy.

Blood Pressure Measurements

Normal blood pressures for cattle and horses are listed in Table 30.2.[33–36] The values for horses represent a summary of data from numerous authors as cited in the references given. Accuracy of pressure recordings is greatly influenced by the choice of catheter and recording equipment used. While an oscillometric blood pressure device placed over the coccygeal artery corrected to the height of the heart is good for estimating blood pressure noninvasively and assessing marked trends, its accuracy and precision is low when compared with invasive blood pressure monitoring in standing horses.[37] Pulmonary artery wedge pressure (PAWP) is an indicator of left atrial mean pressure so long as balloon inflation of the catheter occludes flow in the segment of the pulmonary artery that is catheterized. PAWP is superior to central venous pressure (CVP) as a monitor of left ventricular function and fluid therapy. However, CVP is a good indication of intravascular volume in horses with dehydration.[38]

The shape of the pressure curve in the ventricles, aorta, or pulmonary artery may have diagnostic significance in conditions like constrictive pericardial disease (Fig. 30.4); pulmonic stenosis (giant A wave), rare as an isolated defect in large animals; or tricuspid or mitral valve regurgitation (large V wave). These conditions are more commonly assessed by echocardiography. An abnormal rise in pressure going from one chamber to the next indicates a stenotic lesion (uncommon in large animals) at the level of the pressure gradient. The size of the pressure gradient can be used to determine the severity of the lesion.

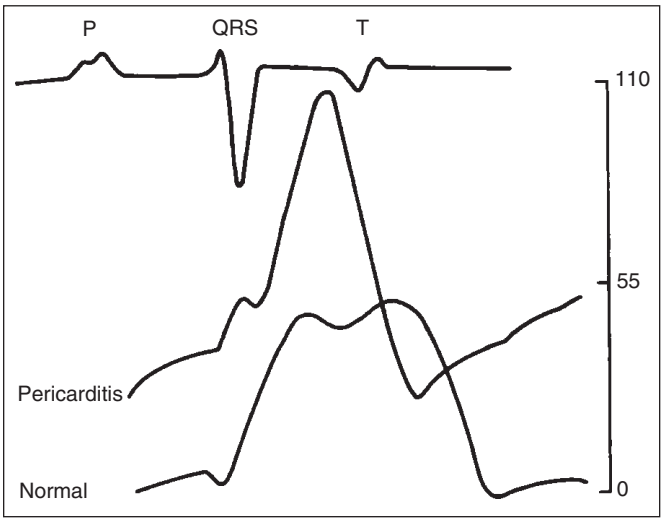

FIG. 30.4 Schematic representation of ventricular pressure curves recorded from a normal horse and a horse with pericarditis, showing the relationship between pressure changes and the electrocardiogram. With pericarditis, the ventricular end-diastolic and systolic pressures are elevated and pressure declines sharply in early diastole.

TABLE 30.2

Cardiac Pressure Measurements in Normal Horses and Cattle[a]

	Horses[33]	Cattle[34]
RA	12–28/22–5 (4–10)	(5)
RV	30–59/24–14 (9–25)	42–56/0–1 (19–28)
PA	34–48/14–22 (16–30)	33–46/19–21 (24–31)
PAW	13/3 (8)	(5–21)[35]
LV	140–148/15–17	(120–144)[36]
AO	131–144/86–100 (110–115)	
CA	142–157/98–119 (113–124)	160–208/110–147 (135–175)

[a]Pressure ranges are reported as systolic/diastolic (mean) in mm Hg unless otherwise designated.

Blood Oxygen Measurements

Blood oxygen measurements are taken from the chambers on the right side of the heart to detect abnormal elevations indicative of a left-to-right shunt (ASD, VSD, patent ductus arteriosus [PDA]). Criteria for oxygen step-ups have not been established for large animals, but human guidelines have been accepted for qualitative assessment of shunts.[39,40] In humans, oxygen content step-ups of the following magnitude are considered abnormal and indicative of a left-to-right shunt.[41]

- ≥1.9 volume percent from the superior vena cava to the right atrium
- ≥0.9 volume percent from the right atrium to the right ventricle
- ≥0.5 volume percent from the right ventricle to the pulmonary artery

Because oxygen content depends on hemoglobin concentration, oxygen saturation, which is independent of hemoglobin concentration, may be a more accurate indicator of shunts in anemic or polycythemic patients. Changes in the animal's physiologic status during sampling (cardiac output, ventilation, oxygen consumption); incomplete mixing of shunted blood; and variable time intervals between sampling can be potential sources of error. Several samples within a single chamber improve reliability of results. Small shunts and shunts in animals with low systemic arterial oxygen tension may not be detected by this technique.

Shunt calculations can be made once oxygen saturation or content has been measured in each of the right heart chambers, the pulmonary artery, and a systemic artery. For a left-to-right shunt, the pulmonary flow/systemic flow ratio (QP/QS) is determined as follows:

$$\mathrm{QP/QS} = \frac{\mathrm{SA}O_2 - \mathrm{MV}O_2}{\mathrm{SA}O_2 - \mathrm{PA}O_2}$$

in which SAO_2 is the arterial blood oxygen content, MVO_2 is the mixed venous blood oxygen content, and PAO_2 is the pulmonary artery oxygen content. A 2:1 QP/QS represents a 50% left-to-right shunt, indicating that 50% of the pulmonary flow is from the left side of the heart.

For a right-to-left shunt, the QP/QS is determined as follows:

$$\mathrm{QP/QS} = \frac{\mathrm{SA}O_2 - \mathrm{MV}O_2}{\mathrm{PV}O_2 - \mathrm{MV}O_2}$$

in which PVO_2 is the pulmonary venous oxygen content (assumed to be 98% of oxygen capacity plus 0.3 mL of dissolved oxygen).[42]

Cardiac Output and Ventricular Function Assessment

Cardiac output is determined by indicator dilution methods (usually by dye dilution or thermodilution or, more recently, by lithium dilution), by the Fick method, or by using 2D or Doppler echocardiography. The Fick method requires use of a face mask and simultaneous determination of mixed venous and arterial blood samples. Dye dilution and thermodilution results are comparable when 30 to 40 mL of 5% dextrose are injected rapidly at 32° F (0° C).[40] Lithium dilution compares favorably with thermodilution in anesthetized horses and foals.[43,44] Volumetric echocardiography using the Bullet method achieves results similar to those obtained with the lithium dilution method in anesthetized foals.[45] Transthoracic Doppler echocardiography was closely correlated with thermodilution in standing horses.[46]

Cardiac output values in the resting horse range from 32 to 40 L/min.[47] Cardiac index is the cardiac output divided by a measure of body size (body weight in kilograms) and is expressed in mL/kg/min.[47] The normal cardiac index for the adult horse ranges from 72 to 88 mL/kg/min.[47,48] Cardiac output values of 20.9 to 23.6 L/min have been reported in normal anesthetized horses.[43] In cattle a cardiac index of approximately 110 mL/kg/min has been reported.[36] Cardiac output measurements in clinical patients vary with heart rate, excitement, hydration, and many other factors and are best determined in the pulmonary artery. Electronic integration and computation of area under the curve by means of battery-powered units that can display results instantly provide the most reliable results.[49]

Cardiac output results or indicator dilution curves can provide quantitative and qualitative assessment of cardiac shunts. Characteristic changes in the temperature-time curve (thermodilution methods) or dye concentration–time curve indicate the presence of a left-to-right, right-to-left, or bidirectional shunt. Calculation of the cardiac output in the chamber just proximal to the shunt and distal to it can give a quantitative estimate of the size of the shunt.[40]

Angiocardiography

Angiocardiography is used in neonates or animals small enough to have the entire cardiac silhouette visualized on a single radiograph cassette. The contrast medium must be injected rapidly, and in most cases this is done with a pressure injector. Specialized radiographic requirements include rapid film change capabilities, rapid image sequence acquisition, or cineradiography. Angiocardiography is used to confirm the presence of an intracardiac shunt (ASD, VSD) or extracardiac shunt (PDA, truncus arteriosus) or valve dysfunction, to visualize chamber size, or to estimate contractility. Angiocardiography is performed in anesthetized animals.

Nuclear Angiocardiography

In nuclear angiocardiography, specialized equipment captures sequential digitized images of the right side of the heart, lung, and left side of the heart after rapid injection of radiographic tracer into peripheral circulation. A more extensive review of this subject has been published.[50] Nuclear angiocardiography can be used to confirm valvular dysfunction, which is manifested by chamber enlargement or prolonged washout of affected vessels or cardiac chambers and is quantitated by the regurgitant fraction. It also can reveal enlargement of chambers and prolonged washout resulting from cardiac failure. The presence of intracardiac or extracardiac shunts is demonstrated by the simultaneous visualization of left- and right-side cardiac chambers or slow washout downstream of the shunt. In addition, nuclear angiocardiography is used to calculate cardiac output and ejection fraction (EF) and other indices of cardiac function.

Congenital Cardiovascular Disease

The cause of congenital cardiac defects has not been established, although hereditary factors may be responsible for some defects. In humans, additional factors such as maternal infection, age, and nutritional status have been identified; fetal anoxia from placental insufficiency, fetal infection or metabolic dysfunction, or other causes may contribute to the development of congenital cardiac defects. The same factors may apply in animals. Congenital cardiac defects in large animals can occur alone or in combination. The most commonly reported is VSD.[25,39,51–54] Multiple cardiac anomalies including PDA,[55,56] tetralogy of Fallot,[57,58] truncus arteriosus,[59,60] total anomalous pulmonary venous connection,[61] and Eisenmenger complex in calves[62] have been reported. Congenital anomalies of the tricuspid,[59,63–65] mitral,[66] and pulmonic valves[59,67,68] are uncommon. Congenital abnormalities of the aorta are reported in calves and foals but

VetBooks.ir

are also uncommon.[54,69,70] ASD occurs more commonly in calves than in foals and is frequently accompanied by other defects.[54,60,71,72] Hypoplasia of the left and right ventricles has been infrequently reported in calves and foals.[54,73,74]

Congenital cardiovascular disease should be suspected in a young patient if examination reveals a holosystolic (pansystolic), holodiastolic, or continuous murmur or a murmur with a palpable thrill or wide radiation over the thorax. Cyanosis at rest or with exercise in a patient with a cardiac murmur warrants consideration of a right-to-left cardiac shunt, obstructive pulmonary disease, or severe stenosis of the structures of the right side of the heart. The presence of any of these findings in a young animal with a history of lethargy, weakness, or failure to thrive constitutes grounds to suspect congenital cardiovascular disease.

Ventricular Septal Defect

DEFINITION AND ETIOLOGY. A VSD is an opening in the interventricular septum that creates communication between the left and right ventricles. In large animals most defects occur in the perimembranous septum and are imaged ventral to the right and/or noncoronary cusp of the aortic valve and cranioventral to the septal leaflet of the tricuspid valve, including or adjacent to the fibrous part of the interventricular septum.[25,39,52,54] VSD can occur as a single defect or as part of a complex anomaly. Many cardiac malformations such as tetralogy and pentalogy of Fallot, truncus or pseudotruncus arteriosus, common atrioventricular canal defect, tricuspid atresia, and double outlet right ventricle include a VSD. The cause of VSD is unknown, although it has been documented to be a heritable defect in Limousine[54] and possibly Hereford[75] cattle. VDSs are more common in Welsh Mountain ponies (Section A) and in the Arabian, Standardbred, and Quarter Horse breeds, suggesting a possible hereditary predisposition.[76,77] The defect is thought to result either from failure of fusion of a part of the endocardial cushion and the muscular ventricular septum or failure of fusion of the truncal and conal septa.[78]

Clinical Signs and Differential Diagnosis

The clinical signs of an isolated VSD vary and depend on the size of the defect, direction of the shunted blood, and presence of concurrent valvular or myocardial disease. In isolated VSD the blood flow is shunted from the left ventricle to the right ventricle through the defect in the interventricular septum. The size of the shunt depends on the size of the defect and the pressures in the left ventricle, right ventricle, and pulmonary artery.

VSD is suspected when there is a loud, grade ≥4 to 6/6 harsh, plateau-shaped pansystolic murmur with its point of maximal intensity (PMI) in the tricuspid valve area and a slightly softer (usually one grade softer), more crescendo-decrescendo holosystolic murmur that is loudest in the pulmonic valve area. The murmur on the left side has its PMI in the pulmonic valve area, associated with a relative pulmonic stenosis (increased blood flow across a normal pulmonic valve). Occasionally there is splitting of the second heart sound. The murmur may be the only clinical sign identified if the defect is small or moderate size. On the other hand, poor growth, lethargy, dyspnea, exercise intolerance, and signs of CHF can be exhibited by animals with a large VSD. This usually develops by the time the animal is 5 years old. CHF may develop later in horses with a moderate-sized VSD and cardiomyopathy or in those with a moderate to large VSD with aortic prolapse who then develop aortic regurgitation (AR). Occasionally there is a diastolic murmur of aortic insufficiency associated with a large VSD, the location of which compromises the support of one of the aortic valve cusps.[10,25,53] Cardiac arrhythmias, particularly AF, may be associated with VSD when there is cardiac enlargement or failure. The development of AF may be the "tipping point" for the development of congestive heart failure.

If the systolic murmur is loudest on the left side of the thorax, a subpulmonic VSD or a complex anomaly with pulmonic stenosis (or some form of right ventricular outflow tract [RVOT] obstruction) should be suspected.[10,25,53,79] The pulmonic murmur is usually louder than the tricuspid murmur in large animals with tetralogy of Fallot. Large animals with tetralogy of Fallot may have cyanosis at rest (uncommon in horses) or with exercise or exertion. Cyanosis is also a distinguishing feature of Eisenmenger complex, a defect in which right-sided heart resistance to blood flow causes the shunt associated with VSD to become right to left (which is rare). Congenital abnormalities of the mitral and tricuspid valves (dysplasia) cause a loud systolic murmur audible on both sides of the thorax but are rare. The PMI of the left-sided systolic murmur is more caudally located (in the mitral to aortic valve area) than the relative pulmonic stenosis murmur. Usually the murmur of mitral regurgitation (MR) is louder than the murmur of tricuspid regurgitation (TR). An innocent flow murmur of neonates can usually be distinguished from VSD by its crescendo-decrescendo shape, PMI at the left heart base, lack of radiation, and low to moderate intensity.

Clinical Pathology

Echocardiography is the diagnostic technique of choice for identifying a VSD. With 2D echocardiography the VSD can be imaged directly (Fig. 30.5, *A*) and the shunt size, location, and direction demonstrated with color-flow Doppler echocardiography (Video 30.1) or the injection of microbubbles. Maximal shunt velocity is obtained with continuous-wave Doppler echocardiography (Fig. 30.5, *B*). Careful scanning of the interventricular septum should be performed with 2D echocardiography to directly image the VSD and measure its maximal diameter in two mutually perpendicular planes.[10,25,53] The typical perimembranous VSD (≤2.5 cm in both planes) is missed if the long-axis view of the left ventricular outflow tract (LVOT) is not examined. The membranous VSD is located underneath the right and/or noncoronary leaflet of the aortic valve and ventral to the septal leaflet of the tricuspid valve. If a perimembranous defect is not found, the entire septum should be carefully scanned in all imaging planes to detect the VSD. The subpulmonic location, more common in calves, is easy to miss. This defect is usually best imaged in the short-axis view, scanning the interventricular septum between the LVOT and RVOT. With a left-to-right shunt a high-velocity turbulent jet is depicted from the right parasternal window, originating in the left ventricle, traversing through the defect in the interventricular septum into the right ventricle with color-flow Doppler echocardiography (Video 30.1), whereas a negative contrast jet is imaged in the right ventricle with a right-sided injection of microbubbles.[10,25,53] Moderate to large VSDs show left atrial and left ventricular enlargement, right ventricular enlargement, and pulmonary artery dilation. The left atrial–to–aortic root ratio is increased. Aortic valve prolapse and AR may also be detected because of loss of support of the aortic root from the VSD, more likely with larger VSDs and VSDs with malalignment of the ascending aorta with the upper portion of the interventricular septum. Myocardial dysfunction and subsequent CHF may occur with a large VSD. Most horses with VSDs that are compatible with a normal life expectancy ultimately develop MR secondary to the chronic left atrial and ventricular volume overload. Continuous-wave Doppler echocardiography should be used to noninvasively assess the hemodynamic significance of the shunt (see Fig. 30.5, *B*). A peak shunt flow velocity of 4.5 m/s or greater indicates a restrictive VSD with normal or near-normal right ventricular pressures.[77] The radiographic presence of cardiomegaly and increased vascularization of the lungs provide only nonspecific evidence of VSD. If polycythemia is found, a complicated VSD should be suspected.

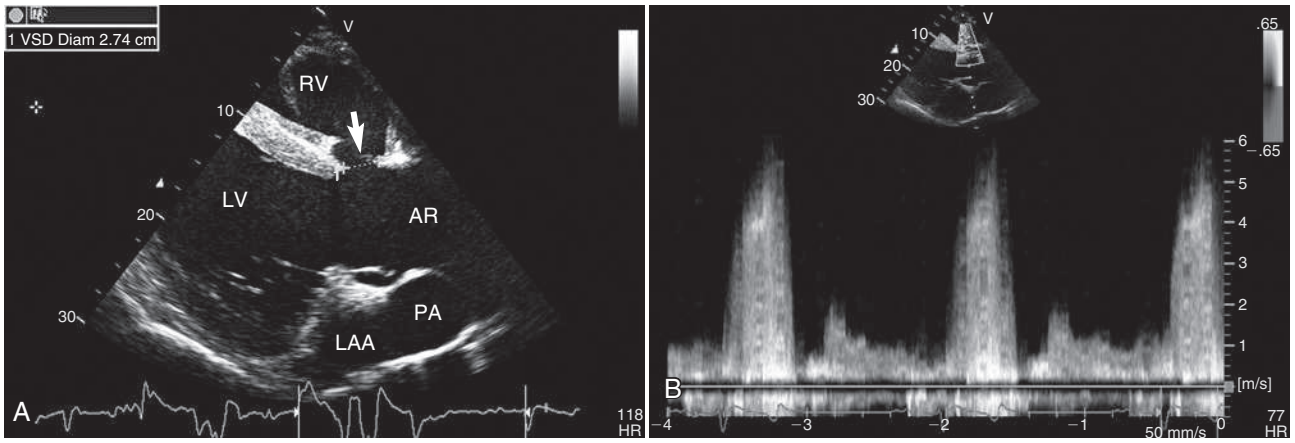

FIG. 30.5 Two-dimensional echocardiographic image **(A)** and continuous-wave Doppler spectral tracing **(B)** of a ventricular septal defect (VSD) *(arrow)* in a Thoroughbred gelding who presented for poor racing performance. The VSD is located just underneath and cranial to the septal leaflet of the tricuspid valve and just ventral to the noncoronary and right coronary cusp of the aortic valve and measured 2.74 cm in this view. There is significant left ventricular enlargement in this gelding. The right ventricle *(RV)*, left ventricle *(LV)*, left atrial appendage *(LAA)*, aortic root *(AR)*, and pulmonary artery *(PA)* are all visible in this view. The spectral tracing shows a peak shunt velocity of over 5 m/s in systole. Some turbulent flow (spectral broadening) is also detected in diastole, with a peak flow velocity of approximately 1.75 m/s.

Cardiac catheterization can be used for qualitative and quantitative assessment of the VSD but has been supplanted by echocardiographic diagnosis. Elevated cardiac pressures provide qualitative evidence of a VSD. Right ventricular systolic pressure elevation is most common and may equal left ventricular pressure with a large VSD. Pulmonary artery pressure (PAP) can be increased as a result of increased blood flow from the left-to-right shunt or increased pulmonary vascular resistance and decreased flow (restrictive pulmonary hypertension). Elevation of left or right ventricular diastolic pressure provides evidence of cardiac failure in the patient with VSD. Oximetric data (oxygen content or oxygen saturation) can be used to locate the shunt and provide some evidence of the size of the defect. A step-up in oxygen content or saturation between the right atrium and the pulmonary artery suggests a moderate or large VSD. Because most VSDs are located high in the RVOT, there may be inadequate mixing of shunted blood in the right ventricle to detect the shunt in this chamber, unless the catheter is directed to the outflow tract for sampling. When the oxygen step-up is detected first in the pulmonary artery, a PDA cannot be ruled out. A small shunt may be missed by oximetry as described earlier under oxygen sampling.

By using the indicator dilution methods described previously, the shape of the concentration-time or temperature-time curve can be used to demonstrate the left-to-right shunt of a VSD. A comparison of the cardiac output measured in the right ventricle with the cardiac output measured in the pulmonary artery can give an estimation of the percent of pulmonary blood flow coming from shunted blood and therefore an estimation of the size of the defect.[40]

Angiocardiography in the anesthetized neonate can definitively demonstrate VSD if there is simultaneous opacification of the left and right ventricles when dye is injected into the left ventricle but has been supplanted by color Doppler echocardiography.

Pathophysiology

A small VSD may provide enough resistance to flow that the left-to-right shunt is minimal and the patient remains asymptomatic. Horses can race successfully with small VSDs (≤2.5 cm in diameter with peak shunt velocities ≥4.5 m/s), although they are not usually successful as elite racehorses.[10,25,77] In smaller horses and ponies or very large horses, a VSD-to–aortic root ratio less than 0.3 is unlikely to be hemodynamically significant.[76,77] Most horses in this study that presented with CHF or exercise intolerance had a VSD-to–aortic root diameter of 0.64.[76] VSDs produce a left-to-right shunt because the pressure in the left ventricle exceeds that in the right ventricle. A peak shunt velocity of 3.5 to 4.5 m/s indicates an increased right ventricular pressure and a less restrictive VSD, but the defect is usually compatible with a normal life expectancy. A peak shunt velocity less than 3.5 m/s is indicative of a large shunt that is hemodynamically significant. These animals usually develop CHF by 5 years of age. Occasionally the VSD is so large that the pressure between the two chambers is equalized. The right ventricle, pulmonary circulation, left atrium, and left ventricle must compensate for this volume overload, which generally results in dilation of cardiac chambers and development of pulmonary hypertension.

Simultaneous pulmonary disease or left-sided heart failure due to chronic volume overload can increase pulmonary vascular resistance. In addition to volume overload, the right ventricle is subjected to a chronic pressure overload that may be sufficient to reverse the direction of the shunt (Eisenmenger complex, more common in cattle). Because of the pressure and volume overload with moderate to large VSDs, patients with this condition run a greater risk of developing CHF.

Considerable turbulence associated with left-to-right shunts and endocardial damage increase the risk of endocarditis in patients with VSD.[80] Because the VSD is usually located high in the LVOT, structural support of the aortic valve cusps may be lost, especially with large VSDs and/or malalignment VSDs, and AR may develop.[10,25,77] Significant AR adds to the left ventricular volume overload caused by the VSD.

Epidemiology

The true incidence of VSD in large animals is unknown, although it is recognized as the most common congenital cardiac defect. In one study, 36 calves had 78 congenital cardiac defects, of which 11 were VSDs.[54]

Necropsy Findings

VSD is usually located high in the interventricular septum just ventral to the right or noncoronary cusp of the aortic valve in the left ventricle and underneath the septal leaflet of the tricuspid valve or caudal or ventral to the crista terminalis in the right ventricle.[77] It can be an isolated defect or accompanied by other cardiac or organ anomalies. If the defect is moderate or large, there is right ventricular, left atrial, and left ventricular enlargement and pulmonary artery dilation.

VetBooks.ir

Increased pulmonary blood flow can lead to lung congestion and secondary pneumonia is not uncommon. If pulmonary vascular resistance is increased, right ventricular hypertrophy may be present. There may be secondary endocarditis (infrequent in large animals)[80] or endocardial lesions as a result of turbulent blood flow across the defect.

Treatment and Prognosis

There is no practical treatment for VSD in large animals. A complete echocardiographic examination is indicated to identify the presence and significance of a VSD. The size of the VSD, peak shunt velocity through the VSD, degree of left atrial and left ventricular volume overload, presence of aortic valve prolapse, detection of AR or MR, and myocardial function all have to be assessed to determine the VSD's significance. It is important to identify those animals with moderate to large defects, because the prognosis for normal production or function is poor. Horses with large defects (>3.5 cm or VSD/aortic root ratio of 0.64) and peak shunt velocities through the defect of less than 3.5 m/s are likely to develop CHF early in life and have a shortened life expectancy.[25,76] These horses are not suitable for use by a child or in a lesson program. Animals with small defects may remain asymptomatic throughout life. Rarely, spontaneous closure of the VSD may occur.[81] It is important to recognize that small defects, which provide a large resistance to flow, can produce loud murmurs, so murmur intensity is not a good predictor of defect size.

VSDs may be heritable in some breeds, and because of the increased risk of heart failure and other cardiac complications, breeding animals with this defect is not advised. As a general rule, bull studs do not accept animals with this defect into a breeding program.

Patent Ductus Arteriosus

DEFINITION AND ETIOLOGY. A PDA is persistent patency of the vessel (normally present in the fetus) that connects the pulmonary arterial system to the aorta. The ductus arteriosus fails to close at birth when breathing begins and placental circulation is removed. Closure of the ductus arteriosus occurs in response to decreasing pulmonary vascular resistance and increased systemic vascular resistance.

A PDA can occur as a single defect (rare in large animals) or with other cardiac anomalies. In large animals the most common other defects reported with PDA are tetralogy of Fallot and pseudotruncus arteriosus.

Clinical Signs and Differential Diagnosis

The clinical signs of PDA depend on the length and diameter of the ductus arteriosus, direction of the shunted blood, and presence of other cardiac defects. A PDA should be suspected when a continuous "machinery murmur" is auscultated. The murmur may be heard on the left and right sides of the thorax but is usually loudest in the left third or fourth intercostal space at the level of the point of the shoulder. The intensity of the murmur increases with increased heart rate, exercise, or excitement. The arterial pulses are usually bounding because of the runoff of blood from the systemic to the pulmonary circulation. Occasionally the PDA is manifested by a holosystolic murmur[82] because the diastolic component is barely audible, except at the left heart base. Large PDAs can exist without producing a murmur. In the animal with increased pulmonary vascular resistance and reversal of the shunt, there may be cyanosis of the caudal parts of the body if the PDA enters the aorta caudal to the brachiocephalic trunk (rare). Stunting of growth may also occur.

Other causes of a continuous murmur in neonatal large animals are extremely rare, but detecting a continuous machinery murmur should lead the veterinary clinician to suspect a complex congenital cardiac defect that includes a PDA, rather than an isolated defect. In older horses an aorticocardiac fistula should be suspected, particularly if the machinery murmur is of recent onset and is loudest on the right side of the chest. If the horse is a Friesian, an aortopulmonary fistula should be suspected. A systolic and diastolic murmur can be present in young animals with a large VSD causing AR. A similar murmur is possible with vegetative endocarditis of one of the atrioventricular or semilunar valves, producing insufficiency and stenosis of the affected valve. These latter conditions should not have the machinery murmur characteristic of the PDA. A loud systolic ejection murmur, which is confused with a PDA, frequently can be heard at the left heart base of foals shortly after closure of the PDA. This murmur may persist for 2 to 3 months.[55]

Clinical Pathology

No characteristic clinicopathologic changes are associated with a PDA. Radiography may show enlargement of the cardiac silhouette and pulmonary overcirculation in an uncomplicated PDA. Pulmonary venous congestion, interstitial pulmonary edema, and alveolar edema are evidence of a large PDA with left-sided heart failure. These signs are not specific for PDA and can be present with any congenital heart defect that results in a left-to-right shunt. No consistent electrocardiographic pattern has been identified with PDA. Echocardiographic detection of an enlarged left atrium and left ventricle, with a pattern of left ventricular volume overload and increased values for the ratio of the left atrial to aortic root dimension, are consistent with a PDA.[10,53,82,83] Direct visualization of the ductus arteriosus echocardiographically is difficult but is most successful from the left cardiac window looking dorsally between the aorta and main pulmonary artery. A PDA arising from the pulmonary artery has been imaged echocardiographically in an 11-month-old Friesian-Holstein heifer.[56] A PDA has also been imaged by the author in a 9-year-old Quarter Horse mare. High-velocity turbulent flow in the pulmonary artery and ductus arteriosus is detected throughout the cardiac cycle with pulsed-wave, continuous-wave, or color-flow Doppler echocardiography.[10]

Cardiac angiocardiography and nuclear angiocardiography using a selective aortic angiogram provide definitive evidence of a PDA. Oximetric data show a step-up in oxygen content or saturation in the pulmonary artery proportional to shunt size. Indicator dilution methods also provide evidence of a left-to-right shunt occurring in the pulmonary artery in cases of an uncomplicated PDA. Pulmonary arterial and right ventricular pressures may be increased with a large PDA.

Pathophysiology

Normally the ductus arteriosus narrows near term and constricts rapidly after birth in response to lowered pulmonary vascular resistance, increased systemic vascular resistance, increased blood volume, and increased left ventricular pressure when breathing begins and the placental circulation is removed. If the ductus arteriosus is large or the resistance to flow across the ductus is minimal, there is a significant left-to-right shunt that produces a large left ventricular volume overload. The left ventricular response may be failure or, with time, dilation (primarily) and hypertrophy. Pulmonary hypertension and congestion result. The right ventricle can be affected by the pulmonary pressure load, and right ventricular hypertrophy can also develop. If the pulmonary resistance equals or exceeds the systemic vascular resistance, a right-to-left shunt occurs.

Epidemiology

Normal foals may have a PDA for a few days after birth, but functional closure of the ductus arteriosus is expected by 96 hours of age.[82] Normal ruminants rarely have a PDA after birth, and if one is present it is considered abnormal. Functional closure may precede anatomic closure of the PDA. This defect

is uncommon in older animals. No evidence suggests that this is an inherited defect in horses or cattle.

Necropsy Findings

The ductus arteriosus can be of variable length and diameter but is patent between the aorta and pulmonary artery. The PDA often enters the aorta caudal to the origin of the brachiocephalic trunk. Changes in the left and right ventricles and lung and pulmonary vasculature are variable and depend on the size of the shunt. When the PDA is large, there may be cardiomegaly with left atrial and left ventricular dilation, right ventricular hypertrophy, dilation of the pulmonary artery, pulmonary congestion, and edema.

Treatment and Prognosis

There is insufficient evidence on which to base a prognosis for animals with PDA. The condition can be corrected surgically in neonates, but future performance has not been documented. Animals with small defects may remain asymptomatic throughout life. However, a marked dilatation of the pulmonary artery around the shunt is a safety concern in a horse that is to be ridden or driven, as pulmonary artery rupture is possible. The prognosis is poor if the defect is large, because the risk for left (primarily) and right ventricular failure is increased. Pharmacologic closure of the PDA using inhibitors of prostaglandin synthesis has been successful in humans but is not without risk of complications and recurrence. The efficacy of prostaglandin inhibitors has not been evaluated in large animals.

Tetralogy and Pentalogy of Fallot

DEFINITION AND ETIOLOGY. Tetralogy and pentalogy of Fallot are characterized by biventricular origin (overriding) of the aorta, VSD, obstruction of pulmonary arterial flow, and secondary right ventricular hypertrophy. When there is an associated ASD or PDA, the anomaly is referred to as *pentalogy of Fallot.* The defect is caused by abnormal development of the conal septum in the embryonic heart, which leads to narrowing of the right ventricular infundibulum (pulmonic stenosis), an inability of the conal septum to participate in closure of the interventricular foramen (VSD), and overriding of the aorta. Right ventricular hypertrophy due to pulmonary outflow obstruction develops.

Clinical Signs and Differential Diagnosis

Tetralogy of Fallot is one of the more common congenital cardiac defects that cause cyanosis in large animals. Resting cyanosis is rare in horses, although it may be detectable after exercise. Cyanosis of the oral and nasal mucosa, tongue, vaginal mucous membranes, and occasionally the nose and skin of light-colored animals is noticed when >5 g/dL of hemoglobin are reduced (unoxygenated). Exercise intolerance is often marked and is usually characterized by dyspnea or collapse. Frequently the owner complains of slow growth or small size. A loud pansystolic murmur associated with a palpable thrill is loudest in the left third to fourth intercostal spaces. The murmur may be a crescendo-decrescendo murmur of pulmonic stenosis or the harsh, plateau-shaped murmur of a VSD; one of these usually predominates. A harsh band-shaped pansystolic murmur is also auscultated in the tricuspid valve area but is usually one or two grades softer than the pulmonic stenosis murmur. Excitement of the animal may result in auscultation of a gallop rhythm or an early systolic ejection click. A continuous machinery murmur associated with continuous shunting through the PDA can be auscultated in some patients with pentalogy of Fallot.

Tetralogy and pentalogy of Fallot must be distinguished from other causes of cyanosis in young animals. Respiratory distress syndrome of neonates can be distinguished by the presence of tachypnea, dyspnea, and abnormal lung sounds in the absence of a cardiac murmur. Cyanosis caused by central nervous system disease has other neurologic manifestations. Cyanosis from congenital cardiac disease may be caused by a right-to-left shunt or heart failure with pulmonary edema. Cyanosis resulting from heart failure or respiratory disease improves with oxygen administration, whereas the patient with a right-to-left cardiac shunt fails to improve. Right-to-left cardiac shunting does or can occur with tetralogy and pentalogy of Fallot, reverse PDA or VSD (rare), tricuspid valve or right ventricular atresia, left ventricular hypoplasia, persistent truncus arteriosus, pseudotruncus arteriosus, and other complex congenital cardiac disease, all of which may occur with cyanosis and a cardiac murmur. A complete echocardiographic examination (Video 30.2) using a segmental approach to cardiac anatomy is necessary to accurately diagnose the correct congenital cardiac malformation and has widely supplanted other methods of diagnosing complex congenital cardiac disease in large animals. Radiography and cardiac catheterization provide supplemental information that may be helpful in distinguishing among the causes of right-to-left cardiac shunting.

Clinical Pathology

Increased packed cell volume (PCV), red blood cell count, and hemoglobin concentration (polycythemia) may be present in some animals with tetralogy and pentalogy of Fallot.[58] However, polycythemia is uncommon in foals with cyanotic congenital cardiac disease and the PCV is usually <45% in most calves. The degree of arterial hypoxemia is variable, depending on the amount of right-to-left or bidirectional shunting. Electrocardiographic changes are usually nonspecific, but a right-axis deviation may be detected.[58] Radiographs of the lungs may show decreased vascularity. Echocardiography easily visualizes the four components of tetralogy of Fallot. The VSD and overriding aorta are usually clearly visible with 2D echocardiography (see Video 30.2). The malalignment VSD is usually large and located just below the right cusp of the aortic valve, separated from the pulmonic valve by the crista supraventricularis. The aortic root is usually large and dextroposed, and it overrides the VSD. Echocardiography shows increased thickness of the right ventricular wall, ventricular septal hypertrophy, paradoxical septal motion, and similar left and right ventricular internal dimensions. Narrowing of the RVOT, pulmonic stenosis, or a hypoplastic pulmonary artery (most common) may be imaged as the cause of the RVOT obstruction. Pulsed-wave, continuous-wave, and color-flow Doppler echocardiography can be used to further characterize the abnormalities of blood flow associated with tetralogy of Fallot, in particular the severity of the RVOT obstruction. Contrast echocardiography also nicely demonstrates the path of blood flow with a peripheral venous injection. Contrast echoes are imaged entering the right ventricle from the right atrium, and then simultaneous opacification of the pulmonary artery, left ventricle, and aorta occurs.

Cardiac catheterization can be used to demonstrate equalization of ventricular pressures and a pressure gradient between the right ventricle and pulmonary artery. Oximetry should demonstrate decreased oxygen content in the left ventricle compared with the pulmonary vein. Angiocardiography demonstrates simultaneous filling of the right ventricle, left ventricle, and overriding aorta, with decreased pulmonary artery filling and increased right ventricular trabeculation (hypertrophy).

Pathophysiology

The VSD is usually large, resulting in equalization of pressures in the two ventricles and aorta. The degree of shunting is controlled by the resistance across the stenotic RVOT compared with the resistance across the aortic valve. If the RVOT is severely obstructed, the clinical signs of cyanosis are more marked. Excitement, drugs, or increased myocardial contractility from any cause decreases right ventricular volume and worsens

clinical signs. Right ventricular failure is usually not a consequence of the pressure overload because of equalization of the ventricular pressures.

Epidemiology

The prevalence of tetralogy and pentalogy of Fallot in large animals has not been documented, but these defects seem to be more common in calves than foals. There is no evidence that these disorders are inherited.

Necropsy Findings

Examination of the heart reveals a rounded apex caused by right ventricular enlargement. A high, usually large VSD; a dextroposed overriding aorta that straddles the VSD and the left and right ventricle; right ventricular hypertrophy; and septal hypertrophy are present. There is usually right ventricular infundibular narrowing and a hypoplastic pulmonary artery, although there may be valvular pulmonic stenosis with a poststenotic dilation. The right and left atria may be enlarged.

Treatment and Prognosis

There is no practical treatment for tetralogy and pentalogy of Fallot in large animals. When cyanosis or exercise intolerance is present or growth is stunted (the latter two are common findings in affected animals), the prognosis for long-term survival, production, or performance is poor. Affected foals should not be used for performance or broken to ride if they live long enough. As with many congenital cardiac diseases, the intensity of the murmur is not a good predictor of the severity of the condition, and further diagnostic tests are indicated.

OTHER CONGENITAL CARDIAC DEFECTS

Atrial Septal Defect. ASD is a connection between the left and right atria at the septal level. The most common type of defect is the ostium secundum defect, of which patent foramen ovale (PFO) is seen most frequently. PFO is relatively common in calves and is due to failure of the septum primum, the valve of the foramen ovale, to become adherent to the crista dividens after birth, when changes in left and right atrial pressures produce functional closure of the foramen ovale. PFO is frequently associated with PDA in calves.[54]

Animals with an ASD are frequently asymptomatic, but a holosystolic crescendo-decrescendo murmur may be heard at the left heart base. The shunt is usually left to right, and the murmur is the result of increased volume being ejected across the pulmonic valve. If the defect is large, right atrial, right ventricular, and left atrial dilation may be present. Differential diagnostic considerations are a functional murmur, pulmonic stenosis, VSD, or PDA. A definitive diagnosis can be made by 2D echocardiography, in which an enlarged right atrium, right ventricle, and left atrium are imaged. Pulsed-wave Doppler, color-flow, or contrast echocardiography can be used to demonstrate the shunt through the ASD.

Pulmonic Valve Stenosis. Pulmonic valve stenosis is rare as a single defect but has been reported in a foal with VSD and as one of multiple defects in calves and foals.[10,54,68] Clinical signs of cardiac murmur, cyanosis, and polycythemia are variable and depend largely on the other cardiac defects present. Characterization of the severity of the pulmonic stenosis and other associated cardiac defects can be performed with a complete echocardiographic examination.

Tricuspid Valve Atresia. Tricuspid valve atresia has been reported in foals[59,63–65] in conjunction with other cardiac defects. The abnormalities associated with tricuspid atresia include PFO, VSD, small right ventricle, large left ventricle, and large mitral valve orifice. The foals showed cyanosis and a crescendo-decrescendo or band-shaped holosystolic or pansystolic murmur audible over the left and right heart base. Tachycardia, tachypnea, and weak peripheral pulses also were present. Polycythemia was commonly reported. Echocardiographic diagnosis of tricuspid atresia in foals has been reported.[59,64] A thick echo in the region of the tricuspid valve that does not separate in diastole (absent tricuspid valve), an ASD (usually PFO), a VSD, a small right ventricle, a large left ventricle, and a large mitral valve orifice are the echocardiographic findings in tricuspid atresia. Blood flow (right to left) through the PFO into the left atrium and left ventricle, followed by simultaneous opacification of the aorta and right ventricle, is detected with contrast echocardiography. Affected foals rarely live past weanling age. Necropsy showed tricuspid atresia, along with ASD, VSD, small right ventricle, and large left ventricle. Pulmonic valve stenosis and dextropositioning of the aorta have also been reported.

Mitral Valve Dysplasia. Mitral valve dysplasia is a rarely reported early developmental anomaly in the horse.[10,66,84] Affected foals have a grade 3/6 to 5/6 holosystolic decrescendo or coarse-type murmur loudest in the mitral to aortic valve area. Echocardiographically in the foal with mitral valve dysplasia, the mitral valve leaflets appeared thickened, bright, and irregularly nodular with a cleft in the free wall leaflet and abnormal papillary muscle and chordae tendineae.[66] In the other foal, the parachute configuration of the mitral valve was readily imaged echocardiographically.[84] The foals died or were humanely euthanized due to their poor prognosis. Other congenital variations in the configuration of mitral valve leaflets, usually the free wall and accessory leaflets, occur more frequently in horses, usually compatible with a normal life expectancy. These horses usually a have mild MR with little or no progression over many years.

Ventricular Hypoplasia. Ventricular hypoplasia has been reported in foals and calves.[54,73] The defect may be present with other cardiac defects and is usually associated with early death. The defect was present in three closely related Holstein calves, suggesting possible genetic factors.[54]

Truncus or Pseudotruncus Arteriosus. *Persistent truncus arteriosus* refers to the condition in which one arterial vessel leaves the heart above a VSD. The coronary and pulmonary arteries and aorta arise from this vessel. Persistent truncus arteriosus has been diagnosed in foals and calves.[60] Subclassifications of this condition have been applied to humans, depending on the origin of the pulmonary trunk or arteries. Pseudotruncus arteriosus has also been described in foals and a calf and is characterized by the presence of a remnant of an atretic pulmonary trunk.[59,85] With pseudotruncus arteriosus, the pulmonary blood supply comes from bronchial arteries or a PDA. Clinical manifestations of these conditions include tachycardia, exercise intolerance, and a cardiac murmur. The murmur may be a continuous machinery murmur if a PDA is also present; holosystolic and crescendo-decrescendo, loudest at the left heart base; or the coarse murmur of the VSD may be auscultated, although the relative pulmonic stenosis component is absent. Cyanosis, dyspnea, or syncope may be seen with exercise or excitement. CHF and stunted growth may be present. Polycythemia was detected in a calf with a pseudotruncus arteriosus.[85] The presence of cyanosis with the cardiac murmur helps differentiate this condition from a simple VSD or PDA. Definitive diagnosis may be made by echocardiography, angiocardiography, or nuclear angiocardiography. These foals and calves have a guarded to grave prognosis. Their life expectancy depends on the magnitude of their pulmonary blood flow.

Aortic Anomalies. Dextropositioning or transposition of the aorta are the most common aortic anomalies of foals and calves and are seen most frequently with other defects. Other aortic anomalies of foals and calves are persistence of the right aortic arch and double aortic arch, which may cause esophageal compression. The clinical presentation is one of esophageal obstruction. Interruption of the aortic arch in two foals with VSD, ASD, and PDA has been reported.[70] The foals showed

VetBooks.ir

weakness, lethargy, cyanosis, and tachycardia. The murmur was pansystolic and plateau shaped, with the PMI on the right side of the thorax. Radiology showed cardiomegaly and increased vascularization of the lungs. Cardiac catheterization showed left ventricular failure.

Bicuspid and quadricuspid cusps of the aortic and pulmonic valves occur in large animals and usually result in both stenosis and valvular insufficiency. An aneurysm of the sinus of Valsalva was detected in a 3-year-old Thoroughbred gelding as an incidental finding.[86] Occasionally a diastolic murmur may be associated with AR in horses with sinus of Valsalva aneurysms.[87] These sinus of Valsalva aneurysms usually rupture later in life, and the horse develops acute distress, colic, and uniform VT. A continuous machinery murmur associated with the presence of an aorticocardiac fistula (ACF) is usually present on the right side of the thorax (see Vascular Disease).

Eisenmenger Complex. Eisenmenger complex has been described in a stunted 24-month-old Holstein heifer that had a loud, crescendo-decrescendo, pansystolic murmur heard best over the pulmonic valve.[62] The heifer had a prominent gallop rhythm from a loud fourth heart sound, exercise intolerance without cyanosis, and polycythemia. Cardiac catheterization showed increased pressures in the right atria, right ventricle, and pulmonary artery, with normal left-sided pressures. The echocardiogram was characterized by a VSD, overriding aorta, and dilation of the pulmonary trunk, a feature that distinguished this from tetralogy of Fallot. Left ventricular function was decreased, and at necropsy the heart was enlarged and rounded with a dilated pulmonary trunk and small aorta. The right ventricle was dilated and hypertrophied, whereas the left atria and ventricle were only mildly dilated.

Ectopia Cordis Cervicalis. Ectopia cordis cervicalis is a relatively common defect of cattle.[54,69] Although this defect usually results in the heart being in the cervical region, a few animals may have the heart in the pectoral region (14%) or abdomen (3%).[69] Various defects are associated with ectopia cordis cervicalis, including defects of the heart, great vessels, neck (torticollis), ribs, and sternebrae. The heart is usually contained within the pericardium under the muscles of the skin in the ventral cervical area, with the double apex of the heart pointing craniodorsally. The ligaments of the pericardium are most frequently attached to the mandibles and the parotid fascia cranially, the cervical fascia laterally, and the first rib or manubrium caudally. The lung may lack the cardiac notch and often protrudes to the base of the heart. Although the prognosis for a productive life is poor, some calves lived until about 1 year of age.

Miscellaneous Cardiac Defects. Other cardiac defects occur, but the defect has been recorded infrequently. Complete atrioventricular canal defect has been reported in several foals.[71,72,88] Anomalous coronary artery development has been reported at postmortem examination in both calves and horses and has been thought to be the cause of death in most cases.[89–91] Congenital hematomas of the atrioventricular valves also have been noted, but the significance is unknown.[54] Endocardial fibroelastosis, an anomalous development of the endocardium associated with left ventricular hypertrophy, is usually a severe defect resulting in death of the animal. The frequency of this defect in large animals is not established.

Valvular Heart Disease

Definition and Etiology

In adult animals, disorders of the tricuspid, pulmonic, mitral, or aortic valves are usually acquired, resulting in insufficiency of the affected valve. These disorders may be the result of degenerative changes, infection (bacterial or viral endocarditis or myocarditis), inflammation (valvulitis), trauma, myocardial disease (cardiomyopathy), or unknown causes. They are usually manifested by a cardiac murmur, most frequently of valvular regurgitation, with the PMI at the location of the affected valve or in the direction of the regurgitant blood flow. The mitral and aortic valves are the most common location of degenerative valve disease in horses.[92] Chronic active infection such as foot abscesses, rumenitis, reticular abscess, or other septic process may lead to sustained or recurrent bacteremia, predisposing the animal to the development of bacterial endocarditis, particularly in cattle, or a nonvegetative valvulitis, probably more common in horses. Experimentally, valvular vegetative endocarditis can be induced by intravenous (IV) administration of bacteria without preliminary damage to a valve.[93] Rupture of a valve leaflet or chordae tendineae can cause valvular heart disease, as can dilation of a cardiac chamber from any cause or rupture of the aortic root or of a sinus of Valsalva aneurysm.[87,94–96] In rare cases neoplasia, primarily lymphosarcoma of cattle, can cause valvular heart disease. Congenital valvular heart disease in adult animals is rare. The most common bacterial isolates from equine and bovine endocarditis cases are streptococci and *Pasturella* or *Actinobacillus* spp. and *Trueperella pyogenes* (formerly *Arcanobacterium [Actinomyces] pyogenes*) in horses and cattle, respectively, although a wide variety of organisms has been isolated from large animals with endocarditis.[97–105]

Clinical Signs and Differential Diagnosis

Most animals with valvular heart disease have no clinical signs, but a cardiac murmur is usually detected during a routine examination. Clinical signs vary depending on lesion severity and its rate of development. Murmurs of valvular heart disease are frequently holosystolic (Fig. 30.6), pansystolic, or holodiastolic (Fig. 30.7). They radiate from the PMI in the direction of the abnormal blood flow; are coarse and band-shaped, crescendo or musical or honking (if systolic), or decrescendo and blowing or musical or sound like a "dive bomber" (if diastolic); and are usually moderate to loud in intensity (≥grade 3/6) but may be softer if holodiastolic. All these characteristics help distinguish these murmurs from functional or innocent murmurs, which generally occur early or late in systole or diastole but can be holosystolic; are soft and blowing or crescendo-decrescendo in quality; are localized to a small area; do not radiate; and are soft to moderate in intensity (≤3/6). Murmur intensity is not a reliable indicator of lesion severity except in horses with tricuspid regurgitation (TR), in which

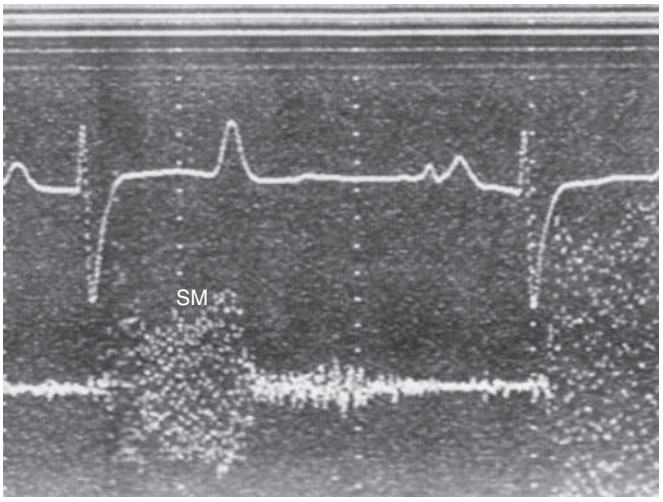

FIG. 30.6 Phonocardiogram obtained from a horse with a ruptured mitral valve chorda tendineae. A loud plateau-shaped holosystolic murmur *(SM)*, which is variable in intensity, occurs when the free wall leaflet of the mitral valve is prolapsing into the left atrium.

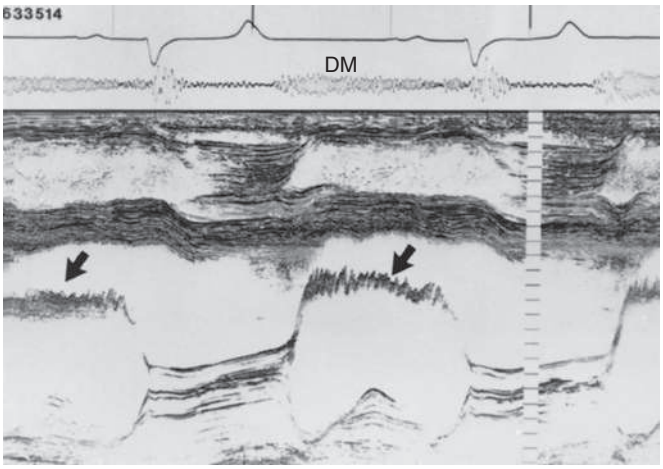

FIG. 30.7 Phonocardiogram and M-mode echocardiogram obtained from a horse with a holodiastolic murmur *(DM)* caused by aortic valve regurgitation. The M-mode echocardiogram shows diastolic flutter *(arrows)* of the septal mitral valve leaflet, characteristic of aortic valve insufficiency.

the longer, louder murmurs are associated with a larger jet of TR.[106] In cattle in particular, severely involved valves (usually in cattle with endocarditis) commonly have faint or no audible murmurs.

The location of the PMI of the murmur is helpful in distinguishing which valve is involved, although more than one valve can be affected in the same animal. The PMI for lesions of the mitral valve is often in the mitral valve area, although murmurs of MR usually radiate dorsally toward the left heart base and aortic valve area. Therefore loud systolic murmurs with the PMI in the aortic or mitral valve area in horses are usually MR murmurs. Disorders of the tricuspid valve commonly have the PMI on the right side of the thorax (third to fourth intercostal spaces [horses] or second to third intercostal spaces [cattle]). Rarely the murmur may also be heard on the left side of the thorax cranial to the pulmonic valve location in the second intercostal space. Aortic and pulmonic valve lesions produce murmurs with the PMI at the left heart base in the fourth or third intercostal space, respectively. Acquired valvular lesions of the mitral and tricuspid valves produce primarily systolic murmurs.[26,97,98,100,106–111] Diastolic tricuspid flow murmurs have been reported, however, and may be associated with right-sided mural or valvular masses in horses[80] or may be physiologic, associated with normal blood flow across the atrioventricular valves.[112,113] Lesions of the aortic and pulmonic valves may produce diastolic murmurs, systolic murmurs (rare), or both,[97,114–116] but diastolic murmurs of regurgitation are most common in large animals. AR associated with degenerative valve disease is most common in horses, whereas pulmonic regurgitation (PR) associated with bacterial endocarditis is more common in cattle. Aortic valve lesions in horses have primarily holodiastolic, decrescendo, musical murmurs (see Fig. 30.7) but can also be decrescendo, soft, and blowing. AR murmurs are accompanied by a water-hammer or bounding arterial pulse if the AR is associated with a significant left ventricular volume overload.[26,97,117,118] The musical quality of the murmur (harmonic) indicates that some part of the aortic valve is vibrating during diastole. The arterial pulse quality becomes more bounding as the AR becomes more severe and is a good clinical indicator of the degree of left ventricular volume overload. Ventricular premature beats and AF may also be detected in horses with significant AR.[118]

Besides the cardiac murmur, animals with valvular heart disease may have exercise intolerance, arrhythmias, weight loss, or signs of CHF evidenced by tachycardia, coughing, respiratory distress, jugular venous distention, subcutaneous edema, and ascites (uncommon in large animals, especially horses). In adult cattle, mammary vein distention is another sign of CHF.[98] Cardiac enlargement may be noted as an increased area of auscultation and/or percussion or caudal dislocation of the apical impulse of the heart. AF may be present. This development is usually an indicator of atrial enlargement in animals with valvular heart disease. If TR is present, there may be abnormal systolic jugular venous pulsations. If MR is present there may be tachycardia, tachypnea, poor recovery to resting respiratory rate after exercise, coughing, and frothy pulmonary edema (uncommon). Lung sounds may be harsh at rest and on deep inspiration may include crackles or moist bubbly sounds (both of the later auscultatory findings are rare). Most horses with pulmonary edema have only harsh breath sounds that are detected at rest and on deep inspiration.

One of the clinical signs of bacterial endocarditis is a cardiac murmur, the PMI and timing of which depend on the valve or valves affected. Other signs may include tachycardia, arrhythmias, auscultation of prominent heart sounds, tachypnea, coughing, recurring fever, anorexia, weight loss, or signs of CHF. Evidence of disseminated sepsis such as pneumonia, hematuria, or pyuria is usually present in cattle but not in horses. Shifting leg lameness and swollen joints or tendon sheaths are common but usually have an immune-mediated cause, although a horse with bacterial endocarditis and septic tenosynovitis has been reported.[101] Mastitis and decreased milk production are common in cattle. The presence of weight loss, fever, and signs of recurring sepsis help distinguish bacterial endocarditis from other forms of acquired valvular disease.

The clinical signs of a major mitral valve ruptured chordae tendineae (RCT) or its characteristic murmur distinguish this disease from other mitral valve diseases. The murmur is usually a widely radiating musical murmur of MR (see Fig. 30.6) with a distinctive honking quality (the honking quality is consistent with vibration of the mitral valve chorda tendineae or leaflet with blood flow in systole).[118] However, the honking quality may be absent and replaced by a band-shaped pansystolic murmur. There may be evidence of acute hemodynamic collapse. Acute onset of respiratory distress with coughing and expectorating foamy pulmonary edema fluid (this fluid is also detected at the external nares) is a relatively consistent feature with a major RCT. Signs of right-sided heart failure (jugular venous distention, subcutaneous edema, and ascites) may develop rapidly. Atrial arrhythmias, most frequently AF, often develop secondary to atrial enlargement. Supraventricular arrhythmias have also been reported in foals with a mitral RCT.[109] Acute onset of respiratory distress, along with a honking systolic murmur, distinguishes mitral RCT from other causes of MR. The honking systolic murmur of a mitral RCT can also be heard in the absence of any clinical signs in horses with a minor chordal rupture. The murmur of mitral valve prolapse (MVP) is also a distinctive murmur and should be suspected in horses whenever a crescendo midsystolic to late-systolic or holosystolic murmur is auscultated with the PMI over the mitral valve area.[26,118,119] A similar murmur is frequently auscultated in horses with tricuspid valve prolapse (TVP). Murmurs of MVP or TVP can be detected in horses with all degrees of valvular insufficiency. Most frequently, however, only small amounts of valvular regurgitation are associated with valvular prolapse. An increased prevalence of MR and TR has been reported in young horses in training.[120–123]

Clinical Pathology

Diagnosis of valvular disease is best performed with a complete echocardiographic examination including M-mode, 2D, and Doppler echocardiography. Two-dimensional echocardiography is superior to M-mode for detection of valvular abnormalities (Figs. 30.8 and 30.9), measurement of valvular

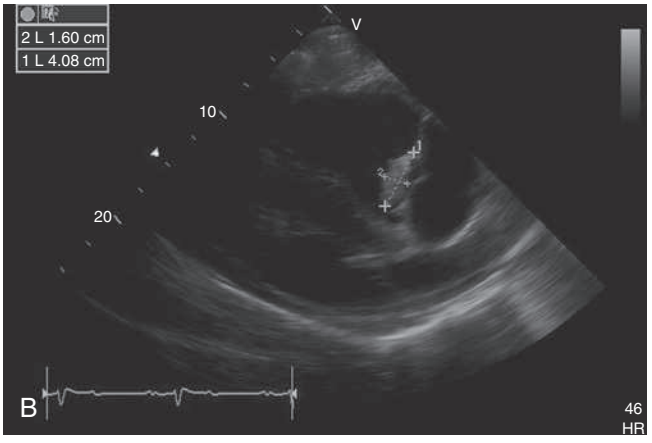

FIG. 30.9 Echocardiograms of a bacterial endocarditis lesion on the aortic valve of a horse. The lesion can be seen on the aortic valve M-mode **(A)** as a thick echoic band *(arrow)* and is measured in the two-dimensional echocardiographic image of the left parasternal long-axis view **(B).**

masses (see Fig. 30.9, *B*) (Video 30.3), and global assessment of ventricular function, but chamber enlargement, high-frequency vibrations of the valve leaflets (Video 30.4), and shortening fraction (an indication of ventricular systolic function) can be determined by both. Pulsed-wave, continuous-wave, and color-flow Doppler echocardiography can be used to semiquantitate the severity of valvular regurgitation and should

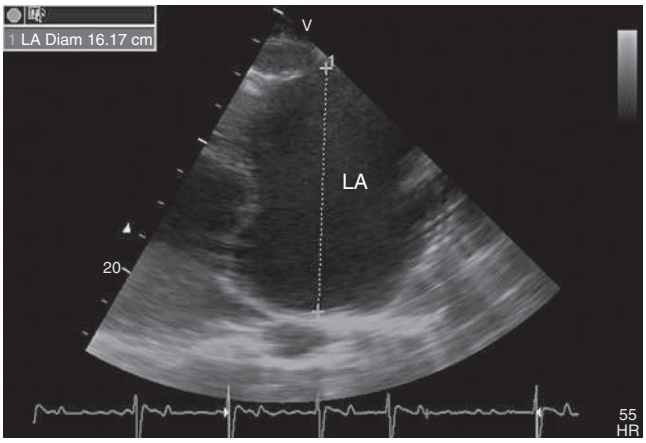

FIG. 30.10 Left parasternal echocardiographic image of the left atrium *(LA)* and mitral valve from a horse with left atrial enlargement (16.17 cm).

be performed from both sides of the thorax, interrogating the left atrium in multiple imaging planes.[10,119,124,125] The size of the regurgitant jet at its origin and the extent of the jet within the left atrium detected with pulsed-wave and/or color-flow echocardiography are two indicators of the severity of the valvular insufficiency.[26] Detection of proximal flow convergence indicates hemodynamically significant MR. The duration of the MR jet is also important in assessing severity. Clinically insignificant jets of regurgitation are detected only just behind the valve when it is closed. Valvular insufficiency is mild when the jet occupies one third or less of the receiving chamber, moderate when the jet occupies greater than one third but less than two thirds of the receiving chamber, and severe when the jet occupies greater than two thirds of the receiving chamber. The intensity and shape of the spectral Doppler tracing of the MR jet also provide information about its severity. Severe MR is associated with an intense triangular rather than parabolic signal that increases rapidly at the onset of systole.

Echocardiographic signs of MR are increased left atrial (Fig. 30.10; also see Fig. 30.3) and left ventricular dimensions, rounding of the left ventricular apex, and a pattern of left-sided volume overload. Left ventricular function may be normal (if MR is mild) or the FS may be increased (if there is a significant left ventricular volume overload associated with acute moderate to severe MR), unless there is concomitant myocardial disease. Normal or decreased contractility is present with chronic, severe MR. A round, turgid left atrium with bulging of the interatrial septum toward the right is another indication of hemodynamically severe MR. A larger-than-normal pulmonary artery (larger than the aortic root) is compatible with severe pulmonary hypertension and left-sided heart failure. A smaller-than-normal aortic root is detected echocardiographically in horses in low-output left-sided heart failure (Video 30.5).[10,26,109,110,119]

The cause of the valvular regurgitation can often be determined. Endocarditis, mitral RCT (see Fig. 30.8), a flail valve leaflet, valvular prolapse, or thickening of the valve leaflet are readily imaged echocardiographically.[110] The regurgitant jet detected with pulsed-wave or color-flow Doppler echocardiography usually originates from the site of the valvular abnormalities detected with 2D echocardiography. In some animals, the lesion responsible for the valvular insufficiency is not visualized with 2D echocardiography, but the regurgitant orifice is detected with pulsed-wave or color-flow Doppler echocardiography.[6,10,125] A mitral RCT is diagnosed by finding a mobile linear echo everting into the left atrium (see Fig. 30.8) or a flail leaflet that may prolapse into the left atrium during systole, systolic and chaotic diastolic mitral valve flutter,

rapid mitral valve opening with increased excursion of the affected leaflet, and lack of coaptation of the mitral valve in systole. The asynchronous movement of any portion of the valve leaflet during any phase of the cardiac cycle indicates the presence of a flail valve leaflet.[10,26,107,110]

TR may produce echocardiographic evidence of right atrial and right ventricular enlargement with paradoxical septal motion. Frequently the cause of tricuspid valve regurgitation in cattle is bacterial endocarditis, and the incompetent valve can be visualized. In cattle, neoplasia of the right atrium, tricuspid valve, or right ventricle can usually be visualized when present.[126] TR is common in horses with no obvious valvular lesion.[113,121,127] However, tricuspid valve bacterial endocarditis is detected in some horses with septic jugular vein thrombophlebitis.[128]

AR is diagnosed echocardiographically by observing left ventricular dilation, increased aortic root diameter (Fig. 30.11), increased left ventricular FS (if the AR is moderate to severe and left ventricular function is normal), diastolic fluttering of the septal mitral valve leaflet (see Fig. 30.7), or less frequently by observing high-frequency vibrations of the interventricular septum (Fig. 30.12) or aortic valve in diastole.[10,26,115,117,129] Rarely, premature closure of the mitral valve is detected. Thickening of the left cusp of the aortic valve is frequently detected echocardiographically, but prolapse, fenestration, healed endocarditis lesions, and tears of the aortic cusps also occur. A decrease in the aortic root diameter during diastole is an echocardiographic indicator of increased severity of the AR.

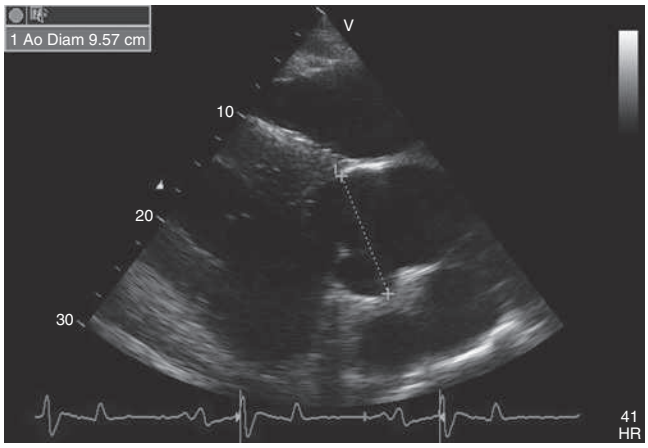

FIG. 30.11 Two-dimensional echocardiographic image of an enlarged aortic root (9.57 cm) obtained from an aged gelding with moderate aortic regurgitation that has been present for several years.

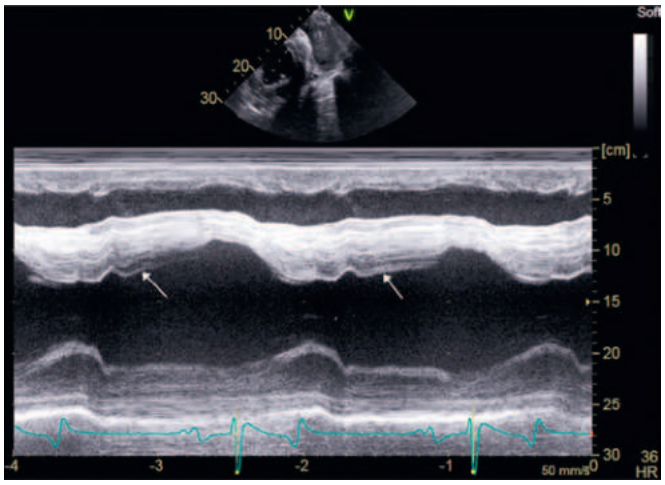

FIG. 30.12 M-mode echocardiogram obtained from a gelding with moderate chronic aortic regurgitation. Notice the high-frequency vibrations *(arrows)* on the interventricular septum.

Acquired pulmonic valve lesions are uncommon in large animals and when present are usually associated with bacterial endocarditis.[116,130] Diagnosis is established by finding the mass associated with the pulmonic valve. Severe PR associated with pulmonic valve rupture has been reported in one horse.[131] PR is most common in horses with pulmonary hypertension and CHF but is rarely detected clinically.

Lesions of bacterial endocarditis (see Fig. 30.9 and see Video 30.3) may have a shaggy, ragged, or cystic appearance on 2D echocardiography. These lesions are even better visualized with 4D echocardiography. Occasionally the only abnormality noticed is valve thickening, with ventricular hyperkinesis and enlargement of the chambers on the side of the affected valve. Acoustic reverberation and production of microbubbles have also been associated with valvular bacterial endocarditis.[109,112] Other laboratory evidence of bacterial endocarditis includes anemia, neutrophilia (a left shift may be present), an increased serum globulin concentration, increased serum amyloid A (SAA), and hyperfibrinogenemia. Liver enzymes are frequently mildly elevated, and a urinalysis sometimes shows hematuria or pyuria. Positive blood cultures taken during febrile episodes confirm the diagnosis when associated with these findings, but many times culture results are negative in large animals with bacterial endocarditis. Other laboratory evidence of disseminated sepsis includes neutrophilic response in peritoneal, tracheal wash, or joint fluid. Ventricular arrhythmias (VA) are frequently detected electrocardiographically in individuals with mitral or, more commonly, aortic valve endocarditis. Radiographic or sonographic evidence of disseminated pneumonia may also be found with bacterial endocarditis, usually in large animals with a right-sided lesion.

Other laboratory evidence of valvular heart disease is nonspecific. The ECG is valuable for documenting cardiac arrhythmias occurring secondary to chamber enlargement or the underlying myocardial disease. Radiographic findings of cardiac enlargement, increased pulmonary vascular pattern, or pulmonary edema are also nonspecific. Cardiac catheterization and pressure measurements help determine the degree of cardiac dysfunction. Nuclear angiocardiography shows cardiac enlargement or prolonged washout of contrast material. Time-activity curves can be helpful in accurately documenting ventricular dysfunction and the valvular regurgitant fraction.[50]

Pathophysiology

Acquired valvular heart disease that is slow in onset or gradually progressive may be asymptomatic at first, but cardiac changes occur that eventually may lead to CHF in some large animals. Valvular incompetence from endocarditis, degenerative changes, RCT, or other causes results in volume overload of the recipient chamber. Initially the output of the chamber is increased to maintain forward output, but the increased volume of the recipient chamber leads to compensatory dilation and a mild elevation in pressure. Compensatory hypertrophy may also result. In the later stages of valvular regurgitation, contractile function of the volume-overloaded chamber may diminish, leading to further elevation of pressure and decreased compliance. In the case of severe AR and MR, this causes elevation of left atrial pressure and eventually pulmonary venous hypertension. PAWP is higher at rest and during exercise in horses with moderate MR.[132] With severe TR, right atrial pressure or CVP increases. Increased myocardial oxygen consumption is a natural sequela, and biventricular failure can ensue.

If valvular heart disease is acute in onset, as with major RCT of the mitral valve, the regurgitation and volume overload are imposed on the left atrium, which cannot dilate and adapt acutely to the increased diastolic filling. The sudden

VetBooks.ir

hemodynamic change leads to pulmonary venous hypertension and acute pulmonary edema. However, most horses with MR do not have acute fulminant pulmonary edema. Instead, chronic pulmonary hypertension leading to subtle respiratory signs associated with interstitial pulmonary edema and the subsequent development of right-sided CHF are common in horses with severe MR.[110] In one study, 12 of 14 horses with CHF had jugular distentions or pulsations, 10 had abnormal lung sounds (crackles), and 9 had a cough.[133]

Bacterial endocarditis of the mitral or tricuspid valve may lead to RCT. Mitral RCT has been reported in adult horses and foals with bacterial endocarditis, leading to acute left-sided CHF.[109] In addition to the hemodynamic load placed on the heart from an incompetent valve, bacterial endocarditis also results in disseminated sepsis. The vegetations are made up of layers of fibrin, blood cells, necrotic tissue, and bacteria and are relatively resistant to short-term antimicrobial therapy. Disseminated sepsis may be the cause of death or the reason for culling of the animal. Myocardial necrosis of a papillary muscle was associated with mitral chordal rupture in one foal.[109]

Epidemiology

Acquired valvular heart disease is common in large animals, involving 356 of 1557 horses (22.9%) in one abattoir survey.[92] Endocarditis, one form of valvular heart disease, was reported in 4% of cattle in another study.[134] Bacterial endocarditis most commonly affects the tricuspid valve in cattle but has been reported on the pulmonic, mitral, and aortic valves as well.[98,111,115,116] Most cases of tricuspid valve bacterial endocarditis have been reported in horses with septic jugular vein thrombophlebitis.[97,100,135] Tricuspid valve endocarditis has also been reported in a horse with a VSD.[80] Aortic and mitral valve endocarditis are most common in horses, occurring with nearly equal frequency.[99,100] In the largest survey of acquired valvular heart disease in horses, the aortic valve was affected most commonly with degenerative valve changes, followed by the mitral valve, tricuspid valve, and (uncommonly) pulmonic valve.[92] Not all valvular lesions are associated with incompetency of the valve. Degenerative valvular changes, particularly changes involving the aortic valve, are seen more commonly in older horses.

Necropsy Findings

Acquired valvular disease is associated with finding nodular thickening, fibrous bands, valve fenestrations, rupture of mitral valve chordae tendineae, fibrinous masses typical of endocarditis, or combinations of these lesions on postmortem examination. There may be associated or secondary changes varying from enlargement of a chamber or vessel to degeneration, inflammation, and fibrosis. Enlargement (primarily dilation) of the chamber receiving the regurgitant flow, in addition to enlargement (primarily dilation) of the chamber or vessel from which the regurgitant flow arises, is commonly detected. Jet lesions, usually found in the receiving chamber, are associated with the high-velocity turbulent regurgitant blood flow.

Subcutaneous edema, congestion and mottling of the liver, and increased pericardial, pleural, or peritoneal fluid may be present and indicate CHF. Ascites associated with CHF is uncommon in large animals, particularly in horses. A primary source of chronic or active infection, along with evidence of bacterial embolization, may be seen in cattle with endocarditis but is rare in horses.

Treatment and Prognosis

Treatment and prognosis of acquired valvular heart disease depend on the cause, onset, duration, and severity of the lesion. In general, the prognosis is guarded to poor when evidence of valvular incompetence includes tachycardia, exercise intolerance, signs of CHF, or echocardiographic evidence of severe chamber enlargement. Degenerative valve disease may be asymptomatic except for a cardiac murmur, or it may be mild, but it generally is slowly progressive and therefore historically has been given a guarded prognosis. A more accurate prognosis for horses with murmurs can now be obtained from a complete echocardiographic examination, including Doppler echocardiography.[10,26,118] The valve affected, the lesions detected on the valve leaflets, the degree of chamber enlargement and volume overload detected, the echocardiographic assessment of myocardial function, and the severity of the regurgitation determined with Doppler echocardiography, coupled with the animal's age and intended use, can be used to formulate a prognosis.[10,26,118] Valvular regurgitation associated with no detectable abnormalities, valvular prolapse, and mild valvular thickening usually has a fair to good prognosis if the amount of valvular regurgitation is small.[10,26,118,136,137] Individuals with RCT, flail valve leaflets, and marked valvular thickening usually have moderate to severe regurgitation, which is likely to progress more rapidly and usually warrants a guarded to poor prognosis.[10,26,110,118,138] MR is the most likely valvular insufficiency to be associated with clinical signs of cardiovascular disease, whereas primary AR and TR infrequently result in the development of CHF or death of the animal, except in horses with severe AR. Bacterial endocarditis has a guarded to grave prognosis, even with long-term antibiotic therapy, and frequently results in sudden death of the animal, although bacteriologic cures are possible. When a bacteriologic cure occurs, severe scarring of the affected valve ensues. The severity of the valve damage depends on the size of the original endocarditis lesion. This scarring can lead to rapid progression of the regurgitation and, ultimately, result in the animal's demise.

Despite the guarded long-term prognosis, palliative therapy can be applied for most forms of acquired valvular heart disease. Bacterial endocarditis is treated with long-term administration (ideally intravenously) of bactericidal antimicrobials, the choice of which is based on blood culture and sensitivity results. Continuous IV infusion of antimicrobials is the ideal initial treatment when feasible. In cattle, initial therapy is directed at the likelihood of a gram-positive infection. Combination antibiotic therapy consisting of penicillin and an aminoglycoside is recommended for broad-spectrum coverage in a horse until the results of culture and sensitivity testing are available. Using rifampin at an oral (PO) dose of 5 mg/kg twice daily in combination with another antibiotic with appropriate spectrum has improved the short-term outlook for large animals with bacterial endocarditis. Clopidogrel (2 mg/kg/day PO) has largely replaced aspirin and subcutaneous SC low-dose heparin in the horse in patients with valvular endocarditis in an attempt to prevent platelet adhesion and increased size of the valvular mass. In ruminants however, aspirin (100 mg/kg/day PO) and subcutaneous (SC) low-dose sodium heparin (30 to 40 units/kg twice daily) continue to be used. Early diagnosis and aggressive treatment with the appropriate antimicrobials for a prolonged period are important for successful treatment of bacterial endocarditis. The long-term outcome for successfully treated cases is still poor because the scarring that results as the endocarditis lesion heals may lead to severe valvular regurgitation and death of the animal, particularly with left-sided bacterial endocarditis lesions.[26,100–102,139] Compliance and economics are also major drawbacks in treating endocarditis.

The hemodynamic consequences of valvular heart disease (volume overload or CHF) may be improved by using diuretics. Furosemide has been used most commonly at a dose of 1 mg/kg as needed. With the low bioavailability of PO furosemide, IV administration is preferred to obtain the maximal diuretic effect.[140] Digoxin can be used to improve contractility when CHF has occurred. Conditions such as AR or MR may

VetBooks.ir

BOX 30.1

Guidelines for Digoxin Therapy in Horses and Cattle

Horses

Priming dose IV: 4.4–7.5 µg/kg q12h for 2 doses (rarely used)
Maintenance dosage IV: 2.2 µg/kg q12h (most commonly used)–3.75 µg/kg q12h
Maintenance dosage PO: 11 µg/kg q12h (most commonly used)–17.5 µg/kg q12h

Cattle

Priming dose IV: 22 µg/kg
Maintenance dosage IV: infusion of 0.86 µg/kg/h, or give 11 µg/kg tid

IV, Intravenous; *PO*, by mouth; *tid*, three times daily.

show little or no long-term improvement, although many individuals improve for 2 to 6 months or more, before the CHF becomes refractory to treatment. Administration of a maintenance dose of digoxin at 2.2 µg/kg IV twice daily or 11 µg/kg PO twice daily has resulted in therapeutic plasma digoxin concentrations and clinical improvement in horses with CHF, with no significant adverse effects (Box 30.1).[141] Loading doses are rarely used because of problems with digoxin toxicity.[142] An IV loading dose of 12 to 14 µg/kg can be used in horses but must be divided into three administrations, followed by a maintenance dose of 6 to 7 µg/kg daily.[143] Digoxin is administered IV to cattle at a loading dose of 22 µg/kg followed by a maintenance dosage of 11 µg/kg three times daily or, preferably, at an infusion rate of 0.86 µg/kg/h.[144] Although the 11 µg/kg IV tid dosing may slightly increase the risk of digoxin toxicity, it is more practical than the q4h administration of 3.4 µg/kg IV.

Horses benefit from the use of vasodilators, as do other species. Clinical and echocardiographic improvement has been seen in horses with moderate MR or AR treated with the angiotensin-converting enzyme (ACE) inhibitor, benazepril at 1 mg/kg PO twice daily.[145] Benazepril at 0.5 mg/kg PO once daily was shown to be effective at inhibiting serum ACE activity in healthy horses compared with other ACE inhibitors.[146] Quinapril at 120 mg/horse/day increases stroke volume and cardiac output after 8 weeks of treatment in horses with MR.[147] Clinical and echocardiographic improvement has been seen in horses with CHF. Although enalapril appeared effective in horses with moderate to severe MR or AR and in horses with CHF, at a dose of 0.5 mg/kg PO twice daily, oral enalapril (single-dose or once-daily administration) did not significantly reduce ACE activity in normal horses and ponies.[148,149] Ramipril at 50 µg/kg daily PO was beneficial in treating one horse with CHF.[150] Clinical improvement has also been seen with hydralazine at 0.05 to 1.5 mg/kg PO twice daily. Although the short-term outlook may be improved with the use of these cardiovascular drugs, the prognosis is guarded for long-term survival or production.

Prevention and Control

Many causes of acquired valvular heart disease cannot be controlled. Appropriate therapy for chronic active infections and careful attention to asepsis with IV medication and other invasive procedures may help prevent endocarditis and possibly nonvegetative valvulitis. Effective parasite control measures may eliminate some predisposing causes of valvular heart disease, such as trauma to heart valves, microembolism, or infarction in horses.

Brisket Disease, Cor Pulmonale, and Pulmonary Hypertension

Definition and Etiology

Cor pulmonale is a term used to refer to the effect of lung dysfunction on the heart and is therefore a secondary form of heart disease. Regardless of the cause, the underlying feature is pulmonary hypertension that leads to right ventricular hypertrophy, dilation, or failure. The primary cause of cor pulmonale in cattle is high-mountain disease (HMD), also called *high-altitude disease* or *brisket disease*, which leads to hypoxic vasoconstriction from high-altitude dwelling. Some cattle are resistant to developing cor pulmonale when grazed at high altitudes, but others are genetically much more susceptible.[151,152] Pneumonia, lungworm, and prolonged exposure to cold temperatures contribute to the development of HMD. The disease is worsened by ingestion of locoweed (*Oxytropis* and *Astragalus* spp.).[153,154] Chronic pulmonary disease such as bronchopneumonia or lungworm infection in cattle can also result in cor pulmonale.[155] In the horse, right-sided heart dysfunction (e.g., decreased cardiac output, increased right ventricular end-diastolic pressure, increased right atrial pressure or CVP, jugular venous distention, or subcutaneous edema) associated with chronic pulmonary disease is rare but may be more common than previously recognized. However, right-sided heart dysfunction associated with pulmonary hypertension and left-sided heart dysfunction is a common cause of CHF.

Clinical Signs and Differential Diagnosis

Frequently the primary presenting clinical sign of brisket disease is subcutaneous edema of the brisket, ventral thorax, submandibular area, and occasionally the limbs. Lethargy, weakness, bulging eyes, diarrhea, collapse, and death occur.[151] Jugular venous distention or pulsations may be present. Dyspnea and tachypnea are frequent. Tachycardia is present, and a gallop rhythm may be auscultated. Splitting of the second heart sound (S_2) is a variable finding. Pulmonary hypertension may accentuate the separation of the aortic and pulmonic valve closures, producing audible splitting of S_2 that is most noticeable during inspiration. In some horses with moderate or severe equine asthma (also known as recurrent airway obstruction [RAO]) and increased vascular impedance, pulmonic valve closure occurs early and only a single S_2 is audible.[156]

A cardiac murmur may be auscultated, caused either by TR or a pulmonic valve ejection murmur. The murmur of TR, which is secondary to right ventricular dilation, is regurgitant or plateau shaped, with the PMI over the right thorax or, less frequently, the left second intercostal space. The pulmonic valve ejection murmur, found less commonly, is audible as a crescendo-decrescendo murmur at the left heart base.[6] Pleural or pericardial effusion is not common with cor pulmonale.[157] In horses with RAO leading to cor pulmonale, tachypnea, labored breathing, coughing, and exercise intolerance are common complaints. Wheezes are usually auscultated bilaterally in the thorax of affected horses.

These clinical signs are not specific for brisket disease (cor pulmonale) and largely reflect right-sided heart failure. Other considerations when signs of right-sided heart failure are present should be bacterial endocarditis or TR from any cause, cardiomyopathy, cardiac lymphosarcoma or other thoracic neoplasms, traumatic reticulopericarditis or other causes of pericarditis, left-sided heart failure, pleuritis or pleural effusion, and congenital pulmonic valve stenosis (rare). With pericarditis, heart sounds may be muffled, or the characteristic "washing machine murmur/rub" may be audible. Left-sided heart failure is frequently accompanied by pleural effusion, pulmonary edema, and weak peripheral pulses. In horses, however, expectoration of pulmonary edema fluid occurs only with sudden onset of

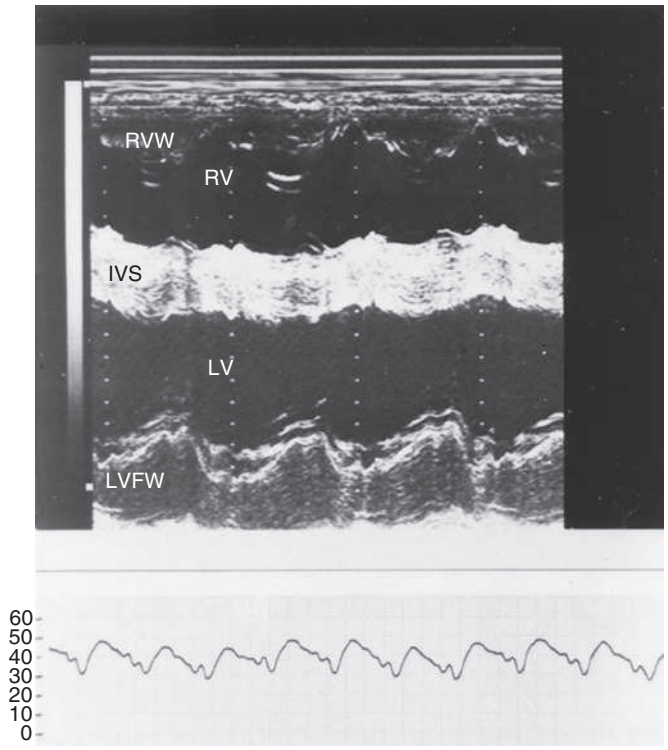

FIG. 30.13 M-mode echocardiogram and pulmonary artery pressure (PAP) curve obtained from a cow with pulmonary hypertension and cor pulmonale. The echocardiogram shows mild thickening of the right ventricular wall *(RVW)* and interventricular septum *(IVS)*, dilation of the right ventricle *(RV)*, and abnormal septal motion. *LV,* Left ventricle; *LVFW,* left ventricular free wall. The PAP curve demonstrates elevated systolic and diastolic pressures. (PAP curve in millimeters of mercury [mm Hg].)

severe left-sided heart failure. In horses with chronic left-sided heart failure, tachypnea, coughing, poor recovery after exercise, and harsh lung sounds may be all that is detected.

Clinical Pathology

A complete blood cell count (CBC) may reveal a neutrophilia in cases of cor pulmonale caused by primary lung disease. Radiography of the thorax reveals primary pulmonary disease such as bronchopneumonia, bronchiectasis, or chronic bronchitis in cattle that have developed this disease at low altitudes. Radiographic findings in horses with RAO usually reveal an interstitial pattern. Arterial blood gases demonstrate the presence of hypoxia and may also show hypercapnia. Transtracheal wash fluid cytology and bacterial culture may provide evidence of the cause of the primary lung disease. Fecal sedimentation helps rule out parasitic bronchitis or pneumonia. Electrocardiographic findings are not specific. An echocardiogram may provide further evidence of pulmonary hypertension and right-sided heart dysfunction by showing right ventricular hypertrophy and dilation, increased septal thickness, and abnormal septal motion (Fig. 30.13).[158,159] Dilation of the pulmonary artery is also detected with 2D echocardiography and is a sensitive indicator of pulmonary hypertension or increased flow through the pulmonary artery. A dilated pulmonary artery has been reported in horses with cor pulmonale and in horses with acute pulmonary obstruction from RAO.[159,160] Cardiac catheterization reveals elevated pressure in the pulmonary artery, right ventricle, and right atrium. Elevation of right ventricular end-diastolic pressure is a sign of right ventricular failure.

Pathophysiology

Pulmonary arteriolar constriction is the response to hypoxia from high-altitude dwelling or pulmonary disease. The response to hypoxia varies depending on the amount of smooth muscle in the pulmonary arteries. In cattle, increased pulmonary vascular resistance and pulmonary hypertension frequently develop. Chronic pulmonary artery hypertension causes a pressure overload on the right ventricle, which responds to the increased workload with hypertrophy, dilation, or failure, depending on the speed with which the condition develops. The disease is progressive, and at some stage the right ventricular myocardium is unable to compensate, dilates, and fails. With failure come the typical signs of jugular venous distention and development of subcutaneous edema. Chronic right-sided heart failure may result in diastolic dysfunction of the left ventricle.

Epidemiology

The disease is more common in cattle than in other animal species, especially when cattle are kept at altitudes over 6000 feet, where the incidence has been estimated at 0.5% to 5% in cattle native to high altitude.[151,152] In cattle adapted to low altitude and moved to higher altitude for grazing, however, the incidence is much higher.[151,152,161] Mainly calves and yearlings are affected. A genetic predisposition to develop pulmonary arterial constriction when subjected to hypoxia at high altitude is present in many breeds. Some breeds and pedigrees within breeds are more resistant than others to the effects of high altitude, and the inheritance appears to be complex.[151,152] More cases of HMD are detected in the fall and winter and are due to cold weather exacerbating pulmonary hypertension.[152] Ingestion of swainsonine contained in locoweed (*Oxytropis* and *Astragalus* spp.) also predisposes cattle to right-sided heart failure at high altitudes by causing toxic myocardial damage.[153] Pulmonary hypertension has also been detected in cattle fed ionophores at high altitude.[151]

Necropsy Findings

There is evidence of right-sided heart failure (e.g., subcutaneous edema) in the submandibular area, brisket, and ventral abdomen. Findings include dilation and hypertrophy of the right ventricle, congestion of the liver, and ascites. Perirenal edema, mesenteric edema, and pleural effusion are often present. The lung may have evidence of concurrent pneumonia, bronchitis, bronchiectasis, or emphysema. Lesions of locoweed toxicity may be found in other organs in cattle.[153] Lesions of chronic interstitial pulmonary disease are found in horses with equine asthma.

Treatment and Prognosis

Removing the animal from high altitude, treating the primary lung disease, and administering oxygen may help eliminate the hypoxia and thus the pulmonary hypertension. Cor pulmonale from high altitude is potentially reversible when the animal is returned to a lower altitude. However, cattle with other lung disease and a mean PAP of 50 to 55 mm Hg rarely have their mean PAP return to an acceptable level for high-altitude living.[151] The heart failure can be treated with digoxin and diuretics. Beneficial effects of vasodilator therapy have not been documented. Once heart failure signs have developed, the prognosis is guarded even with appropriate treatment. Removing the horse from the environment inducing equine asthma is critical to treating the cor pulmonale. A more detailed discussion of the treatment and management of horses with equine asthma can be found in Chapter 31.

Prevention and Control

Selection of breeding stock with low or normal PAPs at altitudes above 5000 feet (mean PAP <35 mm Hg) helps eliminate the predisposing genetic susceptibility to the effects of hypoxia of high altitude.[151,152,161] Recently, more specific guidelines have been formulated for the selection of cattle to be kept at high altitudes.[151] Cattle older than 12 months of age with a mean

VetBooks.ir

PAP of less than 41 mm Hg at over 5000 feet elevation are good to select for breeding stock for high altitudes and should have a low risk of HMD. Cattle with a mean PAP of 49 or higher at any elevation are at high risk for developing HMD and should not be selected as high-altitude breeding stock.[151] Cattle with a mean PAP in between these two guidelines are at risk and should be used with caution at high altitudes.[151] The disease can also be controlled by removing susceptible animals from high altitude and preventing locoweed ingestion. Herd health practices such as avoiding crowding and poor ventilation and using appropriate vaccinations to reduce the incidence of pulmonary disease help reduce the incidence of other causes of cor pulmonale.

Myocardial Disease: Myocarditis and Cardiomyopathy

Definition and Etiology

Myocarditis is inflammation of the myocardium caused by bacterial, viral, or parasitic organisms or thromboembolic disease caused by these organisms. In large animals, recognized bacterial causes include *Staphylococcus aureus*, *Streptococcus equi*, *Clostridium chauvoei*, and *Mycobacterium* spp. Myocarditis can also occur after bacteremia, septicemia, pericarditis, or endocarditis, regardless of the causative agent. Known viral causes of myocarditis include foot-and-mouth disease, equine infectious anemia, equine viral arteritis, equine influenza, and African horse sickness. Parasitic causes of myocarditis may include strongylosis[162] or onchocerciasis in horses and toxoplasmosis, cysticercosis, or sarcocystic infection in ruminants.[163,164] Currently it is thought that infection with the spirochete *Borrelia burgdorferi* may be a cause of myocarditis in domestic animals, as it is in human beings.[165] Cardiomyopathy is a subacute or chronic disease of the ventricular myocardium that occurs without anatomic valvular disease, congenital malformations of the heart or vessels, or pulmonary disease. In large animals, dilated cardiomyopathy is the most common cardiomyopathy. However, hypertensive cardiomyopathy occurs in horses associated with chronic renal disease, pain associated with chronic laminitis, and to some extent in ponies with equine metabolic syndrome (EMS) where left ventricular hypertrophy has been detected.[166] Dilated cardiomyopathy is associated with ventricular dilation, increased ventricular mass, and decreased systolic function. Although the cause is frequently undetermined,[126,167,168] several conditions have been related to or identified with cardiomyopathy. An inherited cardiomyopathy thought to be linked to the red Holstein gene has been found in Holstein-Friesian cattle in Canada, Australia, the Netherlands, and Switzerland.[169–171] There is also a cardiomyopathy associated with a curly hair coat in polled Herefords and in Japanese black calves.[172–173] Cardiomyopathy has been associated with ingestion of monensin, lasalocid, salinomycin, gossypol, *Cassia occidentalis*, and *Phalaris* spp. Vitamin E and selenium deficiency, copper deficiency, excessive molybdenum, or high sulfates (secondary copper deficiency) may cause cardiomyopathy.[174–184] Consumption of plants in the Acer family and several other plants cause myocardial injury, myocarditis and cardiomyopathy.[185,186] Myocardial infiltration by neoplasia, such as lymphosarcoma or fibrosarcoma, also may cause cardiomyopathy. A fibrofatty infiltration of the right ventricle and interventricular septum similar to arrhythmogenic right ventricular dysplasia occurs in horses.[187–189] Envenomation associated with rattlesnake bite can result in myocardial necrosis and secondary cardiomyopathy.[190–192] The most common cause of cardiomyopathy in horses is probably myocarditis, although the inciting insult is usually difficult to identify.

Clinical Signs and Differential Diagnosis

The manifestations of myocarditis are highly variable depending on the extent of the disease, location of the inflammation within the myocardium, and associated systemic illness. Myocarditis can easily be missed because of the lack of specific cardiac signs or the predominance of signs related to the organ system with primary involvement (e.g., strangles in horses or mastitis in cattle). Animals suspected of having myocarditis are often febrile or have a recent history of fever and may have tachycardia. The elevated heart rate may be sinus tachycardia or other paroxysmal or sustained supraventricular or VA because cardiac arrhythmias are common. Premature beats are also often detected in large animals with suspected myocarditis and may be present in animals with a normal or increased heart rate. Occasionally, acute myocarditis is associated with auscultation of a pronounced gallop rhythm or a cardiac murmur of TR or MR. Jugular venous distention, other signs of CHF such as peripheral edema, and signs of circulatory collapse may be present. Horses may show evidence of myalgia, reluctance to move, or exercise intolerance. With these signs it may be difficult to distinguish myocarditis from colic, respiratory disease, lameness, or septicemia. If signs are more clearly cardiac (e.g., murmur, arrhythmia, jugular venous pulsations), the practitioner should rule out endocarditis, cardiomyopathy, cardiac neoplasia, and CHF from another cause.

The clinical signs associated with dilated cardiomyopathy can also be variable but are usually more clearly associated with heart disease. Most animals have signs of cardiac failure, such as peripheral edema and jugular venous distention or pulsations (Fig. 30.14). Auscultation frequently reveals tachycardia, gallop rhythm, muffled heart sounds, or a cardiac arrhythmia. Cardiac murmurs of TR or MR are usually present secondary to the ventricular dilation. Breath sounds are increased, tachypnea is present, and percussion of the thorax frequently reveals signs of pleural or pericardial fluid. Occasionally, respiratory distress is evident with hyperpnea, dyspnea, coughing, and presence of a bloody froth at the nostril. Nonspecific signs of cardiomyopathy, such as exercise intolerance, syncope, diarrhea, or anorexia,

FIG. 30.14 Holstein cow with cardiomyopathy showing signs of congestive heart failure (submandibular and brisket edema, jugular venous distention, and pulsations).

VetBooks.ir

may also be present. In cattle, decreased milk production and abomasal displacement have been associated with dilated cardiomyopathy.[169] Palpable liver enlargement has also been reported in cattle with cardiomyopathy.[170] Most affected cows develop clinical signs within 3 months of calving.[170]

The clinical signs of hypertrophic cardiomyopathy in horses are usually primarily referable to the underlying disease. Tachycardia is common but is also expected in many horses with chronic laminitis and renal failure. Both of these diseases in their chronic stages coupled with tachycardia should prompt obtaining a blood pressure measurement to determine if echocardiographic evaluation is indicated.

Sudden death can be a feature of myocarditis and dilated or hypertensive cardiomyopathy, and it frequently follows stress or exercise. Recumbency, collapse, and sudden death are common presenting signs in animals with ionophore toxicosis, envenomation, and consumption of large amounts of the seeds containing hypoglycin A from predominately trees of the *Acer* species.[174–180,182,184,185,190,191] In many animals with inherited cardiomyopathy, death occurs within 6 months of age.[171–173] In Holstein-Friesian cattle with suspected inherited cardiomyopathy, heart failure and death may not occur until cattle are 2 to 4 years old.[169,170] Other acquired causes of cardiomyopathy can occur at any age.

When animals show clinical signs of dilated cardiomyopathy, many differential diagnoses should be considered. If the animal is young, other congenital heart defects, cor pulmonale, and nutritional myodegeneration should be considered. In adults, bacterial endocarditis, cardiac neoplasia, thoracic abscess, pericarditis, pleuritis, and diaphragmatic hernia may also have similar clinical manifestations. Although the cause of dilated cardiomyopathy may be difficult to determine, nutritional (vitamin E, selenium, or copper deficiency); toxic (monensin, gossypol, salinomycin, lasalocid, hypoglycin A, *Cassia* spp., or *Phalaris*); infectious (viral, bacterial, or parasitic); or drug-induced causes should be investigated.

Clinical Pathology

Depending on the cause of the myocardial disease, the clinicopathologic findings may vary. Routine CBC may be normal, or a neutrophilic leukocytosis may be present. No consistent changes are expected in the serum chemistry profile, but serum albumin concentration may be slightly decreased, and serum urea nitrogen, creatinine, γ-glutamyltranspeptidase (GGT), sorbitol dehydrogenase (SDH), and bilirubin concentrations may be increased because of congestive liver disease when signs of CHF are present. Serum concentrations of creatine kinase (CK) and lactic dehydrogenase (LDH) may be elevated, but hepatic and skeletal muscle contribution to these elevations cannot be ruled out. Large elevations of the myocardial isoenzymes of CK (myocardial bound [MB]) and LDH (LDH_1) were detected in one outbreak of monensin toxicosis[177] and have been detected in other horses with myocardial necrosis of unknown etiology. A better indication of myocardial disease may be the elevation of cardiac troponin I (cTnI), which has been detected in horses with acute gastrointestinal (GI) disease, as well as in many types of myocardial diseases.[185,193,194] Marked elevations of cTnI have been reported in a horse with multiform VT and myocardial necrosis of unknown cause,[195] as well as in a horse with VT and aortic septal rupture.[196] Elevations of cTnI were detected in horses following exposure to lethal and sublethal concentrations of monensin and lasalosid.[183,184,197] Analysis of pericardial or pleural fluid reveals a transudate with low protein concentration (<2.5 g/dL) and cellularity (white blood cell [WBC] count < 2500/μL), with the predominant cell type being mononuclear cells unless the myocarditis is an extension of pericarditis. Serum should be tested for serologic evidence of bovine leukosis (BLV) infection in adult cattle, α-tocopherol, glutathione peroxidase, and copper concentrations. Whole blood selenium levels should be determined. In infectious myocarditis or inherited cardiomyopathy, results of these tests will most likely be normal. A negative BLV test result essentially eliminates lymphosarcoma as a cause of the myocardial disease; a positive test result does not confirm a causal relationship. In horses, serum should be tested for serologic evidence of a variety of equine viruses, particularly influenza, equine viral arteritis, and herpesvirus. Hemoglobinuria, if present, suggests consideration of monensin, gossypol, or nutritional myodegeneration as the cause of myocardial disease. Arterial blood oxygen tension may be reduced below 80 mm Hg in animals with myocardial disease.

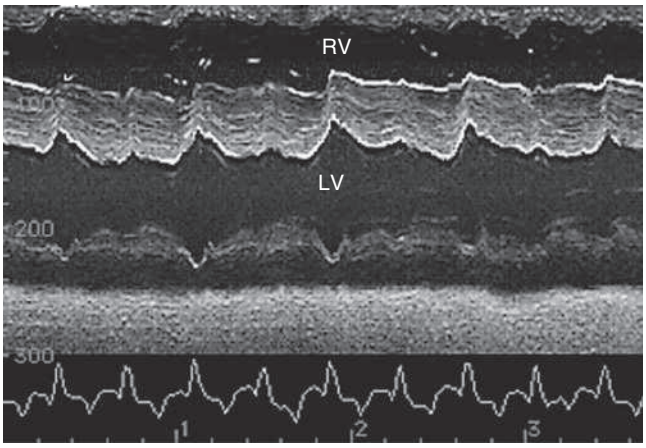

FIG. 30.15 M-mode echocardiogram of the left ventricle *(LV)* obtained from a mare with sustained uniform ventricular tachycardia. Note the small end-diastolic and end-systolic dimensions of the left ventricle and the little variation between systole and diastole in this dimension. *RV,* Right ventricle.

An ECG may demonstrate sinus tachycardia or other cardiac arrhythmias; the frequency and severity of these arrhythmias are best demonstrated with continuous ECG monitoring. There may be some evidence of conduction abnormalities in the base-apex lead, but these findings are not specific for myocardial disease. Echocardiography may be normal in animals with myocarditis, or the abnormalities detected may be caused by the arrhythmias present. A small left ventricular internal diameter, thickened left ventricular free wall and interventricular septum, small aortic root diameter, and decreased FS may be detected in animals with sustained VT and decreased cardiac output (Fig. 30.15). A small left ventricular internal diameter, thickened left ventricular free wall, interventricular septum, and right ventricular free wall with an increased relative and mean wall thickness and left ventricular mass is present echocardiographically in horses with hypertensive cardiomyopathy.[166] More frequently, however, there is increased ventricular chamber size, decreased thickness of the interventricular septum and left ventricular free wall, and decreased myocardial function (decreased FS, decreased EF, and myocardial dyskinesis), especially in more severe cases of myocarditis and in animals with dilated cardiomyopathy (Fig. 30.16 and Video 30.6). In humans with myocarditis there may be evidence of abnormal left ventricular wall motion, paradoxical motion of the interventricular septum, or an echo-free pericardial space.[174] Additional echocardiographic features of dilated cardiomyopathy are increased end-systolic and end-diastolic dimensions of the left and right ventricles (see Fig. 30.16), increased left atrial size, and an increased left atrial–to–aortic root dimension ratio. There may be abnormal mitral valve closure (increased EF slope) and increased separation of the septal mitral valve leaflet and interventricular septum. A decreased aortic root diameter may be detected along with a shortened ET in animals with low-output, left-sided heart failure. An enlarged pulmonary artery indicative of pulmonary hypertension (Fig. 30.17) may also be present.

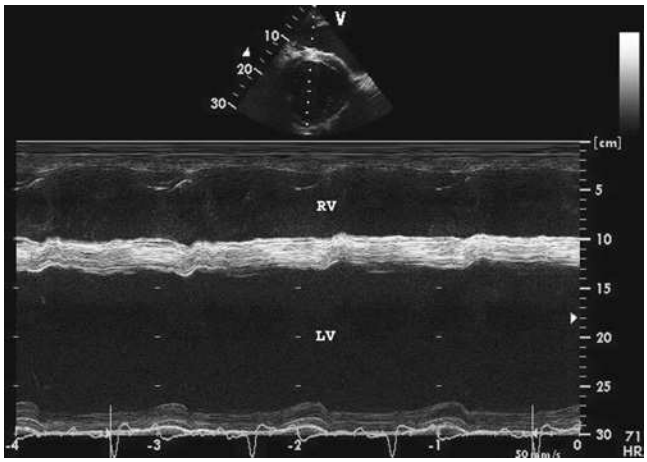

FIG. 30.16 M-mode echocardiogram of the left ventricle obtained from a mare with cardiomyopathy and severe left ventricular dysfunction. Note the large end-diastolic dimension of her left ventricle *(LV)*, the thin interventricular septum and left ventricular free wall, and the poor left ventricular contractility. The fractional shortening in this mare varied from 2% to 8%. *RV,* Right ventricle.

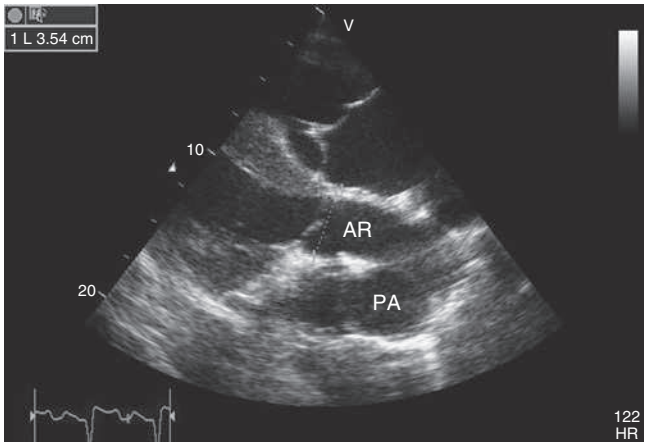

FIG. 30.17 Two-dimensional echocardiogram of the aorta *(AR)* and main pulmonary artery *(PA)* obtained from a foal with cardiomyopathy and severe mitral and TR. The pulmonary artery is larger than the aorta, indicative of pulmonary hypertension and impending left-sided CHF. The aorta measured 3.54 cm at its origin.

Cardiac catheterization may reveal elevated intracardiac pressures (right atrial, right ventricular, pulmonary artery, pulmonary capillary wedge, and left ventricular end-diastolic) in animals with dilated cardiomyopathy. Horses with acute infectious myocarditis may show hypotension and a narrow pulse pressure. Nuclear angiocardiography may be used to show decreased EF[50] in animals with myocardial disease.

Pathophysiology

The pathophysiologic changes associated with myocardial disease depend on the specific nature and extent of the disease. Acute myocarditis or angiopathic myocardial lesions[162] may go on to develop into idiopathic dilated cardiomyopathy. It is speculated that changes in cellular metabolism occur with either acute myocarditis or dilated cardiomyopathy, resulting in ECG abnormalities and reduced myocardial performance (reduced cardiac output). In an attempt to compensate for reduced cardiac output, circulating fluid volume is increased by activation of the renin-angiotensin-aldosterone system and arterial resistance is increased. These compensatory mechanisms frequently lead to only minor improvement in the cardiac output of the failing heart, and the increase in ventricular preload (venous return) and afterload (arterial resistance) may cause pulmonary edema and a further reduction in cardiac contractility. Ventricular dilation, further reduction in cardiac output, and signs of heart failure occur.

Epidemiology

The prevalence of acute myocarditis is difficult to estimate because frequently the disease goes undiagnosed, is mild or masked by disease in another organ system, or the animal recovers spontaneously. Similarly, it is difficult to assess the clinical significance of postmortem findings of myocardial inflammation and fibrosis. The morbidity of myocarditis in large animals is probably underestimated because it is rarely the cause of mortality and is associated with viral, bacterial, and parasitic infections that manifest without specific signs of cardiovascular disease.

Inherited cardiomyopathy has been reported in cattle in Japan, Australia, the Netherlands, Canada, and Switzerland, with the incidence in inbred populations reaching 3% to 5%.[170,171] A familial form of dilated cardiomyopathy has also been reported in cattle in Sweden, Denmark, Australia, and the United Kingdom.[170] These cattle may be genetically linked by the presence of the red gene in Holstein-Friesian cattle.[169] Although in some cattle, inherited cardiomyopathy resulted in death by 6 months of age,[171,173] other cattle failed to show clinical signs until 2 to 6 years of age.[126,168,170,172] No sex predilection is recognized in inherited cardiomyopathy of cattle.

The morbidity and mortality from cardiomyopathy stemming from other causes in cattle and horses is not known. From the number of clinical reports, inherited cardiomyopathy seems to be more prevalent in cattle than in horses. Idiopathic dilated cardiomyopathy or cardiomyopathy secondary to viral or bacterial infections may be more common in horses and is a cause for the acute onset of CHF in horses of racing age.

Necropsy Findings

There may be no gross lesions associated with myocarditis. Depending on the relationship between death and the occurrence of myocarditis, microscopic examination of the myocardium may show increased fibrous tissue in the interstitium in the absence of inflammation, or there may be foci of inflammatory cells (typically mononuclear cells), variation in the cross-sectional area of the cardiac myocytes, degeneration of adjacent myocardial fibers, myocardial necrosis, and fibrosis. Replacement of the myocardium by fibroadipose tissue has been reported in horses that experienced unexpected sudden death and were thought to have arrhythmogenic right ventricular cardiomyopathy at postmortem examination.[187–189] Focal interstitial nephritis and fibrosis were reported in eight of nine Holstein-Friesian cattle with dilated cardiomyopathy in Scotland.[170] Often the inciting cause of myocardial necrosis in horses is unknown.[195] Samples of gastric or ruminal contents should be obtained and submitted for analysis of ionophores if ionophore toxicosis is suspected. Feed samples should also be obtained and submitted for ionophore analysis in these cases. Submitting the heart muscle itself for ionophore analysis is the best tissue for identifying toxicosis and is superior to gastric contents.[198]

On gross examination, the lesions of cardiomyopathy are recognized more easily as enlargement of the heart, which may be rounded to globose. Biatrial, biventricular, and pulmonary artery dilation are usually present. Patchy or uniform streaks of myocardial pallor may be detected. In rare cases, one of the chambers or major vessels (usually pulmonary artery) may rupture. Generalized edema is frequently found as ascites (uncommon in horses), pericardial or pleural effusion, and edema of the mesentery and subcutaneous tissues. There may be evidence of vascular congestion of the liver, lungs, and

spleen. The kidneys may be pale and swollen and have an irregular, granular, pitted surface.

Microscopically the lesions of cardiomyopathy are characterized as myocardial vacuolation and degeneration with necrosis and fibrosis. Calcification may be associated with these lesions. Occasionally there is increased vascularization with proliferative regeneration of myofibers. Loss of cardiac myocytes and replacement by fibro-fatty tissue occurs in horses with arrhythmogenic right ventricular cardiomyopathy.[187–189] In some cases of cardiomyopathy, no histopathologic abnormalities are found.

Treatment and Prognosis

Treatment of myocarditis includes treating the underlying causative agent if it is recognized and controlling complications such as arrhythmias, CHF, or shock. Thromboembolism is rarely a complication recognized in animals. Prompt administration of vitamin E may be beneficial to the survivors in cases of ionophore toxicosis. Performance animals should be rested. Corticosteroids may be beneficial in animals with severe toxemia, complicated arrhythmias, or intractable heart failure, but their use in early cases of myocarditis or in infections suspected of having a viral cause is controversial because viral recrudescence may occur. However, in many cases corticosteroids appear to have a beneficial effect. Prognosis is good if there are no signs of heart failure and if cardiac arrhythmias are managed successfully. Prognosis is guarded to poor if signs of CHF are present.

Therapeutic strategies currently used for treatment of dilated cardiomyopathy include positive inotropic agents (digoxin), diuretics, vasodilators, rest, and in some cases removal of pleural or abdominal fluid. The advantages of vasodilators (venodilators to relieve pulmonary edema and arterial dilators to reduce preload and afterload and improve contractility) in the treatment of cardiomyopathy are recognized in humans and small animals.[199]

Digoxin is the positive inotropic agent used almost exclusively in large animals but is contraindicated in animals with acute monensin toxicosis. A priming or loading dose can be used in horses with acute severe CHF, followed by a maintenance dose, or more frequently, the horse is started on a maintenance dose from the onset of therapy. In horses, the drug can be administered PO or parenterally. In cattle, low bioavailability limits its use to the IV route of administration.[177] Guidelines for the use of digoxin are given in Box 30.1.[141,200,201] In general, maintenance dosages are used because of the lowered risk of adverse reactions. A peak and trough serum digoxin concentration should be obtained 3 to 5 days after digoxin therapy is begun, and the dosage should then be adjusted accordingly. Ideally, the trough and peak digoxin concentration should be between 1 and 2 ng/mL.

Dehydration, acid-base imbalance, and electrolyte abnormalities should be corrected before digoxin therapy. The dose of digoxin should be decreased in animals with elevated creatinine or blood urea nitrogen (BUN) until these values return to normal. In horses, the IV loading dose of digoxin should be administered slowly or divided and given at a rate of one third of the loading dose hourly until completion.[200] Alternatively, therapy can be initiated with the maintenance dose. Close monitoring of body weight, appetite, electrolyte concentrations, creatinine or BUN concentration, and cardiac rhythm is essential during therapy. Therapeutic drug monitoring with digoxin plasma concentrations can be helpful during initial therapy, when the volume of distribution of the drug and the patient's body weight may be in a state of flux. Samples for determination of peak serum digoxin concentrations should be obtained 1 to 2 hours after digoxin administration and should not exceed 2.5 ng/mL.[141,202]

The diuretic used most commonly in large animals is furosemide. It is administered parenterally at the rate of 1 mg/kg twice daily or as needed to control edema. Oral absorption of furosemide is poor or variable in horses.[140] A continuous-rate infusion of furosemide is recommended in horses when rapid profound diuresis is needed.[203] The half-life and diuretic effect of bumetanide, a sulfonamide diuretic, are shorter than those of furosemide in horses.[204] The PK/PD information about torsemide, a new loop diuretic that is much more potent than furosemide, indicates it may be a better diuretic for long-term diuresis in horses.[205] The recommended dosage is 0.5 to 1 mg/kg orally twice daily, which should be adjusted accordingly thereafter. Electrolyte concentrations and water consumption should be monitored closely in patients receiving diuretics.

The vasodilator used most frequently in horses in the United States is the ACE inhibitor benazepril. However, the cost of the ACE inhibitors varies wildly in different countries, so other ACE inhibitors or hydralazine are often used because of cost and availability issues. Other ACE inhibitors that have been used but are less effective include quinapril, ramipril, and enalapril. These vasodilators have resulted in clinical improvement in animals treated for CHF. Benazepril at 1 mg/kg PO twice daily has recently been shown to be most effective at suppressing ACE activity.[145,150] Quinapril at a dose of 0.25 mg/kg PO once daily has also been shown to increase stroke volume and cardiac output in horses with MR after 8 weeks of therapy.[146] Ramipril resulted in clinical and echocardiographic improvement of a horse with CHF at a dosage of 50 µg/kg daily PO.[149] Enalapril has been used at a dose of 0.5 mg/kg PO twice daily in the management of horses with moderate to severe MR or AR and in the treatment of horses with CHF. However, after a single 0.5-mg/kg oral dose of enalapril, neither enalapril nor enalaprilat was detectable in the serum, and ACE activity was not significantly reduced.[147] Hydralazine is administered PO at a dose of 0.5 to 1.5 mg/kg twice daily.

Control of cardiac arrhythmias should be attempted in animals that are hemodynamically unstable or threatened with development of worsening arrhythmias. Quinidine is usually the drug of choice for control of atrial and VA in cattle and is one of the drugs of choice in horses. Procainamide, lidocaine, propafenone, phenytoin, and sotalol have also been successful in treating VA in horses (Table 30.3). Although flecainide has been used successfully in horses, its use is not recommended due to the risk of sudden cardiac arrest. Although administration is limited to the IV route in cattle, oral or IV administration in horses results in adequate plasma concentrations to control arrhythmias. Quinidine is administered IV by infusion or divided bolus injections as shown in Box 30.2.

When quinidine is used IV, concurrent IV administration of a balanced electrolyte solution at the rate of 3 to 4 mL/kg/h may be desirable to maintain blood pressure in animals with severely compromised cardiovascular status.

Prognosis for animals with dilated cardiomyopathy is poor. Echocardiography is useful in determining the severity of the myocardial dysfunction and in formulating a prognosis. The results of the initial echocardiographic examination were the best prognostic indicator of survival in a recent outbreak of monensin toxicosis.[177] Recovery of animals with cardiomyopathy is unusual, constant therapy is required for maintenance of animals with CHF, and sudden death can occur at any time. Some animals may have significant myocardial dysfunction without CHF and are "cardiac cripples," comfortable at pasture but not safe to use for performance. These animals may later develop CHF.

Prevention and Control

Maintenance of a good vaccination program may limit the bacterial and viral causes of myocarditis. Parasite control may also reduce myocardial injury that predisposes to myocarditis or cardiomyopathy in horses. Toxic myocardial diseases are prevented by making horse feed in mills where feeds containing

VetBooks.ir

VetBooks.ir

TABLE 30.3

Drug Therapy for Ventricular Tachycardia

Drug	Usual Dose
Bretylium tosylate	0.5-5 mg/kg IV for life-threatening ventricular tachycardia or ventricular fibrillation
Dexamethasone	0.05-0.22 mg/kg, IV or IM
Furosemide	1-2 mg/kg IV as needed for pulmonary edema
Lidocaine	*Equine:* 0.25-0.5 mg/kg slowly IV every 10-15 min; repeat up to a total of 1.5 mg/kg *Bovine:* 0.5 mg/kg, slowly IV; can repeat in 15 min
Magnesium SO_4	IV infusion at 1 g/min to effect, up to a maximum of 25 g
Procainamide	1 mg/kg/min IV to a maximum of 20 mg/kg
Propafenone	*Equine:* 2 mg/kg PO tid 0.5-1 mg/kg in 5% dextrose slowly IV over 5-8 min for refractory sustained ventricular tachycardia (not available in United States)
Propranolol	0.03 mg/kg IV
Quinidine gluconate (IV)	1.5-2 mg/kg boluses every 10 min, not to exceed a total dose of 12 mg/kg
Sotalol	*Equine:* 1-4 mg/kg PO bid; 1 mg/kg IV results in high plasma concentrations (dose to treat ventricular arrhythmias needs to be determined)

bid, Twice daily; *IM*, intramuscular; *IV*, intravenous; *PO*, by mouth; *tid*, three times daily.

BOX 30.2

Quinidine Administration in Horses and Cattle

Horses

IV: 1.5-2 mg/kg every 10 min until conversion or desired effect, not to exceed a total dose of 12 mg/kg

PO: 22 mg/kg (1 g/100 lb of body weight) q2h until conversion or desired effect, not to exceed a total dose of 132 mg/kg q2h. If quinidine plasma concentrations cannot be obtained promptly, a total dose of 88 mg/kg q2h should not be exceeded.

Cattle

IV: 48 mg/kg infused IV over a 4-hr period

IV, Intravenous; *PO*, by mouth.

ionophores are not made, by proper mixing of feeds containing monensin, salinomycin, or lasalocid in feed mills in which horse feed is made, by not shipping bulk horse feed in trucks in which medicated ionophore-containing feed has been transported, and by preventing horses from ingesting these medicated feeds. Gossypol toxicity can be prevented by feeding no cottonseed meal or cottonseed meal with low gossypol content, especially when feeding preruminants.[206] Feeding of cottonseed meal can be limited by providing more forage or additional protein sources in the diet of ruminants so that ingestion of gossypol is limited to concentrations of 1 to 2 g/kg or less of feed for adult cattle and 0.5 to 1 g/kg or less of feed for immature cattle.[207] Nutritional myocardial disease can be prevented by adequate feeding of vitamin E, selenium, and copper with supplementation as required. Inherited cardiomyopathy is controlled by avoiding breeding of known or suspected carriers of the polled Hereford and Holstein-Friesian breeds. Not grazing horses on pastures containing *Acer* spp. will eliminate myocardial injury associated with consumption of the hypoglycin A toxin that causes atypical myopathy.[208]

Pericarditis

Definition and Etiology

Pericarditis is inflammation of the pericardium that results in accumulation of fluid or exudate between the visceral and parietal pericardium. Pericarditis in large animals occurs with trauma from penetration of ingested foreign objects or external wounds, hematogenous spread (septicemia) of infection, extension of infection from the lung or pleura, viral infections such as equine viral arteritis or equine influenza, and neoplasia. Pericarditis has also been associated with the mare reproductive loss syndrome (MRLS), with *Actinobacillus* species isolated in the majority of these horses.[209] Idiopathic pericarditis, characterized by an aseptic inflammatory exudate, is not uncommon in horses and has recently been reported in cattle.[210–217] Autoimmune, hereditary, and metabolic causes of pericarditis have not been documented in large animals.

Clinical Signs and Differential Diagnosis

The clinical presentation of pericarditis can vary depending on the volume and rate of development of the pericardial effusion and the cause. Nonspecific clinical signs—fever, anorexia, depression, or weight loss—may be the chief complaints, but more frequently, peripheral edema, jugular venous distention and pulsations, tachypnea, or dyspnea is the presenting clinical sign. Cattle may exhibit pain by an abnormal stance characterized by abducted elbows, a spontaneous or induced expiratory grunt, reluctance to move, or preference to stand with the forequarters elevated. Horses may show signs of colic or syncopal episodes.

The most consistent findings on auscultation are tachycardia, muffling of heart sounds, and absence of lung sounds in the ventral thorax. Dorsally the lung sounds are louder than normal. These findings are in contrast to pleuritis, an important diagnostic rule-out for pericarditis, in which lung sounds are muffled ventrally but heart sounds are not, and radiation of the heart sounds occurs over a wider area than normal.[218] In cattle, splashing sounds are frequently audible in the cardiac auscultation area, a sound some refer to as a "washing machine murmur or rub." This is attributed to accumulation of gas and fluid in the pericardium and is indicative of the presence of gas-forming (anaerobic) organisms and a grave prognosis. In cattle this murmur distinguishes pericarditis from cardiac neoplasia or other causes of CHF. The splashing sounds are absent in horses and muffled heart sounds are the rule, but pericardial friction rubs may be auscultated, especially after pericardial fluid accumulation has been relieved.[213] A gallop rhythm may be auscultated in either horses or cattle.

Mucous membranes may be congested and have a prolonged capillary refill time. Jugular venous distention and pulsations are usually present. Arterial pulses are weak. The latter findings may help distinguish pericarditis from primary pleuritis. Percussion of the thorax reveals ventral dullness, and pleural effusion is frequently present in horses with pericarditis. A concurrent pleuropneumonia or septic pleuritis is present in some horses.[215,219–222] Ascites is infrequently detected in horses with pericarditis, but concurrent peritonitis has been reported.[223]

Clinical Pathology

CBC changes are nonspecific and depend on the cause of the pericarditis. There may be hemoconcentration if the animal is dehydrated or toxemic, or there may be a mild anemia associated with chronic infectious pericarditis. WBC count may be normal or increased. There may be an absolute

neutrophilia or a lymphopenia. Frequently the fibrinogen concentration or SAA is elevated. Serum chemistries are usually normal except for albumin concentration, which may be low[212,213] and accompanied by an elevation in globulin concentration. Liver enzyme, bilirubin, serum urea nitrogen, and creatinine concentrations are frequently mildly elevated, consistent with the development of CHF. Laboratory evidence of dehydration (increased PCV, total protein, serum urea nitrogen, and creatinine concentrations) may be exaggerated when diuretics have been administered previously. Although total serum LDH concentration may be elevated, more specific information may come from finding an increase in the cTnI or the myocardial isoenzymes CK and LDH. An elevated cTnI was reported in one cow with hemorrhagic pericarditis.[216] Electrolyte concentrations are frequently normal, but serum calcium and potassium concentrations may be low because of anorexia. Decreased sodium and chloride concentrations have been reported in horses with pericarditis.[213] No consistent abnormalities in arterial or venous blood gas concentrations have been reported in large animals with pericarditis.

Radiography is not a sensitive diagnostic test for pericarditis in horses, although an enlarged rounded cardiac silhouette is detected with large pericardial effusions. In cattle, traumatic pericarditis frequently results in fluid and gas accumulation in the pericardium that is detectable radiographically and relatively specific for this disease. A metallic foreign body is usually detected radiographically in the cranial reticulum or caudal thorax in cattle with traumatic pericarditis (Fig. 30.18). Radiographic changes may not be detected in early or uncomplicated pericarditis. If fluid accumulation is large and there is concurrent pleural effusion, changes are indistinguishable from those associated with pleuritis. An enlarged, rounded cardiac silhouette is not specific for pericarditis and is seen with other causes of generalized cardiomegaly. An obscured cardiac silhouette, vena cava, and diaphragm, with dorsal displacement of the trachea, may be seen with pericarditis or pleuritis. The lungs, which may be aerated only dorsally, frequently have interstitial infiltrates.

The ECG changes most commonly associated with pericarditis in large animals are decreased amplitude of the QRS complexes (<1.5 mV in the base-apex lead)[213,214,223] (Fig. 30.19), electrical alternans (altered configuration of the P, QRS, or T complexes on a regular basis), and ST-segment elevation or slurring.[212,213,219,223,224] A right-axis deviation in the standard limb leads may be apparent.[212,224] Cardiac arrhythmias (usually atrial or ventricular premature beats) may be detected in affected animals, suggesting a concurrent myocarditis (Fig. 30.20). In some animals, no ECG changes are evident.[225]

Echocardiography reveals findings specific for pericarditis and is used to confirm the diagnosis noninvasively. An echo-free space between the visceral and parietal pericardium is evident (Fig. 30.21) and apparent even with a minimum amount of fluid accumulation.[218,219] Frequently, hypoechoic to echoic strands that correspond to fibrin are imaged in the pericardial space, with a hypoechoic to echoic layer covering the epicardial surface of the heart in large animals with pericarditis (Fig. 30.22). The pericardial effusion is often anechoic to hypoechoic, but more echoic pericardial fluid is occasionally seen, consistent with a more exudative fluid. Bright hyperechoic pinpoint echoes representing free gas are often imaged in cattle with pericarditis (Fig. 30.23). Gas in the pericardial sac of cattle with splashy heart sounds may limit the ability to obtain an echocardiographic evaluation of all cardiac structures. The visualization of intrapericardial gas is a sensitive indicator of anaerobic pericarditis. Pericardial effusion is differentiated from pleural effusion by finding the fluid- or fluid and gas–filled space surrounding the right ventricle and left ventricular free wall within the pericardial sac. Pericardial effusion is rarely imaged behind the left atrium, whereas pleural fluid is frequently imaged

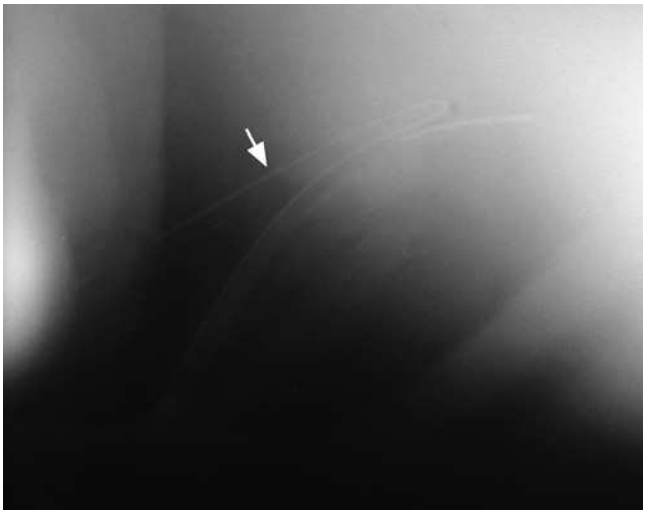

FIG. 30.18 Lateral radiograph of the caudal thorax and cranial reticulum showing a wire *(arrow)* in a cow with traumatic reticuloperitonitis.

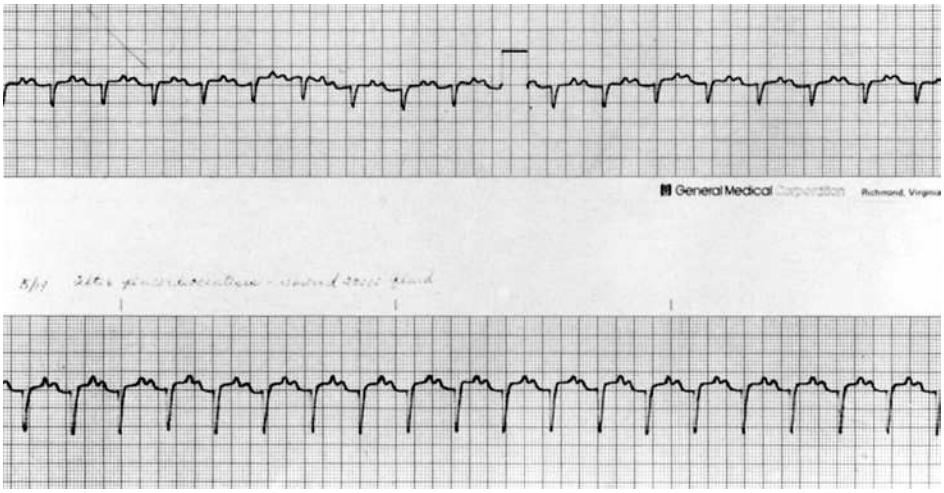

FIG. 30.19 Base-apex lead electrocardiogram taken from a cow before *(upper strip)* and after *(lower strip)* removal of 2 L of pericardial fluid. The markedly decreased amplitude (0.6 mV) of the QRS complexes is improved (1.2 mV) after pericardiocentesis.

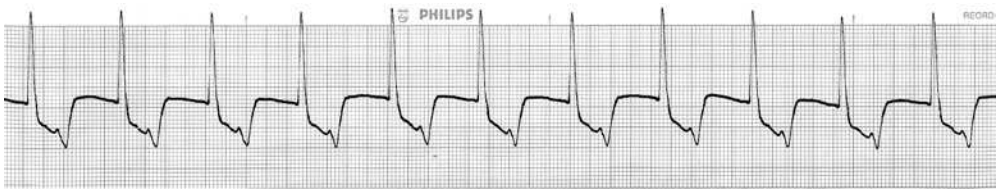

FIG. 30.20 Electrocardiogram (rhythm strip) obtained from a horse with pericarditis and junctional tachycardia. Note the P wave at the same place in the QT interval.

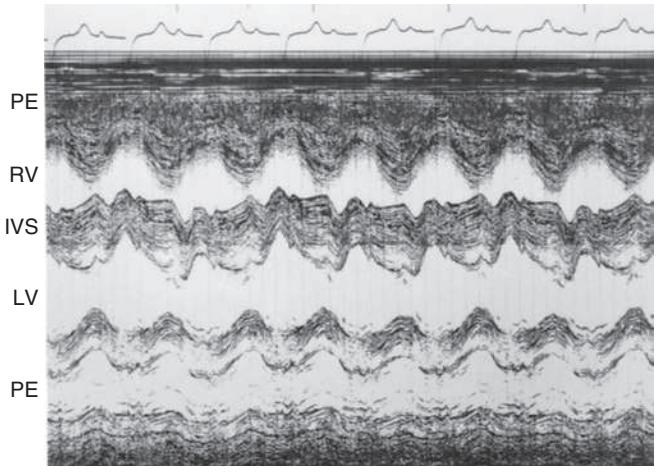

FIG. 30.21 M-mode echocardiogram obtained from a cow with traumatic pericarditis. There is a separation between the visceral and parietal pericardium cranial to the right ventricle *(RV)* and caudal to the left ventricle. The cranial pericardial effusion *(PE)* is echogenic, suggesting that fibrin or debris is present. The left ventricular *(LV)* dimension is reduced, and there is marked cranial motion of the interventricular septum *(IVS)* just before the QRS complex.

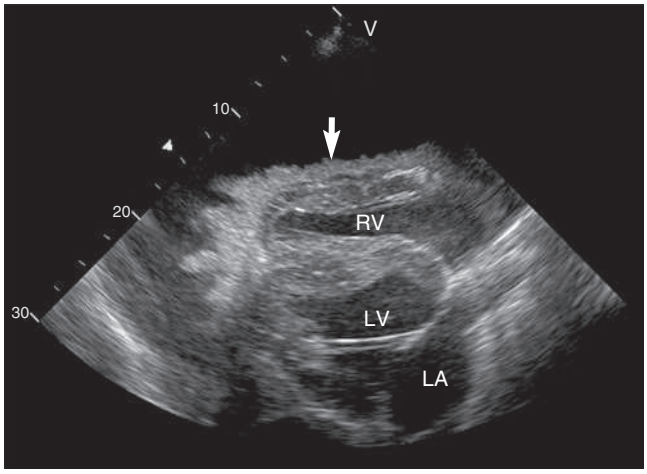

FIG. 30.22 Two-dimensional echocardiogram obtained from a horse with fibrinous pericarditis. Note the thick layer of echoic fibrin *(arrow)* covering the epicardial surface of the heart. There is a large anechoic pericardial effusion causing right ventricular *(RV)* collapse. The left atrial *(LA)* and left ventricular *(LV)* dimensions are reduced.

there. Right ventricular diastolic collapse (see Fig. 30.22) and right atrial collapse are common findings with large pericardial effusions and are an indication of the development of cardiac tamponade and hemodynamically significant pericardial effusion (Video 30.7).[214] Other echocardiographic findings consistent with pericarditis are decreased left ventricular chamber dimension, decreased left ventricular free wall motion, and decreased parietal pericardial motion.[214,215,219,226] Increased (see Fig. 30.21)

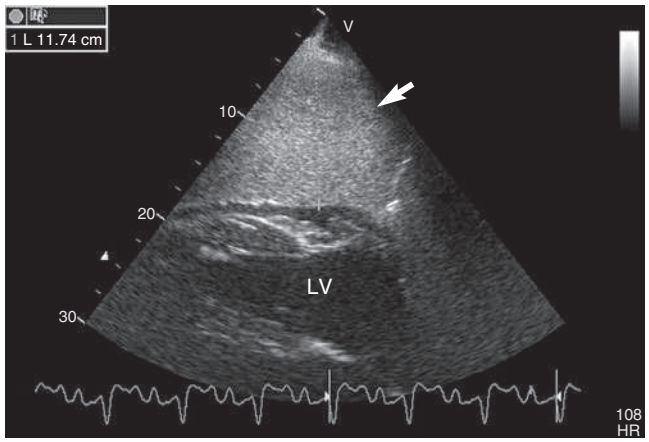

FIG. 30.23 Two-dimensional echocardiogram obtained from a cow with anaerobic pericarditis. Note the large amount (11.74 cm) of hyperechoic fluid *(arrow)* between the pericardium and left ventricle *(LV)* consistent with gaseous fluid.

or paradoxical motion (cranial motion beginning before the QRS complex) of the interventricular septum may be apparent.[226]

The site for pericardiocentesis should be selected echocardiographically. Pericardial fluid is obtained most commonly from the left fifth (fourth in cattle) intercostal space 2.5 to 10 cm dorsal to the olecranon, above the level of the lateral thoracic vein, the safest site for pericardiocentesis. When there is a large volume of pericardial effusion, pericardiocentesis can be productive from the right side at about the same location. If at all possible, a pericardial catheter (large-bore Argyle tube) should be inserted into the pericardial space at the time of the initial pericardiocentesis to enable repeated drainage and lavage of the pericardial sac (Fig. 30.24). Fluid analysis and bacterial and viral culture results depend on the cause. In cattle with traumatic pericarditis, fluid analysis usually reveals elevated protein concentration (>3.5 g/dL) and an elevated WBC count (>2500/μL) composed primarily of neutrophils. The fluid is urine colored to slightly blood tinged and foamy, and it has a foul odor. A mixed population of gram-positive and gram-negative aerobic and anaerobic bacteria (GI flora) are usually present. Protozoa may be found in unusual circumstances. Hemorrhagic effusion has been reported in several cows with idiopathic pericarditis that responded favorably to pericardial drainage (usually with lavage) along with systemic antimicrobial therapy.[216] In horses, protein concentration of the pericardial fluid is elevated (≥2.5 g/dL) and the WBC count is normal or elevated with a population predominantly of neutrophils, although red blood cells, lymphocytes, eosinophils, mesothelial cells, and histiocytes have been observed.[212–214,219,223] Bacterial (aerobic and anaerobic) cultures and viral cultures may be negative. *Actinobacillus* organisms were frequently isolated from mares with pericarditis in association with the MRLS.[209] Paired serum may support a viral cause. Analysis of pleural and peritoneal fluid (when present) usually reveals fluid characterized as a modified transudate or as mildly inflammatory.

VetBooks.ir

FIG. 30.24 Insertion of a pericardial chest tube into the left fifth intercostal space for drainage and lavage of the pericardial space. Note that the left foreleg is being pulled forward, the clinician is inserting the large-bore Argyle chest tube into the left fifth intercostal space above the lateral thoracic vein, and the cow is wearing a radiotelemetry electrocardiogram system underneath the surcingle.

Cardiac catheterization demonstrates an elevation in central venous or right atrial pressure, and the atrial and ventricular pressure curve may be abnormal in appearance. Right atrial, right ventricular, and pulmonary artery end-diastolic pressures may equilibrate.[224] In combination, these findings are relatively specific for pericarditis.

Pathophysiology

Accumulation of fluid in the pericardium occurs as a result of inflammation. The rate of fluid accumulation and the degree to which the pericardial pressure increases determine the pathophysiologic consequences. Generally pericarditis results in decreased distensibility (increased ventricular end-diastolic pressure) of the heart, which impairs the ability of the heart to fill during diastole. The elevation in end-diastolic pressure and impairment of ventricular filling elevate atrial pressure and reduce venous flow or venous return to the heart and diastolic perfusion of the myocardium. The result is a depression of ventricular contractility, stroke volume, and consequently cardiac output. In addition, arterial pressure and renal blood flow are decreased. Initially, compensatory mechanisms consisting of vasoconstriction, increased heart rate, and sodium retention (increased vascular volume) may maintain cardiac output. Failure to maintain cardiac output results in circulatory collapse.

Pericarditis can be classified as primarily effusive, constrictive, or a combination of both.[224] The hemodynamic consequences of effusive pericarditis are primarily caused by the physical presence of pericardial fluid, whereas constrictive pericarditis is classified as such, because the reduction in ventricular compliance is due to fibrinous or fibrotic involvement of the pericardium and epicardium. Removal of pericardial fluid results in improved cardiac performance in effusive pericarditis but is of limited usefulness in constrictive pericarditis.

Epidemiology

Pericarditis is uncommon in horses; when it does occur, it is most frequently idiopathic and can occur in a horse of any age. History of a recent respiratory tract infection is not uncommon. Exposure of horses to Eastern tent caterpillars was the greatest risk factor for the development of fibrinous pericarditis during the MRLS epidemic.[227] Traumatic pericarditis has been reported in horses but is rare.[228] Traumatic pericarditis is not uncommon in cattle, but it occurs in less than 10% of cattle with traumatic reticuloperitonitis.[75] Most cattle are affected in late gestation or at parturition. Idiopathic pericarditis is rare in cattle. Cattle with idiopathic hemorrhagic pericarditis may eventually develop cardiac lymphosarcoma.[210]

Necropsy Findings

Gross postmortem examination shows distention of the pericardial sac with serosanguineous or urine-colored fluid that is foamy and may be malodorous (cattle). There may be organization of fibrinous exudate and fibrosis that is also evident on the epicardium (Fig. 30.25) and may infiltrate the myocardium. Pleural effusion may be present. Other signs of CHF such as pulmonary congestion, pulmonary edema, and chronic passive congestion of the liver may be present. If the cause is traumatic, the offending object may be well contained in a fibrous tract located between the reticulum and the pericardium.

Histopathologic examination reveals pericardial, epicardial, and occasionally myocardial fibrosis and inflammation with neutrophilic, lymphocytic, eosinophilic, or plasma cell infiltrates. Bacteria may be visible. The liver may show diffuse centrilobular necrosis, fatty change, dilation and congestion of sinusoids, and perivenous fibrosis.

Treatment and Prognosis

Treatment of traumatic pericarditis in cattle is generally unrewarding and is usually addressed toward salvage or short-term survival to calving. Repeated pericardial drainage by means of pericardiocentesis or a fifth rib resection, lavage, or pericardiectomy may be useful for short-term survival, but the prognosis for return to normal function is poor because CHF results from involvement of not only the pericardium but also the epicardium and myocardium (see Fig. 30.25). Thoracotomy by a split-rib technique followed by pericardiectomy has been effective in treating some cattle with traumatic, restrictive pericarditis.[229]

Treatment of pericarditis not caused by trauma has been successful in horses, but the initial prognosis should be guarded. Aggressive treatment of horses with moderate to large pericardial effusions should include the placement of a large-bore indwelling chest tube into the pericardial sac under echocardiographic guidance and drainage and lavage of the pericardial sac, with local infusion of antibiotics in addition to the initial broad-spectrum antimicrobial therapy. Obtaining a sample for cytologic examination and culture and sensitivity testing via a pericardiocentesis should be postponed until an indwelling catheter can be safely inserted, if pericardial drainage and lavage is considered as a probable treatment, because it is difficult to insert the catheter once the pericardiocentesis has been performed. The pericardial drainage and lavage, performed once or twice daily as needed, has been effective in treating idiopathic or septic pericarditis in horses.[10,214,215,219,223] The indwelling tube should remain in situ until the fluid recovered at the time of drainage is consistently less than or equal to the volume instilled in the pericardial sac with antimicrobials 12 to 24 hours earlier. The ECG should be monitored because occasionally cardiac arrhythmias occur during the therapeutic procedure or during a routine pericardiocentesis. All horses with pericarditis should initially be treated for septic pericarditis with systemic broad-spectrum bactericidal antimicrobial drugs. The antimicrobial choice should be based on the most likely causative agents and modified as needed by the results of culture and sensitivity testing. Fibrinous pericarditis has been successfully treated in horses with broad-spectrum bactericidal antimicrobials when the amount of pericardial fluid detected echocardiographically was too small to safely obtain a sample for cytologic evaluation and culture and sensitivity testing. Treatment of idiopathic pericarditis with corticosteroids should be initiated only after the results of these diagnostic studies demonstrate no evidence of sepsis. Pericardiotomy or (preferably) pericardiectomy are

VetBooks.ir

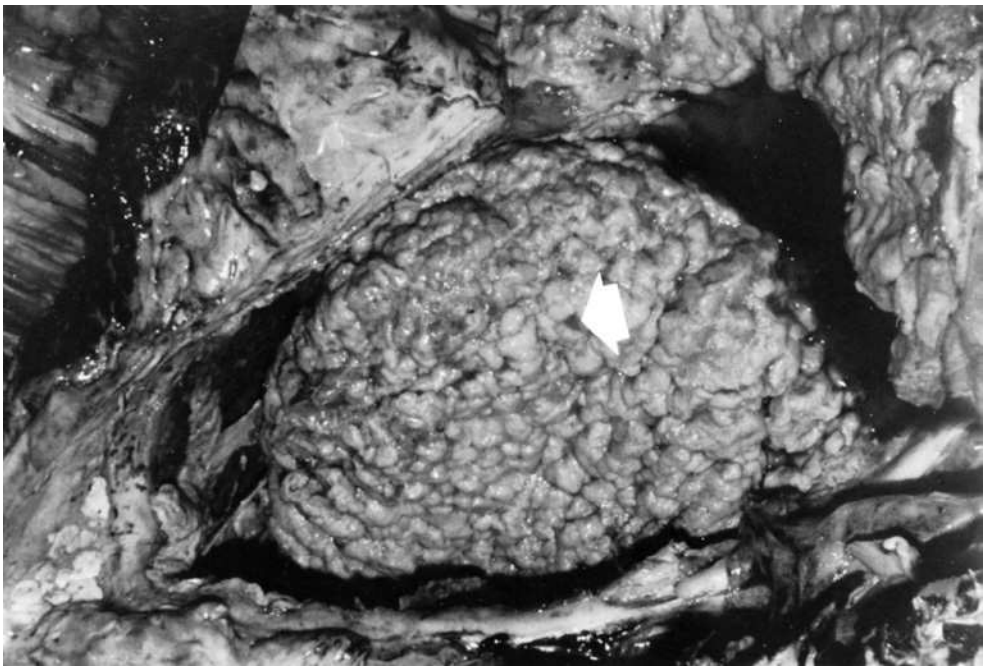

FIG. 30.25 Postmortem photograph of a cow with constrictive pericarditis. The pericardium is opened and reflected, revealing the epicardium *(arrow)* covered in fibrinopurulent exudate.

the treatments of choice if signs of constrictive pericarditis are present. However, the long-term prognosis for large animals after this surgery is guarded. A partial pericardiectomy was performed in one horse with constrictive pericarditis but was only transiently successful.[220]

In traumatic pericarditis the antibiotic selected must be capable of covering gram-positive and gram-negative aerobic and anaerobic bacteria. Nonsteroidal antiinflammatory drugs (NSAIDs) have been deemed useful as adjunctive therapy, as have corticosteroids if bacterial culture of the fluid is negative and no evidence of sepsis is detected cytologically.

Although diuretics are effective in eliminating the severity of peripheral edema, they further reduce venous return and preload in animals with pericarditis. The result is further compromise of cardiac output and worsening of heart failure.

Prevention and Control

Traumatic pericarditis in cattle can be prevented by routine administration of magnets to heifers at the time of pregnancy diagnosis. At each subsequent pregnancy diagnosis, the cow should be checked for the presence of the magnet in the reticulum. It is not beneficial to have more than one magnet present at one time.

Horses should not be grazed on pastures containing trees infected with Eastern tent caterpillars. Removal of black cherry trees from equine pastures removes the preferred host tree for the Eastern tent caterpillar. Some types of infectious pericarditis in horses may be controlled by routine vaccination against the common respiratory pathogens.

Cardiac Tumors

Definition and Etiology

The heart may be the primary site of neoplastic disease or be involved secondarily by tumors from adjacent structures, such as the lungs, pleura, lymph nodes, or diaphragm. Cardiac neoplasia is uncommon in large animals. The most common primary cardiac tumor is lymphosarcoma. Mesotheliomas, melanomas, lipomas, fibrosarcoma, adenocarcinomas, and other carcinomas, especially squamous cell carcinomas in horses, may involve structures adjacent to the heart and may extend to the heart or heart base, producing signs of heart disease.[230,231] An infiltrative cardiac lipoma has been reported in a horse, but no signs of cardiac disease were attributed to it.[232] A metastatic anaplastic pulmonary carcinoma caused signs of CHF in one horse,[231] and disseminated hemangiosarcoma with myocardial involvement was thought to be responsible for VA in another horse.[233] Primary pericardial hemangiosarcomas have also been reported in a horse.[234]

Clinical Signs and Differential Diagnosis

The clinical signs of cardiac neoplasia are nonspecific and depend on the cardiac site involved and other sites of tumor manifestation. Nonspecific signs of neoplasia are common and include anorexia, depression, weight loss, and fever. These signs can be produced by any site of chronic disease, and in large animals, pneumonia, peritonitis, enteritis, and liver and kidney disease are considered differential diagnoses, among others. If the tumor involves the pericardium, signs of pericarditis or pericardial effusion such as tachycardia, pain, jugular venous distention, peripheral edema, and weak arterial pulses may be seen. Myocardial involvement, as is most common with lymphosarcoma, may result in cardiac signs that include tachycardia, cardiac arrhythmias, and cardiac murmur (atrioventricular valve insufficiency) or signs of CHF such as peripheral edema, ascites, and diarrhea. Clinical signs attributable to tumor involvement of the endocardium (e.g., obliteration of a cardiac chamber, valvular obstruction or damage, embolic showering) are rare in large animals.

Tumor involvement of other organ systems and tissues can be manifested by lymphadenopathy, peripheral edema, diarrhea, melena, dysphagia, tachypnea, pleural effusion, or rectal palpation of abdominal masses.

Clinical Pathology

Cardiac tumors present no consistent clinicopathologic feature. The CBC from horses or cattle with lymphosarcoma may reveal neoplastic lymphocytes. The absence of leukemic changes

VetBooks.ir

does not rule out lymphosarcoma. Cattle with lymphosarcoma may test positive for fecal occult blood. A serum chemistry profile may reveal nonspecific changes, such as hypoalbuminemia, hyperglobulinemia, or elevated liver enzyme concentrations, depending on the other organ systems affected by the tumor or the animal's debilitation. Diagnosis of the cardiac tumor is based on histopathology of tumor tissue. Tumor cells may be found in pericardial or pleural fluid or adjacent lymph nodes. Serologic evidence (agar gel immunodiffusion or radioimmunoassay) of BLV infection does not confirm a diagnosis of lymphosarcoma, but a negative test result virtually rules out the adult or enzootic form of lymphosarcoma in cattle. No evidence of BLV infection is found in cattle with the thymic form of lymphosarcoma.

If electrocardiographic evidence of cardiac tumors is present, it is nonspecific. Cardiac tumors may produce cardiac arrhythmias, reduce amplitude of the QRS complexes, or alter the normal appearance of the P, QRS, and T complexes. Two-dimensional echocardiography or an ultrasound examination of the lungs or pleura may show evidence of the cardiac tumor by providing direct evidence of echogenic masses involving the heart or surrounding tissue, abnormal fluid accumulation, or myocardial functional changes. Ultrasound findings can determine whether any masses can be safely biopsied to confirm the diagnosis.

Radiographs may provide evidence of cardiac tumors by showing abnormal soft tissue densities in the thorax that obscure the cardiac silhouette or ventral lung borders.

Pathophysiology

Lymphosarcoma, the most common cause of cardiac tumors in cattle, has a predilection for the right atrial myocardium. Right ventricular myocardial involvement is not uncommon; left atrial or left ventricular involvement is rarer. Involvement of the right side of the heart may result in little or no evidence of heart disease. More commonly, the myocardial involvement results in dilation of the chamber involved. As a consequence, the tricuspid valve ring may be dilated, and TR occurs. Chamber enlargement or infiltration of the myocardial conduction system may cause cardiac arrhythmias. Myocardial function may be impaired so that signs of right-sided heart failure become apparent, including tachycardia, peripheral edema, jugular venous distention or pulsations, pericardial or pleural effusion, hepatic congestion, and ascites.

Epidemiology

Cardiac tumors are rare in large animals. The most common cause in cattle is lymphosarcoma. Although more than 50% of cattle in some parts of the United States are infected with BLV, only 1% to 5% develop lymphosarcoma.[235–237] In herds with more than 50% of cattle infected with BLV, the incidence of lymphosarcoma may be higher. Cardiac involvement is common in cattle with the adult or enzootic form of BLV, a disease that occurs most commonly in cattle older than 4 years old.[238] Thymic lymphosarcoma, which is not associated with BLV infection, also involves the heart but is much less common, occurring in cattle younger than 30 months of age.

Lymphosarcoma, mesothelioma, and squamous cell carcinoma are probably the most common causes of neoplastic involvement of the equine heart, but the prevalence is not documented.

Necropsy Findings

Necropsy findings depend on the type of cardiac tumor. Direct involvement of the myocardium with lymphosarcoma is associated with finding diffuse infiltration by a pale, tan, homogeneous tissue that frequently causes enlargement of the cardiac chamber. Involvement of the right atrium (Fig. 30.26) is the most common manifestation of adult enzootic BLV, but any area of the myocardium and pericardium may be involved. Intracavitary extension of the tumor may be evident (see Fig. 30.26). Histologic evaluation of the tumor shows diffuse infiltrates of lymphoblastic cells that obliterate the normal architecture of the myocardium.

Other tumors, such as fibrosarcoma, squamous cell carcinoma, pulmonary carcinoma, thymic lymphosarcoma, mesothelioma,

FIG. 30.26 Postmortem photograph of a cow with lymphosarcoma demonstrating right atrial myocardial infiltration by a tumor and extension of the tumor into the atrial lumen.

and melanoma, may involve the heart by extension or metastasis from other sites in the thorax.

Treatment and Prognosis

No definitive treatment exists for cardiac neoplasias, and the prognosis for survival is poor. Death is expected within 6 months with most cardiac tumors. Lymphosarcoma of the heart in cattle has a grave prognosis and is usually associated with death within a few months. Short-term improvement has been achieved in cattle with lymphosarcoma treated with a combination of corticosteroids, L-asparaginase, and cytotoxin. Thoracoscopic pericardiotomy has been used as a palliative treatment in a cow with pericardial lymphoma.[239]

Prevention and Control

Prevention and control of BLV can be accomplished by isolation of BLV-positive and BLV-negative animals; use of individual or sterilized supplies, such as needles, rectal examination sleeves, tattooing, dehorning, and ear-tagging equipment on each animal; rigorous attention to a vector control program; and feeding colostrum from serologically negative cows only.[236,240] Frequent testing (at least every 6 months) and isolation of serologically positive animals over 6 months of age should be performed. Prevention and control of other cardiac tumors are not possible.

Vascular Disease: Aneurysms, Thrombosis, and Embolism

Definition and Etiology

Aneurysms, which are vascular dilations, develop from weakening of the medial elastic coat of blood vessels. The medial weakness may be primary or caused by progression of an intimal atherosclerotic lesion that has enlarged from hemorrhage, calcification, ulceration, and thrombus formation. The specific causes of aneurysms in large animals are unknown, but trauma (internal or external), sepsis, parasite migration, degenerative vascular disease, atherosclerosis, or aging changes (dilation, elongation, and loss of elasticity of blood vessels) may play a role.[241–243] Histopathologic study of the Friesian with aortopulmonary fistulation and thoracic aortic rupture suggest an underlying connective tissue disorder of the aortic media collagen or elastin as the root cause.[244] Congenital aneurysms of the sinus of Valsalva have been reported in horses.[87,94–96] Hypertension can accelerate degeneration of the wall.

Thrombosis is the formation of a clot that obstructs blood flow in the circulatory system. The causes of thrombosis are numerous and include trauma, venous stasis, and catheterization for administering medication or fluids. Needle penetration, indwelling catheters, thrombogenic solutions, or bacterial contamination can cause thrombosis associated with catheterization. Secondary thrombosis can result from perivascular inflammation caused by cellulitis, lymphangitis, or other sources of bacterial invasion around the blood vessel. Mural thrombi, which occur in cardiac chambers associated with low-flow states and/or a coagulopathy, also may occur in large animals, although they have been rarely diagnosed antemortem in the heart.[245] Thrombosis usually occurs when intimal disease is present, but it may occur in arteries with no intimal disease when a hypercoagulable state exists, such as with dehydration, endotoxemia, anemia, hypotension, stress, or stasis.[246–248] This type of thrombosis is frequently a complication of acute infectious disease (particularly acute toxic enteritis or colitis), neoplasia, or any chronic debilitating disease.

An *embolism* is foreign material carried in the bloodstream. Emboli frequently arise from an arterial or venous thrombus, but unusual emboli include catheters and other foreign bodies inadvertently introduced into the circulatory system. In large animals, emboli occur most commonly in bacterial endocarditis, thrombophlebitis, omphalophlebitis, and parasitic arteritis. Aortoiliac thromboembolism has been reported as a complication of valvular endocarditis in a calf and mural endocarditis in a cow.[249,250]

Clinical Signs and Differential Diagnosis

Sites of thrombosis associated with thrombophlebitis are likely to have pain, swelling, redness, and palpable thickening of the involved vein. These signs frequently occur within 12 to 24 hours after catheter removal when the thrombus is associated with catheterization. If there is bilateral jugular venous thrombosis, sudden, marked swelling of the head may occur. If the thrombosis involves the terminal aorta and iliac arteries in horses, the signs are frequently a vague hindlimb lameness, exercise intolerance, or poor performance. These nonspecific signs make it necessary to rule out lameness from other causes, cardiac disease, or respiratory problems. Failure to ejaculate has been reported in breeding stallions with aortoiliac thrombosis.[251] Aortoiliac thrombosis in horses is also characterized by heavy sweating after exercise, except over the hindlimbs, which are cool. With severe aortoiliac thrombosis the affected limb can be cool to the touch at rest or can be cold with no palpable femoral arterial pulse. Saphenous vein filling is slow or nonexistent in affected horses, and the metatarsal and other peripheral arterial pulses of the hindlimbs are weak. Rectal examination may be normal, or weak, absent, or asymmetric iliac pulses may be palpated. Fremitus of the iliac arteries or terminal part of the aorta may be palpated. The terminal part of the aorta may feel larger or firmer than normal, or an aneurysmal dilation may be detected. Hindlimb weakness, inability to bear weight on the affected limb(s), and cold limbs with weak or absent femoral arterial pulses occur in affected calves.[252] With verminous arteritis of the cranial mesenteric artery, a thickened, dilated cranial mesenteric artery or aorta may be palpated that may be firmer than normal and have a weak pulse, or fremitus may be palpated. In calves with aortic or aortoiliac thrombosis weakness, lameness, knuckling, paresis or paralysis of the hindlimbs, inability to rise, and cold hindlimbs lacking a femoral arterial pulse have been described.[249,253–255]

The signs attributable to embolism and thrombosis may be identical. Embolism is usually manifested by an acute episode of pain or fever, abnormal pulsation in a peripheral vessel, or a change in skin temperature. If there is peripheral vessel showering, superficial veins may be collapsed and muscular weakness may be present. Embolic showering usually occurs in animals suspected of having or known to have thrombus formation.

Clinical signs associated with an aneurysm depend on its location and may vary from being asymptomatic to being a noticeable enlargement or mass associated with a blood vessel or causing colic, syncope, seizures, or sudden death on rupture. In a peripheral artery, a pulsatile expansile mass may be visualized or palpated. Other considerations for this finding are a false aneurysm and an arteriovenous fistula. A false aneurysm is clinically indistinguishable from a true aneurysm but can be distinguished ultrasonographically. A false aneurysm is caused by a break in the continuity of all three coats of the arterial wall rather than in the tunica media alone. This results in extravascular accumulation of blood in adjacent tissues. Signs attributable to low blood flow (e.g., lameness, colic, edema) may be present with arterial aneurysms. Aneurysms of the cranial mesenteric artery frequently manifest as chronic episodes of colic. With involvement of major cardiac vessels, there may be pain, an auscultable heart murmur, rapid tachycardia, signs of CHF, acute onset of pulmonary edema, or sudden death when the aneurysm ruptures. The latter signs make aneurysms difficult to distinguish from the clinical signs of a horse with valvular heart disease or cardiomyopathy. One cause of an aorticocardiac fistula in horses is the result of rupture of an

VetBooks.ir

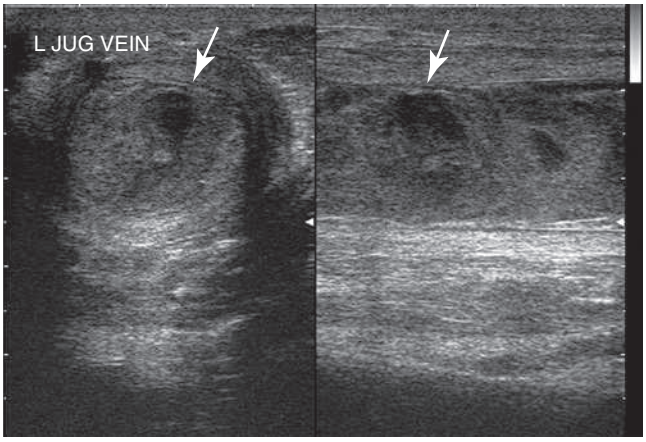

FIG. 30.29 Sonogram of the left jugular vein from a horse with septic thrombophlebitis. Note the cavitary appearance in the center of the thrombus *(arrows)* consistent with infection.

aneurysm of the sinus of Valsalva.[87,94–96] Aortopulmonary rupture and fistulation occur in young to middle-aged Friesians, resulting in similar clinical signs in some horses, along with collapse, coughing, intermittent lameness, and fever.[256,257]

Clinical Pathology

Aneurysms or pseudoaneurysms may be visualized radiographically as soft tissue density masses continuous with a vessel wall (true aneurysm) or extending outward from a vessel wall (false aneurysm).[242,243] However, the majority of the aneurysms involving the aorta and aortic root are not visible radiographically. Echocardiography is useful in the diagnosis of aneurysms involving the aortic root (Fig. 30.27).[86,87,94–96] Echocardiographic diagnosis of rupture of aortic arch with pseudoaneurysm or aortopulmonary fistulation requires obtaining additional echocardiographic views, following the aorta and pulmonary artery cranially and dorsally.[257] Recently aortic arch rupture has also been diagnosed with transesophageal echocardiography.[257] Angiography can be used in the diagnosis of peripheral vessel swelling or suspected thrombosis but is of little use in diagnosis of aneurysms of major vessels in adult animals. Ultrasonography may be used for the diagnosis of aneurysms or thrombosis of major arteries and peripheral vessels. In aortoiliac thrombosis of horses, ultrasound has been used to determine the origin of the thrombus and the extent of occlusion of the involved arteries (Fig. 30.28).[258] Abdominal ultrasonography of the upper left flank dorsal to the left kidney has been used to diagnose aortoiliac thrombosis in calves.[253] Diagnostic ultrasound has been used to detect thrombi in the caudal vena cava in cattle.[259,260] Although the occluding thrombus is not imaged, detecting a distended oval or round caudal vena cava rather than the normal triangular vessel in the eleventh and twelfth intercostal spaces is consistent with this diagnosis in cattle. Thrombi have been detected ultrasonographically in the hindlimb in both horses and cattle.[261–265] Jugular vein thrombophlebitis has also been diagnosed ultrasonographically in both horses and cattle (Fig. 30.29).[128,266] Similarly, diagnostic ultrasound has been used to image the cranial mesenteric artery, its branches, and the aorta in horses with verminous arteritis.[267] Aneurysms appear as dilated vascular structures or vascular outpouchings continuous with the vessel wall,[86] whereas a thrombus is apparent as a hypoechoic to echogenic mass within a blood vessel.[128] Cavitation of an occlusive thrombus is suggestive of septic thrombophlebitis (see Fig. 30.29), whereas a nonseptic thrombus usually has a homogeneously hypoechoic to echoic appearance.[128] Complete occlusion of the vessel can be determined ultrasonographically, or flow within an aneurysm or alongside a thrombus determined. Doppler ultrasound provides a more sophisticated method for determining blood flow and vessel patency.

In the case of catheter-associated thrombosis, a positive catheter tip culture (>10^3 colony-forming units) along with a positive blood culture provides evidence of septic thrombophlebitis.[268] An aseptic ultrasound-guided aspiration of the cavitary lesion within a heterogeneous thrombus can be performed, and the aspirate submitted for culture and sensitivity testing.[128] Septic thrombophlebitis from any cause or embolic showering of septic thrombi may be accompanied by neutrophilic leukocytosis and elevation in fibrinogen concentration or SAA.

Pathophysiology

Irritation of the intimal lining of a blood vessel, stasis of blood flow, or existence of a hypercoagulable state triggers the clotting cascade and sets the stage for development of thrombosis. Further injury causes hemorrhage, more thrombosis, ulceration, and calcification. These in turn can compromise the media of the vessel, predisposing to aneurysm formation, and impinge on the lumen of the vessel, causing obstruction to blood flow. Either aneurysm or thrombosis can occlude blood flow to vital structures or organs, resulting in ischemia.

VetBooks.ir

Thrombosis in any sizable vein causes venous hypertension, passive congestion, and subsequent edema and pain of the structure. As the thrombus matures, it adheres to the wall more, but with clot retraction and lysis, recanalization may occur. However, parts of the thrombus may protrude into the moving bloodstream and serve as the source of embolic showering, even during thrombus organization. The most common site for an embolus to lodge has not been established in large animals; the femoral and iliac arteries are common locations in humans. Emboli usually lodge at bifurcations, where the caliber of the artery is suddenly reduced.

The most common outcome of aneurysm of a major vessel is thought to be rupture. Rupture of sinus of Valsalva aneurysms into the right atrium, right ventricle, and interventricular septum has been reported in the horse.[94–96] VT often occurs with rupture of an aortic sinus of Valsalva aneurysm and dissection into the interventricular septum.[95,96] Unruptured aneurysms may have other complications, such as thrombosis or embolization of the thrombus. The frequency of rupture or embolic showering from thrombosis is unknown in animals. In Friesians, rupture of the aorta occurs into the pulmonary artery at the level of the ligamentum arteriosum and into the surrounding perivascular structures.[256,257]

FIG. 30.30 Ascending aorta from a horse that experienced an acute onset of uniform ventricular tachycardia after exercise and died within 3 hours of onset. Note the irregular calcified surface of the aorta, consistent with atherosclerosis.

Epidemiology

The significance of thromboembolism in large animals is poorly defined. Spontaneous thromboembolism is commonly associated with parasitism in horses, and the aorta and cranial mesenteric arteries are the sites most frequently involved.[162] Aortoiliac thrombosis is also a recognized syndrome diagnosed most frequently in heavily exercised horses. Although historically parasitism has been associated with aortoiliac thrombosis in horses, other causes of this syndrome are probable but have not been elucidated. Thrombotic disease can occur in any animal having repeated IV injections or being catheterized for administration of medication or fluids, but it is particularly common in horses with acute toxic enteritis, colitis, or sepsis. Careful skin preparation and aseptic technique are important factors in minimizing the likelihood of the patient developing catheter-related thrombophlebitis. Low doses of heparin have been effective in limiting the development of catheter-related thrombophlebitis in cattle.[269] Large intestinal disease, hypoproteinemia, endotoxemia, salmonellosis, fever, diarrhea, and locally produced fluids have all been identified as risk factors for catheter-associated thrombophlebitis.[248,270,271]

Arteriosclerosis is recognized in horses and in cattle. In cattle the lesion is most frequently caused by excessive vitamin D_3 supplementation or ingestion of calcinogenic plants, such as *Solanum malacoxylon*, *Cestrum diurnum*, or *Trisetum flavescens*.[272] In horses the arteriosclerotic lesions were caused by lesions induced by *Strongylus vulgaris*.[97] Ingestion of calcinogenic plants also occurs in horses, resulting in lesions in the aorta.

Aneurysms are uncommon in large animals but have been documented as the cause of sudden death in breeding stallions and racing Thoroughbred and Standardbred horses.[96,97] Aneurysms of the sinus of Valsalva are one cause of aortic rupture in older horses and are probably congenital in horses, as they are in humans.[86,94–96] Aortic root rupture also occurs without the presence of a preexisting aneurysm and has been associated with medial necrosis of the aorta. Psuedoaneurysm of the aorta in young Friesians is at the level of the ligamentum arteriosus, is a breed problem, and can result in sudden cardiac death, although many horses have a more chronic course.[256,257]

Necropsy Findings

Aneurysms are detected grossly as dilations of the involved blood vessel. Aneurysms of the sinus of Valsalva are characterized by an absent tunica media in the wall of the aorta, causing the aneurysmal dilation.[76,86] Rupture of a sinus of Valsalva aneurysm may occur into the right atrium, right ventricle, or interventricular septum, resulting in an ACF and volume overload.[76,86,87,95,96] Rupture through the tricuspid valve or chordae tendineae may also occur. Subendocardial dissection of blood down the interventricular septum may occur. Subsequent ruptures into the left ventricle and of the mitral chordae tendineae have also been reported. Pseudoaneurysms of the aorta with rupture at the ligamentum arteriosum and into the pulmonary artery occur in the Friesian breed.[244,256,257] Aneurysms of the major vessels leaving the heart may involve more than one vessel by dissection and hemorrhage. Aneurysms may contain thrombi or parasites, and there may be evidence of embolic showering of thrombi into peripheral vessels or other organ systems, especially the lungs. Histologically there may be necrosis and inflammation at the site of the aneurysm with foci of mineralization.

Thrombosis and arteriosclerotic lesions are recognized as rounded, well-demarcated fibrous plaques frequently located in the thoracic and cranial abdominal aorta (Fig. 30.30). The plaques may contain a central calcified core or parasitic larvae. Microscopically there is a thin layer of fibrin, platelets, and inflammatory cells in early lesions, whereas older lesions have a greater fibrous component. Thrombotic lesions may be associated with proliferation of the underlying aortic intima. In horses, parasitic larvae may be found.

Treatment and Prognosis

Aneurysms of major vessels carry a guarded to grave prognosis because surgical correction is rarely attempted and spontaneous rupture is thought to be relatively common. Intact aneurysms of the sinus of Valsalva can be detected echocardiographically, and once an aneurysm has been detected, the horse should be removed from all athletic competition because of the risk of rupture.[86,118] The occlusion of an ACF has been successfully performed with an Amplatzer occluder device in a breeding stallion.[273] This stallion survived to discharge but was euthanized a month and half later due to worsening of his underlying heart disease.

Treatment of thrombosis consists of removal of the catheter, if present, and resting the affected vessel. Warm compresses or hydrotherapy may be helpful in some animals. Topical NSAIDs (diclofenac sodium) may also be useful. Support wraps may be useful to control swelling. The effectiveness of anticoagulant therapy (clopidogrel usually at 2 mg/kg twice daily PO in horses, aspirin at 100 mg/kg once daily PO, ruminants;

10 mg/kg once daily, horses; or sodium heparin at 30 to 40 units/kg SC twice daily) or antiinflammatory drugs for dissolving a thrombus is questionable. Anticoagulant therapy may be useful in preventing additional thrombus formation or propagation of the existing thrombus. Ultrasonographic guidance can be used to obtain a sterile aspirate of the cavitated area of the thrombus for culture and sensitivity testing when septic thrombophlebitis is suspected.[128] Broad-spectrum bactericidal antimicrobial therapy should be instituted for suspected septic thrombophlebitis or when a cavitated thrombus is detected ultrasonographically and modified, if necessary, on the basis of the results of culture and sensitivity testing.[128] Bacterial endocarditis, particularly involving the tricuspid valve, is a potential complication of septic jugular vein thrombophlebitis. With the exception of a jugular venous thrombus or some horses with aortoiliofemoral thrombosis, surgical removal of an embolism or thrombus is rarely attempted in large animals. Surgical resection of a jugular vein with septic thrombophlebitis has been performed successfully when the surgeon could ligate the affected vein above and below the thrombus. Jugular vein thrombectomy with removal of the contents of the affected portion of the vein has been performed successfully in horses.[274] Although the prognosis for complete resolution of the thrombophlebitis is guarded, especially if the thrombus is infected, many veins do recannulate with complete resolution of the thrombus and without vascular stricture. However, the time course is slow, and persistent local induration and obstruction to blood flow may persist. The prognosis for nonracehorses to return to the same level of performance is good.[275] However, Standardbred racehorses in this same study had a decreased chance of returning to racing at the same level.[275]

The prognosis for horses and calves with aortoiliac thrombosis is guarded. Although most calves with aortoiliac thrombosis have died or were euthanized, two calves have survived. One calf received antithrombotic treatment with unfragmented heparin and aspirin, and the other was treated with ketoprofen, acepromazine, and local heat. A wide variety of medical treatments have been proposed for horses with aortoiliac thrombosis, including sodium gluconate, larvicidal deworming, phenylbutazone, and a controlled exercise program. Success has been variable. Surgical thrombectomy has also been successful in some horses.[276–278]

Prevention and Control

Thrombosis and embolization from IV catheters can be prevented or their incidence reduced by aseptic insertion, stabilization of the catheter, use of topical antiseptics, application of a sterile dressing, daily inspection of the catheter and vein, and replacement of the catheter at another site (preferably in another vein) if phlebitis occurs. Dwell time is a significant factor in the development of thrombophlebitis, and catheters should be replaced by new ones at another site every 72 hours.[279] Attempts should be made to place long-term catheters in large peripheral or central veins where contact between the endothelium and catheter is minimized and medications administered are diluted by the large volume of blood flow. Catheters left in place for prolonged periods should be of silicone rubber or polyurethane.[268] Clopidogrel (2 mg/kg PO twice daily, horses), aspirin (100 mg/kg PO once daily, ruminants; 10 mg/kg/day, horses), and low-dose heparin (30-40 units/kg SC twice daily, ruminants and horses) therapy should be considered to prevent thrombus formation in septic or endotoxic patients. Horses are much more prone to jugular thrombosis than are ruminants.

Parasite control is important in the control of thromboembolic disease and aneurysm in horses. Aneurysms of the sinus of Valsalva may be detected by routine echocardiographic screening of horses but occur so infrequently that this is not practical. In cattle, arteriosclerotic lesions are prevented by proper calcium and vitamin D supplementation.

Atrial Fibrillation

Definition and Etiology

Atrial fibrillation (AF) is a cardiac arrhythmia characterized by a lack of coordinated atrial electrical activity. It is caused by an abnormality of impulse conduction that results from multiple small rapid and random reentrant activation of the atria or by one or more discrete rotors. High resting vagal tone, commonly found in horses, shortens the action potential duration in atrial myocardial cells, making AF more likely to occur. AF can occur in the presence of atrial enlargement from atrial myocardial disease, atrioventricular valvular regurgitation, ventricular failure, myocarditis, endocarditis, autonomic nervous system imbalance, electrolyte or acid-base disturbances, anesthetic drugs or tranquilizer administration, unknown causes, or in the absence of detectable underlying cardiac disease ("lone" AF). Although "lone" AF has been a term used when no underlying cardiac disease can be found, in all likelihood, underlying atrial myocardial disease is present at the microscopic level that we are currently unable to detect.

Clinical Signs and Differential Diagnosis

Large animals with AF may be asymptomatic at rest, and AF may be detected as an incidental finding in an otherwise normal horse. Horses that perform in rigorous athletic events usually have a history of exercise intolerance or poor performance. Other complaints may be exercise-induced epistaxis, respiratory disease, weakness, syncope, myopathy, colic, or CHF. Cattle with AF usually have underlying GI disease.[280,281] Atrial premature depolarizations have also been reported in cattle with GI disease and may be a prelude to the development of AF.[281] Foot rot, pneumonia, and endocarditis have also been associated with AF in cattle. Anorexia and decreased milk production are common in cattle with AF. AF and the clinical signs associated with it in horses and in cattle can be paroxysmal. Paroxysmal AF usually lasts no more than 24 to 48 hours before spontaneous conversion to sinus rhythm occurs.[282] Spontaneous conversion usually occurs in horses with small atria and an otherwise normal heart or in cattle with correction of the underlying problem. Transient potassium depletion associated with the administration of furosemide is a common cause of paroxysmal AF in horses. Administration of bicarbonate "milkshakes" has also been implicated in horses with paroxysmal AF. AF has also been associated with iatrogenic hyperthyroidism in horses due to the administration of Thyro L or supplements containing kelp or ground-up shellfish.

Animals with AF have an irregularly irregular cardiac rhythm. In horses with AF, there is a high degree of underlying periodicity.[283] Heart sounds vary in intensity, and no fourth heart sound is audible. The heart rate may be slow, normal, or elevated. In cattle with severe abdominal disease, the heart rate usually reflects the severity of the underlying disease. In horses the resting heart rate is usually normal to slightly elevated and is rarely above 50 beats per minute (bpm) unless there is underlying myocardial or valvular disease or the horse has another reason for tachycardia (colic, etc.). During exercise, horses with AF develop abnormally high heart rates that are usually 40 to 60 bpm higher than expected for each level of exercise, far exceeding the peak heart rate of 240 bpm at maximal exercise.[284–286] The arterial pulse varies in intensity. A pulse deficit occurs when two beats occur in rapid succession and is infrequent unless the heart rate is elevated. Cardiac murmurs of grade 3/6 or louder are present in less than 50% of the horses and in even fewer cattle with AF.[287–289] Signs of CHF (peripheral edema, jugular venous distention) may be present in some animals, but they are not caused by the arrhythmia. In these cases, AF occurs secondary to the atrial enlargement that occurs with the underlying valvular or myocardial disease.

VetBooks.ir

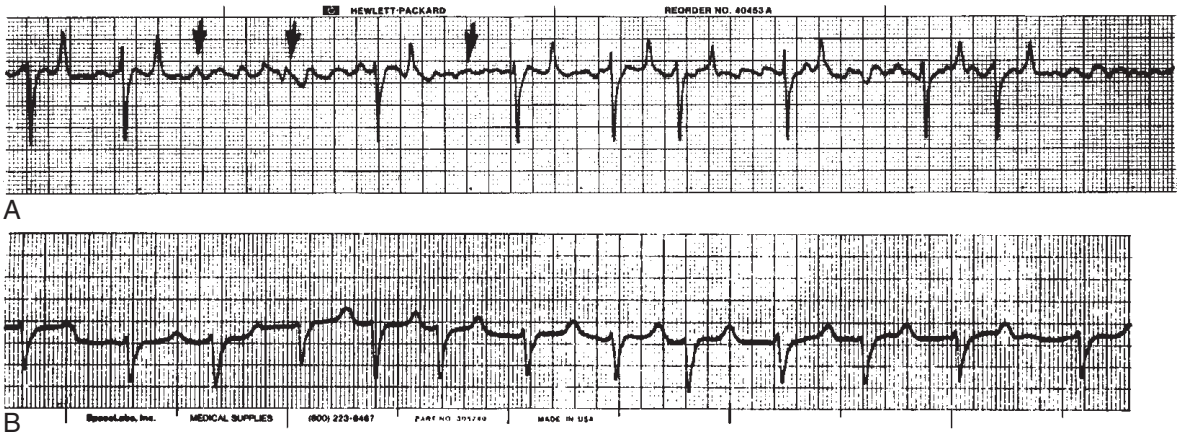

FIG. 30.31 Electrocardiograms showing atrial fibrillation in a horse **(A)** and cow **(B).** The irregular QT intervals and absence of P waves are apparent. *Arrows* point to fibrillation waves, which are apparent only in **A.**

Absence of an auscultable fourth heart sound in the presence of an irregular cardiac rhythm with no underlying regularity distinguishes AF from other cardiac arrhythmias. Sinus arrhythmia, which is also an irregular rhythm, has an audible fourth heart sound. Second-degree AV block, which is usually a regularly irregular rhythm, also has an audible fourth heart sound. However, underlying sinus arrhythmia is usually present in these horses, making it more difficult to distinguish second-degree AV block with sinus arrhythmia from AF. Any increase in sympathetic tone, such as occurs with exercise or excitement, should result in a regular rhythm in horses with second-degree AV block while those with AF will have persistent irregular rhythm. Ventricular and atrial ectopic beats usually occur with a relatively regular underlying rhythm. A complicated ventricular rhythm with more than one focus of activation may have characteristics similar to those of AF and must be distinguished from it by an ECG. Atrial tachycardia with varying degrees of atrioventricular block has similar auscultatory characteristics, and the underlying fourth heart sounds may be missed if the animal is auscultated in a noisy environment.

Clinical Pathology

In cattle with AF, acid-base and electrolyte disturbances occur frequently and are most likely attributable to the underlying primary disease. Most cattle with AF have GI disease, and the most consistent acid-base disturbance is metabolic alkalosis.[289] Hypocalcemia, hypokalemia, and hypochloremia may also be seen in cattle with AF. Experimental induction of metabolic alkalosis with hypokalemia in cattle has been associated with development of AF.[290] Most horses with AF have normal electrolytes, although the fractional excretion of potassium may be low, particularly in horses that sweat excessively or are routinely receiving furosemide for exercise-induced pulmonary hemorrhage. cTnI may be elevated in horses with acute AF, particularly if the sample was obtained 4 to 6 hours after the onset of AF. In most horses, this will decrease rapidly in next day or two following the onset of AF. If the cTnI continues to climb or is very high, active myocardial disease should be suspected. Elevations of T3 or T4 may be present in horses that have been receiving supplements containing kelp, shellfish, or Thyro-L.

The diagnosis of AF is made by ECG. The arrhythmia is characterized by an irregular R-R interval. The ventricular response rate is low, normal, or high, depending on the presence of heart disease or the severity of the primary disease. The ventricular complexes have normal polarity and amplitude but vary slightly in appearance from beat to beat. Similarly, the QT interval and appearance of the T wave vary. P waves are absent, replaced by fine undulations of the baseline called *fibrillation* or *f waves*. In some leads the f waves are barely visible, particularly in cattle (Fig. 30.31). In some cases, atrial flutter may be present with larger saw-tooth baseline undulations called *flutter* or *F waves*.

The echocardiogram is used to determine whether cardiac disease is present. The most significant change associated with the arrhythmia is a mild reduction in shortening fraction (24% to 28%) that occurs, in part, secondary to the loss of the atrial contribution to ventricular filling.[291] Absence of the second (atrial) opening of the mitral valve, corresponding to atrial contractions, is also detected with AF.[292] Conversion to sinus rhythm usually results in these echocardiographic findings returning to normal within several days if there is no underlying myocardial disease.[291,293] Similar improvement occurs in horses with MR and AR after conversion to normal sinus rhythm.[293] In many large animals with AF, no evidence of heart disease can be detected echocardiographically; these animals are often considered to have "lone" AF. However, both electrical and structural remodeling of the atria occur in the horse with AF, which, although reversible early on, contributes to the persistence and recurrence of AF.[294–296]

Abnormal echocardiographic dimensions, if detected, indicate that underlying heart disease is present. Measurement of the maximal left atrial dimension in the two-chambered view of the left atrium and left ventricle from the left cardiac window should be performed in peak systole to determine whether there is left atrial enlargement. This measurement is a more sensitive indicator of left atrial enlargement than the M-mode left atrium–to–aortic root ratio. In normal Standardbred and Thoroughbred horses, the left atrial diameter in this view should be 13.5 cm or less. Measurement of the left atrium–to–aortic root ratio can be performed in the 2D short-axis view of the aorta across the maximal short-axis diameter of the left atrium to obtain additional information about left atrial size.[24] Measurement of the maximal diameter and area of the left atrium can also be performed in the four-chambered view in peak systole if the heart can be imaged in its entirety.[24]

Cardiac catheterization reveals normal cardiac output and blood pressure measurements in most awake horses with AF, but conversion to normal sinus rhythm may induce a reduction in mean right atrial, pulmonary arterial, and aortic pressures.[297] Similar studies have not been reported in cattle.

Pathophysiology

Experimentally, rapid stimulation of the atrium can initiate AF, which can be sustained if the animal has a large heart and sufficient vagal tone.[281,298–301] In horses and cattle the normal

VetBooks.ir

atria may be large enough to support AF once it is established. In addition, both species have a high vagal tone at rest. This combination of factors may be responsible for the large number of benign or functional cases of AF in large animals. The ventricular response during AF results from rate-dependent concealment of AF wavelets bombarding the AV node.[283] Cardiac diseases such as endocarditis, atrioventricular valvular regurgitation, and CHF that result in atrial enlargement and rapid stimulation of the atria provide a setting in which AF can develop and can be sustained naturally. Microscopic cardiac pathology might also create the proper setting for the development of conduction block and reentry.

During AF there is no coordinated contraction of the atria, so ventricular filling is passive. Although this might be expected to reduce cardiac output, there is no evidence this occurs in resting horses without concurrent MR or AR.[297] In several horses with AR or AR with MR, a decreased cardiac output was detected compared with horses without valvular insufficiencies before conversion.[293] The cardiac output increased significantly in warmblood horses with valvular regurgitation after conversion. During exercise, however, the heart rate of horses with AF exceeds normal limits, often by 40 to 60 bpm for each level of exercise. This results in a decreased cardiac output and the resultant exercise intolerance that occurs in horses performing high-intensity athletic work. Even higher heart rates were reported in warmblood horses during lungeing exercise, with the majority of these horses exhibiting QRS complexes with abnormal morphology during exercise.[302] Blood flow to other organs and viscera, although not studied, may be altered in large animals with AF, resulting in reduced GI motility, colic, reduced muscle blood flow, and poor milk production.

Atrial pressures are elevated in horses with AF.[297,303] Sustained high pressure is likely to produce dilation of the atria. With progressive dilation, secondary atrioventricular valve regurgitation may occur. During AF, blood flow to the atrial myocardium is reduced, and progressive fibrosis can also be a consequence of chronic AF. Sustained AF may result in progressive cardiac disease, although it is usually well tolerated in the horse.

Epidemiology

Standardbred, Thoroughbred, and draft horses have been reported to have the highest incidence of AF.[285,287,288] Racehorses have been diagnosed most frequently, but AF has been found in all types of horses.[287,288,293] Horses of all ages are susceptible to AF, but it occurs infrequently in ponies, foals, weanlings, and yearlings. Older horses, ponies, foals, weanlings, and yearlings with AF more frequently have underlying heart disease associated with the arrhythmia.

In cattle, AF is diagnosed more frequently in dairy cattle than in beef cattle, but there is no apparent breed predilection.[280,289] It is commonly associated with GI disease or abdominal pain in cattle.[280,281,289] Foot rot and pneumonia can also be associated with development of AF in cattle.

Necropsy Findings

Many cattle and horses have "lone" AF without apparent underlying heart disease, so the necropsy findings reflect the primary disease. Microscopic cardiac pathology has been found in horses with AF that consists of focal atrial myocardial fibrosis, microvascular alterations, and cardiac nerve abnormalities.[304–306] Multifocal or large areas of myocardial fibrosis were detected in dairy cows with idiopathic AF.[307] Whether these changes predisposed to the development of AF, were a consequence of AF, or were aging changes has not been established. A minority of horses and cattle have endocarditis, CHF, or valvular lesions, and the necropsy findings reflect these conditions. In horses with AF, mitral valve disease was the most common valvular lesion.[288] Pharmacologic and transvenous electrical cardioversion (TVEC) are both options for conversion of AF to normal sinus rhythm in horses.[288,308–319]

Treatment and Prognosis

Quinidine is the drug of choice for pharmacologic conversion of AF to normal sinus rhythm in horses and cattle. The drug is a negative inotrope at high dosages, causes systemic hypotension, increases the ventricular response rate, and can produce undesirable side effects and toxicity—it must be used with caution. In animals with CHF, quinidine therapy has considerable risk.[288] Because most large animals have little or no underlying cardiac pathology, treatment with quinidine is usually successful in restoring normal sinus rhythm. Treated animals should be monitored frequently by physical examination, with careful auscultation and ECG recording. Continuous ECG recording using radiotelemetry should be performed throughout treatment.[311] Animals should have normal acid-base balance and electrolyte concentrations before treatment. They should be adequately hydrated, allowed to drink and eat, or given additional oral fluids (horses) or IV fluids (cattle) during therapy. IV administration of quinidine gluconate is successful in converting horses with recent-onset AF to sinus rhythm.[312] Quinidine gluconate is most successful when administered to horses with AF of 2 weeks or less. However, quinidine gluconate had been successful in converting horses with AF of 2 to 4 weeks' duration. Horses with longer durations of AF should be treated with quinidine sulfate via nasogastric intubation. Quinidine is poorly absorbed after oral administration to cattle, so it must be given by IV infusion to obtain therapeutic concentrations. Cattle should be given IV fluids during quinidine infusion. Quinidine therapy should always be discontinued when conversion to normal sinus rhythm occurs.

Quinidine sulfate is the preparation most economically used in large animals, although quinidine gluconate has resulted in successful conversion of a cow with AF.[320] Before therapy, a baseline ECG is recorded. Horses are given a dose of 22 mg/kg of body weight in a suspension of water via nasogastric tube. At 2 hours (when blood concentration of quinidine should have peaked), they are evaluated closely for idiosyncratic or toxic reactions, such as nasal edema, cutaneous reactions (urticaria or wheals), laminitis, colic, marked diarrhea, or ataxia. An ECG is recorded. If conversion to normal sinus rhythm has not occurred and the QRS duration is not greater than 25% of the pretreatment QRS duration, and none of the aforementioned abnormalities have occurred, another dose is administered. Two hours after each dose is administered via nasogastric intubation, an ECG is recorded. If there has been no conversion to normal sinus rhythm and the horse is not exhibiting toxic or adverse reactions to quinidine, another dose is administered, up to a maximum of four doses. A plasma quinidine concentration should be obtained 1 hour after the fourth dose administered every 2 hours to be sure the horse will be able to tolerate another dose without experiencing toxicity. If the QRS complex is prolonged by more than 25% of the pretreatment value or if a fast (>80 to 100 bpm) sustained supraventricular arrhythmia, ventricular rhythm, colic, marked diarrhea, ataxia, nasal edema, or laminitis develops, therapy should be discontinued. Although laminitis is a frequently reported complication of quinidine sulfate therapy in the older literature, the actual incidence of laminitis associated with quinidine administration is rare.[311] Nasal mucosal edema, neurologic signs, and prolongation of the QRS duration to greater than 25% of the pretreatment value are all signs of quinidine toxicity; if detected, the drug should be discontinued. Colic associated with high dosages of quinidine should also prompt discontinuation of treatment (at least for this attempt at conversion). If conversion has not occurred after a total of four to six doses (one every 2 hours) or after a cumulative dose of 88 to 132 mg/kg of quinidine sulfate has been administered,

VetBooks.ir

treatment intervals should be prolonged to every 6 hours (approximate half-life of quinidine).[311] Only four doses of quinidine sulfate should be administered every 2 hours before switching to every 6 hours if plasma quinidine concentrations cannot be obtained in a timely fashion. The every-6-hour treatment can be continued until the horse converts or shows toxic or adverse side effects or the owner elects to discontinue treatment. The advantage of this treatment regimen is that steady-state plasma and myocardial concentrations of the drug are usually achieved. There is less quinidine toxicity, a lower total dose of quinidine sulfate is used, and horses that did not convert after the standard every-2-hour administration may convert with this treatment regimen. Digoxin at 11 μg/kg PO twice daily can then be added to the therapeutic regimen if conversion has not occurred in 24 to 48 hours; it appears to be helpful in some horses.[311] Concurrent administration of digoxin and quinidine will result in an increased plasma digoxin concentration,[321] so to prevent digoxin toxicity, concentrations should be monitored beginning the second day of combined quinidine and digoxin therapy. If this is not possible, the horse should not receive more than 2 days of combined digoxin and quinidine therapy.

TVEC has been successful in converting horses to normal sinus rhythm and is the preferred treatment for equine AF in some hospitals with the necessary equipment and specialists trained in this procedure. TVEC is particularly useful in horses in which adverse or toxic reactions to quinidine prompted discontinuation of antiarrhythmic therapy with the result that conversion to normal sinus rhythm was not achieved.[316,319] TVEC is also the treatment of choice for horses that have marked resting tachycardia or excessively high heart rates. TVEC is also a good option for those with aberrant conduction or VA with sympathetic stimulation or exercise.

Quinidine sulfate at a dose of 48 mg/kg is suspended in 4 L of saline or lactated Ringer solution when cattle are treated for AF. This dose is administered at a rate of 1 L/h. IV fluids are administered simultaneously in the opposite jugular vein. Cattle should be monitored continuously during the infusion. Cattle frequently become depressed and develop diarrhea during the infusion of quinidine. These signs are side effects, and therapy can be continued. The infusion rate should be slowed if the ventricular response rate exceeds 100 bpm. If the QRS complex is visibly prolonged or a fast (>120 bpm) supraventricular arrhythmia or ventricular rhythm develops, therapy is temporarily discontinued. Just before conversion, some cattle have blepharospasm and are ataxic. The infusion should be discontinued as soon as conversion occurs. Therapy should be discontinued after the 4 L infusion even if conversion to normal sinus rhythm has not occurred.

During quinidine therapy the ECG shows predictable changes. The fibrillation waves become coarser and less frequent. The R-R interval becomes more regular as the heart rate increases. Before conversion there may be a rapid regular atrial rate with more than one saw-toothed flutter (F) wave or P wave for each QRS complex (atrial flutter or atrial tachycardia with atrioventricular block, respectively). At the time of conversion, a single P wave is present for each QRS complex. Frequently a large T_a wave is present and the ST segment is elevated. The ECG should be normal within 12 hours of conversion. A continuous 24-hour ECG is recommended in horses with AF after conversion to determine whether frequent atrial premature depolarizations are present. If the continuous ECG is normal and left atrial and ventricular function has returned to normal, the horse can be returned to training. If frequent trial premature complexes (APCs) are detected or left atrial contractile dysfunction persists, the horse should be rested and treatment with corticosteroids or antiarrhythmics considered. The horse should not be returned to work until the APCs have resolved and left atrial contractile function has returned to normal. IV amiodarone and flecainide have been used to convert horses with AF,[314,315,317] but amiodarone is less successful than quinidine for this purpose.[314,317] VA was common in horses given flecainide, limiting its usefulness as a treatment for AF in horses.[315]

The resting ventricular response rate should be less than 60 bpm in horses and 100 bpm in cattle before quinidine therapy. TVEC is the preferred treatment in horses with high resting heart rates and high heart rate responses to stimulation or during prior quinidine therapy. Digoxin is recommended before quinidine therapy in horses where TVEC is not an option and in cattle with fast heart rates. One or two doses of digoxin (11 μg/kg PO twice daily) are administered before initiation of quinidine therapy in horses with only mild tachycardia. In horses with very labile heart rates or problems with rapid ventricular response rate during a previous conversion, digoxin can be administered for up to 5 to 7 days before initiation of quinidine therapy. Cattle are given digoxin by IV infusion at 0.86 μg/kg/h or 11 μg/kg three times daily. The side effects of quinidine treatment (e.g., rapid ventricular response rate) may be decreased in animals pretreated with digoxin. Digoxin is also indicated as a pretreatment in horses with AF and very low FS (<24%), indicative of underlying myocardial disease. Because cattle with successfully treated primary GI disease frequently convert to normal sinus rhythm spontaneously—usually within 5 days of resolution of the primary problem—treatment is delayed for this period.[289] Cattle that do not convert spontaneously in 5 days, have chronic GI problems, or have AF with adverse hemodynamic effects (poor peripheral perfusion, weak arterial pulses, and/or pulse deficit) are selected for quinidine therapy. The prognosis for cattle with AF is good if the primary problem has been resolved and conversion to normal sinus rhythm occurs. Prognosis for cattle with chronic GI disease is guarded, but many show improved appetite and milk production when AF is resolved. Unless heart disease is present, few cattle experience a recurrence of AF. A small percentage of cattle fail to respond to quinidine therapy, and their prognosis is guarded to poor because milk production and appetite are intermittently poor and heart disease can be progressive.

Horses with paroxysmal AF have a good prognosis for return to performance, and few have a recurrence of the arrhythmia. If possible, predisposing factors such as transient potassium depletion should be removed by discontinuing furosemide administration or adding oral KCl to the diet. Oral bicarbonate milkshakes and thyroid hormone supplementation or supplements containing kelp or shellfish should be avoided. Horses with "lone" sustained AF have a good prognosis for conversion to normal sinus rhythm and a return to previous performance level.[287,288] Horses with sustained AF associated with mild to moderate valvular regurgitation and atrial enlargement often have a recurrence of AF but can usually be successfully converted when indicated. Even mild MR is associated with an increased risk of recurrence of AF. Horses with heart rates over 60 bpm or with signs of CHF have a guarded to grave prognosis, and conversion to sinus rhythm is rarely warranted. Treatment of the underlying cardiac disease (if possible) is warranted, and the horse should be treated for CHF with digoxin, diuretics, and vasodilators as needed. Recurrence of AF and side effects of quinidine therapy are more frequent in horses that have had AF for longer than 4 months before treatment.[288] The recurrence rate for horses with recent onset AF is 15% and increases with longer duration AF up to 45% or more. This may be the result of atrial remodeling and the associated microscopic cardiac lesions that developed with chronic AF.

In horses with permanent AF or in those in which conversion of AF is not an option, an exercising ECG is indicated if ridden or driven exercise is desired, to be sure that these horses are safe to ride for an informed adult rider. The exercise test

should be slightly more rigorous than their regular exercise, if possible. Their heart rates should not exceed 220 bpm at the maximal exercise desired. Heart rate control with oral digoxin or sotalol have been used to slow the ventricular response rate during exercise, but more work is needed to determine the efficacy and safety of this long term.[322] Those with aberrant conduction and multiform VA during exercise should be retired from ridden or driven work.[118]

Ventricular Tachycardia

Definition and Etiology

Ventricular tachycardia (VT) is a cardiac arrhythmia characterized by a rapid rhythm originating in the ventricle. This rhythm originates below the bundle of His in the specialized conduction system, surrounding ventricular myocardium, or both.[323] VT may be caused by disorders in impulse formation, impulse conduction, or a combination of the two.[323] Ventricular reentry is an important mechanism in the genesis of sustained VT, whereas abnormal automaticity is probably responsible for idioventricular rhythms and parasystole. Changes in autonomic tone may also be important in the genesis of VT. Early afterdepolarizations are thought to be the mechanism responsible for ventricular tachyarrhythmias associated with sympathetic stimulation. Late coupled ventricular complexes or a very premature ventricular depolarization are usually required to initiate VT. VT can occur when there is myocarditis, myocardial necrosis, fibrosis, fibro-fatty infiltrate or neoplasia, bacterial endocarditis (especially involving the aortic or mitral valve), autonomic nervous system imbalance, hypoxia, ischemia, electrolyte or metabolic disturbances, anesthesia, drug administration, sepsis, endotoxemia, toxic myocardial injury, or aortic root rupture, or it may be associated with other, unknown causes.[96,233,248,324,325]

Clinical Signs and Differential Diagnosis

The clinical signs detected depend on the ventricular rate, type of VT (uniform or multiform), duration of VT, and severity of the underlying cardiac disease.[325] Large animals with VT may be asymptomatic at rest if the rhythm is relatively slow and uniform, or they may have severe CHF with rapid uniform or multiform VT.[325] Exercise intolerance is common and may be so severe that the animal has frequent syncope. Other complaints include depression, weakness, colic, respiratory distress, coughing, ventral edema, and pulmonary edema. Acute viral or bacterial respiratory disease with high fever may precede development of VT in horses or may occur concurrently with it. Gastrointestinal disease and primary myocardial disease are more common in horses with VT.[324,326] Horses with severe hemorrhage are also at increased risk for VA.[327] In cattle, VT occurs most frequently secondary to sepsis and toxemia. Anorexia and decreased milk production are common in affected cows.

Animals with sustained VT have a rapid heart rate with a regular (uniform) or irregular (multiform) rhythm.[328–331] Heart rates as high as 300 bpm have been detected in horses with VT. Heart sounds vary in intensity, with some loud booming sounds ("bruit de cannon"). Arterial pulse may be variable or uniform, with normal (slower rate) or weak (rapid rate) intensity pulses. Pulse deficits frequently occur, particularly with rapid or multiform VT. Jugular pulses are commonly detected in large animals with VT. The large pulse waves seen in the jugular vein are cannon "a" waves that occur when the right atrium and ventricle contract simultaneously. Cardiac murmurs are not commonly detected. Signs of CHF are usually present when VT is rapid and sustained but are uncommon in animals with slower or paroxysmal VT.[328–330] Signs of right-sided CHF (ventral edema, venous distention) usually predominate with sustained uniform VT and increase in severity the longer the duration and more rapid the rate of the arrhythmia. Signs of left-sided CHF (coughing, expectoration of foamy fluid, respiratory distress) usually predominate with multiform VT.

The presence of jugular pulses and bruit de cannon in an animal with a rapid regular rhythm helps distinguish VT from sinus or supraventricular tachycardia. Multiform VT can be difficult to distinguish from AF, because both arrhythmias have an irregular rhythm with heart sounds that vary in intensity. Jugular pulses may also be detected in large animals with AF but are usually less prominent than in animals with VT. Although large animals with multiform VA usually have more severe clinical signs, an ECG is necessary to distinguish these arrhythmias.

Clinical Pathology

Electrolyte, metabolic, or toxic causes of VT may be present in large animals with primary GI disease. Hypomagnesemia and hypokalemia have also been associated with development of VT.[331] Serum creatinine and BUN may be elevated in horses and cattle in CHF associated with prerenal azotemia. Serum osmolality, BUN, and creatinine increase and urine osmolality decreases acutely in horses with experimental monensin toxicosis.[177] Initial decreases in serum potassium and serum calcium have also been reported in these animals. Marked elevations of cTnI have been seen in horses with VT.[195,196,326] cTnI is a more sensitive indicator of myocardial injury; therefore cTnI is currently preferred for detection of myocardial injury in horses, cattle, South American camelids, and small ruminants. Cardiac isoenzymes of CK and LDH are often elevated if there is recent myocardial injury associated with VT. Elevation of the myocardial fraction of CK (CK-MB) in excess of 5% of the total CK is compatible with myocardial injury in horses.[177] A neutrophilic leukocytosis, elevated SAA, and hyperfibrinogenemia may be detected in animals with infectious myocarditis or bacterial endocarditis or may be elevated owing to the primary underlying disease. In most large animals with VT, however, hematologic findings are normal.

The diagnosis of VT is made from the ECG. A series of four or more ventricular premature complexes (VPCs) is diagnostic of VT.[324,332] The electrocardiographic appearance of the VPC may be widened and bizarre, or the QRS duration and appearance of the QRS and T may be near normal, especially in horses (Fig. 30.32).[324,325] Although the duration of QRS complexes that are ventricular in origin is usually within the normal range reported for horses, it is usually longer than the QRS duration of the horse's normal sinus beats.[324] The major direction of the QRS complex is usually oriented opposite to that of the T wave. The R-R intervals may be regular or irregular. The morphology of the QRS complexes may be similar (uniform) or may vary widely with multiform VT (Fig. 30.33). Atrioventricular dissociation is usually present, with an atrial rate slower than the ventricular rate. Fusion beats and capture beats may be detected. VT can be sustained or paroxysmal.

The echocardiogram is used to determine whether cardiac disease is present. The echocardiogram is usually abnormal in large animals with primary myocardial disease and normal in large animals with secondary VT, except for the changes associated with the VT itself (see Fig. 30.15). Abnormal echocardiographic findings that may be detected in large animals with primary myocardial disease include myocardial dyskinesis, hypokinesis, and akinesis; abnormal myocardial echogenicity; decreased FS, ET, and EF; loss of the normal systolic and diastolic undulations of the aortic root; and detection of spontaneous contrast, small aortic root, and large pulmonary artery. Occasionally the echocardiographic abnormalities created by VT may be difficult to distinguish from those of primary myocardial disease. Rupture of the aortic root at the right sinus of Valsalva should be considered in horses with acute onset of uniform VT and colic.

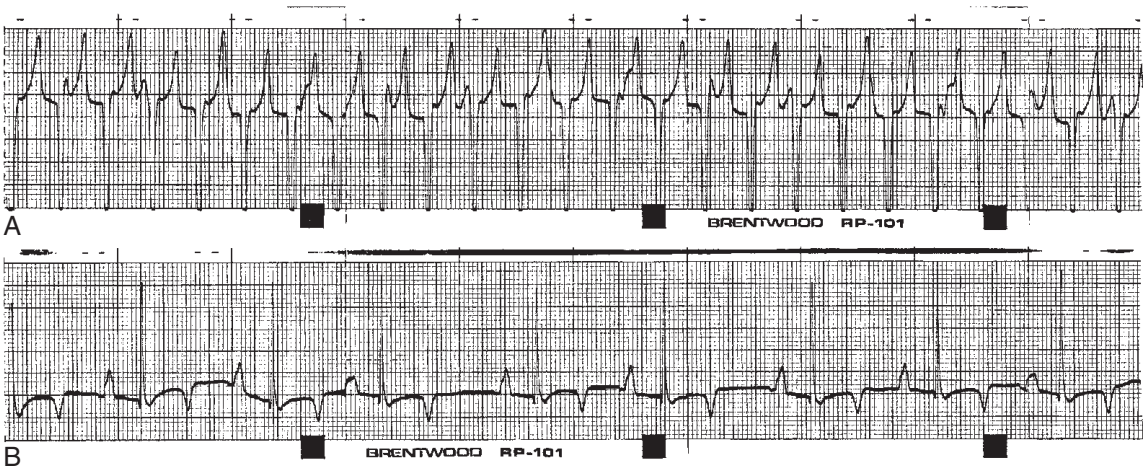

FIG. 30.32 Lead II electrocardiogram obtained from a horse with sustained uniform venticular tachycardia (VT) and congestive heart failure before **(A)** and after **(B)** conversion to sinus rhythm. Note the abnormal QRS and T configuration and slower atrial rate during the sustained VT.

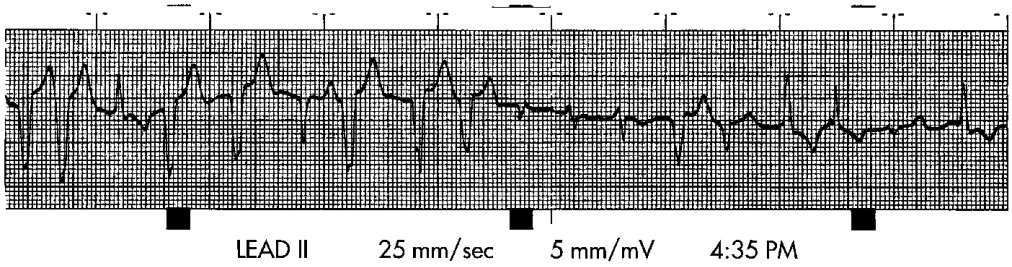

FIG. 30.33 Lead II electrocardiogram obtained from a horse with multiform ventricular tachycardia and acute onset of pulmonary edema. Note the multiple different QRS and T configurations and the elevated ventricular rate.

Cardiac catheterization may reveal severe hypotension and low cardiac output. In healthy ponies with pacing-induced VT, stroke volume decreased significantly when the ventricle was paced at 150, 200, and 250 bpm.[333] Mean left atrial pressure, mean pulmonary arterial pressure, and right ventricular systolic pressure increased significantly when the ventricle was paced at 220 and 250 bpm. Aortic pressure and cardiac output decreased in these ponies at 250 bpm, but the decrease from resting values was not statistically significant. Myocardial perfusion in the papillary muscles and subendocardium decreased significantly with pacing-induced VT at a rate of 250 bpm. Decreases in cardiac output, arterial blood pressure, and myocardial perfusion are even more marked in animals with underlying myocardial disease or multiform VT, as are the changes in left atrial, pulmonary arterial, and right ventricular pressure.

Pathophysiology

VT is probably initiated spontaneously by late coupled ventricular complexes, whereas one very early ventricular premature depolarization can often initiate VT electrically.[323] Sympathetic stimulation may also provoke VT by increasing the amplitude of the early afterdepolarizations, culminating in a run of VT.[323] This may be the mechanism of some of the exercise-induced VT in horses. Reentry in the ventricle is an important cause of sustained VT, particularly in human patients with dilated cardiomyopathy and ischemic heart disease. The area of reentry is reportedly small (<1.4 cm^2).[323] Reentry is also thought to be an important mechanism in horses with sustained VT.[330,334,335] Delayed afterdepolarizations may trigger VT in humans and dogs and may be the mechanism for digitalis-induced VT.[323] Abnormal action potentials have also been demonstrated in ventricular myocardium resected from human beings with recurrent VT.[323] Depressed automaticity and afterdepolarizations have been associated with acute myocardial ischemia, whereas automaticity and afterdepolarizations are enhanced in Purkinje fibers surviving myocardial infarction. Idioventricular rhythms and parasystole may be caused by abnormal automaticity.

Cardiac diseases such as endocarditis may result in septic myocardial emboli and myocardial ischemia. Aortic root rupture and dissection of blood into the interventricular septum disrupts conduction and usually results in a uniform VT. Myocarditis, myocardial necrosis, and fibrosis or a fibro-fatty infiltrate also may result in abnormalities of impulse formation and conduction, leading to VT.[336] The excitement of the high-performance situation (sympathetic stimulation) and the decreased myocardial perfusion that may occur at peak exercise may make exercise-induced VT more common in racehorses and other types of high-performance horses.

Epidemiology

VT has been reported in all large animals, although horses may have the highest incidence. VT leading to ventricular fibrillation is thought to be one of the leading causes of sudden cardiac death in horses when other causes of death cannot be found on postmortem examination.[335,337,338] Male horses are at increased risk for aortic root and sinus of Valsalva rupture and are usually middle-aged at the time of rupture. However, aortic rupture has been seen in horses as young as 3 years of age. VT is also more likely in large animals of any age with primary GI disease and in horses following severe hemorrhage.

Necropsy Findings

If VT is not associated with primary myocardial disease, necropsy findings reflect the underlying disease. Gross and microscopic cardiac pathology has been found in horses with

VetBooks.ir

VT (see Fig. 30.30), although in some horses no cardiac pathology is found. Areas of myocardial necrosis, inflammatory cell infiltrate, fibrosis, fibro-fatty infiltration, infarction, microvascular alterations, and cardiac nerve abnormalities have been reported in horses with VT.[305,330,335,336] CHF is most likely in large animal patients with multiform VT and heart rates in excess of 180 bpm. Bacterial endocarditis and secondary septic emboli dissemination through the coronary arteries as a result of VT occurs in a minority of large animal patients. Aortic root rupture and rupture of a sinus of Valsalva aneurysm with dissection of blood into the interventricular septum are infrequently detected in horses.

Treatment and Prognosis

Treatment and prognosis for VT depends on the suspected cause of the arrhythmia, severity of the animal's clinical signs, and electrocardiographic abnormalities detected.[324,325] Relatively slow, uniform VT often resolves or improves significantly with correction of the underlying electrolyte or metabolic imbalances, without requiring antiarrhythmic therapy. These animals usually have an excellent prognosis for conversion with correction of the underlying problem. Similarly, in large animals with sepsis or toxemia, hemodynamically and electrically stable VT often resolves with treatment of the underlying disease. Uniform, hemodynamically stable VT in animals with myocarditis may resolve with rest and/or corticosteroid therapy. A minimum of 4 to 8 weeks of rest is indicated in these patients before returning to work, once the VT has resolved.

Treatment with antiarrhythmics is indicated in any animal with hemodynamically unstable or life-threatening VT. Treatment with antiarrhythmics is indicated if clinical signs of CHF or cardiovascular collapse are present or if the rate of sustained VT is extremely high. In horses with sustained uniform VT, a heart rate in excess of 120 bpm usually warrants antiarrhythmic therapy, whereas in cattle, antiarrhythmic therapy may not be indicated until the heart rate exceeds 140 bpm or greater. Horses with rapid sustained uniform VT (≥120 bpm) need antiarrhythmic therapy, because signs of CHF will develop after several days or weeks with this arrhythmia, if not already present. Rapidity of CHF onset is related to heart rate and type of primary myocardial disease, if present. These horses usually have a good prognosis for conversion and return to their previous performance level with appropriate antiarrhythmic therapy (many times three or more antiarrhythmic drugs must be tried before conversion occurs) and rest before the horse is returned to work.

ECG findings associated with life-threatening VT include a multifocal origin for the ventricular premature depolarizations, torsades de pointes (wide VT), and the presence of an R wave superimposed on the preceding T wave ("R on T"). Large animal patients with clinical signs of CHF and hemodynamic collapse with rapid (heart rate <120 bpm) multiform VT (±R on T) should be treated as a cardiovascular emergency; sudden death from ventricular fibrillation is likely without antiarrhythmic therapy. Large animals with multiform VT (±R on T) must be given a guarded to grave prognosis for survival because most have severe underlying myocardial disease. Often conversion to sinus rhythm may not be successful before the animal develops ventricular fibrillation and dies. If successfully converted to sinus rhythm, many of these animals die or are euthanized because of the severity of the underlying cardiac disease.

Several antiarrhythmic choices are available to the large animal practitioner for correcting life-threatening VT (see Table 30.3). Lidocaine hydrochloride—the most readily available drug for most large animal practitioners—is rapidly acting, administered IV, and has a short duration of action and minimal hemodynamic effects. However, this drug has central nervous system side effects in horses (hyperexcitability and seizures) and must be used at a lower dosage than in cattle. Quinidine gluconate (or quinidine sulfate in cattle) is effective in large animals but is less rapidly acting, has negative inotropic effects at large doses or if primary myocardial disease is present, causes hypotension, and can produce undesirable adverse or toxic reactions. Magnesium sulfate can cause hypotension but has no other recognized adverse cardiovascular effects. It is less rapidly acting than lidocaine, but in both normomagnesemic and hypomagnesemic patients it may be effective when other antiarrhythmics fail. IV procainamide, IV and oral propafenone, and IV flecainide have also been used successfully in horses with VT. IV propafenone is indicated for refractory VT and has been used successfully in several horses that did not respond to lidocaine, quinidine, procainamide, or magnesium sulfate. However, it is currently unavailable in the United States. Sotalol has been successful in several horses with VT and is available in an intravenous formulation.[339] Other antiarrhythmics such as propranolol have been used with less success but have converted large animals with sustained VT.

Diagnostic Procedures for the Respiratory System

General Evaluation of the Patient With Respiratory Disease

Kara M. Lascola • Pamela A. Wilkins

History

As with any disease process, acquisition of an accurate and appropriate history is the first step undertaken in evaluating the patient with a complaint thought to be related to the respiratory tract. Animals with respiratory disease may have widely varied histories, so a thorough anamnesis is necessary. Age and breed may play a role in the development of respiratory disease, such as congenital defects or neoplastic disease, or in inherited or acquired immunodeficiency syndromes seen in certain breeds. The environment in which the animal is maintained can contribute to the development or severity of respiratory disease. For example, equine recurrent airway obstruction (RAO) and inflammatory airway disease (IAD) may manifest following a change to a new environment. Stressful events, such as weaning or long-distance transport, can predispose both horses and cattle to respiratory disease. It is important to know if certain diseases are either endemic or epidemic where the animal is kept or has recently resided. Any recent traumatic or potentially traumatic event should be noted. A thorough vaccination history should be obtained, as should an accurate history of any treatments or supplements and the patient's response.

Presenting Signs or Chief Complaints

Unilateral or bilateral nasal discharge is a common finding or complaint associated with respiratory disease. Respiratory noise at rest or during exercise is commonly associated with abnormalities of the upper airway and may accompany inequalities of airflow present at the nares. Normal animals may periodically cough or sneeze, but an increase in either activity may indicate involvement of the respiratory tract. Exercise intolerance or reduction in athletic performance should prompt evaluation of the respiratory system. Other clinical signs that should encourage the clinician to conduct a thorough evaluation of the respiratory tract include abnormal breathing patterns (tachypnea, hyperpnea, dyspnea), cyanosis, hemoptysis, epistaxis, unusual swellings (facial, pharyngeal, cervical), lymphadenopathy, ataxia or reluctance to move, foul smell to the breath, weight loss, and ventral abdominal, sternal, or limb edema.

Physical Examination

The initial physical examination occurs at some distance from the patient and involves evaluation of the demeanor, posture, mental status, and way of movement of the patient. It is important to note if the patient has an abnormal stance, such as standing with the head and neck extended. If the patient is unwilling to move or stands with elbows abducted, this suggests that pleural pain is present. Ideally the respiratory rate can be determined by observation, as can the respiratory pattern. Although some respiratory diseases are not manifest at rest, important clues can be gained from observation of the patient at rest in many others. The normal resting respiratory rate of an adult horse is 8 to 16 breaths/min, of adult cattle is 15 to 35 breaths/min, and of sheep and goats is 12 to 20 breaths/min. There is some small abdominal component during the expiratory phase. The normal rate for neonates is up to 60 breaths/min at birth and less than 30 breaths/min by 1 month of age; respiratory rate decreases toward the adult rate with age. High ambient temperature, fever, and excitement can all increase respiratory rate. Normal breathing, which is quiet and apparently effortless, is termed *eupnea*. The term *dyspnea* is a breathing pattern that is inferred by the observer to reflect difficulty in breathing; the animal will appear distressed, and the work of breathing is obviously increased, although the actual rate may be within normal limits. Other terms used to describe breathing patterns include *tachypnea*, characterized by rapid rate and shallow depth or low tidal volume; *hyperpnea*, with increased frequency and depth of breathing (an example would be during postexercise recovery); and *apnea*, in which there is no discernible breathing. Two additional terms include *hypoventilation* and *hyperventilation*, both of which require a change in arterial carbon dioxide partial pressure as a component of their definitions. Hyperventilation is a pattern that increases alveolar ventilation and causes arterial hypocapnia, whereas hypoventilation alters gas exchange in such a way to cause arterial hypercapnia, or retention of carbon dioxide.

Closer examination can reveal some of the physical manifestations of presenting complaints listed previously. Beginning

VetBooks.ir

with the head, the clinician should determine that airflow is even from both nostrils, as differences can indicate either congenital or acquired abnormalities ranging from choanal atresia to the presence of upper airway masses. Abnormal respiratory sounds can sometimes be present at rest and may be heard at the nares. Abnormal breath odors may be detected. The frontal and maxillary sinuses should be percussed; identification of abnormal resonance, usually dullness, may be made easier by performing this with the mouth held open. Palpation of the submandibular regions, larynx, and pharyngeal and cervical regions should be performed to identify any abnormal lymph node enlargement, masses, or areas of muscular atrophy. Both jugular veins should be checked for patency and the presence of any evidence of injection sites or infections that may contribute to abnormal upper airway function by interfering with normal recurrent laryngeal nerve or vagosympathetic trunk function.

Coughing represents a nonspecific irritation of receptors in the airway and can be induced by many mechanisms. It can be, and usually is, a normal protective reflex that allows the animal to clear material from the airway. Cough can be associated with increased mucus production, production of other respiratory secretions, or decreased mucociliary clearance. In older horses cough is often associated with severe RAO, whereas in younger horses cough is more commonly associated with infectious diseases and IAD (see discussion of these disorders later in this chapter). Normal animals should not cough when the larynx or trachea is palpated.

Nasal discharge can be unilateral or bilateral, scant or copious, clear, mucoid, mucopurulent, or even bloody. The nature and character of nasal discharge can provide some information about a possible source of the discharge, but this information should not be overinterpreted. Horses, for example, have a tendency to swallow excess airway secretions, and the volume of secretions may be underestimated. Whereas unilateral nasal discharge is often suggestive of a source in front of the larynx, bilateral nasal discharge can be of either upper or lower airway origin. Skin depigmentation of the ventral nares or presence of mucoid material in feed or water containers are clues to the presence of nasal discharge.

Hemoptysis is the coughing up of blood from the airways or lungs. It is important to determine conclusively that the blood has come from the respiratory system. Epistaxis is defined as blood seen at the nares and often originates in the nasal passages, sinuses, turbinates, nasopharynx, or equine guttural pouches, although the lung can be, and is, a source on occasion, as in exercise-induced pulmonary hemorrhage (EIPH) or following lung biopsy. Bilateral epistaxis generally indicates bleeding caudal to the choanae. Because animals tend to swallow excessive respiratory secretions, bleeding can be occult and may not be seen unless the animal drops its head toward the ground. Significant blood loss can occur in this manner, unseen by owners.

Examination of the oral mucous membranes may reveal cyanosis, which is bluish discoloration of the oral, nasal, or vulvar mucous membranes. Cyanosis does not become apparent until approximately one third of the total normal hemoglobin is deoxygenated; this reflects a profound decrease in oxygen saturation of hemoglobin and is suggestive of severe hypoxemia. Since the total quantity of deoxygenated hemoglobin lends the mucous membranes the bluish color, very anemic patients may lack sufficient deoxygenated hemoglobin to appear blue, which makes appreciation of cyanosis impossible in these patients. One caveat is that all newborns are cyanotic for the first few breaths and only become pink when they have established neonatal, as opposed to fetal, cardiorespiratory circulation and have fully inflated their lungs to allow for gas exchange.

It is important that auscultation of the thorax take place in as quiet an environment as possible. In addition, auscultation of the lung fields should be performed under two breathing conditions, eupnea and hyperpnea, with the latter induced by the use of a rebreathing maneuver (bag). The purpose of this technique is to cause the animal to rebreathe its own expired carbon dioxide. The resultant increase in $PaCO_2$ stimulates deeper and more frequent breathing efforts, making recognition of abnormal lung sounds simpler. The rebreathing bag must be large enough to accommodate two to three times the normal tidal volume of the animal and should be held in such a manner as to prevent the bag from occluding the patient's nostrils. Once the bag is removed, the animal will usually take several very deep breaths, and the examiner should take advantage of these breaths to reexamine areas where suspicious sounds were heard during rebreathing. Coughing and prolonged time of return to baseline respiratory patterns should be noted. This technique is contraindicated in animals demonstrating increased respiratory effort at rest.

Normal breath sounds are those produced by turbulence within the tracheobronchial tree and may vary considerably depending on location within the lung, breathing pattern, and condition of the animal.[1] Only airways from the larynx to segmental bronchi contribute to sound generation. Vesicular sounds—the quietest sounds, heard over the middle and diaphragmatic lung regions—correlate best with regional ventilation and mainly represent segmental bronchial sounds; they do not represent airflow in terminal conducting airways and alveoli, which is silent due to the nature of its flow. Bronchial sounds are louder and heard best over the trachea and base of the lung. Common abnormalities found during auscultation include ventral areas of dullness if pleural effusion is significant, dorsal areas of dullness or hyperresonance with pneumothorax, and dorsal harsh lung sounds. The degree of variation in normal lung sounds is large, and auscultatory findings do not always correlate well with the degree of lung abnormality. That said, abnormal lung sounds are always potentially clinically important.

Adventitious lung sounds are divided into short discontinuous sounds called *crackles* and longer continuous sounds called *wheezes*, replacing the older terms *rales* and *rhonchi*, respectively. Crackles are most commonly generated by sudden pressure equalization when collapsed airway segments open. Although an air-fluid interface is required, crackles do not necessarily imply excessive secretions or pulmonary edema. They are often end-inspiratory and associated with reinflation of atalectatic lung. Crackles may be normal when auscultated in the newborn or over the previously down-side lung of a laterally recumbent neonate. Disease processes that generate crackles include pneumonia, interstitial fibrosis, chronic obstructive lung disease, congestive heart failure, and atelectasis.[2]

Wheezes commonly represent oscillation of airway walls before complete closing (expiratory) or opening (inspiratory). Intrathoracic airways are usually involved in expiratory wheezes and include the lower trachea and main, lobar, and segmental bronchi. Disappearance of a wheeze after coughing indicates secretory rather than tissue component origin. Disease processes responsible for wheezes include airway stenosis or external compression, airway lumen compromise by a foreign body, purulent material, cyst or neoplasm, bronchoconstriction, and airway wall thickening as occurs in chronic bronchitis. Expiratory wheezes are a hallmark of obstructive lung diseases such as RAO. Crackles and wheezes may be variably present. A final category of adventitious sounds is the "rubbing" or "creaking" sounds generated by sliding or stretching of inflamed pleural surfaces, commonly termed *pleural friction rubs*.

Percussion of the thorax is performed by methodical tapping over the intercostal spaces of the thorax using a variety of instruments, including plexors, pleximeters, spoons, or fingers. It is of relatively low diagnostic sensitivity but may be useful particularly when thoracic ultrasound is not available. It should be performed when pleural effusion is suspected and in all

VetBooks.ir

ruminants to detect occult pneumonia. Percussion can reveal hyporesonance (dullness) ventrally when pleural effusion is present, reveal hyperresonance dorsally in pneumothorax, and cause some patients with pleurisy to exhibit pleurodynia (pleural pain). Other conditions that can alter resonance of the thorax include diaphragmatic hernia with intrathoracic intestine, pericardial effusion, pulmonary and pleural abscessation, and consolidated lung. It is usually impossible to fully delineate the lung field cranially because of body fat and triceps musculature. There is a distinct region of cardiac dullness for all species on the left side.

Additional Diagnostic Evaluation of the Respiratory Tract

Endoscopy

The upper airway can be directly examined with the aid of an endoscope, the only limitations being the size of the patient, the patency of the airway, available means of restraint, and the size of the available equipment. Standard flexible fiberoptic endoscopes allow direct examination of the nasal passages, ethmoid turbinates, nasal maxillary opening of the sinuses, pharynx, guttural pouch openings, larynx, and cranial trachea (Fig. 31.1). Smaller (8 to 10 mm in diameter) endoscopes can be readily introduced into the equine guttural pouches, with the aid of a biopsy instrument, and longer bronchoscopes (200 to 250 cm) are commonly used to examine main stem bronchi and their initial branches in large animals. Smaller species may require the use of a smaller diameter (3 to 5 mm) endoscope or bronchoscope. Small brushes, used for collecting exfoliated cells for cytologic study, and a variety of biopsy instruments can be used for sampling the airway.

Airway endoscopy in the horse has evolved to include dynamic respiratory endoscopy (e.g., high-speed treadmill, overground endoscopy) during exercise to evaluate the dynamic function of the upper respiratory tract.[3-5] Objective measurements can be made using videoendoscopy with slow motion or freeze-frame features.[3] Treadmill endoscopy is available at specialty practices and typically is performed at high speed (12 to 14 m/s) using incremental standardized testing protocols. Overground telemetric endoscopy is performed during ridden exercise in the field with endoscopy equipment that is attached to the horse.[4,5] Advantages of overground endoscopy include the ability to evaluate the horse under saddle and in natural working conditions. However, standardizing exercise tests in the field may be more challenging. While resting endoscopy can detect many abnormalities involving the upper airways, dynamic upper airway obstructions that develop during exercise may be missed. In these situations dynamic endoscopy, if available, is the preferred diagnostic tool.[5] Sedation or tranquilization will aid many standing endoscopic examinations, but examinations aimed at evaluating pharyngeal and/or laryngeal function are best performed without any form of chemical restraint that might alter function. Most horses will allow standing examination of the upper airway with only physical restraint, such as judicious use of a nose twitch. Introduction of the endoscope into the trachea may elicit coughing. Small ruminants, such as sheep and goats, may require local tracheal administration of 2% lidocaine diluted to a 0.2% to 0.3% solution. If lidocaine is used in small ruminants, it must not reach a toxic dose (~6 mg/kg). Diluted lidocaine can similarly be used in horses and cattle for evaluation of the distal trachea, main stem bronchi, and larger bronchial tree branches. Horses are more sensitive to tracheal and bronchial stimulation and are more likely to require lidocaine than are cattle.

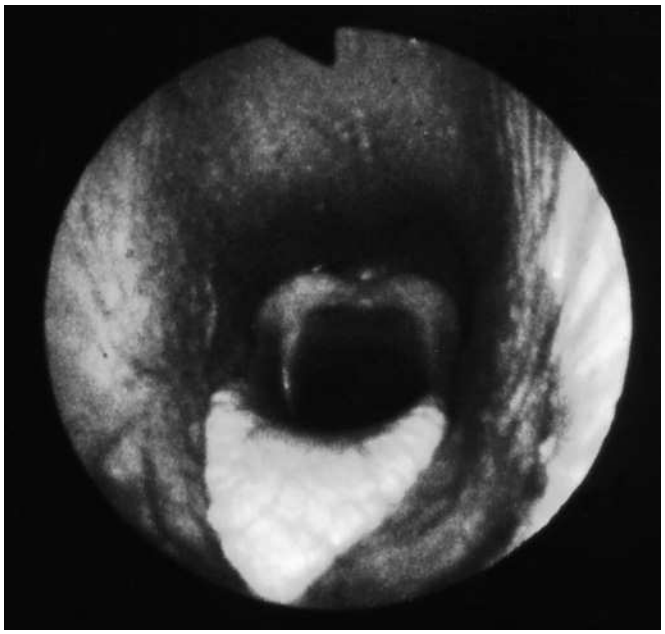

FIG. 31.1 Normal equine larynx. The larynx is directly visualized by endoscopy, with both structure and symmetry evaluated. *(Courtesy Dr. Corinne Sweeney, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.)*

Guttural pouch diseases and upper airway abnormalities, such as pharyngeal lymphoid hyperplasia, laryngeal hemiplegia, epiglottic entrapment, dorsal displacement of the soft palate, pharyngeal cysts, retropharyngeal masses, and epiglottic deformities, are best diagnosed by endoscopic examination. Direct tracheobronchoscopic examination is useful for the diagnosis of tracheal diseases such as tracheal collapse or trauma as well as for the diagnosis of lower airway abnormalities such as EIPH and mild to moderate equine asthma (IAD). Bronchoscopy may also be useful for evaluating additional lower airway abnormalities, including severe equine asthma (RAO), tumors, or abscesses. The degree and nature of airway secretions accumulating in the trachea can be easily assessed with an endoscope, and scoring systems for tracheal mucus and blood have been developed for the diagnosis of mild to moderate IAD[6] and EIPH,[7] respectively. Accumulated secretions in the trachea and distal airways may be sampled by aspirating the secretions through small tubing introduced through the biopsy channel of the endoscope. Because the endoscope has passed through the nonsterile upper airway, samples collected without the use of a sterile, double- or triple-lumen guarded tube are best suited for cytologic, not microbiological, evaluation but may be fully compatible with evaluation using molecular diagnostic techniques.[8-11] Endoscopy has also been used to help remove foreign bodies from the airway, generally aided by the biopsy instrument.

Endoscopic evaluation of the thoracic cavity (thoracoscopy) can be performed in horses under sedation or general anesthesia[12] and has also been described in healthy cattle.[13] The procedure can be useful for the evaluation and treatment of conditions such as thoracic neoplasia, pleuropnemonia or other pleural disorders, and thoracic trauma. Thoracoscopic-guided lung biopsies can also be performed in the horse.[14] Thoracoscopy is performed using standard laparoscopic equipment, including a rigid endoscope, camera, monitor, light source, and insufflation systems when performed under general anesthesia. The provision of supplemental oxygen is essential, and ventilatory support may become necessary during standing procedures.

Diagnostic Imaging

RADIOGRAPHY. Radiographs are indicated for evaluation of congenital abnormalities, diseases, or trauma involving the

VetBooks.ir

respiratory tract or thoracic cavity. Radiographs are frequently performed along with endoscopy or thoracic ultrasound for more thorough evaluation of the upper respiratory tract or lower respiratory tract and thoracic cavity, respectively. Portable equipment needed to perform radiographic evaluation of the upper airway is available in the majority of private practices, while most large referral and university practices have the equipment needed to perform thoracic radiography in larger patients such as adult horses and cattle. Portable systems are generally suitable for thoracic imaging in foals or calves, camelids, and small ruminants. Digital radiography has replaced traditional film-screen radiography in many practices and referral clinics. Advantages to digital systems include portability, speed of image acquisition and processing, and immediate on-site image display as well as a greater range of radiographic exposures and tools for image manipulation.[15,16]

Skull and cervical radiographs offer diagnostic information for evaluation of the upper respiratory tract, including the sinuses, pharyngeal and laryngeal structures, and the extrathoracic trachea. For large animal species, standing lateral skull films are easily obtained, whereas ventrodorsal and oblique projections often require sedation. Certain difficult patients may require general anesthesia. Sinuses affected by neoplasia or inflammation may show abnormal tissue density, a horizontal fluid line on a standing lateral film, bone lysis around the affected sinus, or alveolar periostitis. Thorough evaluation of the sinuses and nasal passages requires lateral, dorsoventral, and oblique views. Foreign bodies may be detected if they are radiopaque. The equine guttural pouches are evident on lateral skull projection, and abnormal fluid accumulation, distortion by enlarged retropharyngeal lymph nodes, and emphysema can be identified.

Radiographic assessment of the thorax of large animals remains preferable to ultrasonographic examination for detection of diffuse parenchymal diseases, such as interstitial pneumonia, pulmonary edema, equine multinodular pulmonary fibrosis, fungal pneumonia, acute respiratory distress syndrome (ARDS), chronic disorders, and deep parenchymal or mediastinal abscesses. Radiographic changes can be nonspecific for a particular disease or minimal to nonexistent in diseases such as EIPH or mild IAD. The thorax in adult horses and cattle is filmed as standing lateral, generally requiring a series of three to four separate but overlapping images to capture the entire lung field; thus the benefit of the ventrodorsal view, in which the two lungs may be compared, is lost. Bilateral standing radiographs may aid in localizing lesions to one hemothorax or the other. In neonates and small ruminants the entire lung field can be imaged in one to two views, and as these animals can be more readily handled and restrained, multiple recumbent views are possible. If significant accumulation of pleural fluid is suspected, ultrasonographic examination should be performed first and radiographs obtained following drainage of excess fluid, as fluid may obscure potentially important parenchymal disease.

Four types of radiographic patterns are described for the thorax: alveolar (airspace), interstitial, bronchial, and vascular. In the alveolar pattern, opaque areas coalesce and fully obliterate vessels and bronchi, and air bronchograms may be prominent. This pattern is commonly found in pulmonary edema, pulmonary hemorrhage, equine multinodular pulmonary fibrosis, ARDS, pneumonia with lung consolidation, and neoplasia. Interstitial patterns are the most common pattern noted in equine thoracic radiographs and are characterized by a blurring of the edges of pulmonary vessels, a diffuse increase in lung density, and variable reticular, linear, and nodular opacities. The *reticular* pattern is most commonly associated with more diffuse infectious lung diseases, pulmonary edema, interstitial pneumonia, and pulmonary fibrosis, whereas the irregular *linear* pattern is seen most commonly with resolving bronchopneumonia. *Nodular* opacities are consistent with abscesses, granulomata, and neoplasms. It is rare to see a pure bronchial pattern in a horse; it is usually seen in association with an interstitial pattern. An exception is paired linear opacities or numerous small circular opacities (donuts) representing thickening of large or medium airways in equine bronchitis or bronchiolitis. The vascular pattern is seen in horses radiographed immediately after exercise or in animals with left-to-right cardiac shunts. Finally, extraparenchymal problems such as pleural effusions or free gas may be seen on thoracic radiographs of large animals. Thoracic radiology is far less sensitive than ultrasonography for evaluation of potential rib fractures.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING. Advanced radiographic modalities such as computed tomography (CT) and magnetic resonance imaging (MRI) have become increasingly available at academic and private referral practices and can aid in the diagnosis and characterization of certain upper airway disorders in large animal species. Advantages to these systems are that they provide high-resolution three-dimensional imaging and minimize superimposition of overlying structures that may complicate interpretation of skull radiographs. An additional advantage of CT is the high speed of image acquisition. Standing CT units allow for imaging of the head and proximal cervical region in sedated adult horses, thus eliminating the need for general anesthesia. CT provides excellent bone and soft-tissue contrast and is often used in the diagnosis of sinonasal disorders such as dental-related sinus disease, neoplasia, and ethmoid hematomas.[17] MRI provides superior soft-tissue detail, and its use is also described for the diagnosis of laryngeal and sinonasal disorders in adult horses.[18,19] MRI is currently more limited in its application toward routine use in large animal species because of the availability of equipment, time required for acquisition of images, and potential costs associated with the procedure.

CT imaging has also become a more desirable tool for the diagnosis of pulmonary and extrapulmonary thoracic disease in hospitalized veterinary species, particularly as the considerable reduction in image acquisition time often eliminates the need for general anesthesia. CT thoracic imaging in large animals is limited to small ponies, foals, calves, and smaller species such as camelids, where it has been described in healthy and sick animals with pulmonary and extrapulmonary disease.[16,20-22] Imaging of the thorax is not possible in larger animals due to restrictions in currently available CT gantry diameters and limitations associated with exposure settings needed to penetrate a larger torso.

Ultrasonography

Thoracic ultrasonography is useful for diagnostic, therapeutic, and prognostic evaluation of the extraparenchymal thorax, the pleural space, and the peripheral (superficial) parenchyma of the lung and should be considered for complete evaluation of any large animal with pulmonary disease. Unlike thoracic radiography in adult large animals, thoracic ultrasonography is an imaging technique readily available to most practitioners. In many instances it is superior to thoracic radiography; examples include evaluation of pleural effusions, assessment of thoracic trauma and rib fractures, evaluation of neoplasms or granulomata, detection of mediastinal masses or abscesses, and guidance of transthoracic lung biopsy.[23-25] Field ultrasonography has also become an important tool in monitoring dairy calves for bovine respiratory disease.[26]

Ultrasonography is generally performed with the patient standing, although in neonates lateral recumbency may be preferred or even necessary.

Although ultrasound waves will not penetrate the aerated portion of the lung, limiting the examination to extraparenchymal surfaces in normal horses, ultrasonography is superior to thoracic radiography for the evaluation of these areas of

VetBooks.ir

the chest. Small amounts of pleural fluid that would be missed on auscultation, percussion, or thoracic radiographs can be detected, and the amount and character of pleural effusion in each hemithorax can be evaluated separately.[23] Clear fluid is anechoic, but inflammatory cells, gas, and fibrin are echogenic, causing opacities that can be seen floating in pleural fluid and altering the general echogenicity of the fluid. Because of this, ultrasound is the method of choice for diagnosis and monitoring of pleural space disease. Ultrasonography should be used to guide catheter placement for thoracocentesis. The pleural surfaces are imaged well by ultrasound with thickened or roughened areas easily detected. Lack of normal independent movement of the visceral and parietal pleural surfaces during the respiratory cycle, suggestive of adhesion formation, can be readily monitored.[23,24]

Consolidated lung is a better acoustic medium than aerated parenchyma and can be well visualized. Pleuropneumonia with consolidation or atelectasis caused by compression of the ventral lung by pleural effusion can be evident. Pulmonary abscesses or masses extending to the lung surface can be imaged, and ultrasound can be used for guidance during transthoracic biopsy.[23,24] Thoracic radiography remains superior to ultrasound in the diagnosis of pulmonary parenchymal disease and pneumothorax; the two techniques can be combined to optimize diagnostic capacity.

Nuclear Medicine Imaging

Nuclear scintigraphy is a specialized technique available at a few specialty referral practices. Gamma-emitting radioisotopes, most commonly technetium-99m, can be used with an external detector (gamma camera) to assess regional pulmonary ventilation and perfusion in the horse. For perfusion scans, the radioisotope is bound to albumin aggregates and injected into a peripheral vein. The aggregates become trapped in the pulmonary arterial vasculature, and the resulting image illustrates the perfusion distribution of the pulmonary arterial system. The ventilation scan is generated when the horse inhales aerosolized radioisotope particles through a closed circuit system.[27] The particles are small enough in diameter to be deposited in the alveoli and small conducting airways, with the gamma camera recording the sites of deposition. Together, the ventilation and perfusion scans allow for evaluation of the ventilation/perfusion (V/Q) ratio, important in evaluation of certain respiratory problems such as chronic EIPH (high V/Q areas), pulmonary thromboembolism (high V/Q areas), and RAO (low V/Q areas). Additional uses are in the evaluation of deposition in the lung of aerosolized radiolabeled medications such as albuterol[28] and in the evaluation of mucociliary clearance or tracheal mucus transport where the time required for a bolus of radioisotope to cover a given tracheal distance is evaluated.[29]

Arterial Blood Gas Analysis

Arterial blood gas measurement is the most sensitive indicator of respiratory function readily available to the clinician. The most easily accessed arteries for sampling are the metatarsal, temporal, facial, and brachial arteries (Fig. 31.2). In cattle the coccygeal artery on the ventral aspect of the tailhead is easily accessible. Heparin is the only acceptable anticoagulant for blood gas samples, and all gas bubbles must be removed and the syringe capped to prevent equilibration of the sample with room air. A short (1-inch), small-gauge (25-gauge) needle and a 1- to 3-mL syringe should be used. Preheparinized syringes with needles can be purchased, or regular syringes and needles may be heparinized by aspirating a small volume of heparin into the syringe via the needle and then forcefully expelling the air and heparin from the syringe three times. This minimizes the effect heparin might have on any reported values from the blood gas analyzer. Pulsation of blood from the needle, spontaneous filling of the syringe, and bright color of the blood all confirm a successful arterial puncture. If arterial puncture is questionable, a comparison sample may be drawn from the jugular vein. Once the sample has been drawn, the vessel should be manually compressed for 2 to 5 minutes to prevent hematoma formation. If the sample will not be analyzed within 10 minutes, it should be placed on ice to slow blood cell metabolism. The patient's body temperature at the time of sampling should also be recorded, as results are frequently reported at both 37° C and as *temperature-corrected values* at the actual rectal temperature of the patient for pH, P_{O_2}, and P_{CO_2} because these values are known to be temperature variable. Clinically, either set of values may be used, but comparisons should be made only between samples reported similarly as either temperature corrected or not. The ranges of normal arterial blood gas values for nonneonates of various species are listed in Table 31.1.

FIG. 31.2 Arterial blood sample drawn from temporal artery for arterial blood gas analysis. *(Courtesy Dr. Eric Birks, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.)*

TABLE 31.1

Normal Arterial pH and P_{CO_2} Values for Various Species (Nonneonate)

Species	Blood pH	P_{CO_2} (mm Hg)
Bovine	7.32-7.45	35-53
Ovine	7.32-7.54	37-46
Equine	7.32-7.44	38-46
Caprine	7.42-7.46	33-38

Portable blood gas analyzers are relatively inexpensive and easy to use and provide rapid return of results, making blood gas analysis in large animals more practical in the field.[30,31] Awareness of potential device-, species-, or age-related differences in reference ranges, as well as awareness of any limitations in accuracy, is critical for proper interpretation of results. Pulse oximetry is also used in some institutions and referral centers. These monitors measure oxygen saturation of hemoglobin, which is useful for diagnosing severe hypoxemia or recognizing desaturation events, but provide no measure of actual arterial oxygen and carbon dioxide partial pressures; as such, these monitors do not replace arterial blood gas evaluation for assessing adequacy of pulmonary gas exchange.

The most common abnormality recognized with arterial blood gas analysis in an animal that is breathing room air is hypoxemia with normocapnia, hypocapnia, or hypercapnia.

VetBooks.ir

Hypoxemia is defined as decreased oxygen tension of the arterial blood (decreased PaO_2), whereas hypoxia is defined as decreased oxygen concentration at the level of the tissue, with or without hypoxemia. Hypoxia results from hypoxemia, decreased perfusion of the tissue bed in question, or decreased oxygen-carrying capacity of the blood due to anemia or hemoglobin alteration. There are five primary means by which hypoxemia develops in any animal: (1) low partial pressure of oxygen in the inspired air, such as seen at high altitude or in an error mixing ventilator gas (altered FiO_2); (2) hypoventilation; (3) V/Q mismatch; (4) diffusion limitation; or (5) intrapulmonary or intracardiac right-to-left shunting of blood. Mild to moderate hypoxemia is not an uncommon finding in neonates, but it must be evaluated in terms of the current age of the foal and its position. The difficulty in obtaining the sample must also be considered, as severe struggling can variably affect the arterial blood gas results.

Hypercapnia (increased $PaCO_2$) develops in response to hypoventilation and may also represent respiratory failure if the lung is significantly involved in the underlying pathology, such as with severe pneumonia or ARDS. It is important to try to distinguish between acute and chronic hypercapnia. Acute hypercapnia is usually accompanied by a relatively dramatic decrease in blood pH of 0.008 pH units for each 1-mm Hg increase in $PaCO_2$. This respiratory acidosis can promote circulatory collapse, particularly in the concurrently hypoxemic and/or hypovolemic patient. The effects of more chronic CO_2 retention are less obvious as the time course allows for adaptation. The pH change is less, about 0.003 pH units per 1-mm Hg increase in $PaCO_2$, as it is balanced by enhanced renal absorption of bicarbonate by the proximal renal tubule. Most patients with acute respiratory distress are in the acute stages of respiratory failure, but chronic adaptation will begin to occur within 6 to 12 hours and will be maximal in 3 to 5 days. An increase in bicarbonate will be noted, particularly if the acidosis is primarily respiratory in origin, and pH may be within the normal range.

Alveolar gas exchange is readily estimated by determining the alveolar-arterial (A-a) gradient for oxygen, computed by subtracting the PaO_2 measured by the arterial blood gas from the calculated alveolar oxygen partial pressure (PAO_2). The PAO_2 is effectively estimated using the partial pressure of inspired oxygen (PiO_2) as follows[32]:

$$PAO_2 = \frac{PiO_2 - PaCO_2}{0.8}$$

The PiO_2 equals the total barometric pressure (760 mm Hg) minus the partial pressure of water vapor (47 mm Hg) multiplied by the fraction of room air that is oxygen (0.21) and thus equals 150 mm Hg for room air at sea level. For patients on supplemental inspired oxygen, the practitioner must remember to recalculate the PiO_2 with the new oxygen fraction (FiO_2) (or, if at altitude, the PO_2 in the inspired gas), which is only possible in patients receiving inspiratory gas through a closed system. The $PaCO_2$ is obtained from the arterial blood gas measurement. The A-a gradient is normally only 4 to 10 mm Hg; an increase beyond this indicates impaired gas exchange within the lungs, most often the result of V/Q mismatching. Only an estimate of the A-a gradient can be calculated in patients receiving intranasal insufflation of oxygen, as neither the FiO_2 nor the PO_2 is known.

A second useful measurement is the PaO_2/FiO_2 ratio, a component of most definitions of ARDS.[33,34] The PaO_2/FiO_2 ratio equals the PaO_2 obtained from the arterial blood gas divided by the FiO_2. The normal PaO_2/FiO_2 ratio in most adult animals is greater than 300 mm Hg. In nonneonatal veterinary species, a PaO_2/FiO_2 ratio of 201 to 300 mm Hg is consistent with veterinary acute lung injury (VetALI), whereas a ratio of 200 mm Hg or less suggests veterinary ARDS (VetARDS). Modified definitions of VetALI and VetARDS exist for neonatal foals (EqNALI and EqNARDS) to account for the relative hypoxemia of normal neonatal foals compared with adults during the first week of life.[35] These conditions are described in greater detail in a later section of this chapter (Acute Respiratory Distress Syndrome).Respiratory Function Testing

Numerous techniques have been developed to evaluate respiratory function. Techniques already discussed in this section include arterial blood gas evaluation for assessing efficiency of gas exchange by the lung and videoendoscopy for the qualitative evaluation of upper airway function. Additional techniques that allow for quantitative measurements of upper airway and pulmonary mechanics that influence normal transport of gas from the periphery to the site of gas exchange are available. In most systems, measurements of pressure, flow, and volume allow for the computation of a variety of ventilatory parameters such as respiratory frequency, minute volume, and tidal volume as well as determination of airway resistance and impedance. Pulmonary function testing is performed in horses for the diagnosis and characterization of equine asthma[36-38] and has been described in healthy adult camelids.[39,40] These techniques are primarily limited to use as research tools.

A variety of techniques have been described for the evaluation of upper airway mechanics in exercising horses. In addition to acquiring measurements of ventilatory parameters, these systems may also allow for the construction of pressure volume curves to assess the work of breathing or tidal breathing flow-volume loops to detect and characterize airway obstruction.[41] Assessment of airway muscle activity using electromyography and respiratory sound analysis have also been described in exercising horses.[42,43] One of the major limitations associated with evaluating airway function in exercising horses is the equipment required for these tests. Face masks equipped with a pneumotachograph or pneumotachometer are required to obtain measurements of airflow, whereas nasotracheal or percutaneous tracheal catheters coupled to pressure transducers are used for measurements of airway pressures. These systems may be cumbersome for the exercising horse, may impede achievement of maximal speeds, or may introduce error into results by altering airway mechanics. Recently an ergospirometer has been described that holds promise for acquiring measurements of oxygen consumption (VO_2) and ventilatory parameters in exercising horses under field testing conditions.[44]

Collection and Evaluation of Respiratory Secretions

TRACHEAL ASPIRATES AND BRONCHOALVEOLAR LAVAGE. Various spaces in the respiratory system can be aspirated or lavaged for diagnostic or therapeutic purposes. The most commonly performed procedure is the percutaneous tracheobronchial aspirate. By aspirating from the airways caudal to the larynx, a sample without pharyngeal contamination can be obtained. As discussed previously, endoscopically guided tracheobronchial aspirates can be obtained, and these compare favorably with traditional percutaneous tracheobronchial aspirates provided that a protected aspiration catheter is used.[8]

In both the horse and the ruminant, the procedure is performed with the animal standing. Sedation or restraint may be needed. A small area over the trachea in the middle third of the neck is clipped and routinely sterilely prepared. The skin is anesthetized using a local block of 2% lidocaine (2 to 3 mL subcutaneously), and a small stab incision is made. A sterile trocar or needle (10-gauge) is introduced on the midline between muscle bundles, with the beveled edge facing ventrally (pointed edge facing dorsally) to decrease the opportunity for inadvertent cutting of the tubing when it is introduced or manipulated, and the ventral tracheal wall is punctured between two cartilaginous rings. The distal end of the trocar or needle

VetBooks.ir

is then advanced distally in the trachea, taking care not to lacerate the dorsal tracheal mucosa. Sterile polyethylene tubing or catheter is introduced through the trocar or needle for about 30 cm. A needle or sharp trocar should be withdrawn to prevent severing the tubing or catheter, but a trochar with rounded edges may be left in place. Approximately 20 to 30 mL of nonbacteriostatic sterile isotonic saline solution is introduced quickly. Intermittent aspiration is performed as the tubing is gradually withdrawn. The tubing can be advanced again if a guarding cannula has been left in place to prevent introduction of skin contamination. Additional saline solution aliquots can also be introduced. Once an adequate sample has been obtained, the tubing is completely withdrawn, followed by the withdrawal of the needle or trocar. Commercially available tracheobronchial aspiration kits are also available for use with horses and foals. Injectable antimicrobial solution or suspension can be infiltrated at the skin incision site if a septic sample is suspected, and in horses and small ruminants a sterile dressing can be applied for 24 hours if desired.

Possible complications include subcutaneous emphysema (usually peritracheal but may extend into the mediastinum), local cellulitis, or cutting of the catheter at the needle and loss into the airway. The latter is usually resolved because the catheter is rapidly coughed up, but if necessary, the severed catheter can be retrieved endoscopically. This complication can be readily avoided by using commercially available kits that use a trochar instead of a needle (MILA [MILA International, Elanger, Ky.]), eliminating the needle point that can sever the catheter. The sample should be cultured for aerobic bacteria, and anaerobic cultures should be made if these organisms are suspected based on evidence of pleural effusion, lung consolidation, abscessation, fetid breath, or history of aspiration. For patients with prior antimicrobial therapy, it is advised to discontinue antibiotics for 72 to 96 hours before culture when possible.

A direct smear and Gram stain can be used as an initial guide for antimicrobial therapy pending culture results. Cytologic evaluation can be extremely valuable in differentiating among infectious, allergic, parasitic, and neoplastic processes. If fluid evaluation cannot be performed shortly after collection, it should be stored at 4° C for no more than 24 hours to avoid neutrophil degeneration or bacterial overgrowth. Transtracheal aspirates from clinically normal horses contain columnar ciliated epithelial cells, a few neutrophils, and multiple mononuclear cells. The presence of squamous epithelial cells suggests oropharyngeal contamination, which may occur if the animal coughs during sample collection. Increased percentages of neutrophils and the presence of mast cells, eosinophils, giant cells, and hemosiderophages have been found in aspirates from normally performing Thoroughbred racehorses, indicating some airway inflammation in "normal" equine atheletes.[10] Mucus, large spores, and fungal hyphae may be found in the absence of airway disease and must not be overinterpreted. In cases of pneumonia, neutrophils may constitute 40% to 90% of the cellular sample. Bacterial pneumonia causes a more degenerate appearance of neutrophils, and intracellular bacteria may be found. Equine lungworm is characterized by the presence of large numbers of eosinophils and occasionally larvae. In ruminants, the most important information gathered in patients with bronchopneumonia is usually the result of culture and antimicrobial sensitivity testing.

Bronchoalveolar lavage (BAL) involves obtaining a sample from the terminal airways and alveolar region and is described in horses, cattle, and camelids.[40,45,46] BAL is performed using a long endoscope (200 to 250 cm) or BAL tube (e.g., double-lumen or cuffed Bivona [Smiths Medical, Norwell, Mass.] or MILA [MILA International, Elanger, Ky.]) introduced through the nares. Endoscopic BAL allows for more exact placement of the end of the endoscope, so a clear understanding of the anatomic location of the distal airway lavage is available. It also allows for the characterization of lower airway secretions and mucosal inflammation. Use of the BAL tube is a blind technique, but most frequently the right dorsal lung is sampled.[47] BAL is contraindicated in horses that are expected to exercise within 24 hours of the procedure and in any animal demonstrating signs of respiratory distress, marked tachypnea, paroxysmal cough, or significant hypoxemia.

Proper sedation and restraint is critical for performing BAL. In horses, the addition of butorphanol may reduce cough that is typically associated with this procedure. Instillation of 0.2% to 0.3% lidocaine, particularly when passing the tube into the trachea or past the level of the carina, may also decrease cough. Passage of the tube into the trachea can be facilitated by stretching the head horizontally. The endoscope or tube should be passed until it is wedged in the most distal bronchus. If using a cuffed BAL tube, the cuff should be inflated to seal the airway once wedged. In adult horses, it is recommended to infuse a total of 250 to 500 mL of warm (37° C), sterile physiologic saline in aliquots of 60 to 250 mL. Smaller lavage volumes may be necessary in foals or smaller species. Fluid may be instilled via prefilled syringes or via a solution administration set using a pressure bag with fluid bag or pressure bulb with fluid bottle. The BAL fluid sample is collected via gentle continuous aspiration with syringes or a suction pump using low suction pressure. Cytologic interpretation does not appear to be influenced by method of fluid collection, but syringe aspiration may minimize the potential for barotrauma in certain horses.[48] Fluid aliquots recovered should be pooled for analysis. The presence of surfactant (foam) and turbidity on gross inspection is suggestive of a properly obtained sample.

BAL has the advantage of sampling the distal airways, but only a limited area of the lung is sampled instead of the pooled secretions from a tracheobronchial aspirate. Bronchoalveolar lavage is considered superior to tracheobronchial aspirate in evaluation of horses with diffuse chronic lung diseases of the peripheral airways. Molecular analysis of fluid can be performed for identification of certain viral or bacterial species. Cytologic findings of BAL and tracheobronchial aspirates correlate poorly, and the latter should be performed prior to BAL if bacterial pneumonia is suspected. Bronchoalveolar lavage cytology is valuable for evaluation of suspected fungal infections, equine asthma, and EIPH. Similar to tracheobronchial fluid, BAL fluid should be processed within a few hours or stored at 4° C. Normal cell distribution of BAL fluid in healthy horses (based on 250-mL lavage volume) reveals predominantly macrophages (50% to 70%) and lymphocytes (30% to 50%) with lower percentages of neutrophils (<5%), mast cells (<3%), and eosinophils (<0.1%).[38] Infused BAL volumes of less than 250 mL will not adequately lavage the distal alveoli and may correspond to falsely increased neutrophil and decreased macrophage numbers.[38] Macrophages are the predominant cell type (89%) in BAL fluid of healthy calves,[46] whereas alpacas may have a greater abundance of neutrophils (10%).[40]

Bronchoscopically or endoscopically guided airway brushing can also be performed for the collection of airway epithelial cells. Cells should be obtained with gentle brushing to avoid trauma and can be collected at several locations along the airway. Cytologic analysis can be performed on direct smears or on cells preserved in fixative solution.

Thoracocentesis

Aspiration from the pleural space is a simple procedure that can be both diagnostic and therapeutic. In the horse with septic or neoplastic effusions, sedation is often unnecessary because the procedure causes only minimal additional discomfort. Following ultrasonographic evaluation of the thorax, a point is chosen where drainage or fluid sampling would seem most appropriate, frequently found in the sixth or seventh intercostal space 10 cm dorsal to the olecranon and above the

VetBooks.ir

lateral thoracic vein. The area should be clipped and surgically prepared. Multiple sites may be needed in horses with loculated pockets of fluid in the pleural cavity. The skin and intercostal tissue down to the pleura are anesthetized with lidocaine, and a stab incision is made. A sterile 2- to 3-inch teat cannula or bitch catheter is introduced immediately cranial to the rib border. The cannula should be attached to sterile intravenous (IV) extension tubing and a three-way stopcock. While the cannula is advanced bluntly through the parietal pleura, a sudden loss of the force required to advance is felt. Aspiration should be attempted at this time. The orientation of the cannula can be varied to reach as much fluid as possible. Normally only a few milliliters of straw-colored fluid are obtained. In cases of pleural effusion, as much as 30 L may be removed from each side of the chest (Fig. 31.3). If fluid is excessive, the tubing can be extended over a bucket for gravity drainage, or a vacuum pump with a fluid trap can be attached. When the procedure is complete, a purse-string suture is placed around the stab incision and the cannula is withdrawn while the suture is tightened. In cases where the effusion is large and expected to continue forming for several days, the drainage can be performed by placing a chest tube instead of a teat cannula. If a chest tube is to be left in place, it should be secured with a Chinese finger-trap suture and the end covered by a Heimlich valve to prevent aspiration of air into the thorax through the tube. If the thorax is being drained rapidly, the patient should be watched carefully for signs of distress, as draining of large volumes can alter cardiovascular parameters significantly.

Increasing opacity, presence of fibrin clumps, and malodor of pleural fluid all suggest relative progression from transudate to septic exudate containing inflammatory cells and debris. A putrid odor suggests the presence of anaerobic bacteria. Samples should be cultured for aerobic and anaerobic organisms. A white blood cell (WBC) count of 10,000/mL or less is considered normal; fewer than 60% are normally neutrophils, the remainder being lymphocytes and macrophages. The proportion and total number of neutrophils increase with pleuritis. Erythrocytes are normally not present in the absence of a traumatic tap. The protein concentration is normally less than 3.5 g/dL, and pH should be approximately 7.4. Additional metabolic values that give early indication of sepsis can be obtained on pleural fluid samples collected after filtration through a blood administration set to remove fibrin and debris potentially detrimental to analytic equipment. Pleural fluid pH, P_{CO_2}, and concentration of glucose, lactate, and bicarbonate can be directly compared with similar analysis of venous blood from the patient. A septic pleural exudate is acidic, with decreased glucose and bicarbonate but increased lactate and P_{CO_2} compared with venous blood concentrations or tensions, apparently reflecting metabolic activity of phagocytic cells and bacteria and development of an anaerobic environment.[49] Of these values, low pleural fluid glucose concentration (<40 mg/dL) has the best correlation with sepsis.[50]

Neoplastic cells may be found in cases of lymphosarcoma, adenocarcinoma, or other neoplasms. Equine gastric squamous cell carcinoma occasionally presents with neoplastic pleural effusion. If neoplastic effusion is suspected but diagnostic cells do not exfoliate into the pleural fluid, thoracoscopy can be used directly to visualize and obtain biopsy samples of intrathoracic lesions.

Mediastinal fenestrations may be occluded by fibrin and cell debris; therefore each side of the thorax should be evaluated separately. In the horse, a transtracheal aspirate for culture should also be performed because of the common association of pleuritis with bacterial pneumonia and pulmonary abscessation. Although identical organisms are generally isolated from both samples, this is sometimes not the case.

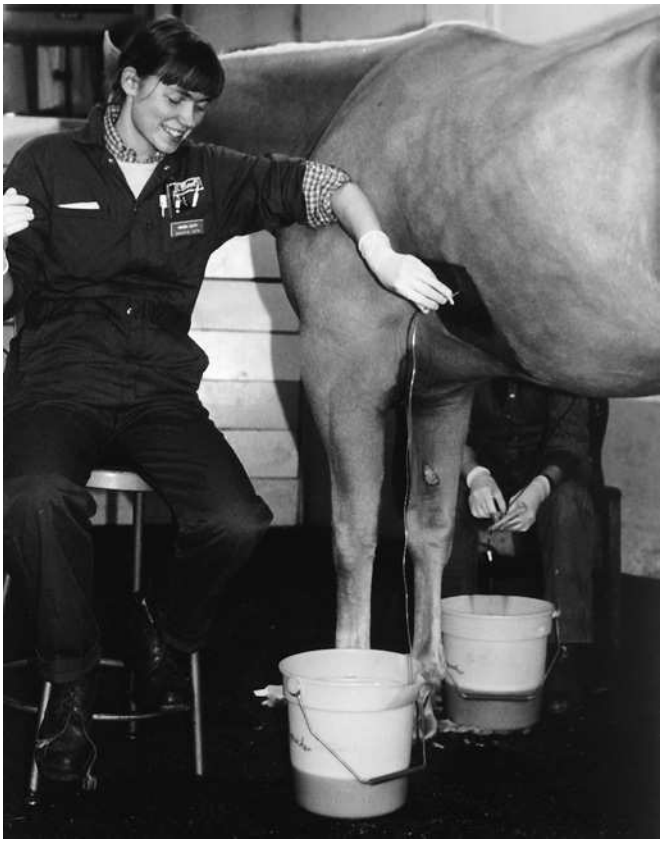

FIG. 31.3 Thoracocentesis and therapeutic drainage in the horse. Pleural effusion can be large and bilateral. Samples should be obtained for culture and cytologic examination at the time the chest is drained. *(Courtesy Dr. Corinne Sweeney, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.)*

Sinus Trephination

Sinus trephination is performed in horses or ruminants and may be indicated when serosanguinous or foul-smelling and purulent nasal discharge, facial malformation, exophthalmos, stertorous breathing, or epistaxis are detected on physical examination and when sinus percussion and imaging findings support it. Trephination is useful for diagnostic aspiration, drainage, and flushing of the sinuses. Sinoscopy may also be indicated, particularly when the true extent of the disease process is difficult to determine or if biopsy samples are needed.

In the horse the frontal, sphenopalatine, and ethmoidal sinuses communicate with the posterior chamber of the maxillary sinus and drain through the nasal maxillary opening into the middle meatus. The anterior chamber of the maxillary sinus is separated by an osseous septum that often breaks down with infection, making the posterior chamber of the maxillary sinus the most productive site for diagnostic aspiration. A line is drawn from the medial canthus of the eye perpendicular to the facial crest. After tranquilization and local anesthesia, the sinus is approached with a Steinmann pin midway on this line. Once the sinus has been entered, it should be aspirated using a sterile 16-gauge needle or canine urinary catheter. One skin suture will suffice for closure. If purulent material or fluid within the sinus is under pressure, some leakage into the subcutaneous space may occur, with resulting cellulitis. The sample should be cultured for aerobic and anaerobic bacteria and examined cytologically for signs of septic inflammation or neoplastic cells.

The frontal sinus is trephined more often for flushing in chronic cases than for diagnostic purposes. The approach is 2.5 cm lateral to the midline of the face and 2.5 cm caudal to the point where the nasal bones begin to diverge.

VetBooks.ir

In cattle the frontal sinus is most often affected, with septic inflammation as a consequence of dehorning. Purulent material frequently accumulates in the postorbital diverticulum of the sinus. The landmarks for sinus trephination in cattle are described later in this chapter.

Postdehorning sinusitis in goats can be a severe condition, especially in animals dehorned when mature. The frontal sinus contains numerous septae, creating poor drainage; the bony plate protecting the brain is thin, so that septic necrosis of bone leading to meningitis may occur. Therefore in mature goats with sinusitis, appropriate systemic antimicrobial therapy and vigorous curettage of the affected areas should be conducted.

Guttural Pouch Catheterization

When indicated by radiography and/or endoscopy, the equine guttural pouches are easily catheterized for diagnostic sampling and lavage. Sampling can also be achieved by placing thin tubing through the biopsy channel of the endoscope, as for tracheobronchial aspiration, and directly aspirating or aspirating after introduction of sterile saline. Lavage can also be performed through the biopsy channel. The patient should be heavily sedated so that the head drops, facilitating drainage of the secretions by gravity. A Chambers mare catheter can be passed blindly through the ventral meatus into the pharynx. The curved end is directed beneath the flap of the medial lamina of the pouch ipsilateral to the nostril used for passage. Successful passage is indicated by lack of resistance while the catheter is inserted deeper than if it were in the pharynx. The position of the catheter tip in the pharynx can be observed through an endoscope placed up the opposite nasal passage. Once the catheter is within the pouch, it can be used to obtain a sample, to drain excessive secretions, or to act as a conduit for flushing. A self-retaining uterine catheter can be left in place for repeated flushing, but the Chambers catheter can be passed repeatedly with no complications.

Airway and Lung Biopsy

Biopsy of the airways or lung is most often performed in the horse and is indicated to obtain a histologic diagnosis or prognostic information primarily in cases of diffuse lung or airway disease. Endobronchial biopsy is performed for the collection of airway samples, whereas parenchymal samples are obtained by means of percutaneous or thoracoscopically guided collection techniques. For endobronchial biopsy, multiple samples can be collected along the upper and lower airways. Histologic analysis of endobrochial samples collected from peripheral airways may have clinical utility for diagnosis of RAO in horses.[51] Thoracoscopically guided pulmonary wedge resection is also an option for collection of a larger parenchymal tissue sample and enables direct visualization of the lung prior to biopsy. The procedure is relatively safe but is more invasive and requires specialized equipment and expertise.[14] For percutaneous biopsy, use of a spring-loaded biopsy instrument with a large-gauge (14-gauge), 15-cm or longer biopsy needle and a sample "slot" length of 22 mm is recommended. Discomfort is minimal, and sedation may or may not be needed. The site for biopsy should be determined following ultrasonographic evaluation and should be away from common locations of major pulmonary vessels. Caudal and dorsal locations are generally chosen. The site should be surgically prepared and infiltrated with local anesthetic down to the pleura. The biopsy needle is inserted through a stab incision just cranial to the rib and directed medially through the intercostal muscles and parietal pleura. The needle should be advanced the distance indicated by ultrasonographic measurement, then sharply advanced less than 1 cm to enter the lung parenchyma and the spring-loaded instrument "fired" to obtain the sample; the biopsy instrument is then withdrawn. After sufficient biopsy specimens have been obtained, a single skin suture can be placed at the incision site, but no additional aftercare is needed. A specimen should be placed directly in 10% formalin or glutaraldehyde for fixation with additional samples submitted for bacterial and fungal culture, and potentially for more advanced molecular diagnostic techniques. Complications of lung biopsy have been reported to range from transient epistaxis or hemoptysis, which is to be expected, to more severe pleural and parenchymal hemorrhage. Lung biopsy is not indicated for pleuropneumonia cases but is generally required to differentiate between equine multinodular pulmonary fibrosis, discrete fungal lesions, and potential neoplasia, when accurate diagnosis is required for therapeutic and prognostic purposes.

Techniques for Identification of Respiratory Pathogens

Infectious respiratory disease can have significant individual and herd health implications. Timely and definitive identification of the causative agents is necessary to ensure that the appropriate therapeutic, prophylactic, and biosecurity protocols are instituted. Although infectious respiratory disease may represent a diagnostic challenge for the equine practitioner, technological innovations have improved the speed and sensitivity with which infectious organisms can be identified.[52] Culture, immunologic tests, and molecular techniques represent the most commonly used tools for pathogen identification. These techniques should not substitute for careful clinical evaluation, and an accurate diagnosis may necessitate the use of more than one diagnostic test. Regardless of the technique chosen, the practitioner should adhere to appropriate guidelines for sample collection and handling, as failure to do so can negatively affect the diagnostic accuracy of a given test.

Conventional culture methods represent indispensable diagnostic techniques when infectious respiratory disease (bacterial, viral, fungal) is suspected. Although these methods are sensitive, they are time consuming, often delaying pathogen identification days to even months, as in the case of certain viral organisms. Variable recovery of organisms from respiratory secretions and contamination may also negatively affect diagnostic accuracy. Matrix-assisted laser desorption/ionization–time-of-flight mass spectrometry (MALDI-TOFMS) is a novel technology that uses pathogen-specific mass spectra ribosomal protein profiles for the identification of fungal and microbial pathogens.[53] Extensive databases of organism-specific MALDI-TOFMS profiles have been generated, and when compared to conventional culture, MALDI-TOFMS can reduce the time required for pathogen identification from days to hours. This has important clinical implications regarding more timely institution of appropriate management.

IMMUNOLOGIC TECHNIQUES. Immunoassays rely on interactions among bacterial, viral, and fungal antigens and radioisotope-, enzyme-, or fluorescent-labeled antibodies. The use of polyclonal antibodies tends to increase the sensitivity of the assay, as the preparation may contain antibodies to multiple epitopes on the target antigen, but at the same time it may also decrease assay specificity due to their heterogeneous nature. Test specificity can be improved by the use of monoclonal antibodies, as these antibodies interact with only a single well-defined epitope or very similar epitopes. Immunofluorescence, although labor intensive and time consuming, is considered highly sensitive and specific, particularly for virus-infected cells. The enzyme-linked immunosorbent assay (ELISA) is available for the diagnosis of a wide range of infectious respiratory diseases. For certain pathogens the ELISA has the advantage of rapid turnaround of results and minimal labor; however, these tests may be subject to false-negative and false-positive results. Virus neutralization (VN) assays are highly accurate and sensitive. Unfortunately, VN is more

VetBooks.ir

expensive, labor intensive, and time consuming compared to other diagnostics.

Immunohistochemistry is a standard diagnostic tool for the identification of viral, bacterial, and protozoal pathogens in tissue sections. This technique depends on polyclonal or monoclonal antibodies binding to a target antigen and the demonstration of this interaction by colored histochemical reactions visible by light microscopy or by emittance of fluorescence. Immunohistochemistry is highly versatile, and assays have been developed to detect a variety of equine respiratory pathogens in tissue sections.

MOLECULAR TECHNIQUES. Molecular-based technology, in particular polymerase chain reaction (PCR) techniques, have greatly advanced the diagnosis and management of viral, fungal, and bacterial respiratory disease. Advantages to these techniques include the speed with which results can be obtained, the superior sensitivity and specificity of these assays, and the ability to obtain quantitative results. Nucleic acid of both live and dead pathogens can be detected at very low concentrations and in a wide variety of specimens, and PCR is often useful to identify organisms that are difficult to grow in culture. The ability to perform parallel ("panel") testing for multiple respiratory pathogens simultaneously from a single sample has greatly increased diagnostic efficiency, particularly when co-infection of multiple pathogens exists. Other advances that have expanded the clinical utility of PCR techniques include identification of virulence-associated genes, discrimination among different viral strains as well as between viable and nonviable organisms, determination of infectious risk, and the ability to simultaneously test for multiple genes from the same organism.

Polymerase chain reaction involves amplification of a target region of DNA. Advances in PCR technology such as reverse transcription PCR (RT-PCR) and real-time, or quantitative, PCR (qPCR) have greatly expanded the applications of standard PCR. RT-PCR enables identification of viruses whose genome is composed of RNA (e.g., influenza, coronavirus) by reverse transcribing the viral RNA into complementary DNA (cDNA) for amplification. Commercially available kits have increased the diagnostic utility of this technique. Real-time PCR (qPCR) combines PCR amplification with simultaneous detection of the amplified products, allowing for quantification of PCR products in a closed tube system. Real-time PCR may also be combined with RT-PCR (qRT-PCR) for the quantification of messenger RNA (mRNA). Compared with traditional PCR, qPCR reduces the risk of contamination and increases the sensitivity and speed of detection.

Adhering to appropriate sample collection and handling protocols is essential for diagnostic accuracy of PCR. For example, sterile synthetic nasal or nasopharyngeal swabs (rayon or dacron tipped) are recommended for viral identification, whereas nasopharyngeal or guttural pouch lavage is recommended for identification of *Streptococcus equi* subsp. *zooepidemicus*. Regardless of the source, samples should not be frozen but refrigerated at 4° C for no more than 2 to 3 days before processing. False-positive results are often due to contamination, and false-negative results may occur from enzyme inhibitors that suppress DNA amplification. Molecular diagnostic techniques are covered in greater detail in Chapter 29.

Novel techniques that have the potential to further our understanding of the pathogenesis as well as the immunologic and genetic bases of respiratory disease include flow cytometry, genome-wide association study (GWAS), and respiratory microbiome analysis. Although these techniques currently are primarily used as research tools, they may have broader clinical applications in the future by contributing to improvements in the prevention, diagnosis, and management of respiratory disease. Flow cytometry is a laser-based technology that detects and quantifies light scatter and fluorescence emitted by fluorescent-labeled cells. Combinations of scattered and fluorescent light are identified and analyzed to derive information about the physical and chemical properties of a large number of cells at one time. It can be used to immunophenotype cells isolated from respiratory secretions and may thus improve characterization of the immunologic response associated with select respiratory diseases.

The goal of a GWAS is to identify genomic features that may influence the risk of disease or the pathogenesis of a disease in animals or humans. The entire genome is evaluated in individuals with and without a particular disease to identify specific genetic variants found more frequently in individuals with disease. It is important to recognize that a GWAS does not determine causation, but only association. It may, however, facilitate identification of candidate genes that can be further investigated. In large animal species GWAS is being used to improve the understanding of genetic influences on susceptibility to severe RAO in warmblood horses,[54] equine viral arteritis in stallions,[55] and bovine respiratory disease in cattle.[56]

The role that the respiratory tract's resident microbial communities may have on respiratory health has received considerable attention through the field of respiratory microbiome analysis. In particular, the respiratory microbiome is thought to contribute to the prevention of colonization by pathogenic organisms, the mitigation of pathogenicity when infection is established, and the structural and immunologic maturation of the respiratory tract.[57] Important areas of ongoing respiratory microbiome research in large animals include characterization of different microbial communities throughout the respiratory tract, identification of factors influencing the development of the microbiota in maturing animals, and understanding how certain events (e.g., transport, physiologic stress, antimicrobial or glucocorticoid administration) may alter the microbiome and potentially influence susceptibility to or pathogenicity of respiratory disease.[58-61]

Pulmonary Function Testing

Daniela Bedenice

Pulmonary function testing (PFT) has emerged as an essential tool in equine referral practice and is largely aimed at describing the severity, anatomic pattern, stability (reactivity), and reversibility of bronchoconstriction caused by noninfectious airway obstruction and inflammation, such as is seen in RAO and IAD.[1] Clinical indications for noninvasive PFT include assessment of horses with intermittent cough, exercise intolerance, abnormal breathing pattern, and excess mucus, as well as early detection of subclinical disease, evaluation of treatment response, intensive care monitoring, and prediction of outcome. PFT is generally divided into the assessment of respiratory mechanics (mechanical properties of the respiratory system) and gas exchange. Analysis of gas exchange investigates ventilation-perfusion matching, shunt, diffusion capacity, and dead space–to–tidal volume ratio (V_D/V_T). Lung mechanics, on the other hand, determine the static and dynamic properties of the lung, including resistance, compliance, functional residual capacity (FRC), and ventilatory parameters.[1]

Mechanics of Breathing

The mechanical function of the lung is essentially defined by static and dynamic properties. Tests that are performed with the respiratory system at equilibrium and zero flow are referred to as *static tests*. Examples include measurement of lung volume subdivisions (e.g., FRC) and compliance of the lung and chest wall.[1]

FRC is a measure of the amount of gas that remains in the lungs at end-expiration (end-expiratory volume). FRC is lower in patients with increased "lung stiffness" (reduced elastic recoil

of the lung) as well as airway inflammation, whereas FRC increases in patients with expiratory airway obstruction and gas trapping.[2] This test can be easily performed in awake clinical patients via a helium dilution technique.[3] In short, the patient is connected to a reservoir bag at end-expiration to rebreathe a standard, commercial breathable gas mixture of 10% helium (He), 20% oxygen, and the remainder nitrogen for 90 seconds. The dilution of He (a nonexchangeable gas) gives a measure of end-expiratory lung volume.[3]

Measurements of static compliance or "elastic recoil of the lung" require breath holds and have applications only to the anesthetized patient. So-called *pressure-volume curves* are generated in the relaxed patient during lung deflation from total lung capacity (TLC), using an esophageal balloon technique. Compliance is defined as the lung volume change per unit of pressure change[2]:

$$\text{Compliance} = \frac{\Delta V}{\Delta P}$$

Reduced lung compliance (i.e., increased lung stiffness) may be associated with increased fibrous tissue (pulmonary fibrosis), atelectasis (e.g., underventilated lung), or an increased pulmonary venous pressure, in which the lung becomes engorged with blood. Emphysema and normal aging of the lung, which leads to alteration in elastic tissue, are causes of increased lung compliance.[2]

In contrast to static tests, tests that are performed with the respiratory system in motion (e.g., during quiet breathing) are referred to as *dynamic*. An example of a dynamic measurement is resistance, a measurement that requires flow. Resistance arises from friction of air molecules against airway walls[1]:

$$\text{Resistance} = \frac{\text{Change in pressure } (\Delta P)}{\text{Change in flow } (\Delta V)}$$

The measurement of pulmonary resistance (R_L) using a flow meter attached to a face mask and an esophageal balloon catheter to measure transpulmonary pressure changes is conventional in the horse but rarely used in the clinical setting.[1] This technique allows computation of both R_L and dynamic compliance (C_{dyn}) at spontaneous breathing frequencies. Maximal transpulmonary pressure change (ΔPPL_{max}) and R_L both increase in cases of obstructive airway disease, whereas C_{dyn} decreases. However, this classic technique is fairly insensitive in detecting subclinical disease[4,5] and has greater utility in the diagnosis of IAD if coupled with a challenge test (i.e., histamine bronchoprovocation [see below]).[6,7]

Forced Oscillation Techniques

In contrast to the conventional methods, noninvasive measurements of total respiratory system resistance via forced oscillation techniques (FOTs) are used in the diagnosis of IAD in horses. In short, oscillometry is the study of lung mechanical function via the application of external forces to the respiratory system.[8] Either a loudspeaker (e.g., impulse oscillometry system [IOS]) or air pressure (e.g., monofrequency forced oscillation) is used to superimpose pulses of flow (4 to 5 L/s peak) through a face mask on the horse's respiratory system during spontaneous breathing. The generated reciprocal pressure waves are subsequently recorded at the airway opening (i.e., face mask). The magnitude and phase relationship between the input of flow and output of pressure are then used to perform the calculations of impedance (total opposition to airflow) and its components, resistance and reactance, at a variety of oscillatory frequencies (generally 1 to 7 Hz).[1] In most horses with IAD (equine asthma) there is a frequency dependence of resistance, with higher values for resistance recorded at the lower oscillatory frequencies (1 to 2 Hz), indicative of bronchoconstriction.[9-11] Horses with moderate to severe lower airway obstruction commonly show high initial baseline values for respiratory resistance at 1 Hz (e.g., >1.0 cm H_2O/L/s).[1] Higher frequencies (≥2 Hz) provide information concerning central airway resistance (R_{aw}). Baseline respiratory resistance measurements using FOTs are often combined with bronchoprovocation tests for the early diagnosis of IAD. In addition, the use of an IOS has been advocated for separate analysis of inspiratory and expiratory impedance parameters, to allow the evaluation of both phases of the respiratory cycle in horses.12

Histamine Bronchoprovocation

Bronchoprovocation is a challenge test that assesses the response of the respiratory system to a bronchoconstrictor agonist (e.g., inhaled histamine).[1] The provocatory concentration necessary to cause a 100% increase in baseline respiratory system resistance is commonly termed $PC100_{RRS}$. Horses with a low $PC100_{RRS}$ (e.g., <8 mg/mL of histamine) are designated as having hyperreactive airways. Airway hyperreactivity (AHR) is an exaggerated narrowing response to a bronchoconstrictive stimulus, which was first found in horses with heaves[13] and is considered a hallmark of IAD. Some studies have documented a correlation between airway reactivity and mast cell percentage in BAL fluid in horses with a history of exercise intolerance.[14] The clinical symptoms associated with AHR are thought to include coughing (increased sensitivity) and exercise intolerance, whereas bronchoconstriction causes uneven ventilation and hypoxemia.[1] Both FOTs and respiratory inductive plethysmography (see below) have been used to assess AHR through histamine bronchoprovocation in client-owned horses. However, where different methodologies are used to assess AHR, comparison of histamine bronchoprovocation test results in horses should be made with caution.

Respiratory Inductive Plethysmography

The objective assessment of respiratory function and breathing pattern may also be obtained through the concurrent application of respiratory inductive plethysmography (RIP) and pneumotachography, which has been validated for the use in humans,[15,16] horses,[17] and sheep.[18] Two elastic bands, each containing a single sinusoidal conducting wire, are temporarily placed around the animal's thorax and abdomen (Fig. 31.4). Stretch and contraction of the bands resulting from normal respiratory movements are measured as voltage changes, which is proportional to the change in circumference and volume of the

FIG. 31.4 Respiratory inductance plethysmography being performed in a horse. *(Courtesy Dr. Andrew Van Eps, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.)*

thorax and abdomen. Simultaneously, measurements of nasal flow are obtained at the airway opening (face mask). This technique rapidly assesses the synchronicity of breathing pattern (e.g., thoracoabdominal asynchrony due to diaphragmatic paralysis)[19] and the individual contribution of the thorax and abdomen to respiration. It further quantifies changes in flow resulting from airway obstruction. Recently, the use of a novel respiratory ultrasonic plethysmography (RUP) system was proposed to detect circumference changes of rib cage and abdominal compartments in large and small animals.[20]

Forced Maneuvers

Forced expiratory maneuvers are commonly performed in humans with suspected asthma. The patient is asked to blow out hard from TLC until the lung is empty. The volume of air expelled in 1 second (FEV_1) corrected for forced vital capacity (FVC) is used as a measure of lower airway obstruction.[1] Couëtil adapted the method of forced maneuvers for routine clinical application in heavily sedated, nasotracheally intubated horses.[21] He further demonstrated flow limitation in horses with early signs of obstructive airway disease (IAD) that was worse in animals with heaves. Remission from heaves showed improvement in flow limitation.[1]

PFT is considered instrumental in the understanding of the pathogenesis, pathophysiology, epidemiology, diagnosis, and treatment of lung disease in the horse.[1] The described tests are aimed at quantifying airway obstruction, airway reactivity, and lung stiffness in the clinical setting. PFT will thus facilitate the diagnosis of subclinical disease and improve the clinician's assessment with regard to aggressive management of lung disease, decisions for ventilation, intensity of monitoring, and assessment of treatment response and prognosis.

Equine Respiratory System

Disorders of the Lung

Bacterial Pneumonia and Pleuropneumonia in Adult Horses

Steeve Giguère

Bacterial infections of the lower respiratory tract are common in adult horses. Lower respiratory tract infections may be localized to the lumen of the airways (called bacterial bronchitis or septic IAD) or may involve the pulmonary parenchyma (called pneumonia). In equine medicine, the term *bronchopneumonia* is often used to refer to lower respiratory tract infection regardless of whether the infection is localized to the bronchi or whether the infection involves both the bronchi and the lung parenchyma. When there is subsequent extension of the infection from the pulmonary parenchyma to the visceral pleura and pleural space, the disease is referred to as pleuropneumonia. The spectrum of clinical signs shown by horses with bronchopneumonia is broad and reflects the severity of the disease process. Early identification of affected animals and immediate initiation of appropriate therapy are essential to prevent mortality and functional impairment of the respiratory system.

Infectious Agents Involved

Adult horses most commonly acquire bacterial pneumonia by aspiration of microorganisms that normally inhabit their nasopharynx or oral cavity.[1,2] β-hemolytic streptococci, particularly *Streptococcus equi* subsp. *zooepidemicus (S. zooepidemicus)* is by far the most common bacterial pathogen isolated from adult horses with bronchopneumonia.[3,4] Nonenteric gram-negative bacteria such as *Pasteurella* spp. and *Actinobacillus* spp. are also frequently isolated, either alone or in combination with *S. zooepidemicus*. Enteric gram-negative bacteria such as *Klebsiella* spp., *Escherichia coli*, *Enterobacter* spp., and *Salmonella enterica* may also be isolated. Other aerobic gram-positives such as *Staphylococcus* spp. and *Rhodococcus equi* or gram-negatives such as *Pseudomonas* spp. and *Bordetella bronchiseptica* are occasionally isolated. *Pseudomonas* spp. are rarely a primary cause of pneumonia in horses, and their presence often reflects contamination of equipment used for taking airway samples (such as endoscopes). *Streptococcus pneumoniae*, a common pathogen of humans, has been positively correlated with lower airway inflammation in young Thoroughbred racehorses in the United Kingdom.[5] The microorganism can also induce pneumonia in ponies following heavy intrabronchial challenge.[6] Its isolation from pneumonic horses in the United States appears to be rare.

Anaerobic bacteria are isolated from approximately one third of adult horses with severe bronchopneumonia, pleuropneumonia, or pulmonary abscessation. The most common anaerobes isolated are *Bacteroides* spp. (particularly *Bacteroides fragilis*), *Clostridium* spp., and *Peptostreptococcus* spp.; *Fusobacterium* spp. and *Eubacterium* spp. may also be isolated.[3,7] Isolation of anaerobes from horses with pneumonia or pleuropneumonia has been associated with a less favorable prognosis in some studies. In one study, the survival rate for 221 pneumonic horses with strictly aerobic isolates from tracheobronchial aspirates was 81.4% compared with 38.3% for the 81 horses in which anaerobes were cultured.[3] Mixed bacterial infections are very common and may represent synergy between aerobic or facultative aerobic and anaerobic bacteria.

The importance of *Mycoplasma* spp. in the development of equine bronchopneumonia and pleuropneumonia is controversial. Several *Mycoplasma* species have been isolated from the respiratory tract of both diseased and healthy horses, with *Mycoplasma felis* and *Mycoplasma equirhinis* being the most common isolates. In one study, isolation of *M. equirhinis* was positively correlated with lower airway inflammation in a group of young Thoroughbred racehorses in the United Kingdom,[8] whereas isolation of *Mycoplasma* spp. was not significantly associated with disease in a similar population in Australia.[9] An outbreak of lower respiratory tract disease caused by *M. felis* infection has been described.[10] *M. felis* has also been isolated from horses with pleuropneumonia, and experimental infection with *M. felis* has resulted in pleuropneumonia.[11,12]

Epidemiology Bacterial bronchopneumonia may affect horses of any age and breed. In one retrospective study of 327 horses with pneumonia or pleuropneumonia, there was no sex predilection but 82% of the horses were younger than 5 years of age.[3] In a retrospective case-control study of risk factors for development of pleuropneumonia, Thoroughbreds were at greater risk and Standardbreds were at lower risk of developing the disease.[13] In the same study, the most significant risk factor for development of pleuropneumonia was long-distance

transport within the week prior to the onset of clinical signs.[13] In another study, 24.4% of 90 horses with pleuropneumonia had recently been transported over long distances, and 12.2% had recently undergone general anesthesia.[14] Five of the postsurgical cases had undergone upper airway surgery.[14] Whether these horses had preexisting lung disease or whether they developed aspiration pneumonia as a result of surgery and general anesthesia could not be ascertained.

Other factors significantly associated with increased risk of developing pleuropneumonia include recent viral respiratory tract infection or exposure to horses with viral infections and racing within 48 hours prior to developing clinical signs.[13] One study in the United Kingdom identified a higher incidence of pneumonia or pleuropneumonia in show jumpers, presumably reflecting the greater distance over which these horses are transported compared to racehorses in that country.[15]

Pathophysiology Colonization of the lungs by opportunistic bacteria occurs when the pulmonary defense mechanisms are compromised or are overwhelmed by massive numbers of bacteria. Several factors can contribute to causing increased numbers of bacteria in the lower airways. Dysphagia or esophageal obstruction will lead to aspiration of large numbers of pharyngeal bacteria, and these disease processes often result in pneumonia. However, the vast majority of horses with bacterial pneumonia or pleuropneumonia do not have a history of dysphagia or esophageal obstruction. Other factors that have been shown to significantly increase bacterial contamination of the lower respiratory tract include confinement with the head elevated, transportation, and high-intensity exercise.[16-18] In one study, confinement of horses with the head elevated resulted in a significant increase in bacterial numbers as well as neutrophilic inflammation in the lower respiratory tract as early as 6 hours after initiating confinement.[17] *Actinobacillus* spp., *Pasteurella* spp., and β-hemolytic streptococci were the predominant bacterial isolates. Lowering the head for 30 minutes every 6 hours to facilitate postural drainage during a 24-hour confinement did not prevent multiplication of bacteria.[17] Clearance of accumulated secretions and bacteria occurred within 8 to 12 hours after release from confinement.[17] In similar confinement experiments, pretreatment with penicillin considerably reduced the number of β-hemolytic streptococci but did not reliably reduce total bacterial numbers.[19] Cilia of many other species such as dogs and humans can transport mucus effectively against gravity, and posture has no effect on tracheal mucociliary transport in these species.[20,21] In contrast, periods of lowered head posture are absolutely essential for normal mucociliary clearance in horses.[22]

In one study, long-distance transport by road over 12 hours resulted in increased bacterial contamination and neutrophilic inflammation in tracheal aspirate fluid when the horses' heads were restrained in an elevated position.[23] This is in contrast to another study in which there was no significant cytologic or bacteriologic changes in BAL fluid from mares whose heads were not restrained in an elevated position during transportation for 12 hours.[24] Collectively, these findings suggest that duration of time with a raised head position is more important than the stress of transport alone in development of airway colonization. Finally, the last factor shown to increase bacterial contamination of the large airways of horses is exercise. In one study, a single bout of high-intensity exercise resulted in a tenfold increase in aerobic and hundredfold increase in anaerobic bacterial counts in tracheal aspirate samples compared to preexercise values.[16]

Pulmonary defense mechanisms can be compromised by numerous factors. These include stress (e.g., transport, intense exercise), viral infections, malnutrition, exposure to dust or noxious gases, immunosuppressive therapy, immunodeficiency disorders, and general anesthesia. Infections with influenza virus and equine herpesvirus 4 (EHV-4) have been shown to significantly decrease mucociliary clearance for up to approximately 30 days post infection in horses.[25] In one study, long-distance transport resulted in a significant reduction in phagocytosis by peripheral blood neutrophils for approximately 36 hours after transport.[23] The effects of long-distance transport on number, viability, and function of cells in BAL fluid have given conflicting results, with no clear pattern emerging.[24,26-28] Similarly, the effects of exercise on the immune system are complex and depend on a multitude of factors, including the intensity or duration of exercise, the specific immune function being analyzed, and the timing of the measurement in relation to exercise. In general, moderate exercise enhances immune function, whereas strenuous exercise tends to be detrimental to immune function.[29] High-intensity exercise in horses leads to a significant decrease in blood neutrophil and bronchoalveolar macrophage phagocytic activity, which may lead to decreased bacterial clearance from the lungs.[30-32] Exercise also affects the adaptive immune system, as lymphocyte proliferation responses and interferon (IFN)–γ production are decreased following high-intensity exercise.[33-35] Strenuous exercise has also been shown to increase susceptibility to experimental influenza virus infection in ponies compared with rested animals.[33]

Regardless of the exact mechanism predisposing to bacterial colonization, the inflammatory response induced by bacterial invasion results in infiltration with neutrophils and other inflammatory cells into the airways and pulmonary parenchyma. Inflammatory cells and their mediators cause damage to the airway epithelium and capillary endothelium, leading to flooding of the terminal airways with inflammatory cells, serum cellular debris, and fibrin. This process is generally more severe in the ventral portions of the lung. In early stages the lungs may be simply edematous, reflecting inflammation and early exudation, whereas in chronic, severe cases the airways may be consolidated or abscessed. These lesions interfere with gas exchange, and if severe enough, the resulting ventilation-perfusion mismatch leads to hypoxemia and clinical signs of respiratory disease.

In severely affected animals, inflammation will extend to the pleural space. The first stage of bacterial pleuropneumonia is an exudative stage, which is characterized by rapid outpouring of sterile pleural fluid into the pleural space in response to inflammation of the pleura. The associated pneumonic process is usually contiguous with the visceral pleura and results in increased permeability of the capillaries in the visceral pleura. If appropriate antimicrobial therapy is initiated at this stage, the pleural effusion may not become septic and may resolve. With progression, the bacteria invade the pleural fluid from the contiguous pneumonic process and the second, fibropurulent, stage evolves. This stage is characterized by the accumulation of large amounts of pleural fluid with many degenerate neutrophils, bacteria, and cellular debris. Fibrin is deposited in a continuous sheet, covering both the visceral and the parietal pleura adjacent to affected areas. As this stage progresses, there is often loculation and formation of limiting membranes. These loculations prevent dissemination of the infection but make drainage of the pleural space with chest tubes increasingly difficult. The last stage is the organization stage, in which fibroblasts grow into the exudate from both the visceral and the parietal pleura surfaces and produce a membrane called the pleural peel. This inelastic pleural peel encases the lung and renders it virtually functionless. At this stage the exudate is generally thick.

Clinical Signs and Physical Examination The spectrum of clinical signs shown by horses with bacterial lung infection is broad and usually reflects the severity of the disease process. Horses with septic IAD and no or minimal involvement of the lung parenchyma may be completely normal at rest. Clinical signs may be limited to exercise intolerance and/or

VetBooks.ir

VetBooks.ir

poor performance, or affected horses may cough or have bilateral nasal discharge during or immediately following exercise. Even in early cases of bronchopneumonia, clinical signs may not be obvious. As the disease progresses, clinical signs may include any combination of fever, anorexia, depression, bilateral nasal discharge, cough, weight loss, tachypnea, and respiratory distress. Nasal discharge is usually mucopurulent but may be hemorrhagic in some cases with pulmonary infarction and necrotizing pneumonia.[36] Halithosis and a foul-smelling nasal discharge may be present and have been associated with infection by anaerobic bacteria. However, the absence of a putrid odor does not rule out infection with anaerobic bacteria.

Because the parietal pleura is highly innervated and painful when inflamed, horses with acute pleuropneumonia often exhibit pleurodynia (pleural pain). Pleurodynia can often be detected by applying digital pressure to the intercostal space, resulting in grunts, intercostal muscle spasm, or even escape maneuvers by the patient when pain is present. Pleurodynia may also be manifested as pawing, stiff forelimb gait, abducted elbows, and reluctance to move. The condition may easily be mistaken for colic, exertional rhabdomyolysis, or laminitis. As more fluid accumulates in the pleural space and the disease becomes chronic, pain is less evident. A plaque of sternal edema is a common clinical finding in horses with pleuropneumonia. This is not a specific finding, as it can occur with many other disease processes.

Careful auscultation after application of a rebreathing bag (if not precluded by respiratory distress) is extremely valuable in defining the presence and sometimes extent of lung involvement. Horses with a large amount of secretions in the trachea often have an audible tracheal rattle. Most horses with bronchopneumonia will cough when the rebreathing bag is applied, whereas horses without bronchopneumonia will not. Occasional inspiratory or expiratory crackles and/or wheezes may be heard over affected areas, which are more commonly located ventrally. Because consolidated lung parenchyma is a good acoustic medium, mild consolidation sometimes results in only increased bronchial sounds. In contrast, the lung sounds may be diminished in areas of severe consolidation, extensive abscess formation, or pleural effusion.

Auscultation of horses with pleuropneumonia reveals normal lung sounds in the dorsal lung fields, with no sound or considerably decreased lung sounds ventrally. Pleural friction rubs are often not heard because they are present only in the acute stage of the disease. If they are heard, friction rubs are present predominantly at the end of inspiration and the early part of expiration. They disappear as inflammation decreases or as pleural fluids accumulate. Cardiac sounds are often heard over a wider area of the chest than normal, probably as a result of enhanced conduction of sound through the pleural fluid. Thoracic percussion is useful to detect and delineate pleural effusion with resonant sounds dorsal and dull sounds ventral to the horizontal line of effusion.

Differential Diagnosis

When physical examination and auscultation indicate pulmonary disease, the major clinical task is differentiating infectious from noninfectious causes. Among infectious causes, bacterial pneumonia is most common. Most viral infections are confined to the upper respiratory tract. The clinical presentation of equine multinodular pulmonary fibrosis may resemble that of horses with bacterial bronchopneumonia. Pulmonary aspergillosis most often follows severe gastrointestinal (GI) disease that had resulted in mucosal compromise.[37] Severe respiratory disease unresponsive to antimicrobial therapy might suggest fungal pneumonia or equine multinodular pulmonary fibrosis. Parasitic pneumonitis is rare in adult horses but may be seen in horses pastured with donkeys or mules. The two major noninfectious causes of pulmonary disease that may be confused with bacterial pneumonia include heaves (also known as RAO) and IAD. Other uncommon causes of noninfectious pulmonary disease that may result in similar clinical signs are pneumothorax, pulmonary edema, smoke inhalation, neoplasia, and idiopathic interstitial pneumonia. The diagnostic tests described below aid in the differentiation between infectious and noninfectious causes of lower respiratory tract disease.

When pleural effusion is present, several differentials should be considered. Bacterial pleuropneumonia is by far the most common cause of pleural effusion in horses. In one study, 90 of 122 horses (73.8%) with pleural effusion had pleuritis secondary to bacterial pneumonia or lung abscessation.[14] Other less common causes of pleural effusion in horses include hemothorax, penetrating chest wounds, esophageal ulceration or rupture, neoplasia, fungal pneumonia, pericarditis, congestive heart failure, diaphragmatic hernia, hypoproteinemia, and chylothorax.

Diagnostic Approach

Presumptive diagnosis of lower respiratory tract infection is generally based on clinical signs and careful auscultation of the lungs with a rebreathing bag. The need for additional diagnostic procedures is determined by the severity and duration of clinical signs, the number of affected animals, the value of the affected animals, and prior treatment used and response to such therapy. Bacterial pneumonia or pleuropneumonia most commonly affects an individual horse on a given farm. In horses suspected of having bacterial pneumonia, the goal of diagnostic evaluation is to rule out diseases of the upper respiratory tract and to determine the cause and severity of lung involvement.

HEMATOLOGY AND BIOCHEMISTRY. Horses with bacterial bronchopneumonia commonly have an inflammatory hematologic profile. Leukocytosis and absolute neutrophilia with or without a left shift are supportive of bacterial infection. Neutropenia with a toxic left shift may also be evident in the acute stages in severely affected animals. Increased fibrinogen and/or serum amyloid A concentrations, hyperglobulinemia, and mild hypoalbuminemia are common. Anemia of chronic inflammation may develop in chronically affected animals. There does not seem to be a good correlation between the severity of clinical signs and the presence or the magnitude of hematologic changes. When plasma fibrinogen concentrations are increased, their sequential measurement provides a useful means of monitoring response to treatment. It must be remembered that a normal hematologic profile does not rule out bacterial bronchopneumonia.

ENDOSCOPY. Endoscopy may be useful to rule out upper airway infection in situations where physical examination and auscultation of the lungs are not conclusive. Presence of mucopurulent secretions in the trachea and bronchi confirms lower respiratory tract disease. However, the presence of mucopurulent secretions does not necessarily indicate a bacterial infection, as this is also a common finding in horses with RAO and IAD. Bronchoscopy may also be useful in locating the affected lung segment in horses with focal pneumonia or draining pulmonary abscesses. It should be noted that exploration of the trachea and lower airways via bronchoscopy may contaminate subsequent samples taken for culture.

TRACHEOBRONCHIAL ASPIRATE FOR CYTOLOGY AND CULTURE. Tracheobronchial aspirate (TBA) for cytologic examination and bacterial culture is one of the most helpful diagnostic procedures available when bronchopneumonia is suspected. BAL is not as useful as TBA in cases of bronchopneumonia because with BAL, only a small portion of a lung is sampled. In contrast to BAL, TBA samples contain a pooled sample of secretions from all portions of the lung, thus

VetBooks.ir

increasing the chances of culturing the pathogen of interest. In one study involving 22 horses diagnosed with pneumonia or pleuropneumonia based on thoracic radiographs or ultrasonography, BAL cytology was abnormal in only 10 horses despite attempts at selectively sampling the affected area.[38] In contrast, all horses had evidence of septic inflammation based on tracheobronchial aspirate cytology.[38] Whenever possible, antimicrobial therapy should be discontinued at least 24 hours before performing TBA. TBA is preferably obtained by sterile percutaneous transtracheal aspiration to avoid contamination from the upper airway. Alternatively, the sample can be collected with a sterile guarded aspiration catheter passed through the biopsy channel of a flexible endoscope.[39,40] Endoscopy has the advantage of allowing selective aspiration of exudate when it is present, which may therefore enhance recovery of bacteria. However, bacterial contamination of nasal or pharyngeal origin more commonly occurs in TBA samples collected via endoscopy. Airway fluid specimens should be submitted for cytology, Gram stain, and aerobic and anaerobic bacterial cultures. The fluid used for anaerobic cultures should be transferred to the laboratory immediately after collection in a manner that prevents or minimizes exposure to air. Anaerobic transport media are commercially available and should be routinely used. Specimens submitted for isolation of anaerobes should not be refrigerated because many anaerobes are intolerant to cold. In horses with pleural effusion, TBA should be obtained even if pleural fluid is available for bacterial culture. In one study, culture of the pleural fluid was negative in 43% of 111 horses with pleuropneumonia, whereas tracheobronchial fluid yielded growth in all cases.[3] Only approximately 5% of cases had growth from the pleural fluid but not from TBA.[3]

Macrophages and columnar ciliated epithelial cells predominate in TBA from healthy horses. The percentage of neutrophils in TBA from apparently healthy horses can be quite variable. In one study, approximately 75% of apparently healthy Thoroughbred racehorses in training had less than 20% well-preserved neutrophils.[41] Occasional plant spores and fungal hyphae may be present either free or in large mononuclear cells. Their presence does not necessarily indicate fungal infection and probably reflects the horse's environment. Degenerated neutrophils displaying karyolysis and cytoplasmic vacuolization are the predominant cell type in horses with bacterial lower respiratory tract infections. Bacteria may be found intracellularly or extracellularly. Presence of squamous epithelial cells indicates contamination with the upper respiratory tract or pharynx and is more common in samples obtained via the endoscope. The trachea is not a perfectly sterile site, and pathogenic bacteria potentially can be isolated from the trachea of normal horses.[39] Therefore culture results should always be interpreted in the context of clinical signs and cytologic examination. If small numbers of bacteria are cultured in the absence of cytologic evidence of sepsis, it is unlikely that they are the cause of the respiratory problem. Similarly, growth of various molds is common in TBA cultures, and the clinical signs, imaging data, and cytologic findings should be considered prior to initiating treatment with antifungal agents.

THORACIC ULTRASONOGRAPHY. Thoracic ultrasonography can be performed using a range of transducers and machine types. The normal aerated lung parenchyma is not penetrated by the ultrasound beam, rendering only the pleural space and superficial lung surface available for study. Ultrasonography is a helpful diagnostic tool when lung involvement includes peripheral areas but may not be as useful as radiography to evaluate the full extent of lung lesions, since lesions with overlying aerated lung will not be detected. However, in most horses with bronchopneumonia the periphery of the lung is affected, enabling the clinician to successfully image some of the lesions. Early ultrasonographic lesions are nonspecific and may include only irregularities of the pleural surface. These lesions may progress to form focal areas of consolidation of various sizes. Consolidated lung varies in appearance from dimples of the pleural surface to large wedge-shaped areas of sonolucent lungs (Fig. 31.5).

Ultrasonography offers a considerable advantage over radiographs in the study of the pleural surfaces and space. A small amount of pleural effusion that would otherwise be missed clinically or by radiography can be detected easily by ultrasonography. Ultrasonography can also be used to assess the nature and approximate volume of fluid, select the optimal site and depth for thoracocentesis, and detect sequelae such as fibrin deposition, pleural adhesions, abscess formation, and pneumothorax. Pleural effusion appears as hypoechoic to anechoic fluid between the parietal pleural surface and the lungs (Fig. 31.6). The echogenicity of the fluid typically reflects the degree of cellularity. Fibrin appears as filamentous strands floating in the effusion (see Fig. 31.6). The presence of small (<1 mm) bright echoes (gas echoes) often indicates anaerobic infections (Fig. 31.7).[42] Gas echoes may also be seen with gangrenous pneumonia or bronchopleural fistulas, or they may result from leakage of air during thoracocentesis.

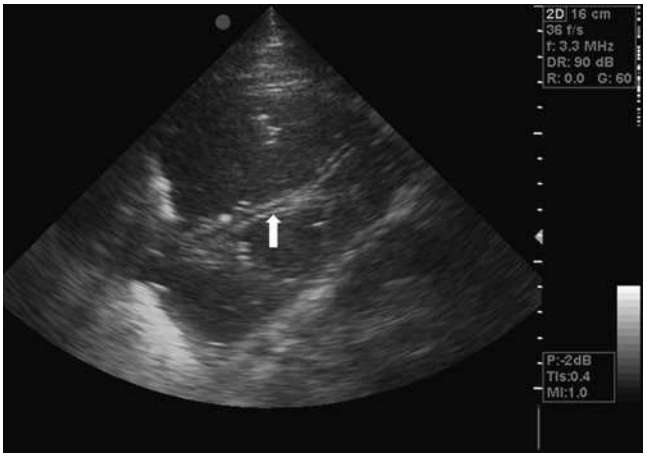

FIG. 31.5 Sonogram of the left thorax obtained from a 3-year-old Thoroughbred gelding. The ventral aspect of the lung is completely consolidated. Notice the liver-like appearance of the wedge-shaped area of the lung. Fluid bronchograms are indicated by a white arrow.

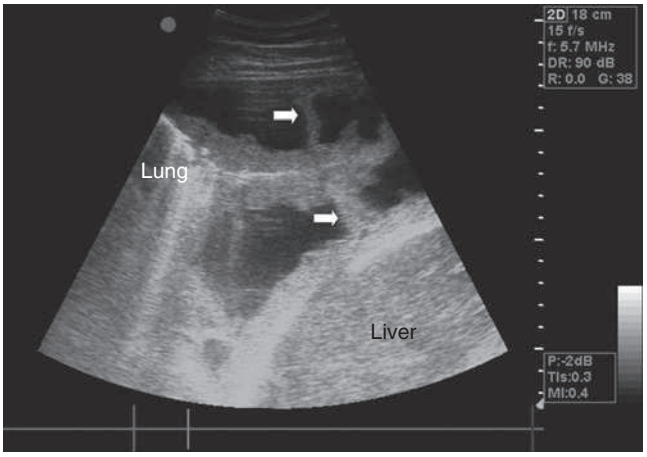

FIG. 31.6 Sonogram of the thorax obtained from a 4-year-old horse with pleuropneumonia. The ventral tip of the lung is atelectatic and covered with fibrin. There are adhesions between the tip of the lung and the diaphragm and chest wall *(white arrows)*.

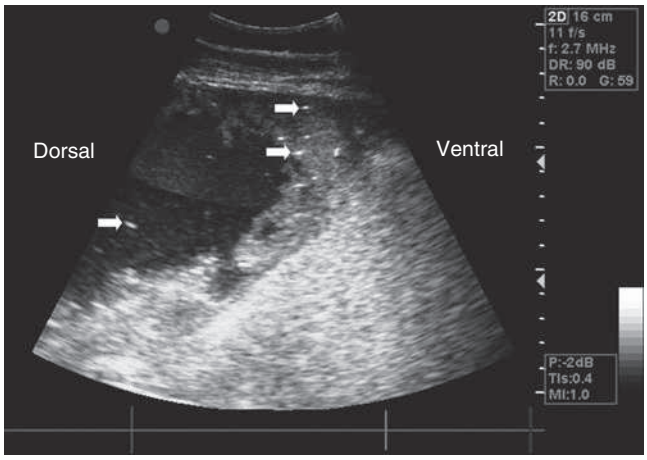

FIG. 31.7 Sonogram of the ventral thorax obtained from a horse being treated for pleuropneumonia. The sonogram shows a pleural abscess filled with fluid dorsally and with hyperechoic material ventrally. There are multiple gas echoes (some indicated by arrows). Multiple anaerobes were obtained on culture of an aspirate.

FIG. 31.8 Lateral thoracic radiograph of the caudoventral lung field from a 4-year-old Thoroughbred mare showing a pronounced alveolar pattern with air bronchograms. The caudal silhouette of the heart is almost completely obscured.

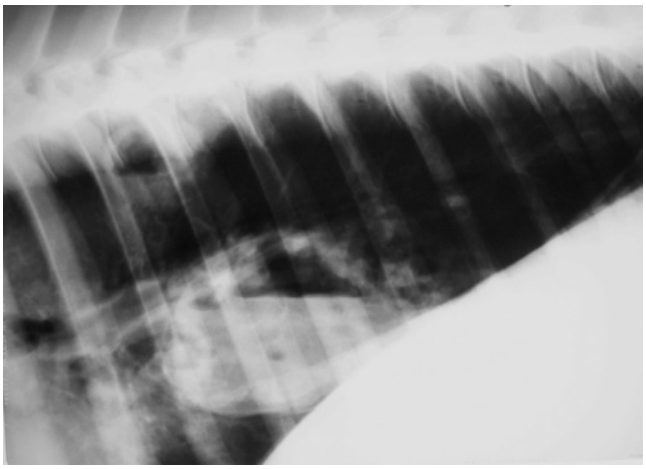

FIG. 31.9 Lateral thoracic radiograph of the caudodorsal lung field from a 3-year-old Thoroughbred filly showing two cavitary abscesses with distinct horizontal lines representing fluid-gas interface.

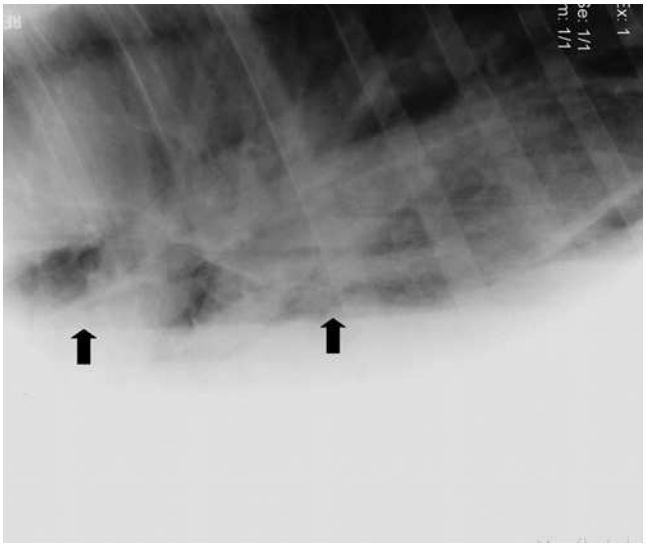

FIG. 31.10 Lateral thoracic radiographs from a 4-year-old Thoroughbred gelding with pleuropneumonia. A large amount of pleural effusion obscures the ventral lung fields. The dorsal aspect of the fluid line is indicated by black arrows. An interstitial pattern is noted in the caudodorsal lung fields.

RADIOGRAPHY. In horses with mild septic IAD, thoracic radiographs may be normal or may reveal only mild bronchial or bronchointerstitial patterns. In more severely affected animals, radiographs demonstrate irregular opacities in the ventral thorax that may obscure the normal vasculature and cardiac silhouette (Fig. 31.8). Air bronchograms are sometimes visible. Abscesses are often present as circular soft-tissue opacities of varying sizes. In some cases they may be cavitated with thick walls and a distinct horizontal line representing fluid gas interface (Fig. 31.9). Pleural effusion appears as a horizontal line demarcating a ventral soft-tissue opacity that obscures the heart and ventral lung fields (Fig. 31.10). When severe pleural effusion is present, it is most efficient to perform thoracic radiographs after the pleural fluid has been drained. Although ultrasonography is superior to radiographs in horses with pleuropneumonia, radiography should still be performed when possible to detect and monitor resolution of deep pulmonary abscesses that may be missed during ultrasonography.

THORACOCENTESIS FOR CYTOLOGY AND CULTURE. Thoracocentesis should be considered in horses with pleural effusion. The procedure can be of diagnostic value by allowing differentiation of septic pleuritis from effusion caused by other disease processes. It can also be of therapeutic value via removal of excessive chest fluid, which allows pulmonary reexpansion and a reduction in respiratory distress. Thoracocentesis is best performed using ultrasound guidance to determine the most appropriate site. A blunt teat cannula is typically used if a small volume of effusion is being sampled strictly for diagnostic purposes. Depending on the volume of effusion, a 16-, 24-,

VetBooks.ir

or 32-French chest tube is used when pleural drainage is also indicated (see the Pleural Drainage section later). An aliquot of pleural fluid is placed into tubes containing anticoagulant solution (ethylenediaminetetraacetic acid, or EDTA) so that cytologic evaluation may be performed. Part of the fluid should be saved in sterile containers with appropriate transport media for subsequent Gram stain and aerobic as well as anaerobic bacterial cultures. The normal parameters for equine pleural fluid have been reviewed[43-45] and are described earlier in this chapter.

THORACOSCOPY. Thoracoscopy is rarely necessary in the initial evaluation of horses with pleuropneumonia. However, the technique might be of diagnostic and therapeutic value in more chronic cases that develop pleural abscesses or pleural adhesions (see the Thoracoscopy section later).[46]

Treatment

SYSTEMIC ANTIMICROBIAL THERAPY. Administration of appropriate antimicrobial agents is the most important part of the therapeutic plan. The choice of the antimicrobial agent depends on the severity of the clinical signs, cost, ease of administration, and, when available, results of bacteriologic culture and susceptibility testing of TBA or pleural fluid. Dosages for commonly used antimicrobial agents are presented in Table 31.2. In early cases of mild bronchopneumonia, the practitioner is justified in suspecting *S. zooepidemicus* as the likely causative microorganism and in treating accordingly. *S. zooepidemicus* is almost invariably susceptible to penicillin, ampicillin, and cephalosporins such as ceftiofur (Table 31.3). The possibility of a mixed infection involving *S. zooepidemicus* and gram-negative microorganisms must be kept in mind when such empirical therapy is unsuccessful. Ceftiofur offers the advantage of having a good spectrum of activity against common nonenteric gram-negative pathogens (e.g., *Pasteurella* spp., *Actinobacillus* spp.) and against many enteric gram-negative pathogens (see Table 31.3). Ceftiofur is available as a sodium salt that requires daily intramuscular administration or as ceftiofur crystalline free acid. Two intramuscular doses of ceftiofur crystalline administered 4 days apart provide therapeutic concentrations of ceftiofur and desfuroylceftiofur-related metabolites in plasma and pulmonary epithelial lining fluid for approximately 10 days from the beginning of treatment.[47-49]

TABLE 31.2

Antimicrobial Agents Commonly Used to Treat Bacterial Bronchopneumonia in Adult Horses

Antimicrobial[a]	Dose	Frequency (h)	Route
β-Lactams			
Benzyl Penicillins			
Penicillin G (Na, K)	22,000 IU/kg	6	IV
Penicillin G (procaine)	22,000 IU/kg	12	IM
Aminobenzyl Penicillins			
Ampicillin sodium	20 mg/kg	8	IV
Ampicillin trihydrate	20 mg/kg	12-24	IM
Cephalosporins			
Cefazolin	10-20 mg/kg	6	IV
Ceftiofur sodium	2.2-4.4 mg/kg	24	IM
Ceftiofur crystalline free acid	6.6 mg/kg	[b]	IM
Aminoglycosides			
Amikacin	10 mg/kg	24	IV or IM
Gentamicin	6.6 mg/kg	24	IV or IM
Fluoroquinolones			
Enrofloxacin[c]	5.5 mg/kg	24	IV
	7.5 mg/kg	24	PO
Tetracyclines			
Oxytetracycline[d]	6.6 mg/kg	12	IV[d]
Doxycycline[e]	10 mg/kg	12	PO[e]
Minocycline	4	12	PO
	2.2	12	IV
Others			
Chloramphenicol	50 mg/kg	6	PO
Metronidazole	25 mg/kg	12	PO
	35 mg/kg	12	Per rectum
Rifampin	5 mg/kg	12	PO
Trimethoprim-sulfonamide	30 mg/kg (combined)	12	PO

[a]Pharmacokinetics data are available for horses, but in most cases safety studies have not been performed in the equine species.

[b]Two doses 4 days apart will provide 10 days of coverage. If a longer treatment period is necessary, weekly (q7days) administration is sufficient after the initial two doses.

[c]Should not be used in young growing horses because of the risk of arthropathy.

[d]Dilute and give by slow IV infusion.

[e]Administer orally only. Intravenous doxycycline has resulted in severe cardiovascular effects, including collapse and death in some horses.

IM, Intramuscular; *IV*, intravenous; *PO*, oral.

TABLE 31.3

In Vitro Antimicrobial Susceptibility of Aerobic Bacterial Isolates Commonly Isolated From Horses With Bronchopneumonia or Pleuropneumonia

Microorganisms (n)[b]	Antimicrobials[a]										
	AMP	AMI	CHL	E	ENR	GM	P	TE	TMS	RIF	XNL
Gram-Positives											
Streptococcus zooepidemicus (758)	99	1	88	94	50	55	99	16	63	98	100
Staphylococcus aureus (211)	41	96	95	76	89	89	44	83	81	95	57[c]
Other staphylococci (149)	41	96	95	76	89	89	44	83	81	95	57[c]
Gram-Negatives											
Escherichia coli (362)	52	95	88	1	94	85	—	71	53	—	92
Enterobacter spp. (132)	25	83	78	2	85	65	—	74	54	—	64
Klebsiella spp. (130)	2	91	74	1	88	71	—	76	60	—	82
Actinobacillus spp. (42)	79	71	86	15	95	91	54	88	71	—	100
Pasteurella spp. (28)	78	100	94	36	89	100	47	93	75	—	100
Pseudomonas spp. (232)	4	88	9	4	54	71	—	41	22	—	17

[a]Percentage of susceptible isolates.

[b]Approximate number of isolates (some isolates were not tested against every antimicrobial agent).

[c]Ceftiofur is rapidly metabolized to desfuroylceftiofur in vivo. Desfuroylceftiofur is as active as ceftiofur against most bacterial pathogens, but most coagulase-positive *Staphylococcus* spp. are resistant. Therefore despite in vitro susceptibility, ceftiofur is not the ideal choice for the treatment of staphylococcal infections.

—, Not tested or testing not warranted; *AMI*, amikacin; *AMP*, ampicillin; *CHL*, chloramphenicol; *E*, erythromycin; *ENR*, enrofloxacin; *GM*, gentamicin; *P*, penicillin; *RIF*, rifampin; *TE*, tetracycline; *TMS*, trimethoprim-sulfonamide; *XNL*, ceftiofur.

Adapted from Giguère S, Afonso T: Antimicrobial drug use in horses. In: Giguère S, Prescott JF, Dowling PM, editors: *Antimicrobial therapy in veterinary medicine*, 5th ed. Ames, IA: Wiley-Blackwell; 2013, pp. 457–472. Isolates were obtained from multiple equine clinical specimens including but not restricted to tracheobronchial aspirates and pleural fluid.

Therapy of horses with mild lower respiratory tract infections should be continued for a minimum of 10 days or until clinical signs resolve. In some cases the duration of therapy needed may preclude continuous intramuscular therapy because of muscle soreness. Trimethoprim-sulfamethoxazole (TMS) combinations offer the advantage of oral administration. The usefulness of TMS combinations for the treatment of severe bacterial respiratory tract infections in horses may be limited by their apparent limited in vivo activity against *S. zooepidemicus*. In contrast to penicillin, TMS was ineffective in eradicating *S. zooepidemicus* in a tissue chamber model of infection in horses.[50,51] This failure of in vivo response was observed despite in vitro susceptibility of the isolate and high concentrations of TMS in the tissue chamber fluid.[50,51] However, in a recent study oral TMS was effective in the treatment of mild to moderate lower respiratory tract infections caused by *S. zooepidemicus*.[52]

In more severe cases of bronchopneumonia and in all cases of pleuropneumonia, antimicrobial therapy ultimately should be selected based on results of culture and in vitro susceptibility testing. Before obtaining these results, selection should be based on knowledge of the prevalence and susceptibility pattern of bacteria commonly isolated from affected horses (see Table 31.3). Polymicrobial and mixed aerobic/anaerobic infections are common; thus broad-spectrum antimicrobial therapy is initially required. A combination of gentamicin for gram-negative coverage and penicillin for gram-positive and anaerobic coverage is commonly used as initial broad-spectrum therapy for moderate to severe bronchopneumonia. Enrofloxacin can be used as a substitute to gentamicin for gram-negative coverage in adult horses. Advantages of enrofloxacin over gentamicin include greater activity against Enterobacteriaceae, better penetration in phagocytic cells and tissues, and better activity in purulent material. However, enrofloxacin should never be used as standalone initial therapy in horses with bronchopneumonia because of its lack of activity against anaerobes and variable activity against streptococci such as *S. zooepidemicus*. Ampicillin or cefazolin can replace penicillin for gram-positive coverage and offer the supplementary advantage of providing additional gram-negative coverage.

Treatment of anaerobic pleuropneumonia is usually empirical, as antimicrobial susceptibility testing of anaerobes is difficult because of their fastidious nutritive and atmospheric requirements. Thus familiarity with antimicrobial susceptibility patterns is helpful in formulating the treatment regimen when an anaerobe is suspected. The majority of anaerobic isolates are susceptible to relatively low concentrations of penicillin. However, *B. fragilis*, a frequently encountered anaerobe in horses with pleuropneumonia, is routinely resistant to penicillin. Other members of the *Bacteroides* family are known to produce β-lactamases and are potentially penicillin resistant. Metronidazole has excellent in vitro activity against a variety of obligate anaerobes, including *B. fragilis*. Oral administration rapidly results in adequate serum levels and thus is an acceptable route of administration for horses with pleuropneumonia. Therefore if anaerobic infection is suspected, oral metronidazole is usually added to the combinations mentioned previously. Malodorous nasal discharge, halitosis, or the presence of gas echoes in pleural effusion seen during ultrasonography suggests the presence of an anaerobic infection. However, the absence of these findings does not rule out anaerobic bacterial infection. Horses with extensive lung consolidation and horses with pleuropneumonia may benefit from having metronidazole added to the treatment regimen. Metronidazole is not effective against aerobes and therefore should always be used in combination therapy. Chloramphenicol is active against most aerobes and anaerobes cultured from horses with bronchopneumonia or pleuropneumonia. However, because of human health concerns, its use should be limited to the treatment of horses with severe anaerobic bacterial infections refractory to metronidazole therapy in countries where its use is allowed. Rifampin is bactericidal and active against streptococci and some species of anaerobes. It penetrates well into abscesses and may be helpful in the treatment of infections with walled-off abscesses. Rifampin should always be used in combination with another

antimicrobial agent to decrease the likelihood of emergence of resistant mutants.

In cases of severe bronchopneumonia, lung abscesses or pleuropneumonia long-term antimicrobial therapy ranging from 3 weeks to several months may be required. In the initial stages of therapy, IV antimicrobials are preferred to achieve higher serum concentrations. Oral antimicrobial agents can be used later in the course of the disease if appropriate based on in vitro susceptibility testing. Clinical signs, lung auscultation, fibrinogen concentrations, and repeated ultrasonographic and/or radiographic examination are useful in assessing response to therapy and deciding when to discontinue antimicrobial therapy. Stall rest must be enforced during therapy of pneumonia, and return to exercise should be gradual and permitted only after the horse is clinically normal and antibiotic therapy has been completed.

AEROSOLIZED ANTIMICROBIAL AGENTS. Aerosolized antimicrobial agents might be a useful adjunct to oral or systemic antimicrobial agents, particularly in horses with chronic septic inflammatory airway disease and no or minimal involvement of the lung parenchyma. The rate and extent of penetration of a drug into most sites outside the vascular space, such as lung tissue, are determined by the drug's concentration in plasma, molecular charge and size, extent of plasma protein binding, and blood flow.[53] In other tissues such as the central nervous system and the eye, a lipid membrane provides a barrier to drug diffusion.[53] There is a similar barrier between blood and the bronchial epithelium, restricting penetration of some drugs into bronchial secretions and epithelial lining fluid of the lower airways.[54] Aerosol administration of antimicrobial agents can result in high drug concentrations in the respiratory tract while minimizing systemic concentrations and their resulting toxicity.

Antimicrobial delivery by inhalation is greatly influenced by the product formulation and type of nebulizer. Aerosol use of IV formulations can lead to exposure to potentially irritant or toxic additives and inappropriate pH or osmolality ranges. In one study, the particle size distribution and particle density of gentamicin sulfate and ceftiofur sodium aerosols were affected by the antimicrobial concentration of the solution.[55] Gentamicin concentrations of 50 mg/mL or ceftiofur concentrations of 25 mg/mL produced the optimal combinations of particle size and aerosol density when a medical ultrasonic nebulizer was used.[55] Development of a silent battery-operated nebulizer for horses (Flexineb [Nortev Ltd., Galway, Ireland]) has greatly facilitated delivery of antimicrobial drugs by inhalation in horses.

In healthy horses, aerosolization of 20 mL of the commercially available IV gentamicin sulfate solution (diluted to 50 mg/mL) using an ultrasonic nebulizer resulted in bronchial lavage fluid concentrations approximately 12 times higher than concentrations achieved by IV administration at a dose of 6.6 mg/kg.[56] In the same study, serum concentrations following aerosol administration were below 1 μg/mL at all times.[56] Once-daily aerosol administration of gentamicin to healthy horses for 7 consecutive days did not result in pulmonary inflammation or drug accumulation in the respiratory tract.[57] The major limitation to the use of aerosolized gentamicin in horses is its lack of activity against *S. zooepidemicus*, the most common bacterial pathogen of the equine respiratory tract. Nebulization of ceftiofur sodium (diluted to 50 mg/mL in sterile water) at a dose of 2.2 mg/kg with the Flexineb mask was well tolerated and resulted in drug concentrations in pulmonary epithelial lining fluid above the minimum inhibitory concentration of the drug required to inhibit the growth of 90% of *S. zooepidemicus*, *Pasteurella* spp., and *Actinobacillus* spp. for approximately 24 hours after administration.[58] Additional studies are required to assess the efficacy of aerosolized antimicrobial agents for the treatment of bacterial respiratory tract infections in horses.

ANCILLARY TREATMENTS. The need for ancillary treatments depends on the severity of the disease and is most often necessary in horses with pleuropneumonia. Nonsteroidal antiinflammatory agents (NSAIDs) may be beneficial to minimize inflammation, provide analgesia, and control high fevers. Additional analgesia may be necessary in horses with severe pleurodynia. Adequate hydration should be maintained in patients receiving these agents for extended periods, especially if aminoglycosides are used concurrently. Intravenous fluid therapy may be necessary to correct hypovolemia in acute stages, but it is rarely required for chronic cases. Intrapharyngeal insufflation of oxygen is indicated in horses that remain severely hypoxemic despite adequate drainage of the pleural cavity. Adequate parenteral or preferably enteral nutritional support via a nasogastric tube is beneficial in horses that remain anorectic for several days. In horses with severe systemic illness, distal limb cryotherapy is indicated in an attempt to prevent development of laminitis.

PLEURAL DRAINAGE. Small amounts of pleural effusion may resorb quite readily with appropriate antimicrobial therapy. Therefore although a small sample of pleural fluid is useful diagnostically, pleural drainage is not necessarily indicated in all cases of pleuropneumonia. Drainage of pleural effusion results in removal of exudate and debris and allows for reexpansion of the lungs. Indications for drainage include a poor response to conservative therapy or the presence of pleural fluid with at least one of the following characteristics: (1) sufficient volume to cause respiratory distress, (2) fetid odor, or (3) cytologic or biochemical evidence of sepsis. Pleurocentesis and chest tube placement are described earlier in this chapter.

PLEURAL LAVAGE. Pleural lavage may be helpful to dilute thick, viscous pleural fluid and remove fibrin, debris, and necrotic tissue. Pleural lavage is most helpful in subacute stages before loculated pockets of pleural fluid develop. However, pleural lavage may help break down fibrous adhesions and establish communication between loculae. Pleural lavage is typically performed by using the same chest tube for infusion and drainage of lavage fluid. Alternatively, lavage can be performed by infusing fluid through a dorsally positioned tube and draining it through a ventrally positioned tube. Approximately 5 L of sterile, warm isotonic fluid solution is infused by gravity flow. After infusion, the chest tube is reconnected to the unidirectional valve for drainage. Allowing the horse to walk once the continuous flow has stopped will often result in drainage of additional fluid. Pleural lavage is probably contraindicated in horses with bronchopleural communications because it may result in spread of septic debris up the airways and into normal areas of the lungs.[59] Coughing and drainage of lavage fluid from the nose during infusion suggest the presence of a bronchopleural fistula (see the Complications of Pleuropneumonia section later).

USE OF FIBRINOLYTIC AGENTS. The use of intrapleural fibrinolytics in the treatment of loculated pleural effusion remains controversial in human medicine.[60] Various fibrinolytic agents such as streptokinase, urokinase, and recombinant tissue plasminogen activators (rtPA; e.g., alteplase, tenecteplase) have been used.[60] Numerous case series in humans have shown that such therapy is fairly safe and may facilitate drainage. However, controlled trials are scarce and have given contradictory results regarding the ultimate benefit of intrapleural fibrinolytic therapy. Subgroup analysis of a meta-analysis of randomized controlled trials indicated that intrapleural fibrinolysis with urokinase might reduce the need for surgery and shorten hospital stay, whereas similar effects were not documented with streptokinase or rtPA.[61]

VetBooks.ir

In recent years, rtPA has been increasingly used as an adjunct therapy for selected human patients with loculated pleural effusion. Several case series indicate a potential benefit for rtPA,[62,63] but large randomized placebo-controlled clinical trials are lacking.[60,62] Fibrinolytic drugs have negligible effects on decreasing the viscosity of purulent material because the viscosity of pus is attributable mainly to its DNA content. Therefore intrapleural recombinant human deoxyribonuclease I (rhDNase I) is sometimes used in combination with rtPA.[64] In a randomized clinical trial, intrapleural rtPA–rhDNase I therapy improved fluid drainage in humans with pleural infection and reduced the frequency of surgical intervention and the duration of the hospital stay, whereas treatment with rhDNase I alone or rtPA alone was ineffective.[65]

Given that fibrinous pleural effusion has been associated with a less favorable outcome in horses with pleuropneumonia,[66] there has been increasing interest in the use of intrapleural fibrinolytic agents. There are isolated reports and a retrospective case series reporting the use of rtPA in horses with fibrinous pleuropneumonia. In one report, 12 mg of alteplase was infused in volumes of 0.9% saline ranging between 250 mL and 2 L.[67] In another report, tenecteplase (12 to 30 mg in 500 mL of 0.9% saline) was administered alone or in combination with 25 mg of rhDNase I.[68] In both reports there was a subjective decrease in the amount of fibrin in the thoracic cavity as assessed by ultrasonography. In a retrospective case series of 25 horses, altepase (0.4 to 20 mg per hemithorax in 10 mL to 2 L of polyionic solution) was administered 1 to 4 times per horse with no evidence of adverse effects and a subjective decrease in the amount of fibrin as assessed by ultrasonography after approximately 65% of treatments.[69] Controlled studies evaluating the safety and efficacy of rtPA and rhDNase I are required before the widespread use of these agents can be recommended in the management of fibrinous pleuritis in horses.

THORACOSCOPY. Thoracoscopy allows direct evaluation of the lungs and pleural cavity. In selected cases, thoracoscopy may be a useful tool to facilitate placement of thoracic drains in abscesses, transect pleural adhesions, and disrupt loculations.[46] The technique can also be used to biopsy or aspirate specific lesions affecting the periphery of the lungs. The procedure can be performed in the standing sedated horse with local anesthesia and is usually very well tolerated.[70]

Adhesions between the lung and the diaphragm or body wall may prevent complete collapse of the lung, making insertion of the instruments more difficult and sometimes limiting the view of the pleural cavity. Adhesions are easier to disrupt during the first week after formation when the tissue is fibrinous rather than fibrous. Transection of mature adhesions is more difficult and can result in severe hemorrhage. Creation of a pneumothorax is a necessary feature of thoracoscopy, and horses should be monitored carefully throughout the procedure. Transient exacerbation in clinical signs of pulmonary disease due to pneumothorax can be alleviated by reinflation of the lungs.

THORACOTOMY. Surgical intervention in horses with pleuropneumonia is not a substitute for adequate medical management, but in carefully selected cases it can save the lives of horses that would have to be euthanized otherwise. The criteria for surgical interventions include (1) failure to respond to antimicrobial therapy, pleural drainage, and pleural lavage; (2) stable systemic medical condition; (3) presence of a large amount of fibrin, debris, or pus in the pleural space; and (4) either a walled-off lesion or presence of a complete mediastinum to avoid creation of a bilateral pneumothorax. Surgical intervention is most beneficial in chronic cases with large unilateral localized pockets of thick debris, especially if there is resolution or at least a significant improvement of the disease in the opposite hemithorax. Before surgical exploration, the nature and location of the lesion must be thoroughly characterized by ultrasonography or thoracoscopy to determine the ideal surgical site. When there is bilateral disease, thoracotomy is performed on the most severely affected side. If necessary, a second thoracotomy can be performed on the opposite side at a later time. Thoracotomy is typically performed with the horse standing. It is common practice to place a large chest tube into the targeted cavity and leave it open to atmospheric air for several hours before thoracotomy.[59] The onset of respiratory distress indicates development of bilateral pneumothorax, in which case standing thoracotomy is contraindicated and pneumothorax must be corrected. Unilateral pneumothorax is usually well tolerated.

The standing surgical procedures most commonly performed include thoracotomy via an intercostal approach and thoracotomy with rib resection. For the intercostal approach, the surgical site is prepared and infiltrated with local anesthetic. The lateral thoracic vein must be identified to avoid inadvertent incision. A vertical incision is made through the skin, intercostal musculature, and pleura. The length of the incision is dictated by the size of the pleural abscess and consistency of its content. When necessary, partial excision of the intercostal muscles will facilitate manual exploration of the cavity and removal of fibrin and necrotic debris. The major advantage of the intercostal approach over rib resection is preservation of thoracic wall integrity and compliance. Thoracotomy with rib resection is elected when the cavity is very large and it is anticipated that extensive manual débridement of fibrin and necrotic debris will be necessary. The advantage of the thoracotomy with rib resection over the intercostal approach is improved access to the thorax, allowing manual removal of large fibrin clumps and necrotic debris (Fig. 31.11). With both rib resection and intercostal approaches, the incision is left open and irrigated

FIG. 31.11 Thoracotomy with rib resection in a Thoroughbred filly with a large pleural abscess in the right hemithorax communicating with another abscess cranial to the heart. In this case, a rib resection was done to facilitate manual removal of purulent material and necrotic debris from both abscesses.

once or twice daily with a sterile isotonic fluid solution. The cavity is periodically débrided via gentle massage, taking care not to disrupt mature adhesions. After adequate formation of granulation tissue, tap water may be used. Depending on the size of the incision, it may take a few weeks to 2 to 3 months for complete closure by second intention. Complications during thoracotomy may include bilateral pneumothorax (if the cavity is not walled off and the mediastinum is not complete) and cardiac dysrhythmias (if the lesion is in close proximity to the heart). The most common long-term complication is the formation of a chronic draining fistula, but by itself this complication does not prevent the horse from returning to its usual occupation. In a retrospective study of 16 horses that had a standing lateral thoracotomy for pleural disease, 14 horses (88%) survived to discharge, and 46% of horses that survived returned to their previous level of athletic activity.[71] In another retrospective study, 9 of 11 horses that had a thoracotomy survived.[4]

Complications of Pleuropneumonia Several complications may occur during medical therapy of severe pneumonia and pleuropneumonia. These complications include jugular vein phlebitis or thrombosis from catheter placement, diarrhea resulting from antimicrobial therapy, pneumothorax or cellulitis secondary to thoracocentesis, coagulopathy, pleural abscesses, bronchopleural fistulas, pericarditis, and laminitis.

Pleural abscesses refractory to antimicrobial therapy are treated by thoracocentesis or thoracotomy (see earlier sections). In some cases of pleuropneumonia, the heart may act as a valve to trap effusion and inflammatory debris in the cranial thorax. Small cranial thoracic masses may result in nonspecific clinical signs such as fever, tachycardia, and sternal edema. Larger abscesses may result in jugular vein distention, forelimb extension (pointing), and caudal displacement of the heart. Diagnosis is made by ultrasonography (Fig. 31.12). It is necessary to pull a forelimb forward to successfully image the cranial thorax. Most horses with cranial thoracic masses will respond to conservative therapy with antimicrobial agents.[72] Drainage of the abscess should be performed in cases refractory to medical therapy or when the mass interferes with normal cardiac function. Cranial thoracic abscesses may be sampled in the standing horse with a front limb pulled forward. However, when drainage and lavage are required, the procedure is best performed under short-term general anesthesia to avoid damage to the heart and major blood vessels present in the cranial thorax. It is not recommended to leave an indwelling tube because the triceps musculature often causes the tube to kink. Repeated drainage and lavage may be necessary in some cases.

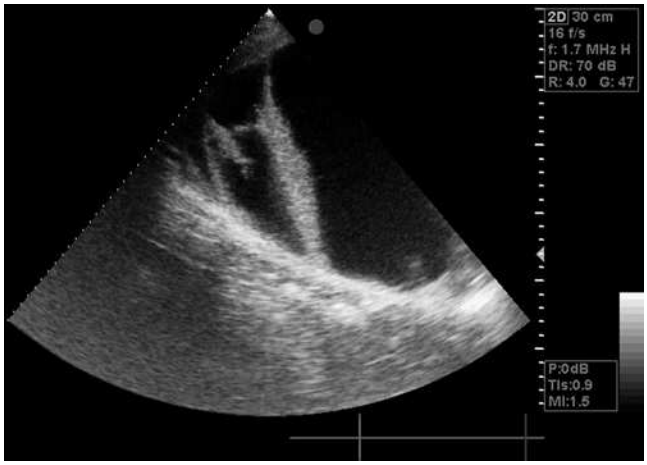

FIG. 31.12 Sonogram of the cranial thorax obtained from the third intercostal space of a 2-year-old Thoroughbred filly with distended jugular veins and pitting edema of the ventral thorax. A large, fluid-filled, loculated abscess was imaged.
