Diseases of Muscle

STEPHANIE J. VALBERG, *Consulting Editor*
SHARON JANE SPIER, STEVEN M. PARISH, MICHAEL MURPHY, and GARY P. CARLSON

Examination of the Muscular System

Stephanie J. Valberg

Clinical evaluation of the muscular system requires a systematic and routine method for examination. Often a veterinarian is asked to examine an animal with a history of a relatively nonspecific disease process that may be the result of muscular dysfunction. Animals with electrolyte imbalances, pleuritis, colic, chronic wasting diseases, poor performance, weakness, and a number of lameness problems may initially have signs similar to those seen with some forms of muscular dysfunction.

A thorough history of the animal or animals involved is an integral part of characterizing the muscle disorder, particularly because many disorders are intermittent in nature and triggered by certain environmental stimuli. A careful description of the animal's muscle tone, muscle mass, gait, degree of pain, exercise intolerance, and weakness while experiencing clinical signs should be obtained. In addition, the duration of illness, intermittency of clinical signs, factors precipitating clinical signs, exercise schedule, diet, current medications, vaccination history, and number of other animals affected and their familial relationships should all be recorded before the muscular system is examined.

Physical Examination

Initially the animal can be observed from all aspects at a distance while the horse is standing with forelimbs and hindlimbs exactly square. The examiner should observe the size, shape, and symmetry of all muscle groups and look for muscle fasciculations. This observation helps provide impressions about tropic changes, alterations in symmetry of particular muscle groups, and spontaneous muscle activity.

The animal can then be walked, trotted, or driven and evaluated for gait abnormalities. The symmetry of the gait and evidence of lameness, weakness, stiffness, and pain associated with movement can be noted. Gait abnormalities may result from pain, muscle weakness, muscle cramping, spasticity, decreased range of joint motion, dysfunction of motor neurons, and ataxia.

Following initial visual evaluation, muscles should be palpated to obtain an overall impression of muscle tone, consistency, sensitivity, swelling, atrophy, and heat. Firm, deep palpation of the lumbar, gluteal, and semimembranosus and semitendinosus muscles may reveal pain, cramps, or fibrosis. Comparisons between muscle groups and areas of the animal can then be made to identify atrophy or swelling. Some animals are tense and demonstrate apparent evidence of myalgia when palpation is first performed. However, given time and patience, many of these animals relax, and muscles or muscle groups that at first examination appeared to be very sensitive or hypertonic may in reality be normal. By this stage it can often be determined whether individual muscles, muscle groups, a limb or limbs, or the whole body musculature is involved. The symmetry or absence of symmetry of affected muscles or muscle groups is also important. Horses should stand perfectly square when comparing bilateral muscle groups.

Fine muscle tremors can be palpated and auscultated with a stethoscope. Concurrent signs of anxiety or pain should be noted, and the animal should be reevaluated in calm surroundings if necessary. In animals with spontaneous muscle activity, muscle groups should also be percussed with a percussion hammer. The triceps, pectoral, gluteal, and semitendinosus muscles are often easily accessed for percussion. A positive percussion sign occurs when the muscle holds a contracture for several seconds, creating a dimpled appearance below the contracted muscle (percussion myotonia) (Fig. 42.1). This occurs as the result of abnormal mechanical irritability and sustained contraction of the percussed fibers. Running a blunt instrument such as artery forceps, a needle cap, or a pen over the lumbar and gluteal muscles should illicit extension (swayback) followed by flexion (hogback) in healthy animals. Guarding against movement may reflect abnormalities in the pelvic or thoracolumbar muscles or pain associated with the thoracolumbar spine or sacroiliac joints.

A tail pull examination while the horse is standing still and walking can be used to assess rear limb weakness. If there is evidence of weakness, differentiation between muscular and neurologic origin is ideal. This requires a detailed neurologic examination and can often be extremely difficult. In general, muscular weakness is not associated with ataxia unless it is extremely severe. Weakness is often manifested by muscle fasciculations, knuckling at the walk, frequent recumbency with difficulty rising, and shifting of weight because of an inability to fix the stifles.

If the primary abnormality identified is related to exertion, a lameness evaluation including flexion tests is often indicated as part of evaluation of the muscular system. Muscle pain may be secondary to changes in movement caused by skeletal pain. The horse should be observed at a walk or trot for any gait abnormalities and in some cases lunged for 15 minutes or ridden until clinical signs are elicited.

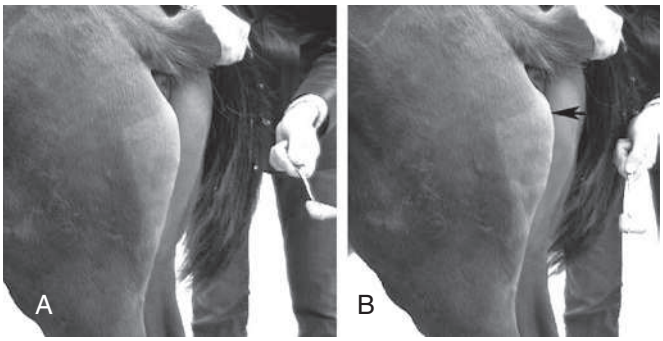

FIG. 42.1 Percussion of the semitendinosus muscle showing the muscle at rest **(A)** and an abnormal persistent firm contracture after tapping the muscle with a percussion hammer **(B)** in a horse with myotonia.

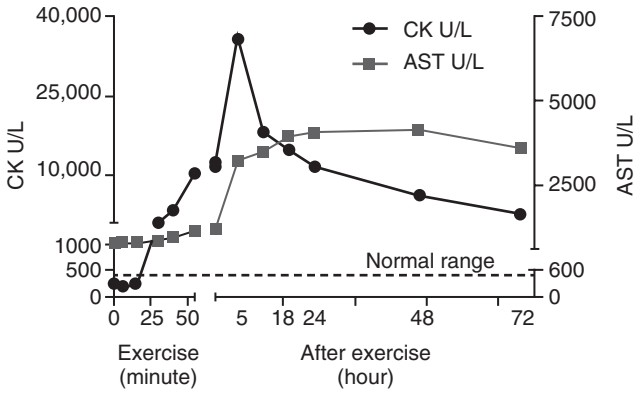

FIG. 42.2 Serum creatine kinase *(CK)* and aspartate transaminase *(AST)* activities over a 3-day period in a Standardbred trotter that developed exertional rhabdomyolysis during 55 minutes of trotting at 5 m/s. Serum CK activity increased during exercise and peaked in the sample obtained 5 hours after exercise. Serum AST was above normal range before exercise, increased after exercise, and peaked 48 hours following exercise.

Clinical Pathology

Serum Enzyme Activities and Myoglobin Concentrations

Serum enzyme activities can be extremely useful in determining whether muscle cell necrosis is a predominant feature of a suspected muscle disease. Under normal conditions the serum activities of the enzymes used to assess muscle damage are low. However, leakage of the enzymes from myocytes into the bloodstream may occur if the cell membrane is disrupted through muscle cell necrosis or if the permeability of the cell membrane is increased. A number of other factors may influence the activities of enzymes within the circulation. These include rate of enzyme production, alternative sources of the enzyme, rates of enzyme excretion and degradation, and alterations to the pathways involved in enzyme removal or inactivation.

Creatine kinase (CK), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH) activities in serum are used to assess muscle damage in large animals. Serum CK offers remarkable sensitivity as an indicator of myonecrosis and is predominantly located in skeletal and heart muscle. It is intimately involved in energy production within the cytoplasm and is readily liberated into the extracellular fluid when the muscle cell membrane is disrupted. Serum CK activity increases within hours of a muscle insult and peaks within 4 to 6 hours after injury (Fig. 42.2). Limited elevations in CK may accompany training, transport, and strenuous exercise. Elevations of CK to 400 or 500 IU/L may occur when training commences or in response to moderate exercise. Extreme fatiguing exercise (e.g., endurance rides or the cross-country phase of a 3-day event) may result in CK activities being increased to more than 1000 IU/L but usually less than 8000 IU/L. These elevations are not typically reflective of an extensive myopathy, and serum activities of CK rapidly return to baseline activities (i.e., <250 IU/L in 24 to 48 hours). Recumbent animals may also have slightly elevated CK activities that are usually less than 3000 IU/L. In contrast, more substantial elevations (from several thousand to hundreds of thousands of IU/L) in the activity of this enzyme may occur with rhabdomyolysis.

Serum AST has high activity in skeletal and cardiac muscle and also in liver, red blood cells (RBCs), and other tissues. Elevations in AST are not specific for myonecrosis, and increases can be the result of hemolysis, muscle, liver, or other organ damage. Alterations in AST activity are an integral component of many serum biochemical "profiles." AST activity rises more slowly in response to myonecrosis than does CK, often peaking 24 hours after the insult (see Fig. 42.2), and the half-life of AST is much longer than that of CK. By comparing serial activities of CK and AST in animals with suspected myopathy, information concerning the progression of myonecrosis may be derived. Thus (1) elevations in CK and AST reflect relatively recent or active myonecrosis; (2) if CK remains persistently elevated, myonecrosis is likely ongoing; and (3) elevated AST activities accompanied by decreasing or normal CK activities indicate that myonecrosis is not continuing. Elevations in serum LDH activity are not specific to skeletal muscle and can occur with rhabdomyolysis, myocardial necrosis, and/or hepatic necrosis.

Under ideal conditions samples for determination of serum CK, AST, and LDH should be harvested as soon as possible because anoxia and lysis of RBCs allows the liberation of AST and LDH. They should be kept chilled (4° C/39° F) if not taken immediately to a laboratory for analysis within 24 hours. When a delay of more than 12 hours is anticipated, freezing of the samples is desirable.

Elevations in plasma/serum myoglobin concentrations provide an indication of recent muscle damage. Unfortunately, few laboratories can routinely measure myoglobin. Normal concentrations in resting horses have been determined by nephelometry (range 0 to 9 μg/L),[1] with measured concentrations with rhabdomyolysis ranging from 10,000 to 800,000 μg/L.[2]

Urinalysis

Urine can be obtained as a free catch sample from horses placed in stalls with fresh bedding or via catheterization. The most accurate reflection of fractional excretion of electrolytes is obtained from samples obtained without tranquilization. Urinalysis is particularly important in horses with myoglobinuria, elevations in creatinine, or suspected electrolyte imbalances. Urine specific gravity, protein content, white blood cell (WBC) count, RBC count, and evaluation of cast formation should be performed to assess the potential for concurrent renal disease. A positive Hemastix test (ortho-toluidine) in the absence of hemolysis or RBCs in urine is highly suggestive of myoglobinuria. Further differentiation of myoglobin from hemoglobin is sometimes warranted, and, where available, electrophoresis, nephelometry, or spectroscopy may be used. Spectroscopy does not always reliably distinguish between myoglobin and hemoglobin.

Electrolyte, mineral, and creatinine concentrations in urine and blood have been used to determine electrolyte balance in horses with muscle cramping or exertional rhabdomyolysis.[3] Problems often encountered, however, are the large fluctuations in daily electrolyte excretion that occur in the same horse and between horses, the interference of high urinary potassium concentrations with measures of sodium concentrations when an ion-specific electrode is used, and the presence of calcium crystals in equine urine, which artifactually decrease the calcium

VetBooks.ir

and magnesium measured if urine samples are not acidified.[4] Renal fractional excretions (FEs) can be calculated using the following formula:

$$FE_x = \frac{S_{Cr} \times U_x \times 100}{U_{Cr} \times S_x}$$

where *U* is urine, *S* is serum, *x* is measured electrolyte, and *Cr* is creatinine.

If urine calcium is to be determined, acidification of urine to dissolve all calcium oxalate crystals is recommended to provide exact calcium excretion. Determination of potassium, chloride, magnesium, and phosphorus concentrations can be performed using ion-specific electrodes or by inductively coupled plasma atomic absorption.

Normal values for FEs of electrolytes depend on a horse's diet. Normal values (%) for horses consuming grass, hay, and a sweet feed mix with available salt are FE_{Na} 0.04 to 0.08, FE_K 35 to 80, FE_{Cl} 0.4 to 1.2, FE_{Ca} 5.3 to 14.5, FE_P 0.05 to 4.1, and FE_{Mg} 14.2 to 21.4.[4,5]

Exercise Testing

Evaluation of muscle disorders that are precipitated by exercise may require an exercise challenge test. Horses should be observed for evidence of exercise intolerance, as well as muscle stiffness. An exercise test should not be used in horses with overt signs of rhabdomyolysis but rather to determine if horses not currently showing clinical signs are prone to exertional rhabdomyolysis. The goal is to induce subclinical elevations in serum CK activity. Abnormal increases in CK are more likely to occur if slow trotting is performed rather than strenuous exercise.[6] Often 15 minutes of exercise at a walk and trot in unfit horses or at a constant slow trot in fit horses will elucidate subclinical elevations of CK. If signs of stiffness develop before this, exercise should be concluded. CK activities in blood samples taken immediately after exercise do not reflect the amount of exercise-induced muscle damage. For best results, blood samples for CK activity should be taken before and 4 to 6 hours after exercise. In healthy horses, 15 to 30 minutes of light exercise rarely causes more than a threefold increase in CK activity.[7,8] Elevations greater than fivefold are indicative of exertional rhabdomyolysis. Standardized treadmill exercise testing can also be used to evaluate muscle responses and measure metabolic responses to exercise.

Electromyography

Electrodiagnostic studies detect spontaneous or evoked potentials of neurogenic or myogenic origin using electrodes positioned in the muscle. Electromyography (EMG) is particularly useful to evaluate large animals with altered muscle tone. EMG of normal skeletal muscle shows a brief burst of electrical activity when the needle is inserted (insertional activity) in muscle and then quiescence, unless motor units are recruited (motor unit action potentials) or the needle is close to a motor end plate (miniature end plate potentials). Normal muscle shows little spontaneous electrical activity unless the muscles contract or the horse moves. Horses with abnormalities in the electrical conduction system of muscle, or denervation of motor units, show abnormal spontaneous electrical activity in the form of fibrillation potentials, positive sharp waves, myotonic discharges, or complex repetitive discharges.[9-12] Fibrillation potentials and positive sharp waves represent spontaneous firing of muscle fibers. Myotonic discharges are bursts of complex high-frequency potentials, whereas complex repetitive discharges are similar but have fixed amplitude and frequency. They both represent abnormal simultaneous firing of groups of muscle fibers. Motor unit action potentials can be evaluated to assess their amplitude, duration, phase, and number of phases. Myopathic changes include a decrease in duration and amplitude of motor unit action potentials.[10,12] More information about the motor unit could be provided by nerve conduction velocities (NCVs); however, the inaccessibility of motor nerves makes measurement difficult in large animals. Both EMG and NCVs are used to classify the primary disease as neuropathic or myopathic, to determine the distribution of the disease, and to provide insight into the pathophysiologic mechanisms of the disease.[9,13] Equipment costs are relatively high, and expertise is required in operation and interpretation of results. Readers are advised to consult Chapter 35 before considering the use of EMG.

Nuclear Scintigraphy

Nuclear scintigraphy is useful for identification of some forms of muscle damage, particularly an area of deep muscle damage that was not suspected on the basis of clinical examination.[14] Technetium 99m methylene diphosphonate (MDP) is taken up in some damaged muscle in the horse and is best seen in the bone phase images (i.e., 3 hours after injection). Scintigraphy has been used in horses with a history of poor performance, with or without stiffness after exercise, to confirm a diagnosis of equine rhabdomyolysis.[15] The mechanism of MDP binding is unknown, but the release of large amounts of calcium from damaged muscle or the exposure of calcium binding sites on protein macromolecules in the damaged muscle may be responsible. Scintigraphy may be helpful in some cases involving focal damage to either proximal forelimb or hindlimb muscles.[14]

Ultrasonography

Diagnostic ultrasonography is potentially useful for identification of muscle trauma, crepitus, fibrosis, and atrophy. Muscles have a rather typical striated echogenic pattern, but this varies according to the muscle group and careful comparisons must be made between similar sites in contralateral limbs, in both transverse and longitudinal images.[14] The appearance of muscle is also sensitive to the way the animal is standing and whether the muscle is under tension, so it is important that the animal is standing squarely and bearing weight evenly. Muscle fascia appears as well-defined, relatively echodense bands.[14] Care must be taken in identifying large vessels and artifacts created by them.

In an acute injury, muscle fiber disruption is seen as relatively hypoechoic areas within muscle, with loss of the normal muscle fiber striation. The jagged edge of the margin of the torn muscle may be increased in echogenicity.[14] Tears in the muscle fascia may be identified. The defect in muscle may be filled by loculated hematoma that is hypoechoic. As the muscle repairs, it becomes progressively more echogenic. Relatively hyperechoic regions may be a result of increased connective tissue or loss of muscle cell mass. Hyperechoic shadowing artifacts usually represent mineralization or gas pockets.[14]

Muscle Biopsy

Examination of muscle fibers, neuromuscular junctions, nerve branches, connective tissue, and blood vessels within a biopsy sample can provide additional information necessary to fully characterize a neuromuscular disorder.[16-18] Routine light and electron microscopic examinations, combined with histochemical evaluations, may provide insights into the particular manifestations of neuromuscular diseases and their rate of progression. A number of basic pathologic responses of muscle can be identified in paraffin-fixed sections. These include inflammatory infiltrates, muscle fiber necrosis, muscle fiber regeneration, increased number of central nuclei, variations in muscle fiber sizes and fiber shapes, vacuolar change, and proliferation of connective tissue. However, there are many pathologic alterations that cannot be detected in formalin-fixed tissue but can readily be seen in histochemical stains of fresh-frozen biopsy samples.[16-18] These include muscle fiber types and their pattern

VetBooks.ir

of distribution, differentiation of neurogenic atrophy from disuse atrophy or a primary myopathy, characterization of vacuolar storage material, characterization of inclusion bodies, assessment of mitochondrial density, and additional clues that may allow identification of a specific disorder or category of muscle disorders. Furthermore, formalin fixation results in artifactual cracking, fiber shrinkage, and leakage of substrates such as glycogen, which can affect proper interpretation of muscle pathology.

When considering collection of muscle biopsies, some general guidelines apply. Preferably, samples should be collected from what is considered abnormal or diseased muscle. A 6-mm-outer-diameter (Jørgen Kruuse A/S, Langeskov, Denmark) percutaneous needle biopsy technique can be used to obtain small muscle samples through a ¼-inch skin incision using a local anesthetic subcutaneously. If this technique is used, enough muscle should be obtained to form a ½-inch-square sample at a minimum. These samples do not, however, tolerate shipment to an outside laboratory. The optimum biopsy for shipment of histopathology tissues to a laboratory is collected using surgical or open techniques, performed under local anesthesia. Care must be exercised to infiltrate only the subcutaneous tissues, not the muscle, with the anesthetic agent. The objective is to obtain approximately a ½-inch cube of tissue; hence a suitably long skin incision is required. Two parallel incisions ½ inch apart should be made longitudinal to the muscle fibers with a scalpel. The muscle should be handled only in one corner using forceps, and crushing should be avoided. The muscle sample is then excised by cross-section incisions ½ inch apart, and the tissue is fixed appropriately. Routine histopathology samples can be placed in formalin; fresh samples can be placed in a watertight hard container after being wrapped in gauze lightly moistened with saline and shipped chilled to laboratories for freezing. On arrival at specialized laboratories, fresh samples for histochemical analysis are fixed in isopentane (methylbutane) chilled in liquid nitrogen to ensure rapid freezing and minimization of freeze artifact. Samples that potentially may be used for biochemical analysis should be immediately frozen in liquid nitrogen. Other routine histopathologic techniques may also be of diagnostic value. A special fixative may be required if such practices are to be undertaken. Samples for electron microscopy (EM) require appropriate fixation in glutaraldehyde preparations. Ideally, thin sections of muscle for EM should be clamped in vivo to maintain fibers at a resting length before they are excised. However, if pathology other than the alignment of thick and thin myofilaments is to be investigated, small muscle pieces can be excised and placed directly in appropriate EM fixative.

Responses of strips of fresh muscle to stimuli such as caffeine, halothane, and a variety of other agents can also be performed by specialized laboratories to diagnose recurrent exertional rhabdomyolysis and susceptibility to malignant hyperthermia but are not routine diagnostic procedures.[19-21]

Classification of Muscle Disorders

Stephanie J. Valberg

A muscle disorder is usually suspected in large animals because of (1) increased, decreased, or abnormal muscle tone; (2) focal or generalized muscle damage (rhabdomyolysis); (3) muscle atrophy; or (4) exercise intolerance not associated with respiratory, cardiovascular, or skeletal causes.

Altered Muscle Tone

Increased muscle tone may be neural in origin. For example, tetanus and strychnine poisoning increase muscle tone as a result of suppressed inhibition of upper motor neurons by interneurons. Increased motor neuron firing also occurs during seizures, with electrolyte imbalances, and with equine ear tick infestation. Visual, tactile, or auditory stimuli often precipitate painful sustained motor unit activity. Other probable neural disorders that intermittently increase muscle tone include periodic spasticity and spastic paresis in cattle, stiff horse syndrome, and "shivers" in draft and warmblood horses. Focal nerve root irritation may also result in focal muscle twitching.

Increased muscle tone can also arise from myopathic disorders. Persistently enhanced muscle tone may occur because of muscle contractures, which are characterized by fixation of myofilaments in a persistently shortened position without neural input.[22] Contractures are usually extremely painful and associated with rhabdomyolysis. Contractures occur with malignant hyperthermia and some forms of exertional myopathy. Intermittent, abnormal muscle contractions without rhabdomyolysis occur when sarcolemmal ion channels within the muscle cell membrane are dysfunctional.[23,24] Caprine myotonia congenita and equine hyperkalemic periodic paralysis are examples of diseases caused by sarcolemmal ion channel dysfunction.

Moderate weakness in horses may be caused by central spinal cord disorders. More profound weakness may arise from neuropathies affecting motor neurons (equine motor neuron disease [EMND], hypocalcemia), decreased neural input at motor end plates (botulism), marked muscle atrophy (EMND) or rhabdomyolysis of postural muscles, or severe electrolyte imbalances (hypokalemia). The few operative motor units fatigue easily, resulting in muscle fasciculations, shifting of weight, low head posture, difficulty prehending grain, and long periods of recumbency and difficulty rising.

Muscle Atrophy

Atrophy is defined as a reduction in muscle size, specifically a reduction in muscle fiber diameter or cross-sectional area. Atrophy may occur in response to a variety of stimuli. Denervation removes the normal low-level tonic neural stimulus that is necessary to maintain muscle fiber mass. Complete denervation of a muscle results in more than a 50% loss of muscle mass within a 2- to 3-week period.[16,25] A good example of this is "Sweeney" in horses, in which the suprascapular nerve is damaged and muscles over the scapula atrophy. Other denervating conditions such as EMND show a slower and more generalized progression of gross muscle atrophy. Electromyographic abnormalities following denervation are apparent within 5 days, and it may take 3 weeks for maximal changes to develop. Increased insertional activity, positive sharp waves, and bizarre high-frequency discharges and fibrillation potentials are seen in denervated muscle.[12] Pyknotic nuclear clumps and small angular slow-twitch type I and fast-twitch type II fibers with concave sides are characteristic of neurogenic atrophy in muscle biopsies. In some cases, hypertrophy of remaining motor units may occur in neurogenic atrophy, and renervation is indicated by target fibers and fiber type grouping.

Muscle atrophy may also be caused by disuse, malnutrition, cachexia, corticosteroid excess, and immune-mediated myositis. Skeletal muscle is a plastic tissue, with approximately 1% to 5% of the contractile mass undergoing remodeling on a daily basis. If a negative nitrogen balance occurs, net protein withdrawal from the skeletal muscle mass begins within 48 to 72 hours. This type of atrophy is distinguished from neurogenic atrophy by a slower progression of atrophy, normal electromyographic findings, and muscle biopsies that are characterized by primarily atrophy of type II muscle fibers. The overall response of skeletal muscle is to maintain essential postural muscle groups, whereas less essential groups undergo significant reduction in muscle mass. With malnutrition, 30% to 50% of the muscle mass may be lost in the first 1 to 2 months.[25] Rapid atrophy is characteristic of immune-mediated myopathies in

Quarter Horse–related breeds, which can result in the loss of 30% of muscle mass within 48 hours due to necrosis and atrophy of myofibers.[26]

Muscle Necrosis

Muscle necrosis (rhabdomyolysis) as evidenced by elevations in serum CK, LDH, and AST can be focal or generalized. Many infectious, toxic, nutritional, ischemic, and idiopathic factors result in muscle fiber necrosis. When attempting to identify an etiology, it is helpful to characterize rhabdomyolysis in horses as associated with exercise or not. Specific causes of exertional and nonexertional rhabdomyolysis are listed in Boxes 42.1 to 42.3.

Necrosis represents injury to organelles within a muscle fiber or within a segment of that fiber. Many myopathies associated with generalized rhabdomyolysis interrupt normal muscle metabolism, and cell death results from an inability to maintain homeostasis within the myofiber. Although a variety of external or internal insults may cause rhabdomyolysis, they often share a final common pathway leading to cell death.[27] Under normal conditions, considerable energy is expended by muscle cells to pump the calcium that accumulates in the sarcoplasm during contraction into the sarcoplasmic reticulum. If cell membrane function is disrupted or if the energy pathways that generate adenosine triphosphate for the calcium pump are impaired, excessive calcium may accumulate in the sarcoplasm. Although some calcium can be sequestered by the mitochondria, eventually mitochondria become overloaded and oxidative metabolism ceases; oxygen free radicals are generated; phospholipases are activated, inducing the arachidonic cascade; calcium-dependent proteases are stimulated; and complement is activated. Lipid storage disorders and antioxidant deficiencies may also cause necrosis through destruction of mitochondrial and sarcolemmal membranes. The contractile proteins within a necrotic segment are destroyed and appear homogenized with no evidence of cross-striations, and mitochondrial and sarcolemmal membranes appear disrupted. When necrosis occurs as a result of internal disruption of muscle homeostasis, the basement membrane of the cell is left intact. Macrophage infiltration and phagocytosis of necrotic debris usually occur within 16 to 48 hours of the muscle injury. Satellite cells migrate along the remaining basement membrane and form regenerative myotubes within 3 to 4 days of injury, with mature muscle fibers developing within a month of the original damage.[16]

Muscle ischemia occurs commonly with acute trauma, the compartment syndrome in recumbent animals, downer syndrome, and vascular occlusion. Compartment syndrome often involves the triceps muscle or extensors of the hindlimb because

they are often compressed in down animals or during anesthesia. Hypotension during surgery contributes to the development of this syndrome. Acute muscle infarction may occur with purpura hemorrhagica or disseminated intravascular coagulation, and on postmortem examination characteristic well-demarcated areas of hemorrhagic necrosis are evident. Muscle areas in contact with the ground in recumbent animals are most susceptible to infarctions in animals with vasculitis. Clinically, acute infarctions are an extremely painful condition that may resemble colic. Chronic occlusive diseases, such as iliac thrombosis, often allow collateral circulation to develop, thereby avoiding acute signs of ischemia at rest. Although muscle has an impressive ability to regenerate, if a disease process is severe enough to disrupt the basement membrane, muscle may be replaced by connective tissue and fat. This occurs most frequently after trauma, such as following tearing of the semimembranosus or tendinosus in horses (fibrotic myopathy), and with severe infarctions.

Disorders of Muscle Tone

There are numerous causes of increased muscle tone in large animals including forms of myotonia, ear tick infestation, and shivers in horses, as well as spastic conditions in cattle.[28-38] A condition that demonstrates enhanced muscle tone in cattle is spastic paresis,[32,33] or Elso heel. Commonly, calves between 2 and 7 months of age are affected and have an extremely straight angle to the hock and stifle. Signs reflect a decreased capacity or inability to flex the hock because of continuous tension on the gastrocnemius muscle when standing. Involvement may be unilateral or bilateral. The Holstein Friesian breed is most commonly affected, although other breeds have been found to suffer the disorder.[32-35] Spastic paresis may have a distinct familial pattern, but environmental exposure to toxins in utero have also been implicated as a cause.[32-34,36]

Clinical signs similar to spastic paresis are seen in horses with shivers, which is most commonly seen in draft horse breeds, warmbloods and warmblood crosses older than 1 year of age, and Thoroughbreds, although it may occur in light horse breeds.[37] Horses are generally taller than 16.3 hands and more often male than female. Suggested causes include genetic, traumatic, infectious, and neurologic diseases, although its exact basis is unknown. The disease primarily affects the hindlimbs and is characterized by periodic, involuntary spasms of the muscles in the pelvic region, pelvic limbs, and tail, which are exacerbated by backing up or picking up the hindlimbs. The affected limb is elevated and then abducted. It may actually shake and shiver, and the tailhead usually elevates concurrently and trembles. In more severely affected animals, on backing up the hindlimb is suddenly raised, semiflexed, and abducted with the hoof held in the air for several seconds or minutes. The tail is elevated simultaneously and trembles. After a variable period of time, the spasms subside, the limb is extended, and the foot is brought slowly to the ground. Surface electromyography indicates that both flexors and extensors fire simultaneously during backing up in horses with shivers, resulting in strong, painful muscle contractions and poorly timed relaxation.[38] There are no distinct myotonic discharges on electromyography with shivers, indicating it is not a true myotonic condition.

Myotonic Disorders

Stephanie J. Valberg

Myotonic muscle disorders represent a heterogeneous group of diseases that share the feature of delayed relaxation of muscle after mechanical stimulation or voluntary contraction. Abnormal muscle membrane excitability appears to be the shared abnormality among myotonic disorders. The nondystrophic myotonias in large animals include myotonia congenita in horses and goats and equine hyperkalemic periodic paralysis.[28] Sarcolemmal ion channel dysfunction causes these nondystrophic myotonias. Dystrophic myotonia, a progressive disease that may also be associated with abnormalities in other body systems, has been reported in horses.[29,30] In addition, it has been noted that some horses with ear tick infestations develop percussion myotonia and painful muscle cramps.[31]

Myotonia

CLINICAL SIGNS. Myotonia congenita in humans, horses, and goats is usually detected in the first year of life.[39-42] Affected animals commonly have conspicuously well-developed musculature and display mild to moderate pelvic limb stiffness. Gait abnormalities are usually most pronounced when exercise begins and frequently diminish as exercise continues. Bilateral bulging (dimpling) of the thigh and rump muscles is often obvious and gives the impression that the animal is well developed (Fig. 42.3). Stimulation of affected muscles, especially percussion, exacerbates the muscle dimpling below a large area of tight contraction (Fig. 42.4). Affected muscles may remain contracted for up to a minute or more with subsequent slow relaxation.[30,42] Myotonia congenita does not usually show progression of clinical signs beyond 6 to 12 months of age in horses.[30]

In goats, myotonia congenita appears to be an autosomal dominant mutation in the skeletal muscle chloride channel (CLCN1) that has incomplete penetrance.[24,41,43] Affected goats are commonly referred to as "fainting goats." Signs are usually recognizable by 6 weeks of age and vary from stiffness after rest to marked general rigidity after visual, tactile, or auditory stimulation. Clinical signs remain throughout the animal's life but are not progressive.[44] An autosomal recessive c.1775A>C mutation was identified in a New Forest pony with congenital myotonia. The missense mutation results in a substitution of aspartic acid for alanine in codon 592 of the C-terminal cytoplasmic domain of the equine CLCN1 protein.[45]

Myotonia dystrophica appears to be a separate form of myotonia in horses.[29,30,46] Severe clinical signs of myotonia that progress to marked muscle atrophy and possibly involve a variety of organ systems have been observed in Quarter Horse, Appaloosa, and Italian-bred foals. Retinal dysplasia, lenticular opacities, and gonadal hypoplasia have been reported in one such Quarter Horse foal.[29] This condition resembles myotonia dystrophica in humans, which is caused by genetic mutations involving either the *DMPK* gene or the *ZNF9* gene.[47,48] In both cases, a short segment of deoxyribonucleic acid (DNA) is abnormally repeated many times, forming an unstable region in the gene, which alters messenger ribonucleic acid (mRNA) processing. The genetic basis of myotonic dystrophy in horses is not yet known.

Diagnosis A tentative diagnosis frequently can be made on the basis of age, clinical signs (stiff gait, particularly at the onset of exercise), muscle bulging, and prolonged contractions following muscle stimulation.

Definitive diagnosis of myotonia is usually based on electromyographic examination. Affected muscle manifests pathognomonic, crescendo-decrescendo, high-frequency repetitive bursts with a characteristic "dive bomber" sound.[29,46,49] This sound is produced by the repetitive firing (after contractions) of affected muscle fibers. After a contraction diminishes, the excitability of muscle fibers is decreased and the action potentials recorded by the EMG reflect the diminution of electrical activity.[50]

Examination of muscle biopsies from foals with myotonia congenita may be normal or may demonstrate extremely variable muscle fiber dimensions up to twice those of normal age-matched controls.[42] Type I fiber hypertrophy or hypotrophy

VetBooks.ir

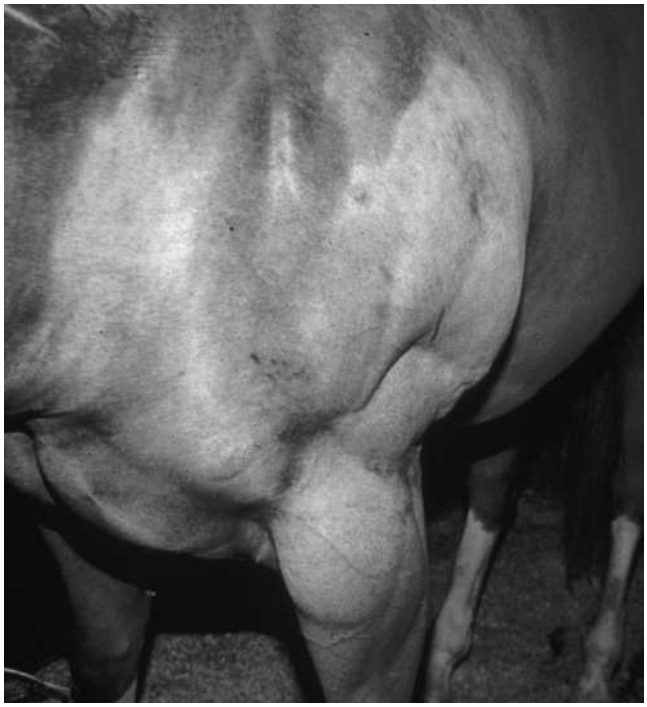

FIG. 42.4 Myotonic dimpling of the triceps in a horse with hyperkalemic periodic paralysis.

may be seen. The major changes noted with myotonic dystrophy are ringed fibers, alterations in the shape and position of myonuclei, sarcoplasmic masses, and an increase in endomysial and perimysial connective tissue.[29,30,46,51] Fiber type grouping and atrophy of both type I and type II muscle fibers may be present.

Treatment Considering that the pathophysiologic basis of myotonia in horses has not been clearly identified, recommendations for specific, effective therapy are almost impossible. In affected humans and dogs, some relief of signs has been provided by drugs such as quinine, procainamide, and phenytoin. However, responses vary among patients. Phenytoin has been reported to be efficacious in two Quarter Horses with hyperkalemic periodic paralysis and myotonic dystrophy.[49]

Prognosis Prognosis appears to be variable and dependent on the severity of clinical signs. Mildly affected animals with congenital myotonia may undergo some amelioration of clinical signs with increasing age over a period of months to years. The reason(s) for this regression of signs is unknown. Other, more severely affected horses, particularly those with dystrophic myotonia, may have progression of signs, including atrophy and fibrosis or pseudohypertrophy to the point at which the animal is no longer able to move without great pain and difficulty (Fig. 42.5). Euthanasia of such animals is often warranted. Although conclusive evidence regarding the genetic basis of dystrophic myotonia in horses is still not available, owners of affected horses should be cautioned as to the possibility of this disease being heritable.

Hyperkalemic Periodic Paralysis

Sharon Jane Spier

Equine hyperkalemic periodic paralysis (HYPP) is caused by an inherited defect in the skeletal muscle sodium channel.[28,52-55] This myopathy manifests as abnormal skeletal muscle membrane excitability leading to episodes of myotonia, or sustained muscle contraction, and paralysis. In humans, numerous muscle membrane channel defects (so-called channelopathies) have been characterized, and the molecular basis for disease is well described.[40] Other reported disorders with suspected membrane defects in horses include myotonic dystrophy and congenital

VetBooks.ir

FIG. 42.5 Marked progressive atrophy of the epaxial and gluteal muscles of a horse with myotonic dystrophy.

myotonia.[29,42] Hyperkalemic periodic paralysis was the first equine disease attributed to a specific genetic mutation and detectable through DNA technology.[54]

Hyperkalemic periodic paralysis is an autosomal dominant trait affecting Quarter Horses, American Paint Horses, Appaloosas, and Quarter Horse crossbred animals worldwide. A "syndrome" in related horses was first recognized in the 1980s by breeders and veterinarians and first reported to be similar to HYPP in humans by Cox at the American Association of Equine Practitioners convention in 1985.[55] In December 2002, this genetic disease was publicly linked to a popular Quarter Horse sire named Impressive. This prolific sire, born in 1969, has more than 500,000 offspring registered with the American Quarter Horse Association (AQHA; AQHA registrar, personal communication, 2012), and these offspring dominate the halter horse industry. Current estimates indicate that 1.5% of Quarter Horses and 4.5% of Paints are affected.[56] Notably, however, 58% of halter horses have the HYPP mutation.[55] Unfortunately, the gene frequency has not decreased in the past 20 years since genetic testing has been available to breeders, and controversy continues among horse breeders whose stock carry this gene (statistics from UCD Veterinary Genetics Laboratory HYPP Testing, 2006). Affected horses appear to have been preferentially selected as breeding stock due to their pronounced muscle development, and there is evidence of selection of HYPP-affected horses as superior halter horses by show judges.[57] In 1996 AQHA officially recognized HYPP as a genetic defect or undesirable trait. To increase public awareness of this genetic defect, mandatory testing for HYPP with results designated on the Registration Certificate began for foals descending from Impressive born after January 1, 1998. In response to requests from the membership, the AQHA Stud Book and Registration Committee ruled that foals born in 2007 and later testing homozygous affected for HYPP (H/H) are not eligible for registration. Breeders opposed to restrictions argue that the disease can be controlled through diet and medication and that these horses are highly successful in the show ring.[58]

■ ***Clinical Signs*** Clinical signs among horses carrying the same mutation range from asymptomatic to daily muscle fasciculations and weakness. In the majority of horses, intermittent clinical signs begin by 2 to 3 years of age with no apparent abnormalities between episodes.[28,53] Ingestion of diets high in potassium (>1.1%), such as those containing alfalfa hay, molasses, electrolyte supplements, and kelp-based supplements, or sudden dietary changes commonly trigger episodes.[59] Fasting, anesthesia or heavy sedation, trailer rides, and stress may also precipitate clinical signs; however, the onset of signs is often unpredictable, without a definable cause. Other possible precipitating factors that have been noted in humans and horses are exposure to cold, fasting, pregnancy, and concurrent disease and rest following exercise. Exercise per se does not appear to stimulate clinical signs, and serum CK shows no change or only modest increases during episodic fasciculations and weakness.

In most cases, clinical episodes begin with a brief period of myotonia, with some horses showing prolapse of the third eyelid. Sweating and muscular fasciculations are observed commonly in the flanks, neck, and shoulders. The muscle fasciculations become more generalized as additional muscle groups are involved. Stimulation and attempts to move may exacerbate muscular tremors. Some horses may develop severe muscle cramping. Muscular weakness during episodes is a common characteristic of HYPP. Horses remain standing during mild attacks. In more severe attacks, clinical signs may progress to apparent weakness with swaying, staggering, dog sitting, or recumbency within a few minutes. Heart and respiratory rates may be elevated, and horses may show manifestations of stress (anxious appearance) yet remain relatively bright and alert during episodes. Affected horses usually respond to noise and painful stimuli during clinical manifestations of the disorder. Episodes last for variable periods, usually from 15 to 60 minutes. Several horses have died during acute episodes. Respiratory distress occurs in some animals as a result of paralysis of upper respiratory muscles, and a tracheostomy may be necessary. In addition, young horses that are homozygous for the HYPP trait have been observed to manifest a respiratory stridor and periodically may develop obstruction of the upper respiratory tract. Horses homozygous for HYPP may present for dysphagia or respiratory distress, and endoscopic findings include pharyngeal collapse and edema, laryngopalatal dislocation, and laryngeal paralysis.[60] After the episode subsides, horses regain their feet and appear normal with no apparent or minimal gait abnormalities. Although HYPP horses appear normal between attacks, electromyographic examination of affected horses reveals abnormal fibrillation potentials, complex repetitive discharges with occasional myotonic potentials, and trains of doublets between episodes.[28,61]

■ ***Etiology*** HYPP results from a point mutation that causes a phenylalanine/leucine substitution in a key part of the voltage-dependent skeletal muscle sodium channel alpha subunit.[54] In horses with HYPP, the resting membrane potential is closer to firing than in normal horses.[62] Sodium channels are normally briefly activated during the initial phase of the muscle action potential. The HYPP mutation results in a failure of a subpopulation of sodium channels to inactivate when serum potassium concentrations are increased. As a result, an excessive inward flux of sodium and outward flux of potassium ensues, resulting in persistent depolarization of muscle cells and temporary weakness (Fig. 42.6).

■ ***Diagnosis*** Descent from the stallion Impressive on the sire or dam's side in a horse with episodic muscle tremors, weakness, or collapse is strongly suggestive of HYPP. Quarter Horse foals born after 1998 that are offspring of an affected parent have a statement recommending DNA testing for HYPP on the Certificate of Registration. In most cases, hyperkalemia (6 to 9 mEq/L), hemoconcentration, and mild hyponatremia occur during clinical manifestations of the disease with normal acid-base balance.[28] Serum potassium concentration returns to normal following the abatement of clinical signs. Some affected horses may have normal serum potassium concentrations during minor episodes of muscle fasciculations.[53] Differentials

VetBooks.ir

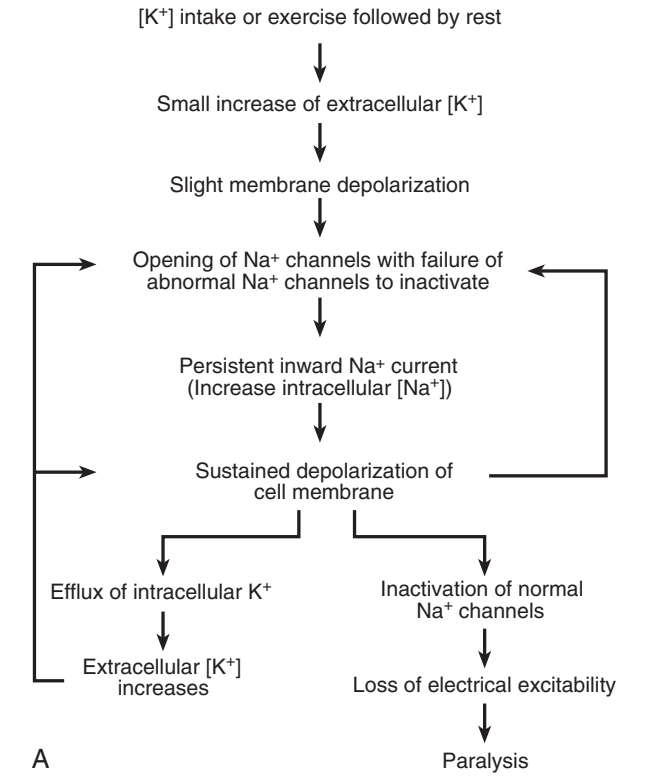

FIG. 42.6 **A,** Explanation for paralytic attacks in horses with hyperkalemic periodic paralysis (HYPP). **B,** A horse suffering from an episode of HYPP.

for hyperkalemia include delay before sample centrifugation, hemolysis, acidosis, renal failure, severe rhabdomyolysis, and high-intensity exercise.

Because veterinarians may not be present during acute episodes, the definitive test for identifying HYPP is the demonstration of the base-pair sequence substitution in the abnormal segment of the DNA encoding for the alpha subunit of the sodium channel.[54] Submission of mane or tail hair should be made to a licensed laboratory.

Treatment Mild exercise can sometimes abort an episode in mild cases or if horses are just beginning to exhibit clinical signs. Feeding grain or corn syrup to stimulate insulin-mediated movement of potassium across cell membranes may also be helpful. Other treatment options, which may abort an episode, include intramuscular (IM) administration of epinephrine (3 mL of 0.006 mg/kg/500 kg) and administration of acetazolamide (3 mg/kg orally [PO], every 8 to 12 hours). Many horses experience spontaneous recovery from episodes of paralysis and appear normal by the time a veterinarian arrives.

TABLE 42.1

Examples of Feed Containing High, Medium, or Low Concentrations of Potassium (K^+)[a]

High-Potassium Feed	K^+ (%)	g K^+/lb Feed
Electrolyte supplements	30	136
Molasses	6	27
Kelp supplements	>4	>18
Alfalfa hay (90% DM)	1.4-2.4	6.4-10.9
Canary grass hay	2.6	2.6
Orchard grass hay	2.4-2.6	10.9-11.8
Soybean meal	2	9.1
Medium-Potassium Feed	**K^+ (%)**	**g K^+/lb Feed**
Fescue hay	1.7-2.1	7.7-9.5
Rice bran	1.8	8.1
Timothy hay	1.4-2.1	6.4-9.5
Coastal Bermuda hay	1.2-1.9	5.5-8.2
Kentucky bluegrass hay	1.4	6.4
Oat hay	1.4	6.4
Low-Potassium Feed	**K^+ (%)**	**g K^+/lb Feed**
Pure fats and oils	0	0
Beet pulp	0.2-0.3	0.9-1.4
Corn, oats, or barley	0.3-0.5	1.4-2.3
Pasture grass (23% DM)	0.3-0.8	1.4-3.6
Wheat	0.4	1.8
Wheat bran	1.2	5.45
Soybean hulls	1.2	5.45

[a]To decrease the frequency of episodes, avoid high-potassium feed; select feed that contains medium to low K^+. Feeding a balanced ration containing less than 1.5% K^+ and meals less than 33 g K^+ decreases fluctuations of blood K^+, lowering the frequency of HYPP symptoms.[12,15,16]

DM, Dry matter.

In severe cases, administration of calcium gluconate (0.2 to 0.4 mL/kg of a 23% solution diluted in 1 L of 5% dextrose) will often provide immediate improvement. An increase in extracellular calcium concentration raises the muscle membrane threshold potential, which decreases membrane hyperexcitability. To reduce the serum potassium, intravenous (IV) dextrose (6 mL/kg of a 5% solution) alone or combined with sodium bicarbonate (1 to 2 mEq/kg) can be used to enhance intracellular movement of potassium. With severe respiratory obstruction, a tracheostomy may be necessary.

Control Decreasing dietary potassium and increasing renal losses of potassium are the primary steps taken to prevent HYPP episodes. Foodstuffs to avoid include high-potassium feeds such as alfalfa hay, orchard grass hay, brome hay, soybean meal, sugar molasses, and beet molasses. Optimally, later cuts of Timothy or Bermuda grass hay and grains such as oats, corn, wheat and barley, and beet pulp should be fed in small meals several times a day (Table 42.1). Regular exercise and/or frequent access to a large paddock or yard are also beneficial. Pasture works well for horses with HYPP because the high water content of pasture grass makes it unlikely that horses will consume large amounts of potassium in a short period of time. Ideally, horses with recurrent episodes of HYPP should be fed a balanced diet containing between 0.6% and 1.1% to 1.5% total potassium concentration and meals containing less than 33 g of potassium.[59,63,64] Horses will adapt to diets higher in potassium over a period of 2 weeks and will experience fewer fluctuations in potassium in blood with subsequent decreased frequency of clinical signs.[63] Because there is a wide variation in potassium concentration of forages depending on maturity and soils, it is advisable to have feeds analyzed for potassium concentrations and other nutrient requirements.[64] Table 42.1

VetBooks.ir

contains examples of feeds containing varying concentrations of potassium. Supplement with vitamin E, selenium, salt, and balanced minerals where indicated to meet nutritional requirements. Commercially available complete feeds with a guaranteed potassium content may be more convenient for some HYPP horses, especially for owners with few horses.

For horses with recurrent episodes of muscle fasciculations even with dietary alterations, acetazolamide (2 to 3 mg/kg PO, every 8 to 12 hours) or hydrochlorothiazide (0.5 to 1 mg/kg PO, every 12 hours) may be helpful. These agents exert their effects through different mechanisms; however, both cause increased renal potassium excretion. In addition, acetazolamide stabilizes blood glucose and potassium by stimulating insulin secretion. Breed registries and other associations may have restrictions on the use of these drugs during competitions, as diuretics may mask prohibited substances.

Prognosis In most cases HYPP is a manageable disorder, although recurrent bouts may occur and severe episodes can be fatal. Owners of affected horses should be strongly discouraged from breeding these animals for the long-term health of the Quarter Horse and other breeds. Because this is a dominant trait, breeding an affected horse to a normal horse results in a 50% chance of producing a foal with HYPP. All affected horses share the same mutation, regardless of whether owners have witnessed symptoms in their horses.[65] Affected horses are not suitable for young or inexperienced riders. Owners of affected horses should advise veterinarians of HYPP status before anesthesia or procedures requiring heavy sedation because these circumstances could precipitate an episode of paralysis.

HYPP-Like Syndrome

Other cases of generalized muscle fasciculations arise in horses after forced exercise or transportation, or in some cases for unknown reasons that last for an hour or less. Horses present with fasciculations in the flanks, lateral neck, and shoulders that can gradually became more generalized. In some cases horses can progress to apparent weakness characterized by swaying, staggering, buckling at the knees, and a basewide stance. An elevated serum potassium at the time of attack has been documented in a Criollo horse.[66] The cause of this type of HYPP-like episode has yet to be determined.

Hypokalemic Myopathy in Dairy Cattle

Etiology Hypokalemic myopathy in dairy cattle occurs when serum potassium concentrations are below 2.5 mmol/L, producing severe signs of muscle weakness.[67-69] Ketosis, anorexia, and enhanced potassium excretion due to the administration of one or more doses of isoflupredone acetate to ketotic cows are common causes of hypokalemia. Isoflupredone acetate has both glucocorticoid and mineralocorticoid activity, resulting in a decrease in mean plasma potassium concentration by 25% two days after one injection (20 mg) and by 46% in cows 3 days after two injections.

Clinical Signs and Diagnosis Clinical signs of hypokalemic myopathy include severe weakness, recumbency, abnormal position of the head and neck, rumen hypomotility or atony, abnormal feces, anorexia, and tachycardia. Cardiac dysrhythmia is also common. Diagnosis is based on clinical signs combined with serum potassium of less than 2.5 mmol/L. Other common clinical chemistry abnormalities include ketosis, metabolic alkalosis, and elevated serum CK and AST activities. Muscle biopsies reveal a vacuolar myopathy.

Treatment Restoration of whole body potassium balance can be difficult, and serum potassium concentrations do not necessarily reflect muscle potassium concentrations. Recommended supplementation includes potassium chloride given orally (0.1 to 0.4 g/kg body weight), not to exceed 230 g potassium chloride orally per 24 hours. Reserve IV potassium (20 to 40 mEq potassium per liter IV solution, up to 80 mEq/L) for recumbent ruminants with severe hypokalemia and rumen atony. Do not to exceed a maximum infusion rate of 0.5 mEq/kg/h. Early treatment should also be directed at resolving the primary cause of ketosis and anorexia, as well as providing supportive care. Survival has been reported at between 22% and 79%.

Muscle Cramping

Stephanie J. Valberg • Gary P. Carlson

Muscle cramps are a painful condition that arises from hyperactivity of motor units caused by repetitive firing of the peripheral and/or central nervous system. The origin of the cramp in most cases is believed to be the intramuscular portion of the motor nerve terminals.[22,70] Most muscle cramps are also accompanied by fasciculations in the same muscle. Muscle cramps can be induced by forceful contraction of a shortened muscle, by changes in the electrolyte composition of extracellular fluid, and by ear tick infestations in horses.[22,31] In contrast, muscle contractures are painful muscle spasms that represent a state of muscle contracture unaccompanied by depolarization of the muscle membrane.[70] Muscle contractures occur with malignant hyperthermia and some forms of exertional myopathies and are invariably accompanied by markedly increased serum CK activity.

Dietary Electrolytes

Muscle stiffness, weakness, and occasional elevations in serum CK can occur when diets are deficient in sodium or potassium. These chronic deficiencies are rarely reflected in serum electrolyte concentration but may be detected by performing renal fractional excretions of electrolytes.[3] Sodium deficiency is particularly common in horses because forage and grain diets are low in sodium and chloride and high in potassium. Supplementation of the equine diet with salt is a necessity. Salt blocks may not be adequate in this regard, and loose salt (1 to 2 oz) added directly in the grain is often the best mechanism of supplementing horses with salt. Some horses may require higher dietary salt supplementation to maintain an adequate sodium balance. Balancing dietary electrolytes has been reported to decrease muscle cramping and serum CK activity in those horses with dietary deficiencies.[3]

Exhaustion in Endurance Horses

Muscle cramping in endurance horses occurs commonly during prolonged exercise in hot weather, particularly when the humidity is high.[71,72] Under such circumstances rectal temperatures reach as high as 41° C, and horses may lose up to 15 L/h of fluids in the form of sweat that is rich in sodium, potassium, and chloride.[73,74]

Clinical Signs Affected horses demonstrate stiffness and cramping in the muscles of locomotion. Pain is a characteristic of the disorder, and affected muscle groups often undergo periodic spasms. In addition, exhausted horses are often dull, depressed, and clinically dehydrated with elevated heart and respiratory rates and persistently elevated body temperature. Common electrolyte abnormalities include a hypochloremic metabolic alkalosis with hypokalemia, hypomagnesemia, and low serum ionized calcium concentrations.[71,72,75] Synchronous diaphragmatic flutter may be seen in association with cramping.[71] Although many of the signs of muscular dysfunction are similar to those of exertional rhabdomyolysis, affected horses do not generally develop myoglobinuria.[71]

Etiology Factors contributing to cramping are dehydration, electrolyte abnormalities, and disturbances in thermoregulatory

and local circulatory function. Whether this disorder is similar to heat cramps seen in human athletes is not known.

Diagnosis A variety of electrolyte abnormalities occur in affected animals.[71,75] Mild cases are distinguished by the presence of muscle cramps that subside with rest or light exercise in heat-stressed horses. In more severe cases clinical signs of dehydration and shock are often present. Horses with muscle cramping will not have marked elevations in serum CK or AST, nor will they exhibit myoglobinuria. Exhausted horses, however, may progress to develop rhabdomyolysis with marked electrolyte derangements. These horses require immediate treatment.

Treatment Under most circumstances the mild form of muscle cramping is self-limiting, and the signs abate with rest or light exercise. However, if evidence of other metabolic derangements exists, treatment for these disorders (e.g., plasma volume expansion with oral or intravenous isotonic polyionic fluids, cooling using water and fans) is frequently beneficial to the horse.[76] Because most horses with this condition are alkalotic, administration of solutions containing sodium bicarbonate is contraindicated. Dietary analysis should be performed to determine the extent of salt and electrolyte supplementation in affected horses. Daily direct addition of 2 oz of sodium chloride and 1 oz of potassium chloride to the feed is recommended for horses with recurrent cramping in addition to electrolyte supplementation before and after endurance rides.

Synchronous Diaphragmatic Flutter

Synchronous diaphragmatic flutter (SDF), also known as "thumps," usually occurs in horses suffering from derangements in fluid and electrolyte balance. Inciting causes include endurance exercise, hypocalcemia, hypoparathyroidism, digestive disturbances, and possibly the administration of medications. A characteristic clinical manifestation of the disease occurs when the diaphragm contracts in synchrony with atrial depolarization.[77-79]

Clinical Signs The classic sign of SDF is a contraction or twitch in the flank region (unilateral or bilateral) as the diaphragm contracts synchronously with the heart. In severe cases this twitch may produce an audible thumping sound. The metabolic derangements leading to SDF may also be clinically apparent in some cases. These may include signs of dehydration and volume depletion. Endurance horses suffering from SDF in association with the exhausted horse syndrome may demonstrate dehydration, inappropriate sweating responses, persistently elevated body temperature, depression, anorexia, and aperistalsis.[71,72] In some horses SDF may be a chronic, recurring problem.[77]

Etiology A variety of stimuli may result in SDF. These include prolonged exercise, particularly during hot weather; hypocalcemia resulting from lactation, transit, or stress; digestive tract dysfunction; furosemide therapy; trauma; and primary hypoparathyroidism.[77,79] The most consistent metabolic derangement reported in horses with SDF is low serum ionized calcium concentrations usually associated with hypochloremic metabolic alkalosis.[77,78] Metabolic alkalosis may alter the ratio of free to bound calcium (increasing calcium binding to protein and decreasing ionized calcium), which possibly induces SDF.

SDF occurs in association with atrial depolarization in horses. It has been postulated that fluid, electrolyte, and acid-base derangements may disrupt the normal membrane potential of the phrenic nerve, which passes directly over the atrium, resulting in nerve discharges in response to atrial depolarization.[77,78,80]

Treatment In most cases SDF is a transient event, usually abating when the underlying cause resolves, either spontaneously or in response to treatment.[77] Most horses undergo rapid remission of signs when given calcium solutions intravenously, as described in the Hypocalcemia in Horses section later. Although hypomagnesemia is often present with SDF, horses do not respond to magnesium supplementation unless calcium is administered concurrently. Response to therapy is also reflected by improved mental status, return of appetite, and gut motility.[77]

Control Electrolyte supplementation and some dietary manipulations may help to reduce the incidence of SDF in some endurance horses suffering recurrent bouts. Providing chloride, potassium, and sodium during prolonged exercise may help to reduce fluid losses and the metabolic alkalosis that commonly accompanies this form of exercise and frequently occurs in association with SDF. Metabolic alkalosis decreases the amount of free calcium available. Supplementation of calcium and magnesium during endurance rides has been suggested as helpful in horses prone to SDF.

Alternative approaches involve reduction of dietary calcium in horses prone to SDF for a few days before an endurance ride. It is postulated that this reduction in dietary calcium stimulates the endocrine homeostatic mechanisms and increases osteoclastic activity. In the short term the horse depends less on dietary calcium and is able to mobilize substantial amounts of calcium in response to the demands imposed by the exercise; calcium losses in sweat are overcome by the release of calcium from endogenous storage pools (bone).[77] Further, horses routinely fed alfalfa hay, which has a relatively high calcium concentration, may be more prone to the development of SDF. Limitation of this foodstuff may be indicated in chronically affected horses.

Hypocalcemia in Horses

Hypocalcemia is a relatively rare disorder in horses that has also been referred to as *lactation tetany*, *transport tetany*, *idiopathic hypocalcemia*, and *eclampsia*.

Clinical Signs Clinical signs are variable and include increased muscle tone; a stiff, stilted gait; rear limb ataxia; muscle fasciculations (especially temporal, masseter, and triceps muscles); trismus; dysphagia; salivation; anxiety; profuse sweating; tachycardia; elevated body temperature; cardiac dysrhythmias; SDF; convulsions; coma; and death.[81,82] Clinical signs may be remarkably similar to some of those seen with tetanus. This disorder may be progressive (in lactating mares in particular) over a 24- to 48-hour period, and some animals die. Clinical signs are related to the magnitude of the serum calcium concentration. Increased excitability is usually the only sign when values are below normal but above 8 mg/dL. Values of 5 to 8 mg/dL usually produce tetanic spasms and incoordination. Concentrations below 5 mg/dL usually result in recumbency and stupor.

Etiology Loss of calcium in milk, especially in mares that produce large amounts of milk, seems to predispose to this disorder.[81,82] Other factors, such as heavily lactating mares grazing lush pastures, hard work or prolonged transport, and ingestion of blister beetles (cantharidin toxicosis), may precipitate attacks. Primary hypoparathyroidism has also been diagnosed in a 3-month-old hypocalcemic warmblood foal with weakness and muscle trembling.[83]

Diagnosis Clinical signs are often highly suggestive of hypocalcemia in affected horses. Historic aspects such as lactation, previous prolonged exercise, or transport may also direct the clinician to the suspected diagnosis.[81] Definitive diagnosis depends on laboratory demonstration of hypocalcemia, with total calcium concentrations as low as 4 to 6 mg/dL in some

VetBooks.ir

cases. In addition, metabolic alkalosis, hypomagnesemia or hypermagnesemia, and hyperphosphatemia or hypophosphatemia have all been found in association with hypocalcemia in horses.[81] These alterations may need correction before a return to normal function is seen in some affected animals.

Treatment Although many mild cases recover without specific treatment, in others this disorder may be life threatening. Therefore therapy should be encouraged in most cases. Treatment involves the IV administration of calcium solutions such as 20% calcium borogluconate or those recommended for the treatment of parturient paresis in cattle.[81] Administration of these solutions at the rate of 250 to 500 mL/500 kg diluted 1:4 with saline or dextrose often results in full recovery, although in some cases it may take several days.[81] Relapses do occur. These preparations should be administered slowly in conjunction with close monitoring of the cardiovascular response. Dilution in saline or dextrose before infusion decreases the chance of cardiotoxicity. Normally there is a positive ionotropic effect in response to calcium administration.[84] However, alterations in rate or rhythm provide evidence to suspend the infusion. If no response to an initial infusion occurs, a second dose may be given 15 to 30 minutes later. Most cases respond to this form of therapy, although in some cases in which signs persist, repeated treatments may be necessary.

Ear Tick-Associated Muscle Cramping

Intermittent painful muscle cramps have been described in a small number of horses with severe *Otobius megnini* infestations.[31] Muscle cramping is not associated with exercise. These horses show intermittent signs of severe muscle cramping of pectoral, triceps, abdominal, or semitendinosus and semimembranosus muscles lasting from minutes to a few hours, with severe pain that often resembles colic. Horses may fall over when stimulated. Between muscle cramps, horses appear to be normal. Percussion of triceps, pectoral, or semitendinosus muscles results in a typical myotonic cramp. Horses have elevated serum CK activities ranging from 4000 to 170,000 IU/L. Numerous ear ticks *(O. megnini)* can be identified in the external ear canal of affected horses. Without treatment for ear ticks, the spasms continue; however, local treatment of the ear ticks using pyrethrins and piperonyl butoxide results in recovery within 12 to 36 hours. Acepromazine may be helpful to relieve painful cramping.

Nonexertional Rhabdomyolysis

Inflammatory Myopathies

Clostridial Myonecrosis

Steven M. Parish • Stephanie J. Valberg

Various species of clostridial organisms cause acute myonecrosis in many farm animal species. Infections are characterized by a rapid clinical course, fever, systemic toxemia, and high mortality.[85-87] Clostridial diseases are infectious but not contagious. Specific bacteria associated with clostridial myonecrosis include *Clostridium chauvoei (Clostridium welchii)*, *Clostridium septicum*, *Clostridium sordellii*, and occasionally *Clostridium novyi* type B, *Clostridium perfringens* type A, and *Clostridium carnis.* Mixed infections involving several agents are common.[88] Synonyms for clostridial diseases include blackleg, malignant edema, false blackleg, gas gangrene, and gangrene. Although there may at times be distinct differences among the specific disease syndromes associated with the different clostridial agents, the pathophysiology of these diseases is similar enough to be covered under the general topic of clostridial myonecrosis.

FIG. 42.7 Clostridial myositis in the left gluteal muscle after an injection of flunixin meglumine, which has progressed to involve the biceps femoris muscle. Fenestrations were created for débridement.

Clinical Signs Commonly, clostridial myonecrosis is rapidly progressive with the development of tremors, ataxia, dyspnea, recumbency, coma, and death within 12 to 24 hours. As such, many affected animals may be found prostrate or dead.[85,86,88] Mortality may approach 100%. Affected animals who are still alive are usually severely depressed, febrile (40° to 41° C/104° to 106° F), tachypneic, anorexic, and lame. These signs are associated with a rapidly developing muscle infection and toxemia. There is usually only one primary site of infection in an affected animal. Any skeletal muscle group in the body can be involved, but most infections affect the limb or trunk muscles. Occasionally muscles such as those around the vulva, tongue, and diaphragm can be involved, or the udder in a cow may be the primary site of sepsis. Areas around recent injections are common sites of myonecrosis in the horse.[87,89] Initially the skin over the area may be swollen, hot, and discolored; however, as the disease progresses, the skin over the area may become cool and insensitive with progressive sloughing. Crepitus may be detectable, indicating subcutaneous gas production. If a wound is present, malodorous serosanguineous fluid may discharge (Fig. 42.7). Aspiration of the swelling often reveals fluid with similar qualities.

Clostridial myonecrosis generally has characteristic pathologic lesions that are absent in most other conditions, making diagnosis relatively straightforward. Differential diagnoses may include other fulminant disease processes in which there is rapid debilitation or death of the animal.

Clinical Pathology Clinicopathologic data alone are seldom specific enough to confirm the presence of clostridial

myonecrosis. Hematology and serum biochemical analyses usually reflect a generalized state of debilitation and toxemia (e.g., hemoconcentration and a stress/toxic leukogram may be present). Elevations in the activities of serum CK and serum AST usually occur; however, they often do not reflect the toxicity of clostridial myonecrosis. Aspirates from the affected tissues can yield diagnostic information. It is preferable to obtain tissue specimens for direct smear examination and fluorescent antibody testing, and for anaerobic bacterial culture from affected tissues.

Pathophysiology Clostridial agents are ubiquitous in the environment and can frequently be cultured from the feces, intestinal tract, and other internal organs of a variety of species.[85] Spore-forming characteristics allow these organisms to remain in the environment for long periods, but the exact mechanisms involved in the pathogenesis of clostridial myonecrosis are not fully known. Development of clostridial myonecrosis following an intramuscular injection or penetrating wound may be the result of direct spore deposition into the tissue in association with penetration. If suitable conditions prevail within the muscle, the spores undergo a conversion into the vegetative, toxin-producing form of the organism. In contrast, the pathogenesis of the disease is more difficult to explain when a wound does not exist. It is postulated that clostridial agents gain access to the body through the alimentary tract and are present in liver and muscle in the dormant spore form.[90] Subsequently, when local tissue is devitalized and conditions become appropriate for the spores to germinate, the rapid vegetative process ensues. Muscle trauma associated with injection, transporting, herding, and handling has often been incriminated as creating a suitable environment for the development of clostridial myonecrosis. The proliferation of clostridial agents in devitalized tissues is associated with the release of powerful exotoxins responsible for the local necrotizing myositis and systemic toxemia. Toxins are released by multiplying clostridia; the toxins vary, depending on the clostridial species involved. Necrotizing (lecithinase) and hemolyzing (hemolysin) toxins, as well as neuraminidase, appear to be of greatest importance. The toxins act locally and systemically to create widespread organ dysfunction. The toxins of *C. sordellii* are the most potent of all the clostridial species, and myonecrosis caused by this organism is fatal.

Epidemiology Clostridial agents are common in the environment, and susceptible animals are constantly exposed to them. Areas where previous death losses from clostridial disease have occurred may have a higher incidence or risk of disease because of increased environmental contamination. In cattle, clostridial myonecrosis is generally a disease of animals between 4 and 24 months of age. However, *C. sordellii* is a more common problem in older feedlot cattle in which excessive muscle bruising may occur. Younger animals are probably protected by colostral immunity and older animals by some degree of acquired immunity. Animals on high planes of nutrition and in excellent body condition are more likely to develop the disease. Infections with *C. chauvoei* occur most commonly during the warmer seasons, with the highest incidence varying from the spring to fall, depending on when calves reach the most susceptible age group. *C. septicum*, *C. novyi*, and *C. perfringens* type A infections can occur at any time and are usually associated with skin wounds such as injection sites, punctures, and castration wounds. The umbilicus may be a site of invasion. Infections in the genital area can occur, usually in association with a recent dystocia.

In sheep and goats, clostridial myonecrosis is most frequently associated with wounds such as those occurring after shearing, docking, and unsanitary surgical procedures. Sheep dipped for parasites after shearing may have an increased risk if the dip becomes contaminated with clostridial spores.

Most reports of clostridial myonecrosis in horses suggest an association with puncture wounds and intramuscular injection sites.[87,89] Intramuscular administration of irritating drugs (including antihistamines, anthelmintics, and phenylbutazone) may enhance the susceptibility to clostridial myonecrosis. Horses often present with or have a history of another complaint such as colic, exertional myopathy, or laminitis for which they have received injections of drugs in the preceding 48 hours.[91] Previously administered drugs (e.g., phenylbutazone) may mask the fever associated with clostridial myonecrosis, potentially confusing the diagnosis.

Necropsy Findings Swelling and autolysis are rapid in animals that have died from clostridial myonecrosis. Blood-stained fluid is often observed discharging from body orifices. Extreme swelling and crepitus may be noted over the affected body area. When acting alone, each of the clostridial agents associated with clostridial myonecrosis produces somewhat different postmortem lesions. However, it is unwise to assume that in clostridial myonecrosis only a single clostridial agent was involved because mixed infections frequently occur.

C. chauvoei infection is characterized by engorgement of the subcutis and adjacent tissues with blood-stained fluids and gas bubbles. Cut tissue from the affected area reveals moist, dark-colored muscle in the periphery of the lesion, with lighter colored, drier muscle with gas bubbles separating the separate bundles of muscle toward the center. Other changes include severe degeneration of parenchymatous tissues caused by the systemic toxemia. The carcass usually has a foul odor similar to that of rancid butter. This odor is a characteristic of most cases of clostridial myonecrosis. The lungs are often congested with edema, and hemorrhage and a fibrinohemorrhagic pleuritis are common. The heart may be friable and show evidence of endocardial hemorrhages, particularly on the right side. The spleen may be normal or enlarged and friable. The liver is usually pale and friable and may be autolytic and porous. Lesions are similar in sheep and cattle, except that there is usually less gas and the muscles are not as dry in affected sheep.

Similar necropsy findings are found with myonecrosis caused by *C. septicum* and *C. novyi* type B. *C. septicum* and *C. perfringens* generally occur as part of mixed wound infections in which abundant malodorous, serosanguineous fluid is found at the wound site. *C. perfringens* is common in horses.

Myonecrosis resulting from *C. sordellii* is most often associated with lesions of the neck or brisket area of cattle. Death is frequently so rapid that subcutaneous gas accumulation is rare. In addition to local myonecrosis, these animals often have massive subendocardial hemorrhages in the left ventricle of the heart and hemorrhage in the trachea, bronchi, and thymus. Extensive perirenal edema and hemorrhagic renal calyces and severe congestion of the lungs are common findings.

Treatment Although clostridial myonecrosis is often fatal, aggressive specific therapy combined with supportive care may be successful in individual cases. A presumptive diagnosis of clostridial disease on the basis of history and clinical signs is usually made before obtaining the results of culture and laboratory determinations such as fluorescent antibody tests. In horses, clostridial myonecrosis resulting from infections with *C. perfringens* seems to be most amenable to treatment and has the best prognosis for survival, although extensive skin sloughing over the affected area is common.[87] Antibiotic therapy, aggressive surgical débridement including fasciotomy, and supportive care are the hallmarks of successful treatment.[87] With most clostridial infections, penicillin is the drug of choice. In horses, Na or K penicillin IV or procaine penicillin IM is used at a dosage of 44,000 U/kg IV every 2 to 4 hours until the animal is stable (1 to 5 days). The IV dose is then reduced to four times a day or is replaced by oral metronidazole (15 mg/kg three or four times daily). In ruminants, similar intravenous or intramuscular drug therapy is indicated. In all cases, prolonged antimicrobial therapy may be necessary.

VetBooks.ir

VetBooks.ir

Surgical intervention at the affected site by means of débridement or fenestration in an attempt to reduce tissue swelling, aerate the tissues, and remove necrotic tissue is considered imperative for survival in horses (see Fig. 42.7). Incisions are made through the skin and into the affected muscle to establish adequate drainage and hopefully alter the anaerobic conditions. Sufficient fenestrations should be made to establish drainage and aeration over the entire affected area.

Use of specific antitoxins is recommended when possible. However, these are often not available or not used for immediate therapy because the exact species of *Clostridium* causing the myonecrosis is not known. Cost considerations may also preclude their use. Supportive fluid therapy and use of analgesics and anti-inflammatory agents for control of pain and swelling are recommended. Short-acting corticosteroids such as dexamethasone, prednisolone, or hydrocortisone may be used for initial therapy of systemic and toxic shock, but continued use is contraindicated in the face of overwhelming sepsis. If required, specific therapy should also be directed toward any other underlying problems.

Prognosis The prognosis for life in all cases of clostridial myonecrosis is guarded to poor. The disease process is often rapidly fulminant, making treatment unrewarding. However, some animals have survived because of early diagnosis, aggressive therapy, and long-term supportive care. This is particularly true in cases involving *C. perfringens* in horses. The owner should be aware from the start of treatment that extensive skin sloughing may involve most of a limb and may force euthanasia to become a consideration at a later stage.

Prevention Protection against clostridial myonecrosis is based on immunization procedures. Although clostridial agents are ubiquitous in the environment and frequently appear in the body of susceptible animals, rarely does adequate natural protection occur, although some colostral and acquired immunity may at times occur. Infection in unprotected animals usually follows a rapid, degenerative clinical course and terminates before the animal can generate an appropriate protective immune response. At present, only ruminants are commonly vaccinated against the agents responsible for clostridial myonecrosis. Vaccines used include multivalent bacterin toxoids containing antigens against two or more clostridial species, including *C. chauvoei*, *C. septicum*, *C. novyi*, *C. sordellii*, and *C. perfringens*. A rational program for protection usually involves vaccinating at an early age to establish immunity. Vaccination age is partly determined by other management factors, including when calves are handled for branding and castration, but 4 to 6 months of age is the usual time of initial vaccination. In areas of heavy exposure it may be necessary to vaccinate at 3 months and again at 4 months. In all clostridial species except *C. chauvoei*, two doses of vaccine are necessary to establish good protection. The duration of immunity is not long, and booster vaccinations should be administered every 6 to 8 months if protection is to be maintained. In many herds it is only necessary to vaccinate animals younger than 3 years of age (i.e., those animals that are at greatest risk), but in some high-risk herds it is necessary to maintain a vaccination program for the life of the animal.

Animals that die of clostridial diseases should be disposed of by deep burial, burning, or removal from the premises to avoid further contamination of the environment.

Rhabdomyolysis Associated With *Streptococcus equi*

Stephanie J. Valberg

Acute Rhabdomyolysis

Severe acute generalized rhabdomyolysis has been reported to occur in Quarter Horses younger than 7 years of age.[92,93] Affected horses have evidence of submandibular lymphadenopathy and/or guttural pouch empyema due to *Streptococcus equi*. Horses develop a stiff gait, which progresses rapidly to markedly firm, swollen, painful epaxial and gluteal muscles. The majority of reported cases became recumbent and unable to rise. They developed unrelenting pain necessitating euthanasia within 24 to 48 hours of hospitalization (Fig. 42.8). Hematologic abnormalities include mature neutrophilia, hyperfibrinogenemia, and marked elevations in CK (115,000 to 587,000 U/L) and AST activities (600 to 14,500 U/L). Titers to the M protein of *S. equi* are low in affected horses, unless horses have been recently vaccinated for strangles. Titers to another protein called myosin binding protein have been high in a small number of horses that were tested.[92]

FIG. 42.8 A horse in severe pain unable to rise due to acute rhabdomyolysis concurrent with guttural pouch empyema from *Streptococcus equi*.

At postmortem examination, large pale areas of necrotic muscle are evident in hindlimb and lumbar muscles. The histopathologic lesions are characterized by severe acute myonecrosis with a degree of macrophage infiltration. Sublumbar muscles often show the most severe and chronic necrosis as indicated by greater macrophage infiltration of myofibers.

One possibile etiology is a toxic shock–like reaction arising from profound nonspecific T-cell stimulation by streptococcal superantigens with the release of high levels of inflammatory cytokines. An alternative explanation for rhabdomyolysis may be a bacteremia with local multiplication and production of exotoxins or proteases within skeletal muscle. *S. equi* virulence factors that may account for muscle necrosis include an unidentified cytotoxic protein, several proteases, streptokinase, and streptolysin S.[94] Although *S. equi* has not been cultured in skeletal muscle from horses with rhabdomyolysis, *S. equi* bacteria have been identified in affected muscle using immunofluorescent stains for both Lancefield group C carbohydrate and *S. equi* M protein.[92] There is currently no evidence that the *S. equi* involved is an atypical genetic strain of *S. equi*.[95] Most recently, a mutation in the gene *MYH1* has been identified in association with immune-mediated myositis, and this mutation may also be responsible for cases of *S. equi*–associated myopathy (see the Immune-Mediated Myositis section).

A high mortality rate has been reported in horses receiving intravenous penicillin therapy once clinical signs of strangles and myopathy were well established. It is possible that early recognition of the signs of muscle stiffness in horses with *S. equi* infections and prompt aggressive treatment may be required for a successful outcome. Although streptococcal species are exquisitely susceptible to β-lactam antibiotics, a mortality rate of 85% has been reported in human group A streptococcal myositis despite penicillin treatment.[96] An antimicrobial that

VetBooks.ir

inhibits protein synthesis, such as rifampin, combined with intravenous penicillin might enhance survival rates in horses with *S. equi* rhabdomyolysis. In addition, flushing infected guttural pouches and draining abscessed lymph nodes will diminish the bacterial load. Nonsteroidal antiinflammatory drugs (NSAIDs) and possibly high doses of short-acting corticosteroids may assist in diminishing the inflammatory response. Control of unrelenting pain is a major challenge in horses with severe rhabdomyolysis. Constant rate infusion of lidocaine, detomidine, or ketamine may provide better anxiety and pain relief than periodic injections of tranquilizers. Horses should be placed in a deeply bedded stall and moved from side to side every 4 hours if they are unable to rise. Some horses may benefit from a sling if they will bear weight on their hindlimbs when assisted to stand.

Infarctive Purpura Hemorrhagica

Stephanie J. Valberg

Infarctive purpura hemorrhagica (IPH) is a severe form of purpura with a high fatality rate. In one study, prevalence of IPH was 3 of 53 cases of purpura.[97] Exposure to *S. equi* within 3 weeks of presentation, vaccination for *S. equi*, and a concurrent *Salmonella infantum* infection are reported as inciting causes. Titers for serum enzyme-linked immunosorbent assay (ELISA) M protein may be markedly elevated.[98] The primary presenting complaint is often painful lameness with limb swelling, muscle stiffness, and/or colic. Careful physical examination reveals classic signs of purpura hemorrhagica such as petechia, oral infarctions resembling ulcers, and moderate well-demarcated limb edema; however, in addition, horses with IPH will have focal firm intramuscular swellings (Fig. 42.9). Horses with evidence of colic may have markedly decreased borborygmi and hemorrhagic gastric reflux.

Hematologic abnormalities include a leukocytosis characterized by a neutrophilia with a left shift and toxic change, hyperproteinemia, hypoalbuminemia, and marked elevations in CK (47,000 to 280,000 U/L) and AST (960 to 7000 U/L) activities.[93,98] Peritoneal fluid obtained by abdominocentesis may be normal or may have an increased total protein, nucleated, and RBC counts if gastrointestinal infarction is present. Ultrasonographic examination of swollen muscle reveals focal hypoechoic lesions within muscle tissue. Biopsies of abnormal muscle show diffuse acute coagulative necrosis, whereas samples from palpably normal muscle tissue show no pathologic abnormalities.

Postmortem findings of horses with IPH include infarction of the skeletal musculature (Fig. 42.10), skin, gastrointestinal tract, pancreas, and lungs, as well as *S. equi* abscessation of a lymph node. Definitive histopathologic findings include leukocytoclastic vasculitis and acute coagulative necrosis resembling infarction in numerous tissues.[98] IPH resembles Henoch-Schönlein purpura in humans, which is characterized by infarctive vasculitis of the skin, kidneys, and gastrointestinal tract due to immunoglobulin A (IgA) immune complex deposition. Immune complexes are present in the sera of horses with purpura hemorrhagica that appear to be primarily composed of IgM or IgA and streptococcal M protein.[99] Deposition of complement near immune complexes in vessel walls may result in cell membrane destruction, cell death, and vascular occlusion. The distinctive feature of IPH in horses is the extensive infarction of skeletal muscle and consequently marked elevation in serum CK and AST activity.

Early recognition of signs and aggressive antibiotic and corticosteroid treatment are essential to combat the high fatality rate with IHP. Treatment of Henoch-Schönlein purpura in humans, including cases with intestinal infarctions, involves high-dose intravenous pulse therapy with methylprednisolone followed by oral corticosteroids plus immunosuppressive agents such as cyclophosphamide and azathioprine. One horse with IPH was successfully treated with penicillin, NSAIDs, and 3 weeks of dexamethasone (0.01 to 0.07 mg/kg IM or IV) followed

FIG. 42.9 Marked swelling of the right adductor muscles of the thigh due to infarctive purpura hemorrhagica.

by a 10-week tapering course of oral prednisolone (2 mg/kg initially).[95]

Immune-Mediated Myositis

Stephanie J. Valberg

The majority of horses with immune-mediated myositis (IMM) are of Quarter Horse bloodlines and are either 8 years of age or younger or 16 years of age or older.[26,100-102] In approximately 40% of horses with IMM, a triggering factor appears to have been exposure to *S. equi* or a respiratory disease. The most prominent clinical sign of IMM in Quarter Horses is rapid onset of muscle atrophy, particularly affecting the back and croup muscles (Fig. 42.11), accompanied by stiffness and malaise. Atrophy may progress to involve 50% of a horse's muscle mass within a week and may lead to generalized weakness.

Hematologic abnormalities are relatively minor in affected Quarter Horses unless a concurrent infection is present and are usually restricted to mild to moderate elevations in serum CK and AST activity. However, in some cases with chronic atrophy, serum muscle enzyme activities are normal. Muscle biopsy of epaxial and gluteal muscles shows lymphocyte vasculitis, angular atrophy, lymphocyte myofiber infiltration, fiber necrosis with macrophage infiltration, and regeneration. Biopsies of semitendinosus or membranous muscles may show some evidence of atrophy and vasculitis, but significant inflammatory infiltrates may be absent in these tissues. The extent of the inflammatory infiltrates in epaxial muscles is such that a diagnosis can often be established from several formalin fixed Tru-Cut samples.

The lymphocytic infiltrate seen in muscle samples from horses with IMM contains a high CD4/CD8 ratio with no evidence of IgG binding to myofibers and some upregulation of major histocompatibility Class I and II staining on muscle cell membranes.[26,103] Recently, a mutation in the gene encoding type 2X myosin heavy chain was found to be associated with IMM in Quarter Horse–related breeds.[104] Genetic testing for IMM will soon be available.

Horses with concurrent evidence of streptococcal infection should be treated with antibiotics. It is likely prudent to avoid intramuscular injections. Administration of corticosteroids appears to immediately improve signs of malaise and inappetence and prevented further progression of muscle atrophy. Recommended dosages are dexamethasone (0.05 mg/kg IM or IV) for 3 days, followed by prednisolone (1 mg/kg PO) for 7 to 10 days, tapered by 100 mg/week over 1 month. Serum CK activity often normalizes after 7 to 10 days. Muscle mass will usually gradually recover over 2 to 3 months. Horses that are not treated with corticosteroids may develop extensive muscle atrophy, but in many cases muscle mass will gradually recover. Recurrence of atrophy in susceptible horses is common and may require reintroduction of corticosteroid therapy. Some horses develop focal residual muscle atrophy.

Equine Inflammatory Myopathies

Other causes of inflammatory myopathies exist in horses apart from IMM.[105] Piroplasmosis, for example, can produce chronic muscle atrophy characterized by muscle fiber atrophy, degeneration, and perivascular perimysial and endomysial lymphocytic infiltrates.[106] Focal symmetric atrophy of cervical muscles and lymphocytic infiltrates has also been reported in a pony with IMM.[107]

Virus-Associated Myopathy

Steven M. Parish

Necrosis of skeletal and cardiac muscle occurs frequently in association with some viral diseases. In most situations, viral-induced muscle damage represents a component of systemic multiple organ system involvement. For example, myocarditis occurs in association with foot-and-mouth disease, equine influenza, and equine infectious anemia. Other diseases causing myocarditis or skeletal muscle manifestations include bovine ephemeral fever, malignant catarrhal fever, bovine viral diarrhea, and bluetongue. Equine influenza A2 and equine herpesvirus 1 have been reported to induce primary muscle stiffness and clinical signs resembling those seen in horses with rhabdomyolysis.[108,109] Details concerning specific clinical manifestations can be found in other sections of this text.

Sarcocystosis

Steven M. Parish • Stephanie J. Valberg

Cysts of the sporozoan parasite *Sarcocystis* are commonly seen in routine histologic sections of the heart, esophageal, and skeletal muscle of cattle, sheep, goats, and horses. More than 90% of horses older than 8 years of age have sarcocysts in their esophageal muscles. Cysts may pose no problem, but with heavy infestations multisystemic dysfunction occurs. Experimentally induced acute disease is characterized by fever, mild anemia, chronic myositis, and muscle wasting.[110,111]

Epidemiology The life cycle of the parasite involves two hosts: carnivores as the definitive host and cattle or horses as the intermediate host. Three species of sarcocysts, *Sarcocystis cruzi*, *Sarcocystis hirsuta*, and *Sarcocystis hominis*, are known to infect cattle; Canidae, Felidae, and primates are the definitive hosts for these species. Three sarcocyst species have been described in horse muscle: *Sarcocystis bertrami*, *Sarcocystis equicanis*, and *Sarcocystis fayeri*.[112,113] Dogs have been identified as the definitive host of these equine sarcocyst species. In sheep and goats, *Sarcocystis ovicanis* and *Sarcocystis capracanis* have been described, with Canidae as the definitive host. The most common mechanism for natural infection in cattle is by ingestion of feeds contaminated with infected carnivore feces. Feedlot workers using feed bunks as toilets may be a source of exposure for feedlot cattle.

Clinical Signs Although low-level natural infection is common in cattle, when administered experimentally, a dose of 200,000 sporocysts of *S. cruzi* is necessary to cause severe clinical disease.[110] Within 4 weeks the animal develops fever (39.4° C/103° F), anorexia, salivation, weight loss, weakness, muscle fasciculations, severe depression, and sometimes death. Fever is the earliest sign and is biphasic relative to two periods of parasitemia, one occurring at 15 to 19 days and another at

VetBooks.ir

25 to 42 days after inoculation. During the second febrile episode, affected calves frequently develop other clinical signs, particularly anemia. Extravascular hemolysis occurs, and hemorrhage into many tissues is common. The mechanisms involved in the hemolytic and hemorrhagic phases are likely to involve immune mechanisms. Mortality is greatest during this phase of the disease. Laboratory analysis may reveal elevations in serum urea nitrogen and bilirubin concentrations, sorbitol dehydrogenase, LDH, CK, and AST activities. If animals survive, these laboratory values usually return to normal in about 2 weeks. Animals surviving this phase commonly continue to be inappetent and have decreased weight gains, muscle atrophy, and hair loss on the neck, rump, and tail. These changes are mediated by alterations in a variety of pathways, the net result being a partitioning away of nutrients that are used for growth.[111] The anemia is ameliorated by a regenerative process, with normal hematologic values obtained in 1 to 2 months after clinical recovery. Similar clinical findings are seen in sheep and goats. Abortion is common. A syndrome similar to that described in cattle has been reported in two horses with malaise, fever, and muscle atrophy.[112,113]

Diagnosis Diagnosis of sarcocystosis requires history, clinical signs, laboratory and serologic evaluation, and the demonstration of immature cysts in muscle biopsies. It is important to differentiate between the muscle cysts caused by *Sarcocystis* and those produced by toxoplasmosis because toxoplasmosis does not cause clinical disease in cattle.

Treatment and Control Specific treatment is effective only in the early stages of sarcocystosis in food animals. Experimental therapy with amprolium or the ionophore antibiotics before the second stage of parasitemia frequently prevents development of clinical sarcocystosis in cattle.[111] Successful treatment of one horse with sarcocystosis using phenylbutazone, trimethoprim-sulfamethoxazole, and pyremethamine has been reported.[113] Control involves preventing gross contamination of cattle and equine feeds with carnivore feces. The common use of ionophore antibiotics (e.g., growth promotants and coccidiostats) in cattle is also likely to help reduce the incidence of sarcocystosis.[114]

Nutritional and Toxic Rhabdomyolysis

Nutritional Myodegeneration

John Maas • Stephanie J. Valberg

Definition and Etiology Nutritional myodegeneration (NMD; also known as white muscle disease, stiff lamb disease, and nutritional muscular dystrophy) is an acute myodegenerative disease of cardiac and skeletal muscle caused by a dietary deficiency of selenium or vitamin E.[115-118] This syndrome occurs in most farm animal species but is most commonly found in young, rapidly growing calves, lambs, kids, and foals, particularly those born to dams that consumed selenium-deficient diets during gestation. An in utero form of NMD may occur with affected animals showing clinical signs soon after birth. The disease has also been reported in yearling and adult cattle and occasionally adult horses. Selenium and vitamin E appear to be synergistic in preventing NMD. However, on the basis of prophylaxis and response to treatment, selenium deficiency appears to be more important.

Clinical Signs There are two distinct syndromes of NMD: a cardiac form and a skeletal form. The cardiac form is associated with acute signs of myocardial decompensation, whereas the skeletal form results in stiffness, weakness, and difficulty in ambulation.

The cardiac form of NMD usually has a sudden onset of depression, weakness, respiratory distress, rapid irregular heartbeat, severe debilitation, and often death within 24 hours. Occasionally an animal responds to therapy, but it often fails to thrive because of residual myocardial damage. Animals with predominantly cardiac signs can also manifest mild skeletal muscle problems associated with NMD. Lesions are present in the heart, diaphragm, and intercostal muscles.

The skeletal form of NMD frequently has a slower onset characterized by muscular weakness, stiffness, trembling, and recumbency with notably hard and painful muscles on palpation. Commonly affected muscle groups may include the gastrocnemius, semitendinosus, semimembranosus, and biceps femoris and muscles of the lumbar, gluteal, and neck regions. If the diaphragm and intercostal muscles are affected, the animal may show respiratory distress and evidence of increased abdominal effort when breathing. The muscles of the tongue may be involved, resulting in dysphagia. Dysphagia, especially in foals and lambs, may be the only sign. Some animals exhibit what appears to be abdominal pain with violent thrashing. Animals with skeletal NMD often respond favorably to treatment and rest. Improvement is evident after a few days, and within 3 to 5 days animals can often stand and walk.

Differentiation of NMD from other diseases causing sudden death or recumbency is important. Infectious diseases resulting in septicemia, pneumonia, and toxemia may have similar presenting signs. Acute heart failure resulting from cardiac anomalies; cardiotoxic agents such as those found in plants (oleander, cassia, yew, white snakeroot, and gossypol toxicity from cottonseed); and the ionophore antibiotics should also be considered. Other diseases causing stiffness of gait, weakness, and recumbency with no change in mental status must be differentiated from NMD. Spinal cord compression, cerebellar disease, suppurative and nonsuppurative meningitis or myelitis, polyarthritis, neurotoxins such as organophosphates, tetanus, pelvic fractures, and parasitic myositis all can cause recumbency. Clostridial myositis and traumatic injuries to muscles, long bones, and joints should be considered. Diseases characterized by abdominal pain may resemble NMD because they may also cause stiffness of gait, weakness, and recumbency.

Clinical Pathology Significantly elevated CK, AST, and LDH activities and myoglobinuria occur during the acute phase of myodegeneration. Progressively decreasing activities of CK can be used as a prognostic indicator of a reduction in the myodegenerative process. In foals, other reported abnormal laboratory findings include variable hyperkalemia, hyperphosphatemia, hyponatremia, and hypochloremia.[118] Evidence of dehydration, reflected by elevated serum protein concentrations and hemoconcentration, is common in nonambulatory animals unable to nurse or drink water.

The selenium status of an animal or members of a group can be determined by laboratory analysis of tissue biopsies and whole blood (Table 42.2). Vitamin E status in serum or plasma is satisfactory for assessing intermediate to long-term nutritional status; however, short-term supplementation or injections can confuse interpretation of circulating levels of selenium or vitamin E. Tissue biopsies and tissue specimens obtained at slaughter and necropsy provide an indication of storage and can also be used to assess herd status and success of supplementation. Whole blood selenium analysis is preferred over plasma and serum.[119] Whole blood selenium concentrations ranging from 0.07 to greater than 0.1 ppm (μg/mL) are considered normal in large animals. Normal liver concentrations of selenium are 0.9 to 1.75 μg/g of dry weight (DW), 0.9 to 3.5 μg/g DW, and 1.05 to 3.5 μg/g DW for cattle, sheep, and horses, respectively.[120] Selenium-dependent glutathione peroxidase (GSH-Px) formed in the RBCs during erythropoiesis also provides an index of body selenium status.

VetBooks.ir

TABLE 42.2

Deficient, Marginal, and Normal Concentrations of Whole Blood Selenium and GSH-Px Activities in Sheep and Cattle[67,71]

Whole Blood Selenium (ppm)	GSH-Px (U/mg Hb/min)	Category	Interpretation
0.01-0.04	0-15	Deficient	Selenium supplementation is always beneficial
0.05-0.06	15-25	Marginal	Selenium supplementation is often beneficial
≥0.07	25-500	Normal	Selenium supplementation is never beneficial

GSH-Px assays are performed by different procedures in individual laboratories, and quantitative relationships between blood selenium concentrations and blood GSH-Px activities can vary. These numeric relationships are site specific, and interpretation must account for these differences.

GSH-Px, Glutathione peroxidase; *Hb*, hemoglobin; *ppm*, parts per million.

Cross-reacting enzymes, such as glutathione reductase, are not found in erythrocytes. Adequate GSH-Px activities are greater than 30 U/mg of hemoglobin per minute in cattle, 60 to 180 U/mg of hemoglobin per minute in sheep, and 20 to 50 U/mg of hemoglobin per minute in horses. However, GSH-Px reference values are only specific to the laboratory where the analysis is performed and must be validated by comparison with blood selenium concentration. The activity of GSH-Px in RBCs of domestic species remains constant for 4 to 6 days when maintained at 39° F (4° C); after this time, significant decreases occur. The critical concentration of vitamin E (α-tocopherol) in plasma is 1.1 to 2 ppm (μg/mL) in large animals. Vitamin E deteriorates rapidly in plasma samples. Therefore plasma or serum samples for α-tocopherol analysis need to be put on ice immediately, protected from light by wrapping in tin foil, and stored (–21° F/–70° C) if analysis is to be delayed.

Pathophysiology

The effects of selenium and vitamin E deficiency have been postulated to result, at least in part, from the destruction of cell membranes and proteins leading to a loss of cellular integrity.[115,121] Selenium, which has been shown to be an essential component of at least five selenoproteins[122] (three GSH-Px enzymes; a deiodinase in liver and kidney that converts T_4 to T_3; and selenoprotein P, a plasma protein of unknown function), and vitamin E (α-tocopherol) serve as biologic antioxidants. During normal cellular metabolism, highly reactive forms of oxygen (free radicals) are produced. These include hydrogen peroxide, hydroperoxides, lipoperoxides, superoxide, various hydroxy radicals, and singlet oxygen. Vitamin E is active within the cell membrane as a lipid-soluble antioxidant that scavenges free radicals that otherwise might react with unsaturated fatty acids to form lipid hydroperoxides. In contrast, GSH-Px destroys hydrogen peroxide and lipoperoxides that have already been formed and converts them to water or relatively harmless alcohols. Other enzymes such as catalase and superoxide dismutase are also involved in this protective process.

Apparently important interrelationships exist among the selenium and vitamin E status of the animal, the level of polyunsaturated fatty acids (PUFAs) in the diet,[115,121] and NMD, particularly in ruminants.[115] PUFAs of dietary origin can undergo peroxidation to hydroperoxides forming toxic free radicals. During active growing periods, pasture grasses and plants contain high concentrations of linolenic acid, a PUFA. Under normal conditions the rumen is thought to be important in saturating dietary unsaturated fatty acids. However, concentrations of PUFAs in the plasma often increase in calves recently turned out to pasture, possibly enhancing the chance of free radical formation and tissue damage. This indicates that the capacity of the various protective mechanisms can be overwhelmed by dietary factors such as high levels of PUFA. Not surprisingly, selenium- or vitamin E–deficient animals may be at a greatly increased risk of tissue oxidative damage when exposed to such diets. However, the potential for induction of NMD by this process should not be overemphasized because calves on a milk diet may be severely affected.

The precise interrelationships among selenium, vitamin E, other metabolic factors, and triggering mechanisms in NMD are not fully understood because many animals deficient in selenium or vitamin E have no evidence of muscle disease. In certain situations, deficiencies of both selenium and vitamin E are necessary for disease to occur. In other animals NMD can occur when a deficiency of only one of the agents is present and the other is normal in blood and tissues.

Epidemiology

NMD occurs in all farm animals and is seen most commonly in young, rapidly growing calves, lambs, kids, and foals. The occurrence of NMD in very young animals usually reflects a deficiency in their dams during a substantial portion, if not all, of the gestation period. The selenium and GSH-Px values of neonatal calves tend to be similar to those of their dams.[123,124]

Marginally to severely selenium-deficient areas occur throughout a large portion of the United States and other countries of the world. Forages and grains produced in the northeastern and eastern seaboards and northwestern regions of the United States are particularly deficient because of low soil levels of selenium. Acid soils and those originating from igneous (volcanic) rock are often selenium deficient, as are those having high sulfur content or soils treated with sulfur-containing fertilizers. Sulfur inhibits selenium uptake by plants and absorption by animals. Different forages in a specific area will also vary in their selenium content. Legumes take up less selenium than do grasses. Also, forage selenium concentrations are lowest during periods of rapid growth such as in the spring and during times of highest rainfall.

Vitamin E deficiency occurs most commonly when animals are fed poor-quality hay, straw, or root crops. Grain treated with propionic acid and having high moisture content is commonly vitamin E deficient. Storage of grain crops for extended periods results in marked decreases in their vitamin E content. Calves fed milk replacers containing fish oil, linseed oil, or soybean or corn oil, all of which increase the dietary levels of unsaturated fatty acids, require increased dietary supplementation of vitamin E to avoid deficiency. In contrast, cereal grains, green growing pastures, and properly prepared hay usually have adequate vitamin E.

In young ruminants the majority of NMD cases occur in calves, 2 to 4 months of age, during the spring and summer months in association with exercise when at pasture, although congenital and perinatal cases do occur. Histologic lesions consistent with NMD have also been seen in late-term aborted fetuses.[120] These findings are suggestive of an in utero form of NMD in large animals. Yearling cattle housed during the winter, fed diets high in grain with high moisture content, and then turned out in the spring may also be affected. Lambs born in confinement and turned out to pasture at 1 to 3 weeks of age frequently develop signs of NMD. Stresses such as

VetBooks.ir

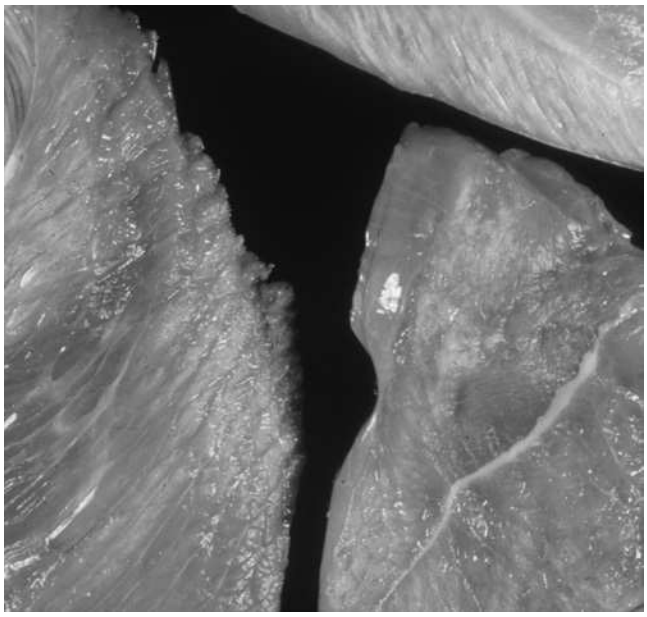

FIG. 42.12 White streaks within diffusely pale skeletal muscle due to nutritional myodegeneration.

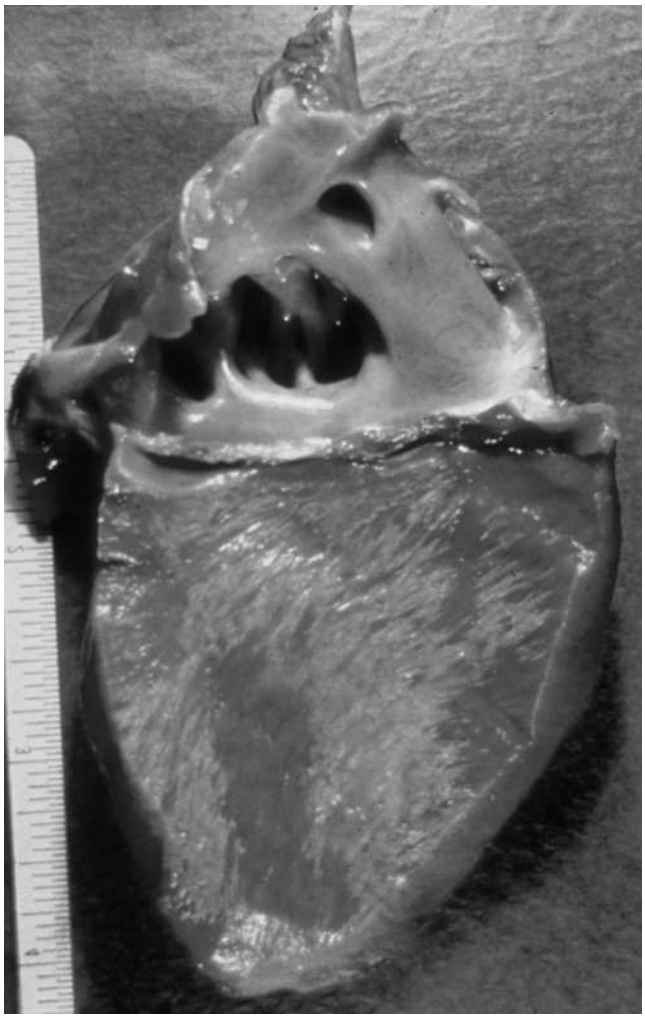

FIG. 42.13 Pale areas of muscle necrosis in the myocardium of a calf with nutritional myodegeneration.

transport, herding, and driving can also precipitate signs of NMD. In horses, NMD generally occurs during the first year of life with most cases observed from birth to weaning.[116,125]

Necropsy Findings Bilaterally symmetric myodegeneration is a consistent finding in NMD. Skeletal muscle degeneration is characterized by pale discoloration and a dry appearance of affected muscle, white streaks in muscle bundles, calcification, and intramuscular edema (Fig. 42.12). The white streaks seen in muscle bundles represent bands of coagulation necrosis or, in chronic cases in which insults may have occurred weeks before, may represent fibrosis and calcification. Affected muscle bundles are often adjacent to apparently normal or minimally affected muscle. The color of normal muscle in young calves is pale because of reduced myoglobin concentrations; therefore close inspection and histologic examination are necessary in cases of suspected NMD. Cardiac muscle undergoes changes similar to those of skeletal muscle. In calves the left ventricle and septum are most frequently involved (Fig. 42.13), but in lambs both ventricles are usually involved. Myocardial degeneration usually extends through the full thickness of the ventricular wall.

Histologically, affected muscle fibers may be hypercontracted and fragmented with some mineralization of muscle fibers and others undergoing macrophage infiltration. In yearling cattle, type I muscle cells are more frequently affected.

Treatment and Prognosis In the cardiac form of NMD, myocardial damage is often extensive and incompatible with life. In contrast, the skeletal form of NMD is more generally amenable to treatment, although the prognosis for clinical recovery from the skeletal form of NMD is guarded and depends often on whether secondary complications such as respiratory disease develop. In all cases of NMD, therapy should involve specific supplementation with selenium and vitamin E and general supportive care.

Alleviation of selenium-responsive NMD requires the use of injectable selenium products. These are available with selenium concentrations varying from 1 to 5 mg/mL, with all products containing 50 mg/mL (68 IU) of vitamin E as DL-α-tocopheryl acetate. The label dose for selenium is 0.055 to 0.067 mg/kg (2.5 to 3 mg/45 kg) body weight given intramuscularly or subcutaneously. Dosage of these injectable products should not be greatly increased above the label dose to prevent an inadvertent selenium toxicosis. However, when using the vitamin E/selenium combinations, the amount of vitamin E in these combination products is present as a preservative for the solution and is therefore insufficient for vitamin E supplementation. Oral supplementation is the general approach to provide additional dietary levels of vitamin E. Vitamin E can be obtained from natural or synthetic sources, which differ in bioavailability. In order for α-tocopherol acetate to be used in the body, the ester has to be removed and the α-tocopherol made water dispersible by the action of bile salts (micellization), which can limit α-tocopherol acetate absorption in the horse. To further enhance the bioavailability of α-tocopherol, water-dispersible formulations of vitamin E have been developed. The biopotency of these compounds in horses is much greater than synthetic vitamin E. When tested, two of the commercially available water-dispersible natural vitamin E products had a bioavailability 5.59 (Elevate WS [Kentucky Performance Products, Versailles, Ky.]) and 6.13 (Nano-E [Kentucky Equine Research, Versailles, Ky.]) times higher than synthetic vitamin E acetate (D-α-tocopheryl acetate). Recommended levels of supplementation for calves range from 15 to 60 mg of DL-α-tocopheryl acetate per kg of dry feed. For horses, a daily supplement of 600 to 1800 mg per os of DL-α-tocopheryl acetate has been recommended.[125]

Studies with injectable selenium show that absorption and distribution occur rapidly.[126] It is thought that incorporation

of selenium into heart, skeletal muscle, and other tissues may be rapid and could account for the rapid improvement in clinical signs seen in reversible cases. The discovery of four new selenoproteins may help explain these clinical observations.[122] This improvement can occur even though blood GSH-Px activity rises slowly because of the delay caused by erythropoiesis and release of RBCs from the bone marrow.[126] However, platelet GSH-Px activity rises within hours and may be a more accurate reflection of changes in muscle and other tissues.

Supportive therapy may include administration of antibiotics to help combat secondary pneumonia and infected decubital lesions that are common in recumbent patients. Provision of adequate energy intake and attention to the fluid and electrolyte balance are of critical importance if recovery is to be successful.

Prevention and Control The prevention and control of NMD are achieved through supplementation of both selenium and vitamin E. The use in ruminants of rumenoreticular boluses, which release a precise amount of selenium daily, has been commonplace in many countries of the world; however, current guidelines should be checked to ensure they are not permitted. These slow-release boluses can replace supplementation by salt mixtures or by injections and are extremely valuable in extensive grazing systems. Alternatively, individual animals can be supplemented by periodic (30- to 60-day intervals) injections of selenium/vitamin E preparations to help maintain body concentrations and assist in transplacental transfer of selenium to the fetus.

Oral supplementation for horses at 1 mg of selenium per day increases blood selenium concentrations above levels known to be associated with NMD.[127] Supplementation of pregnant mares is advised in areas known to be selenium deficient; however, only limited selenium may cross the placenta.[117] Supplementation during lactation increases the levels of selenium in milk and thus provides a potential means of selenium supplementation in foals; however, evidence in cattle indicates that this increased level of selenium in milk may not meet nutrient requirements.

Regardless of the method of supplementation, periodic blood (or tissue) sampling of animals at risk is recommended to ensure desired levels of selenium. In high-risk areas, samples should be taken every 60 to 90 days to determine selenium status in susceptible animals and every 6 to 12 months to monitor supplementation. On the basis of these assessments, adjustments to the rate or extent of selenium supplementation may be made.

Feeding animals properly prepared and stored hay and grain or allowing them access to high-quality green forage should ensure adequate vitamin E intake.

Masseter Muscle Myodegeneration

Adult horses with selenium deficiency may be clinically normal or can present with acute clinical signs of bilateral swelling of the masseter muscles, trismus, dysphagia, and salivation.[128-131] Although postural and locomotor muscles may appear normal on clinical examination, postmortem of horses with masseter muscle myonecrosis has shown histopathologic evidence of bilateral symmetric lesions in muscles of the hind and thoracic limbs. Tachycardia and dysrhythmias may indicate the presence of myocardial damage. Accompanying clinical pathologic findings include pigmenturia, elevated serum AST and CK activity, and elevated cardiac troponin concentrations. Ultrasonography can be used to determine the extent of masseter muscle swelling or atrophy, as well as the presence of myocardial dysfunction. Prognosis is guarded, but there are individual reports of successful treatment. Important aspects of treatment include nutritional support via stomach tube, IV fluids, analgesics, IM selenium (0.055 to 0.067 mg/kg), and oral vitamin E (1000 to 5000 IU/day). Progression to bilateral muscle atrophy is common and may resolve after a period of months. Without early treatment, permanent trismus can occur due to muscular atrophy and fibrosis. Ruleouts for masseter swelling include parasites—most commonly *Trichinella spiralis*, *Halicephalobus* species, or *Haycocknema perplexum*[132]—trauma, and fibrosis due to trauma or chronic abscessation.

Vitamin E–Deficient Myopathy

Some horses with clinical signs of EMND and a deficiency in vitamin E are not diagnosed antemortem with EMND because they lack evidence of neurogenic atrophy in the sacrocaudalis dorsalis (SC) muscle. A recent study suggests that many such undiagnosed cases are the result of a specific myogenic presentation of vitamin E deficiency.[133] With vitamin E–deficient myopathy, the clinical presentation resembles EMND; however, sacrocaudalis muscle lacks evidence of neurogenic atrophy but contains an abnormal moth-eaten staining pattern of mitochondria. Muscle α-tocopherol concentrations from affected horses are low, but serum α-tocopherol concentrations are inconsistently low. This vitamin E–deficient myopathy has likely been missed previously because formalin-fixed biopsy specimens are most often evaluated for a diagnosis of EMND and mitochondrial staining is not possible with this fixative. The observed generalized weakness in the horses with abnormal mitochondrial stains could be due to a reversible manifestation of skeletal muscle mitochondrial oxidative stress associated with vitamin E deficiency. Horses can recover completely after vitamin E therapy (5000 IU/day per os for >3 weeks) (Fig. 42.14). Vitamin E–deficient myopathy could be an entity unto itself or a predecessor to development of EMND, but this distinction was not evaluated in the study because all horses successfully responded to vitamin E therapy, precluding a postmortem examination.

Toxic Causes of Rhabdomyolysis

Stephanie J. Valberg

Ingestion of toxic substances in feed or forage is a common cause of toxic rhabdomyolysis.

IONOPHORES. Ionophores are commonly added to feeds for their growth promotion and coccidiostat properties. Species differences in sensitivity to ionophores and the variety of ionophores on the market have led to several cases of ionophore-induced toxicosis. Rhabdomyolysis and cardiomyopathies are common sequelae to ionophore toxicosis. Experimental studies have indicated that LD50 values for monensin are 2 to 3, 12, 17, 26, and 21 to 36, for horses, sheep, pigs, goats, and cattle, respectively. Feed concentrations of 100 g/ton and 400 g/ton have been fatal to sheep and cattle, respectively.[134,135] Newborn calves dosed with 100 mg lasalocid twice daily, for cryptosporidiosis, experience muscle necrosis.[136] Other ionophores include naracin, salinomycin, and laidlomycin. Ionophores are quickly eliminated from the body after exposure.

CHEMICAL TOXINS. Several chemical agents have been associated with muscle necrosis on rare occasions. Parenteral products, insecticides, and feed contaminants have been implicated. Muscle necrosis has been reported in cattle and pigs after receiving injections of lidocaine, diazepam, digoxin, levamisole, nitroclofene, pentazocine, thiazinamium, chloramphenicol, and oxytetracycline and in horses after injectable ivermectin administration. One of 70 horses poisoned with blister beetles developed muscle necrosis.[137] Animals with organophosphate toxicosis, particularly parathione, may develop muscle necrosis.[138-140] Several miniature horses being fed a complete feed containing tetrachlorovinphos, a feed-through fly control agent, were reported to develop chronic myonecrosis involving masseter, tongue, neck, respiratory and postural

FIG. 42.14 A horse with vitamin E–deficient myopathy before **(A)** and after **(B)** 6 months of vitamin E treatment. Before vitamin E treatment, notice the marked generalized muscle atrophy; following treatment, notice the normal muscle mass.

muscles, and occasionally cardiac muscle.[141] Affected horses showed signs of lethargy, dysphagia, fasciculations, tachypnea, and tachycardia. Muscle tissue showed evidence of chronic myonecrosis and lipid accumulation. Myonecrosis was attributed to acetylcholine accumulation at muscarinic and nicotinic sites producing oxidant stress. Low selenium concentrations may contribute to the toxicosis.

TOXIC PLANTS. Gossypol is of greatest significance in swine. Monogastrics, including young calves, should not ingest feed containing more than 200 ppm gossypol. Mature ruminants may tolerate 20 g of gossypol/head/day. This normally amounts to 5 to 6 lb of whole cottonseed per head per day.[142] Two common forage toxins that cause myonecrosis are *Cassia* spp. and tremetone-containing plants. *Cassia obtusifolia* (sicklepod) is prevalent in the southeastern United States, and ingestion of seeds by swine, ruminants, or horses may cause a degenerative myopathy and cardiomyopathy with evidence of myofiber atrophy, segmental necrosis, and mitochondrial disruption.[142] White snakeroot *(Eupatorium rugosum)* grows in shaded areas of the eastern and central United States, and rayless goldenrod *(Isocoma wrightii)* is common in the Southwest on open pastures. These tremetone-containing plants can cause a fatal cardiomyopathy and severe skeletal muscle degeneration in horses when ingested at 0.5% to 2% of body weight.[143,144] Other grazing livestock are likely to be affected by ingestion of these plants at 2% of body weight. Tremetone remains active in hay and in the stalks of the dead plants on pasture, so both the fresh and the dried form of the plants should be kept from livestock.[145] Microsomal activation of the toxin in the liver may be necessary for toxic effects.[143]

Marshmallow Toxicity

Marshmallow *(Malva parviflora)*, also known as small-flowered mallow, cheeseweed mallow, and little mallow, is a common weed found in pastures of grazing animals with extensive distribution, including in regions of Europe, Asia, North and South America, Australia, and New Zealand. The two cyclopropene fatty acids, malvalic acid and sterculic acid, are thought to be the main toxic components of plants.[146] Horses consuming marshmallow with little else to eat developed signs of sweating and muscle fasciculations progressing to recumbency and had elevated serum CK, AST, and lactate.[146] Increases in serum cyclopropene fatty acids, large increases in C14 to C18 acylcarnitine concentrations, and smaller increases (up to eightfold) in other acylcarnitines such as C2 to C5 suggest that the toxin disrupts long-chain fatty acid metabolism.[146]

Seasonal Pasture Myopathy and Atypical Myopathy

EPIDEMIOLOGY. A highly fatal acquired lipid storage myopathy of pastured horses occurs in the fall and less often in the spring in Europe and central and northeastern parts of North America.[147-151] Affected horses are usually young or new to affected pastures and kept on wooded pastures for more than 12 hours a day without additional feed provided. Windy weather often precedes outbreaks.[152,153]

Clinical Signs Clinical signs develop acutely and include muscular weakness, sweating, fasciculations, stiffness, tachycardia, tachypnea, recumbency, and when urine is observed, myoglobinuria. A rapid rise in respiratory rate is usually followed by collapse and death from respiratory or cardiac failure.

Diagnosis The most notable change in serum biochemistry is a marked increase in serum CK and AST activity, which is often accompanied by hyperglycemia, lactic acidemia, and in some cases elevated serum troponin I concentrations.[154] A definitive diagnosis can be made by a pattern of accumulation of serum acylcarnitines and urine organic acids and glycine conjugates typical of a deficiency in multiple acyl-CoA dehydrogenases, as well as isolation of the conjugated toxic metabolite methylene cyclopropyl acetic acid (MCPA) and hypoglycin A in blood or urine.[155-158] Serum vitamin and selenium, as well as urine tremetone, concentrations are normal. Postmortem findings include extensive necrosis in deep postural and respiratory muscles and, in 50% or more of cases, in myocardium. Frozen sections of myocardium, intercostal, diaphragm, or deep postural muscles show marked intracellular lipid accumulation in oxidative fibers (oil red O stain).[147,150]

Pathophysiology Seeds of *Acer* species trees such as the box elder *(Acer negundo)* and the European sycamore maple *(Acer pseudoplatanus)* (Fig. 42.15) contain the toxic nonproteogenic amino acid hypoglycin A.[157-159] Hypoglycin A is metabolized in the liver to MCPA, and MCPA CoA irreversibly binds to multiple acyl-CoA dehydrogenases, enzymes that are essential for metabolism of short- and medium-chain fatty acids and

VetBooks.ir

FIG. 42.15 Box elder seeds that contain the toxin hypoglycin A, which causes seasonal pasture myopathy.

branched chain amino acids. Accumulation of fat esters can damage muscle cell membranes, and an energy deficiency also arises from an inability to metabolize fat.

Treatment and Prognosis Less than 75% of horses survive.[153] Early aggressive fluid therapy and antioxidant and anti-inflammatory treatment, including dimethyl sulfoxide, vitamin E, vitamin C, riboflavin, and NSAIDs, are indicated.[147] Although many older horses are asymptomatic on pastures with *Acer* species trees, young horses or new horses should not be pastured with box elder or European sycamore maple trees in the fall. Provision of additional feed or reducing grazing time during the fall may also decrease the incidence of pasture-associated myopathies.

Traumatic Rhabdomyolysis

Compartment, Downer, and Muscle Crush Syndromes of Cattle

David R. Hodgson • Stephanie J. Valberg

Muscle damage commonly accompanies the downer syndrome in large animals. The downer syndrome is discussed in greater detail in Chapter 35. Animals weakened by disorders such as hypocalcemia are more prone to tearing adductor or semitendinosus and membranosus muscles in attempts to rise.[25,160] Initial traumatic laceration of muscle leads to edema and inflammation, both of which may exacerbate local tissue degenerative changes. In addition, the weight of a recumbent animal on dependent muscle groups creates significant increases in intramuscular pressure, resulting in decreased perfusion and ischemia of muscle and nerve. Signs of weakness and peroneal or tibial nerve paralysis most commonly accompany this type of injury. Mild elevations in serum CK can be expected in cows that are recumbent, but elevations greater than 5000 U/L usually indicate traumatic muscle damage. Treatment requires correcting the underlying cause of recumbency, fluid therapy if renal damage is evident, NSAIDs, good nursing care, adequate footing and bedding, and lifting or rolling the animal several times a day. Aquatherapy using float tanks for cattle also appears to be beneficial in relieving the pressure on muscle groups.

FIG. 42.16 Postanesthetic myoneuropathy showing paralysis of the right femoral and peroneal nerves.

Postanesthetic Myoneuropathy

Postanesthetic myoneuropathy is a condition that has become much more prevalent since the advent of inhalation general anesthesia. The disorder can be categorized as occurring in two forms: (1) localized myopathy-neuropathy and (2) generalized myopathy somewhat similar to malignant hyperthermia.

Localized Myoneuropathy

CLINICAL SIGNS. Localized myopathy-neuropathy occurs in about 6% of horses undergoing general anesthesia.[148] It is most prevalent in muscles that are in contact with a hard surface during anesthesia or those in which arterial blood supply is compromised through positional occlusion. Commonly affected muscles include triceps, deltoid, masseter, hindlimb extensors, or if the horse has been in dorsal recumbency, the hindlimb adductor and gluteal muscles.[160-162] Injury can also occur to nerves in these areas, resulting in temporary radial, peroneal, or femoral nerve paralysis (Fig. 42.16). Clinical signs may be apparent on recovery or may be delayed for periods of up to 30 to 60 minutes after the horse has recovered from anesthesia. Affected muscles may be swollen, hot, and painful on deep palpation, and the horse is often reluctant to bear weight on the affected limb. Myasthenia (weakness) of affected muscles is common, particularly with peripheral nerve involvement. In some horses this condition may limit the animal's ability to stand for some time following anesthesia. The loss of muscle strength, particularly when involving adductor muscles, can contribute to orthopedic injury during repeated attempts to rise. Many horses with mild to moderate muscle injury recover over a period of hours to days even if untreated.[162]

Etiology A variety of factors acting alone or in combination has been suggested to contribute to this disorder. The most important factors include duration of anesthesia, ischemia, and hypoperfusion as a result of prolonged immobility, muscle compression, systemic hypotension, and hypoxia.[162-166] There is increased lactate efflux from dependent muscles during anesthesia in horses that develop a myopathy, supporting the contention that these muscles experience compromised perfusion.[165,167,168] Halothane anesthesia has a greater propensity than isoflurane to compromise tissue oxygen delivery even in nondependent muscles.[164] If mean arterial pressure is allowed to fall below 70 mm Hg for several hours during inhalation anesthesia, particularly if mechanical ventilation is used, the incidence of postanesthetic myopathy increases substantially.[166,167]

Diagnosis Diagnosis is based on a history of anesthesia or prolonged recumbency, clinical signs, and possibly clinical

pathology examinations. Laboratory findings include elevations in serum CK and subsequently serum AST and serum LDH activities. Elevations in CK activities of thousands to tens of thousands of IU/L are commonly demonstrated in horses with moderate forms of the myopathy.

Treatment Horses demonstrating only minor localized manifestations of the myopathy usually have an uncomplicated recovery with little or no treatment.[162] Supportive care, including the use of anti-inflammatory drugs, dimethyl sulfoxide, and dantrolene sodium 2 to 4 mg/kg PO q8h to q24h for up to 48 hours, is often sufficient in mild to moderate cases.[168] Significant muscle atrophy may develop over the ensuing 3 to 4 weeks but will usually resolve within 2 to 3 months. Treatment of more severe cases is outlined under generalized reactions.

Control Correct positioning and judicious use of padding and water- or air-filled mattresses can reduce dependent muscle pressure by up to 50%, thereby aiding in the reduction of this disorder. In addition, by elevating the upper limb during anesthesia, the pressure on the lower limbs is significantly reduced. Pulling the lower forelimb forward also markedly reduces pressure in the dependent triceps muscle. When the horse is in dorsal recumbency, padding under the shoulders and hips is absolutely imperative.

Maintaining anesthesia at the lightest plane possible for a specific surgical procedure is beneficial in prophylaxis. Similarly, if possible, maintaining systemic mean arterial blood pressure above 80 to 85 mm Hg during anesthesia is advisable. The use of ionotropic agents such as dobutamine during anesthesia has been useful in reducing the occurrence of anesthetic myopathies. Administration of dantrolene sodium (2 to 4 mg/kg PO) 1 hour before induction of anesthesia may result in a reduction in the incidence of this myopathy; however, it should be noted that decreased cardiac output can occur in conjunction with higher dantrolene doses.

Generalized Anesthetic Reactions

CLINICAL SIGNS. Postanesthetic reactions involving multiple muscle groups can result in clinical signs of anxiety, hyperthermia, tachycardia, tachypnea, profuse sweating, and myoglobinuria.[163,164] Horses may not be able to rise and may struggle violently, resulting in prolonged, traumatic recoveries. In some cases a progressive increase in body temperature and muscular contractures may develop under anesthesia, and a fulminant metabolic and respiratory acidosis may be noted.[20,169,170] These animals can die within a matter of hours. In some cases, shock and pigmenturia may lead to renal failure.

Pathogenesis The generalized form of myopathy cannot be explained by the compartmental syndrome alone. Halothane and succinylcholine have been the most frequently implicated inciting agents for generalized anesthetic-induced myonecrosis in all susceptible species, including the horse.[19,169,170] There appear to be several possible explanations for generalized anesthetic reactions. In some cases, systemic hypotension and hypoxemia may create local ischemic lesions, with the pathologic changes becoming more generalized as a result of the stress of anesthesia and the sensitivity of muscle cells to anesthetic agents or muscle relaxants.[162,166] In other cases, malignant hyperthermia[19,169-171] may be responsible for clinical signs of muscle contracture, heat production, and systemic acidosis resulting from excessive calcium release by the sarcoplasmic reticulum. In swine, malignant hyperthermia is caused by a genetic mutation in the ryanodine receptor 1 *(RYR1)* gene.[172] A mutation in the same gene has been identified in Quarter Horses. Horses with this mutation may develop fatal malignant hyperthermia following halothane anesthesia.[173,174] A further possible cause of generalized anesthetic myopathies is the triggering of severe myonecrosis in horses with an underlying exertional myopathy. Horses with recurrent exertional rhabdomyolysis may be at risk for excessive release of calcium from the sarcoplasmic reticulum during halothane anesthesia, and horses with polysaccharide storage myopathy may develop rhabdomyolysis due to metabolic changes with anesthesia.[19,20,175,176]

Diagnosis Diagnosis is based on clinical signs, particularly in horses undergoing inhalation anesthesia. Routine monitoring of body temperature during anesthesia may aid in the early detection of MH. Some animals may also demonstrate metabolic and respiratory acidosis and hyperkalemia.[173] Genetic screening for MH in Quarter Horses and American Paint Horses may be warranted before elective procedures.

Treatment Severely affected cases provide a significant therapeutic challenge. Aims of therapy should include (1) relief of pain, (2) correction of fluid and electrolyte abnormalities, (3) attempts to prevent ongoing necrosis, and (4) high-quality nursing care. Many of the same principles described for treatment of exertional rhabdomyolysis can be used for treatment of postanesthetic myoneuropathy. In severely affected recumbent horses, pain relief and sedation may help prevent struggling and progression of the myopathy.[162,163] Detomidine combined with butorphanol is effective in reducing struggling. Violent struggling only exhausts the horse and increases the potential for further injury and muscle damage. Constant rate infusions of butorphanol, opioids, or detomidine may aid in pain control where practical. Similarly, administration of NSAIDs may help to reduce ongoing degenerative changes in muscle. Dantrolene sodium 2 to 4 mg/kg PO q8h to q24h decreases release of calcium from the sarcoplasmic reticulum, helping to break the cycle of muscle damage. Volume expansion and diuresis may prevent renal toxicity.[162]

The most common metabolic derangement with anesthetic-related myopathies is a metabolic and/or respiratory acidosis. If specific therapy for metabolic acidosis is necessary, intravenous administration of sodium bicarbonate can be used. For optimum results, doses are calculated on the basis of the results of acid-base analysis. If facilities for acid-base analysis are not available and the horse appears severely compromised, IV administration of sodium bicarbonate at a dosage of 0.5 to 1.0 mEq/kg slowly is recommended. If hyperthermia and contracture develop during anesthesia, discontinuation of anesthesia is advisable. Additional attempts to cool the animal with alcohol or cold-water baths may also be indicated. Administration of a large amount of soluble, lyophilized dantrolene sodium for intravenous administration may alleviate clinical signs in these horses. However, availability and expense of the agent in this form restrict its use. A dosage rate of 1 mg/kg IV may be appropriate, although more controlled studies are required.[162]

Good nursing care is important in severely affected horses. This involves providing well-padded areas on which horses can lie. Prevention or minimization of trauma around the eyes and appropriate care of decubital sores are important. Recumbent animals may require frequent turning to allow reperfusion of compressed muscle masses. Continued fluid therapy with polyionic fluids and possibly caloric supplementation may be indicated. The use of slings and pools to assist recumbent animals to rise has also been tried.[162] Recovery from the myopathy may occur with no apparent residual lesions. In contrast, recovery from some severe forms of the disorder may be accompanied by muscle atrophy, fibrosis, and scarring.[162]

Prevention The principles described for localized myoneuropathies apply to the prevention of generalized anesthetic-related myopathies. In addition, dantrolene sodium has been shown to reduce the incidence of MH in susceptible humans

and pigs. Similar effects might be anticipated in horses. Because of limited controlled studies, the dosage rate for prevention of MH in the horse is not clearly defined. Administration at a rate of 4 mg/kg PO 1 to 2 hours before anesthesia may be beneficial in reducing the incidence of MH; however, 6 mg/kg may cause decreased cardiac output and hypotension.[168,177]

Exertional Myopathies in Horses

Local Muscle Strain

Stephanie J. Valberg

Lumbar and Gluteal Muscles

Strain of lumbar and gluteal muscles is common in jumpers, dressage, harness horses, and Thoroughbreds. Deep palpation of epaxial and gluteal muscles results in pain and dorsiflexion of the spine. Several factors may predispose horses to muscle strains, such as an inadequate warm-up, preexisting lameness, exercise to the point of fatigue, and insufficient training. Lameness can be mild, and horses usually are reluctant to engage their hindquarters during exercise. A specific gluteal syndrome has been described in which the accessory head of the middle gluteal muscle becomes acutely painful to palpation.[178] With accessory gluteal head involvement horses become progressively more lame during exercise and will refuse to continue exercise. Horses that show pain but resist dorsiflexion, ventroflexion, and lateral bending on manipulation may have a myopathy secondary to an underlying disorder of the spine or sacroiliac joint.

Adductor Muscles

The gracilis muscle can be torn in horses and cause severe pain and, occasionally, recumbency.[179,180] A careful physical examination reveals swelling of the medial thigh and pain on palpation. Ultrasonography identifies the extent of disrupted muscle fibers. Adequate rest, NSAIDs, and cold therapy form the basis for acute treatment. Stretches and hand walking once the initial pain has dissipated are beneficial combined with application of heat or ultrasound therapy. Exercise should be resumed gradually, preceded by an appropriate warm-up period in a long and low frame. Adequate conditioning should be ensured before starting strenuous exercise. Saddles should be checked for proper fit.

Semitendinosus and Semimembranosus Muscles

Semitendinosus and semimembranosus muscles are frequently damaged in working Quarter Horses, and in chronic cases this can result in a fibrotic myopathy.[181-183] Tearing of the semitendinosus and sometimes the semimembranosus, biceps femoris, and gracilis muscles at the point of a tendinous insertion is usually associated with work that requires abrupt turns and sliding stops. Horses caught in ropes or fences may struggle violently enough to induce sufficient trauma, allowing subsequent development of the myopathy. In one report, 5 of 18 horses developed this condition secondary to intramuscular injections.[183]

Affected muscles in acute cases are painful on deep palpation and may appear warm. Chronically hardened areas within the muscle may represent fibrosis and ossification. The lameness in chronic cases is usually most apparent at the walk and is characterized by an abrupt cessation of the anterior phase of the stride of the affected limb, causing the leg to jerk suddenly to the ground rather than continue its forward motion. Pain is not a feature in chronic fibrotic myopathy, and manipulative tests have little, if any, effect on the degree of dysfunction. The stride has a short anterior phase with a characteristic hoof-slapping gait. The gait reflects a mechanical hindlimb lameness that restricts normal function. Radiographs may indicate ossification of affected muscles.[183]

Diagnosis Serum activities of CK and AST are usually only mildly elevated. In addition to palpation, diagnosis can be confirmed by ultrasonography, thermography, or scintigraphy. Light microscopic evaluation of muscle biopsies is frequently normal in acute cases. Chronically fibrous replacement of muscle fibers is apparent.

Treatment Several surgical procedures for correction of fibrotic myopathy have been described.[169,183]

Exertional Rhabdomyolysis

Stephanie J. Valberg

Exertional rhabdomyolysis (ER) is probably the most common muscle disorder in horses. It is a frequent cause of poor performance in a variety of breeds, including Standardbreds, Thoroughbreds, warmbloods, Arabians, Morgans, Quarter Horses, Appaloosas, and Paints. ER is a complex syndrome that likely has numerous causes. Numerous terms such as tying-up, chronic intermittent rhabdomyolysis, azoturia, Monday morning disease, paralytic myoglobinuria, and exercise-associated myositis have been used for this syndrome.

Clinical Signs Classically, horses develop a stiff, stilted gait, with excessive sweating and a high respiratory rate during or after exercise (Fig. 42.17). Most commonly, signs are seen after only 15 to 30 minutes of light exercise. Following exercise, horses may stretch out as if to urinate, become extremely reluctant to move their hindquarters, and in severe cases show signs of colic or become recumbent. Attempts to move more severely affected animals may result in extreme pain, obvious anxiety, and possible exacerbation of the condition. Firm, painful muscles may be palpated over the back and hindlimb muscles. Scintigraphic evaluation of horses with rhabdomyolysis following exercise shows symmetric damage to the gluteal, semitendinosus, and semimembranosus muscles.[15] Myoglobinuria is a classic feature of more severely affected horses. Endurance horses often show other signs of exhaustion, including a rapid heart rate, dehydration, hyperthermia, synchronous diaphragmatic flutter, and collapse.[71]

FIG. 42.17 Exertional rhabdomyolysis in a horse showing signs of pain, stiffness, sweating, and elevated respiratory rate.

VetBooks.ir

Etiology

A number of factors appear to precipitate episodes of ER. Some successful athletic horses may experience one or two isolated episodes of rhabdomyolysis during their lifetime, suggesting that environmental influences play an important role in sporadic cases.[184-188] Other horses may have chronic episodes of rhabdomyolysis that compromise their ability to compete. An inherent muscle dysfunction precipitated by certain triggering factors likely contributes to rhabdomyolysis in these horses.[7,189,190] Thus ER is a description of a syndrome that has many causes. To identify the cause in individual horses, it may be helpful to initially subdivide cases into those with no intrinsic muscle abnormality (extrinsic or sporadic form) and those with a suspected intrinsic abnormality of muscle function (intrinsic or chronic form). Causes for sporadic and chronic exercise-induced muscle damage are listed in Box 42.2.

Sporadic Exertional Rhabdomyolysis

Most cases of ER can be diagnosed on the basis of the animal's history and clinical signs. Confirmation of rhabdomyolysis requires determination of abnormally elevated serum CK and/or AST. Serum CK is often in the tens to hundreds of thousands of IU/L and AST in the thousands to tens of thousands. The degree of elevation in enzymes reflects the time lapse between rhabdomyolysis and obtaining a blood sample, as well as the extent of myonecrosis. Myoglobinuria is a common finding in severely affected horses. Horses with sporadic forms of ER develop rhabdomyolysis because of an extrinsic event or recurring extrinsic events that induce muscle damage with exercise. Usually a horse is presumed to have sporadic ER the first time it develops ER.[14] If ER recurs once the horse has been rested and gradually returned to exercise, an investigation of an inherent chronic form of ER is usually pursued. Causes of sporadic ER include focal or generalized trauma to muscle, exercise performed beyond any training adaptation or performed to the point of exhaustion, and dietary imbalances that affect muscle function.

Signalment, History, and Diagnosis

Horses with sporadic ER may be of any age, breed, or sex and involved in a wide variety of athletic disciplines.[184] Sporadic ER usually occurs in horses with a history of adequate performance before onset of ER, and a familial history is absent. A diagnosis is made by history, clinical signs, and elevations of serum muscle enzymes. Once external perturbations that affect muscle function are corrected, complete resolution and a successful return to performance are expected. Resolution occurs following a reasonable period of rest, provision of a balanced diet, and a gradual introduction of a training program matched with performance demands. If over time ER recurs despite reasonable management, a diagnosis of chronic ER becomes more likely and further diagnostic testing is appropriate.

Causes

OVEREXERTION. A history of an increase in work intensity without a foundation of consistent training for this level of exercise is usually the basis for suspecting a training imbalance as a cause of ER. Signs of muscle stiffness and gait changes range from mild to severe, and severity is reflected by variable elevations of serum CK activity.[14] Overexertion is a well-described cause of ER in polo horses, with 81% of cases of ER attributed to overexertion and 30% of cases occurring after a day of rest.[188] The incidence of ER is as high as 9% in the United States polo horses, with most of these horses having only one episode of ER early in the polo season.[188]

Pathologic changes are often not evident in light microscopic evaluation of muscle biopsies from individuals performing unaccustomed exercise, but electron microscopy shows significant disruption of the alignment of muscle contractile proteins within muscle fibers. In more severe cases, overt segmental damage to myofibers may be apparent in muscle biopsy. Repetitive overuse of muscles, such as occurs with overtraining, may result in exercise intolerance and is associated with pathologic changes such as increased muscle fiber size variation and centrally located myonuclei in muscle biopsies.[191]

EXHAUSTION. Exhaustion occurs most commonly in endurance horses or racehorses exercising in hot, humid weather. Signs of heat exhaustion include weakness, ataxia, rapid breathing, muscle fasciculations, sweating, and in severe cases collapse. The body temperature may be elevated to 105° to 108° F. Muscles are frequently not firm on palpation, although serum CK activity can be markedly elevated and myoglobinuria may be noted.[71]

DIETARY IMBALANCES. Episodes of ER may be triggered by diets with a high nonstructural carbohydrate (NSC) content and low forage content,[192,193] as well as by diets deficient in electrolytes. They may be exacerbated by inadequate selenium and vitamin E. Electrolyte balance within the body is difficult to determine accurately. One suggested means to practically assess electrolyte balance in horses is to measure urinary fractional excretion of electrolytes.[194] Measurement of urinary electrolyte excretion as an indicator of electrolyte balance is complicated because marked variation can occur from diet, exercise, and sampling technique among individuals, as well as within individuals from day to day.[4] Furthermore, the high calcium crystal concentration of alkaline equine urine requires acidification to accurately assess calcium and magnesium content.[4] The high potassium content interferes with sodium analysis using conventional ion-specific electrodes.[7] Thus although popular in the 1990s,[3,194,195] urinary fractional excretion is now rarely performed in the United States unless there is a strong suspicion that body depletion has occurred and a laboratory with gas chromatography mass spectrometry analysis of acidified urine can be located. It is important to ensure that horses receive sodium chloride in the diet, with higher concentrations needed in horses that compete in hot, humid weather. Between 30 and 50 g/day combined with 15 to 25 g of "lite" salt containing potassium chloride is recommended for horses exercising in hot, humid conditions and sweating extensively. The entire diet should be adequately balanced with calcium and phosphorus (Ca/P ratio of 2:1 is ideal).

Whole blood selenium concentrations measured in ethylenediaminetetraacetic acid (EDTA) or heparin tubes are of value in assessing selenium status in animals housed in areas where soil is deficient in selenium. In cases where selenium has been administered before blood collection, glutathione peroxidase activity can be used to assess potential selenium deficiency.[196] Vitamin E concentration should be measured in serum samples kept chilled and protected from light; however, variability in serum levels can be quite large, and repeat sampling is recommended if marginal levels are identified in the first sample tested. Horses with ER are infrequently deficient in selenium and vitamin E, and alone it may not be responsible for ER[197]; however, anecdotal reports suggest that in some cases supplementation may help to further prevent episodes of ER.

Treatment

Treatment of ER is directed at relieving anxiety and muscle pain and replacing fluid and electrolyte losses. Tranquilizers such as acepromazine (0.04 to 0.06 mg/kg IM or IV), xylazine (0.5-1.1 mg/kg IV), or detomidine (0.02 to 0.04 mg/kg IV) combined with butorphanol (0.01 to 0.04 mg/kg) provide excellent sedation and analgesia. For horses with extreme pain and distress, a constant rate infusion of detomidine, lidocaine, or butorphanol may provide additional pain relief. NSAIDs such as ketoprofen (2.2 mg/kg IV), phenylbutazone (2.2 to 4.4 mg/kg IV or PO), and flunixin meglumine (1.1 mg/kg IV or PO) are frequently used to relieve pain but should

be used with caution on dehydrated animals. Intravenous or intragastric dimethyl sulfoxide (as a <10% solution) is used as an antioxidant, anti-inflammatory, and osmotic diuretic for severely affected horses. Methylprednisolone sodium succinate (2.2 to 4.4 mg/kg) has been advocated by some veterinarians in the acute stage if horses are recumbent. Muscle relaxants such as methocarbamol (5 to 22 mg/kg IV slowly) seem to produce variable results, possibly depending on the dosage used. The administration of dantrium sodium (2 to 4 mg/kg PO) in severely affected horses may decrease muscle contractures and possibly prevent further muscle necrosis. The dose can be repeated q8h to q24h if necessary. Overdosing produces muscle weakness.

Severe rhabdomyolysis can lead to renal compromise due to ischemic and combined nephrotoxic effects of myoglobinuria, dehydration, and NSAIDs. In mildly dehydrated horses, provision of free-choice electrolytes and water or administration of fluids via a nasogastric tube may be adequate. Horses with moderate to severe dehydration require IV administration of balanced polyionic electrolyte solutions. Hyperkalemia can occur with severe rhabdomyolysis, necessitating the use of isotonic sodium chloride. If hypocalcemia is present, then supplementing IV fluids (100 to 200 mL of 23% calcium borogluconate) is recommended, but serum calcium should not exceed a low normal range. Affected animals are usually alkalotic, making bicarbonate therapy inappropriate. In severely affected animals, regular monitoring of serum creatinine is advised to assess the extent of renal damage.

Following rhabdomyolysis, horses should be stall rested on a hay diet for a few days. Small paddock turnout in a quiet area for a few hours twice a day is then helpful. Horses may be hand walked at this time, but more than 5 to 10 minutes at a time may induce another episode of rhabdomyolysis. For horses with sporadic forms of tying-up, rest with regular access to a paddock should continue until serum muscle enzyme concentrations are normal. For chronic cases of tying-up, this much rest may not be appropriate. Training should be resumed gradually, and a regular exercise schedule that matches the degree of exertion to the horse's underlying state of training should be established. Endurance horses should be supplemented with electrolytes and water during an endurance ride and monitored particularly closely during hot, humid conditions.

Management Because the inciting cause is usually temporary in sporadic cases, most horses respond to a few weeks of rest, dietary adjustments, and a gradual increase in training. Regular access to a paddock once stiffness subsides and weekly monitoring of serum CK activity are recommended. Horses are much more susceptible to a second episode of ER in the 2 weeks following an acute episode, and allowing horses the ability to calmly determine their own exercise through turnout often avoids exacerbating rhabdomyolysis. If that is not feasible, hand walking needs to performed with caution and limited to no more than a few minutes initially. While the horse is rested, the diet can be assessed to ensure that the ration is fed in an amount recommended by the manufacturer for the corresponding level of exercise. This will ensure that the proper balance of vitamins and minerals is provided. If excessive calories are provided when fed at the manufacturer's recommended levels, the diet should be switched to a less calorie-dense vitamin/mineral balanced diet. A salt block or 30 to 50 g (1 to 3 tablespoons) of salt per day will provide the necessary additional sodium chloride, with the amount fed depending on the heat, humidity, and intensity of exercise. Once serum CK returns to normal, training can be resumed gradually. A regular exercise schedule, beginning with 20 minutes or less of exercise per day, is gradually increased to eventually match the expected amount of daily exercise to the underlying state of conditioning.

Chronic Exertional Rhabdomyolysis

Horses that have repeated episodes of ER from a young age, from the time of purchase, or after they are put back into training after a long period of rest may have an underlying intrinsic abnormality of muscle function. Many horses with intrinsic muscle defects will have repeated episodes of ER with minimal exercise even when the dietary and training recommendations for sporadic ER are followed. Five specific intrinsic causes of ER have been identified to date (see Box 42.2). Idiopathic ER represents other causes of ER that have yet to be identified. In all of these intrinsic forms of chronic ER, it appears that specific environmental stimuli are necessary to trigger muscle necrosis in genetically susceptible animals. Horses cannot be cured of their susceptibility to this condition, but if the specific form of ER is identified, changes in management can be implemented in order to minimize episodes of rhabdomyolysis.

Polysaccharide Storage Myopathy

Polysaccharide storage myopathy (PSSM) was first recognized as a specific myopathy in Quarter Horse–related breeds in 1992[198]; however, there are individual cases of abnormal polysaccharide inclusion reported in equine muscle dating back to 1979.[17,199,200] The remarkable feature of the first horses reported to have PSSM was twofold-higher muscle glycogen concentrations than normal horses and abnormal granular amylase-resistant inclusions in histologic sections.[198] Similar biopsy findings were reported in Belgian and Percheron draft horses in 1997.[201] Since that time, many hundreds of horses of a variety of breeds have been diagnosed with PSSM.

Terminology Several acronyms are used for polysaccharide storage myopathy besides PSSM,[202] including EPSM or EPSSM (equine polysaccharide storage myopathy).[192,203] Considerable controversy existed as to whether these acronyms encompassed one muscle condition.[192,193,204] In 2008 a mutation in the glycogen synthase 1 *(GYS1)* gene was found to be highly associated with the presence of amylase-resistant polysaccharide in skeletal muscle from Quarter Horses with PSSM.[205] Genetic testing of hundreds of horses previously diagnosed with PSSM by muscle biopsy revealed that the majority of cases of PSSM characterized by amylase-resistant polysaccharide in skeletal muscle had this genetic mutation.[206] However, some cases previously diagnosed with PSSM by muscle biopsy, particularly those with excessive amylase-sensitive glycogen, did not possess the genetic mutation. This suggested that there are at least two forms of PSSM.[206,207] For clarity, the form of PSSM caused by a *GYS1* gene mutation is now called *type 1 (PSSM1)*, whereas the form of PSSM not caused by the *GYS1* mutation and whose origin is yet unknown is now called *type 2 (PSSM2)*.[207] PSSM1 is likely the same disorder described as "azoturia" or "Monday morning disease" in workhorses in the nineteenth and twentieth centuries.[208]

Type 1 Polysaccharide Storage Myopathy

ETIOLOGY. PSSM1 is caused by a single-base-pair mutation in the *GYS1* gene resulting in an arginine to histidine substitution at codon 309. Horses with PSSM1 have a gain of function in glycogen synthase enzyme (in basal and stimulated states) because of an autosomal dominant mutation in the *GYS1* gene encoding glycogen synthase.[205] The higher than normal activity in both basal states and when activated by insulin and glucose 6-phosphate appears to have a novel link to the regulation of energy generation in muscle fibers. A deficit in energy metabolism represented by high myofiber inosine monophosphate was demonstrated in individual muscle fibers of horses with PSSM1 after light exercise in association with high serum CK activity.[209]

[a]Both randomized and nonrandomized samples.

Prevalence

PSSM1 is estimated to have emerged approximately 1600 years ago when the great horse was being developed from European draft and light horse breeds to carry knights with heavy armor into battle.[205] The highest prevalence of PSSM1 appears to occur in draft horses derived from Continental European breeds (Table 42.3).[210] In fact, many Continental European drafts are homozygous for the dominant PSSM1 trait (90% prevalence of PSSM in Trekpaards, with 40% of tested Belgian Trekpaards homozygous). North American Belgians and Percherons also have a high prevalence of PSSM1, with 36% and 54% of horses affected, respectively.[211] In contrast, the prevalence of PSSM is low in United Kingdom–derived breeds such as Shires and Clydesdales,[211] but PSSM1 is present in other U.K. horse breeds such as Irish Draught, Cob, and Connemara.[212] Numerous other breeds, more than 20 in fact, have the *GYS1* mutation responsible for PSSM1.

Prevalence estimates of PSSM1 in Quarter Horses range from 6% to 10% of the breed and 6% to 8% for Paints and Appaloosas.[56,213] The highest frequency of PSSM1 occurs in halter Quarter Horses (28% affected), and the lowest frequency occurs in racing Quarter Horses.[56] The *GYS1* mutation has been identified in approximately 72% of Quarter Horses diagnosed with PSSM by muscle biopsy and in 18% of warmbloods of a variety of types diagnosed with PSSM by muscle biopsy.[214] The prevalence of PSSM1 is very low to nonexistent in light horse breeds such as Arabians, Standardbreds, and Thoroughbreds (see Table 42.3).[215]

Risk Factors

Some horses with PSSM1 are asymptomatic, whereas other horses routinely show stiffness with exercise.[216,217] In a family of warmbloods sired by a stallion with the *GYS1* mutation, the mutation resulted in a sevenfold-higher risk of developing ER, with 34% of horses with the *GYS1* mutation lacking clinical signs of PSSM1.[217] The reason for variability in clinical signs of PSSM1 probably lies in the influence of diet, exercise, other environmental factors, and other genes on the expression of the disease.[192,218,219] There is no significant temperament, body type, or gender predilection for PSSM1.[8] The most common trigger for clinical signs of PSSM1 is less than 20 minutes of exercise at one time.[189,217] Clinical signs occur most commonly at a walk and trot, particularly if the horse has been rested for several days before exercise or is unfit. Diets high in NSCs also increase the risk of muscle pain and stiffness in PSSM1 horses.[218,220] About 40% of owners feel there is a seasonal incidence to the development of clinical signs, which some have attributed to quality of grass available at the time.[189,221] Although exercise is by far the most common trigger for PSSM, Quarter Horse and Paint foals and weanlings may develop rhabdomyolysis in conjunction with a systemic illness.[222]

Diagnosis

A high degree of suspicion of a diagnosis of PSSM1 arises from clinical signs and persistent elevations in serum CK and AST activities.[8,198,218] If horses have normal serum muscle enzymes at rest, an exercise test consisting of a maximum of 15 minutes lunging at a walk and trot may help to determine if subclinical ER is present.[7] Supportive evidence would include a minimum of a threefold elevation in CK activity 4 hours after exercise.

Muscle biopsy provides one means to diagnose PSSM1.[18,198,223] The distinctive features of PSSM1 in muscle biopsy samples are numerous subsarcolemmal vacuoles and dense, crystalline periodic acid–Schiff (PAS)–positive, amylase-resistant inclusions (Fig. 42.18, *A* and *B*). A diagnosis can be made irrespective of diet and proximity of sampling to recent episodes of rhabdomyolysis. A false-negative diagnosis of PSSM1 by muscle biopsy may occur if biopsy samples are small or if horses are younger than 1 year of age.[224]

The gold standard for diagnosis of PSSM1 is genetic testing for the *GYS1* mutation performed on whole blood or hair root samples. It is important to note that in draft horses of

Continental European origin, the very high prevalence of PSSM in essence means that there is a high chance that any clinical sign could be falsely associated with the disease PSSM1.[210] Thus clinical judgment is required to determine whether the clinical signs of the animal could reasonably be associated with a myopathic process.

Clinical Signs

ACUTE. On average, horses show signs of PSSM1 at 5 years of age; however, this can range from 1 to 14 years of age.[189] Acute clinical signs occur when horses are calm and include tucking up of the abdomen, fasciculations in the flank, muscle stiffness, sweating, reluctance to move forward, and overt firm muscle contractures (Fig. 42.19).[189] The hindquarters are frequently affected, but back, abdomen, and forelimb muscles may also be involved. Signs of pain can last for more than 2 hours, and about 10% of cases become recumbent.[189] Less common signs of PSSM in Quarter Horses include gait abnormalities, mild colic, and muscle wasting. During an acute episode of ER, horses with PSSM1 often have markedly elevated serum CK activity of greater than 35,000 U/L, and myoglobinuria may be present. Severe colic-like pain post exercise and myoglobinuric renal failure are less common presenting complaints.[8,225]

CHRONIC

Light Breeds. Chronic signs of PSSM1 in riding horses include a lack of energy when under saddle, reluctance to move forward, stopping and stretching out as if to urinate (see Fig. 42.19), and a sour attitude toward exercise.[189] Horses may have a combination of low-grade reluctance to exercise, poor performance, and repeated episodes of ER.[217,226] PSSM1 may also present in dressage and showjumpers as chronic back pain, failure to round over fences, and fasciculations or pain

FIG. 42.19 Typical stance of a horse with polysaccharide storage myopathy after 10 minutes of walking and trotting. Note the tucked-up abdomen and camped-out stance that were concurrent with firm muscles, fasciculations in the flank, and elevated serum CK activity.

on palpation of lumbar muscles.[227,228] The range of severity of clinical signs of PSSM1 can be wide, with complete incapacitation in rare cases. Serum CK activities are often elevated in unmanaged horses, even when horses are rested.[8] The median CK and AST activities for all PSSM1 Quarter Horses with muscle biopsies submitted to the Equine Neuromuscular Diagnostic Laboratory were 2809 and 1792 U/L, respectively.

A small number of Quarter Horses and Paints have both the *GYS1* mutation and the genetic mutation for malignant hyperthermia *(RYR1)*.[219] This results in particularly severe signs of ER and a limited response to diet and exercise changes. During an episode of ER, excessively high body temperatures may develop, and sudden death can occur in horses with the *RYR1* mutation. This combination occurs most often in halter and pleasure horses.

Draft Horse and Draft Crosses. The average age of draft horses diagnosed with PSSM is about 8 years of age. Many draft horses with PSSM are asymptomatic.[216] Signs of severe rhabdomyolysis and myoglobinuria may occur in horses that are fed high-grain diets, exercised irregularly with little turnout, or put under general anesthesia.[175,189] Rhabdomyolysis can be so severe that it leads to recumbency and death.[175] Other signs of PSSM in draft horses include progressive weakness and muscle loss resulting in difficulty rising in horses with normal serum CK activity. Clinical signs appear to be more severe in homozygotes.[229] Although the condition shivers was previously attributed to PSSM, a recent study found no causal association between these two conditions.[216] The median serum CK and AST activities in draft horses from which biopsies were sent to the Equine Neuromuscular Diagnostic Laboratory were 459 and 537 U/L, respectively.

Pathophysiology

A high-NSC diet increases the propensity to develop muscle pain with aerobic exercise in PSSM1 horses.[192,218] A potential scenario in PSSM1 horses on high-NSC diets could be that nutrient switches do not fully activate enzymes such as pyruvate dehydrogenase during exercise, limiting adequate acetyl-CoA for oxidative metabolism. Although acetyl-CoA could also be supplied by fatty acid oxidation, PSSM horses on high-NSC diets have low plasma nonesterified free fatty acid concentrations, possibly due to suppression of lipolysis by high insulin.[218] A further factor reducing fatty acid oxidation in PSSM horses on high-NSC diets could be that high muscle citrate concentrations direct acetyl-CoA away from the citric acid cycle toward malonyl-CoA, the committed step for fatty acid synthesis.[230] In addition, accumulation of malonyl-CoA causes inhibition of carnitine palmitoyltransferase, the key enzyme necessary to transport long-chain fatty acids into the mitochondria for β-oxidation.[231,232] Thus PSSM horses fed high-NSC diets may be unable to generate sufficient acetyl-CoA from either carbohydrate or fat metabolism to fuel muscle contraction during submaximal exercise. The common occurrence of clinical signs during the first 20 minutes of exercise may be because, at this stage of exercise, muscles rely heavily on glycogen and glucose for energy. Low dietary starch and fat supplementation decrease muscle citrate concentrations and increase plasma free fatty acid concentrations, which may well facilitate muscle fat metabolism in PSSM1 horses.[233]

TYPE 2 POLYSACCHARIDE STORAGE MYOPATHY.

Much less is known about type 2 PSSM because, as it turns out, previous research on PSSM has largely involved horses with type 1 PSSM. Current knowledge of type 2 PSSM is based on retrospective evaluation of cases diagnosed with PSSM by muscle biopsy that are now known to be free of the *GYS1* mutation and on a few years of prospective clinical cases.[223,227]

Prevalence

Approximately 28% of cases of PSSM diagnosed by muscle biopsy in Quarter Horses have PSSM2 because they do not have the *GYS1* mutation.[206] Type 2 PSSM seems to be common both in high-performance Quarter Horse types such as barrel racing, reining, and cutting horses and in pleasure and halter horses. In the United Kingdom approximately 35% of PSSM cases diagnosed by muscle biopsy have PSSM2.[212] Type 2 PSSM also occurs in Paints, Appaloosas, and Morgans. About 80% of cases of PSSM diagnosed by biopsy in warmbloods have PSSM2.[206] Breeds affected include Dutch Warmblood (highest prevalence), Swedish Warmblood, Selle Français, Hanoverian, Friesian, Westphalian, Canadian Warmblood, Irish Sport Horse, Gelderlander, and Icelandic horses. Many other light breeds have also been diagnosed with PSSM2, including Standardbreds, Thoroughbreds, and Arabians.

Pathogenesis

The cause or causes of PSSM2 are currently unknown. Muscle glycogen concentrations are not as high as those found in PSSM1, and glycogenolytic enzyme defects have not been identified in the few cases where enzymes were measured.[223] To date, the only reported abnormality in muscle ultrastructure is an increase in normal beta glycogen particles.[207] It may well be that a group of conditions currently captured under the term *type 2 PSSM* have separate etiologies but share common findings of glycogen accumulation and poor performance. A heritable predisposition is suspected in Quarter Horses but yet to be proven.

Clinical Signs

ACUTE.

In Quarter Horses, Thoroughbreds, Standardbreds, and Arabian horses, exertional rhabdomyolysis is the most common clinical sign of PSSM2.[223] In warmblood horses, episodes of exertional rhabdomyolysis are more intermittent in nature.[223]

CHRONIC.

Chronic signs of PSSM2 are often most closely related to poor performance rather than recurrent ER and elevations in serum CK activity. An undiagnosed gait abnormality, sore muscles, and drop in energy level and willingness to perform after 5 to 10 minutes of exercise are common complaints in horses with PSSM2.[223] Warmbloods with PSSM2 may also have painful, firm back and hindquarter muscles, reluctance to collect and engage the hindquarters, poor rounding over fences, gait abnormalities, and slow onset of atrophy. The mean age of onset of clinical signs in warmbloods is between 8 and 11 years of age, with the median CK and AST activities being 323 and 331 U/L, respectively.

Diagnosis

PSSM2 must be diagnosed by muscle biopsy where increased or abnormal PAS-positive material that is usually amylase sensitive is apparent (see Fig. 42.18, *C* and *D*).[207] Determination of what constitutes an abnormal amount of amylase-sensitive glycogen is subjective, the specificity of the diagnosis may be low, and false-positive diagnoses may occur. Consideration should be made for state of training because highly trained horses have increased glycogen storages as a normal response to training. Further, glycogen is commonly found near capillaries in normal horses, and PAS-positive sarcoplasmic masses can be found in 60% of healthy horses, so these should not be diagnostic criteria for PSSM2.[234] Formalin-fixed sections show a greater deposition of subsarcolemmal glycogen and precipitation of glycogen in one area of a fiber even in healthy horses, and these should not be considered diagnostic criteria for PSSM2.[18] Other histopathologic features that may be present with PSSM2 include centrally located nuclei, subsarcolemmal vacuoles, muscle necrosis, macrophage infiltration of myofibers, regenerative fibers, and fiber atrophy.[223] Some laboratories grade polysaccharide accumulation as mild, moderate, and severe, where mild accumulation represents a category that has a higher chance of being a false-positive diagnosis. Mild PSSM cases in particular should receive a

full physical examination to ensure that there are no other underlying causes for performance problems.

MANAGEMENT OF TYPE 1 AND TYPE 2 POLYSACCHARIDE STORAGE MYOPATHY. Owners need to be aware that any horse diagnosed with PSSM will always have an underlying predilection for muscle soreness. The best that can be done is to manage horses in the most appropriate fashion to minimize clinical signs. With adherence to both diet and exercise recommendations provided in this chapter, at least 70% of horses show notable improvement in clinical signs and many return to acceptable levels of performance.[189,192,227] There is, however, a wide range in the severity of clinical signs shown by horses with PSSM; those horses with severe or recurrent clinical signs will require more stringent adherence to diet and exercise recommendations in order to regain muscle function.

REST. PSSM horses that are confined for days to weeks following an episode of rhabdomyolysis often have persistently elevated serum CK activity.[224] In contrast, PSSM horses kept on pasture with little grain supplementation often show few clinical signs of rhabdomyolysis and have normal serum CK activity.[224] As a result, a common recommendation for horses with PSSM is to limit stall confinement to less than 48 hours after an episode of rhabdomyolysis and then provide turnout in paddocks of gradually increasing size. Providing horses with as much free exercise as possible on pasture appears to be beneficial in the long term. If pasture is lush, a grazing muzzle may be necessary.[226] Following an acute episode, excitable horses may require tranquilization before turnout to avoid excessive galloping. Hand walking horses initially recovering from an episode of PSSM for more than 5 to 10 minutes at a time may trigger another episode of rhabdomyolysis.

EXERCISE. The beneficial response to low-starch, fat-supplemented diets only occurs if it is instituted in conjunction with a regular incremental exercise program.[218] Regular daily exercise in PSSM horses over a 3-week period has been shown to produce a dramatic decrease in serum CK responses to exercise, whereas stall confinement often causes elevations in serum CK activity post exercise.[218,224] One common adaptation to daily training is an increase in oxidative capacity in skeletal muscle. The activity of these enzymes, however, was equally low in control Quarter Horses. Whether the beneficial effect of daily exercise on PSSM horses is a result of improved oxidative enzyme capacities or enhanced substrate flux or both has not been elucidated.

EXERCISE REGIMENS. Important principles to follow when starting exercise programs in PSSM horses include to (1) provide adequate time for adaptation to a new diet before commencing exercise; (2) recognize that the duration of exercise, not its intensity, is of primary importance; (3) ensure the program is gradually introduced and consistently performed; and (4) minimize any days without some form of exercise. If horses have experienced a moderate to marked episode of rhabdomyolysis recently, 2 weeks of turnout and diet change are often beneficial before recommencing exercise. Exercise should be relaxed, and the horse should achieve a long, low frame without collection. For many horses this is most readily done in a round pen or on a lunge line, but it can be done under saddle if needed. Successive daily addition of 2-minute intervals of walk and trot beginning with only 4 minutes of exercise and working up to 30 minutes after 3 weeks is often recommended.[8,14] If horses had minor elevations in 4-hour postexercise CK with the 15-minute exercise test, they may begin at 15 minutes of exercise. Owners often do not recognize that walking the horse for 10 minutes or more initially can trigger muscle soreness in PSSM horses. Advancing the horse too quickly often results in an episode of rhabdomyolysis and repeated frustration for the owner. Work can usually begin under saddle after 3 weeks of ground work and can gradually be increased by adding 2-minute intervals of collection or canter to the initial relaxed warm-up period at a walk and trot. Unless a horse shows an episode of overt rhabdomyolysis during the initial 4 weeks of exercise, reevaluating serum CK activity is not helpful for the first month. This is because it is common to have subclinical elevations in CK activity when exercise is reintroduced, and a return to normal levels often requires 4 to 6 weeks of gradual exercise.[8] Keeping horses with PSSM fit seems the best prevention against further episodes of rhabdomyolysis.

DIETS FOR POLYSACCHARIDE STORAGE MYOPATHY. The basis for designing PSSM diets is the belief that lowering the daily starch and sugar intake and increasing dietary fat content will decrease the glucose load, increase the availability of nonesterified fatty acid for muscle metabolism, and lower serum insulin concentrations.[218] Quarter Horses naturally have little lipid stored within muscle fibers. The end result would thus be decreased uptake of glucose into muscle cells, less substrate available for—and stimulation of—glycogen synthesis, and normalization of substrate flux. Owners report that this type of diet improves clinical signs of muscle pain, stiffness, and exercise tolerance in draft horses, warmbloods, Quarter Horses, and other breeds.[189,192,217,227] Dietary change appears to have less impact on alleviating gait changes such as shivers.[227]

CALORIC BALANCE. The horse's caloric requirements at an ideal body weight are the most important considerations in designing the diet for PSSM. This is because many horses with PSSM are easy keepers and may be overweight at the time of diagnosis. Adding excessive calories in the form of fat to an obese horse may produce metabolic syndrome and is contraindicated. If necessary, caloric intake should be reduced by using a grazing muzzle during turnout, feeding hay with a low NSC content at 1% to 1.5% of body weight, providing a low-calorie ration balancer, and gradually introducing daily exercise. Rather than provide dietary fat to an overweight horse, fasting for 6 hours before exercise can be used to elevate plasma free fatty acids before exercise and alleviate any restrictions in energy metabolism in muscle.

SELECTION OF FORAGE. Quarter Horses have been shown to develop a significant increase in serum insulin concentrations in response to consuming hay with an NSC of 17%, whereas insulin concentrations are fairly stable when fed hay with 12% or 4% NSC content.[220] Because insulin stimulates the already overactive enzyme glycogen synthase in the muscle of PSSM1 horses, selecting hay with 12% or less NSC is advisable. The degree to which the NSC content of hay should be restricted below 12% NSC depends on the caloric requirements of the horse. Feeding a low-NSC hay of 4% provides room to add an adequate amount of fat to the diet of easy keepers without exceeding the daily caloric requirement and inducing excessive weight gain. For example, a 500-kg horse on a routine of light exercise generally requires 18 Mcal/day of digestible energy (DE). Fed at 2% of body weight, a 12% NSC mixed grass hay almost meets the daily caloric requirement by providing 17.4 Mcal/day. Thus with a 12% NSC hay there is only room for 0.6 Mcal of fat per day (72 mL of vegetable oil) in order to achieve 18 Mcal of energy. In contrast, a 4% NSC Blue Grama hay would provide 13.5 Mcal/day, which would allow a reasonable addition of 4.5 Mcal of fat per day (538 mL of vegetable oil).

SELECTION OF FAT SOURCE. High-fat diets increase plasma free fatty acid concentrations and thus the availability of fats for oxidation in skeletal muscle.[218] Long-chain fat diets also appear to increase glycogenolytic, glycolytic, and oxidative flux

in PSSM1 muscle as shown by higher glucose 6-phospate, lower lactate, and higher pyruvate concentrations in the muscle of PSSM1 horses fed and trained on a commercial high-fat diet (Re-Leve [Kentucky Equine Research, Versailles, Ky.]) compared with sweet feed.[220] Thus one means to overcoming limitations in delivery of oxidative substrates in PSSM1 horses is to provide ample long-chain fat in the diet. The major sources of dietary fat for horses are vegetable based, including vegetable oils and rice bran or animal-based fat (tallow [solid rendered fat of cattle and sheep], lard, fish oil). Vegetable oils are highly unsaturated, very digestible (90% to 100%), and very energy dense. Suitable forms include soybean, corn, safflower, canola, flaxseed, linseed, peanut, and coconut. Controlled research studies in exercising PSSM horses have shown a decrease in muscle pain and serum CK in response to the addition of corn oil[233] and also a concentrate of soybean oil and rice bran (Re-Leve).[218] The amount of oil added in these trials constituted at least 13% of daily DE. Some veterinarians have advocated that as much as 25% of DE be fed in the form of fat to PSSM horses.[193] As discussed earlier, the principal consideration here should be whether this provides excessive calories and additional weight gain because feeding 13% DE as fat may well be effective in reducing muscle pain. Limited research has been performed on the form of oil to feed PSSM horses. Whether there is any direct beneficial effect on skeletal muscle of providing energy in the form of omega-3 versus omega-6 fatty acids has yet to be determined. Due to the potential additional oxidant stress of fats, vitamin E (1000 to 5000 U/day) should be fed to horses receiving high-oil diets.

LOW-STARCH, HIGH-FAT CONCENTRATES. Although oils are energy dense and inexpensive, they have the disadvantages of being messy, unpalatable to some horses, prone to rancidity in warm temperatures, and difficult to feed in large amounts. As such, a number of concentrates that contain fats have been developed. The important principle to be met by such feeds is that the starch and sugar components are low enough and the fat supplementation high enough to ensure that in the total diet, the calories supplied by NSC comprise no more than 10% to 15% of the daily DE and the calories supplied by fat comprise about 12% to 15% of daily DE.[218] Common fat sources used in such concentrates include, in addition to the oils mentioned earlier, stabilized rice bran or animal fats. Rice bran and its products are palatable to most horses, have a moderate NSC content approximately 25% by weight, contain approximately 20% fat by weight, as well as vitamin E, and are naturally high in phosphorus. The NSC component of rice bran can vary if the manufacturing process is not careful to exclude the white rice grain. Commercial rice bran products occur as powder or an extruded pellet and are considerably more stable in warm temperatures compared with animal fat and vegetable oils. A number of well-balanced, low-starch, high-fat commercial diets are suitable for horses with PSSM.[218] Some commercial feeds meet the recommended nutritional needs of PSSM horses in one pelleted ration. These feeds typically contain at least 10% to 15% fat by weight and less than 20% NSC by weight. Some feed companies offer similar nutritional content by blending two or more manufactured feeds or by supplementing with oils or rice bran. At present, the NSC content of equine feed products is not consistently listed on the feed tag, and consultation with the feed manufacturer is necessary to obtain this information. Nutritional support is available through most feed manufacturers in designing an appropriate diet. There is a great deal of variation in individual tolerance to dietary starch; however, horses with more severe clinical signs of PSSM appear to require the greatest restriction in starch intake.

EXPECTATIONS. The beneficial effects of low-starch, high-fat diets require that horses are trained daily to enhance enzymes involved in fat and glucose metabolism. It is important to note that a horse diagnosed with PSSM will always have an underlying predilection for muscle soreness, and the best that can be done is to manage horses to minimize clinical signs. With adherence to both diet and exercise recommendations, 70% to 75% of Quarter Horses and warmbloods show notable improvement in clinical signs, and many return to acceptable levels of performance.[189,193,226,227] There is, however, a wide range in the severity of clinical signs shown by horses with PSSM; those horses with severe or recurrent clinical signs will require more stringent adherence to diet and exercise recommendations in order to regain muscle function. PSSM horses that also have the mutation for malignant hyperthermia do not respond as well to diet and exercise recommendations and may continue to develop ER with the possibility of a fatal episode.[207]

Myofibrillar Myopathy

Myofibrillar myopathy (MFM) is a recently identified disorder in horses presenting with exercise intolerance or intermittent ER that is defined by specific histopathology.[235-237] First and foremost, MFM horses have cytoplasmic aggregates of the cytoskeletal protein desmin in scattered muscle fibers. Desmin functions to align sarcomeres at the Z-disc and tether them to the cell membrane. Other ultrastructural derangements evident in electron microscopy include disrupted myofibrillar alignment, ectopic accumulation of cytoskeletal proteins and Z-disc degeneration. In some cases, MFM is also characterized by cytoplasmic aggregates of glycogen similar to PSSM2.[235,237] This is likely because pools of glycogen form within disrupted myofibrils. MFM may represent a more extreme subset of PSSM2. Muscle glycogen concentrations in horses with MFM are similar to controls.

Warmblood horses diagnosed with MFM have an insidious onset of exercise intolerance notable by 6 to 8 years of age characterized by lack of stamina, unwillingness to go forward, inability to collect, abnormal canter transitions, and inability to sustain a normal canter.[237] Unresolved hindlimb lameness, stiffness, muscle pain, and, rarely, an episode of ER are reported. Serum CK and AST activities are usually within normal limits unless samples are taken in conjunction with ER.[237]

Arabian endurance horses diagnosed with MFM usually have a history of intermittent elevations in serum CK activity after endurance rides (>10,000 U/L) or during exercise that follows a week or more of rest.[235,236] Horses do not necessarily always show the same degree of pain, sweating, and reluctance to move as is frequently seen in other forms of acute ER. Myoglobinuria can be observed in horses with only mild muscle stiffness. Between episodes, the heart rate, lactate, CK, and AST responses to exercise are normal.[236]

The best means to manage horses with MFM has yet to be determined. Many horses have been managed in a way similar to horses with PSSM2. There is no information to suggest that limiting NSC or the addition of fat is necessarily of benefit to horses with MFM. The addition of an amino acid supplement (whey based) is currently being tried as a mechanism to enhance turnover and regeneration of myofibrils within muscle cells.[237]

Recurrent Exertional Rhabdomyolysis

The term *recurrent exertional rhabdomyolysis* (RER) describes a subset of ER that is believed to be due to an abnormality in the regulation of muscle contraction and relaxation.[7,19,21,238] Research into RER has primarily been performed in Thoroughbreds and, to a lesser extent, Standardbreds.[21,187,215,239] Scientific studies of RER have used a small number of horses that share common clinical signs of ER and have abnormal muscle contracture tests.[19-21] Broader epidemiologic and genetic studies have assumed that the same pathophysiologic basis for ER exists in

the majority of Thoroughbreds and Standardbreds with similar clinical signs. Whether this is true or not will require more research. There are reports of some Arabians and warmbloods with ER that may also suffer from RER on the basis of overlapping histories, clinical signs, muscle biopsy findings, and response to management.[227]

Pathogenesis

Rhabdomyolysis is triggered suddenly during exercise in RER horses, which results in a sharp rise in serum myoglobin and CK activity.[6] Clinically, the triggering event is often associated with excitement in a horse that already has an underlying nervous temperament.[187,215,239] Serum cortisol concentrations are higher in RER horses than normal horses before exercise and increase during an episode of ER.[240] Serum concentrations of epinephrine and norepinephrine are normal before an episode but increase dramatically in horses with marked elevations in serum CK activity.[240]

EXERCISE AND EXCITEMENT. In Standardbreds, ER commonly begins after 15 to 30 minutes of jogging at 5 m/s, although clinical signs may not be apparent until after exercise.[6,215] In Thoroughbreds exercising on the treadmill, ER most commonly develops with intervals of walk, trot, and canter and is less common if horses are allowed to gallop.[241,242] At the racetrack, ER occurs commonly when RER horses are held back to a paced gallop.[243] During eventing, RER commonly occurs after the excitement of the steeplechase or early in the cross-country phase when horses are held to a predetermined speed. ER rarely occurs when horses are allowed to achieve maximal exercise speeds, such as in racing.[187,215,242-244] A day or more of rest before this type of exercise results in higher serum CK activity post exercise.[215,242]

There is no basis for an association between RER and lactic acidosis.[242]

INTRACELLULAR CALCIUM REGULATION. Horses with RER are believed to have an intrinsic abnormality in intramuscular calcium regulation that is intermittently manifested during exercise.[19,245] Basal muscle intracellular calcium concentrations in RER horses are similar to healthy horses on the basis of assays in muscle cell cultures.[245] Higher intracellular calcium concentrations have been measured in horses of unspecified breeds during an episode of ER[246]; however, this also could be secondary to any insult that impairs energy generation or cell membrane integrity. Contracture testing has been performed in horses using surgically excised bundles of semimembranosus[21] or external intercostal muscle.[247] Waldron-Mease and colleagues[248] and Beech and colleagues[21] found that caffeine contracture thresholds were lower in semimembranosus muscle from Thoroughbreds and Standardbreds susceptible to RER versus breed-matched controls. Lentz and colleagues studied intact external intercostal muscle fibers from six Thoroughbreds with RER and found a lower contracture threshold for triggering agents such as potassium, caffeine, and halothane compared with control horses.[19] An abnormality in intracellular calcium regulation was also supported by a muscle cell culture study of RER Thoroughbred horses.[245] A lower threshold for induction of myoplasmic calcium release by caffeine was found in myotube cultures from six RER Thoroughbreds compared with controls. Thus all of these studies supported an abnormality in intracellular calcium regulation in most of the Thoroughbred or Standardbred horses studied. However, studies of isolated muscle membranes have not conclusively identified any specific abnormalities in intracellular calcium regulation in RER horses.[171] Further, genetic linkage analysis using 96 horses in 4 families of Thoroughbred horses segregating for RER did not find an association linking RER with the calcium regulatory genes *RYR1* (ryanodine receptor), *SERCA* (SR ATPase), or *DHPR1* (dihydropyridine receptor).[249] Thus in spite of many detailed investigations of a small number of horses, the exact defect in regulating muscle contraction in RER horses has yet to be identified.

Prevalence and Risk Factors

Assuming that the majority of cases of ER at racetracks are due to RER, the prevalence in Thoroughbred racehorses is remarkably similar around the world, with estimates ranging from 4.9% in the United States[239] to 5.4% in Australia[184] to 6.7% in the United Kingdom.[187,244] The annual incidence of ER in Standardbred racehorses in Sweden is 6.4%.[215] Exercise obviously increases the prevalence of RER in horses, and episodes are observed more frequently once horses achieve a level of fitness.[215,239]

In Standardbreds and Thoroughbreds, mares more commonly have RER than males,[187,215,239] but no general correlation has been observed between episodes of rhabdomyolysis and stages of the estrus cycle.[250] There is an interaction between age and gender in RER Thoroughbred horses such that the proportion of affected females to males is much higher in young horses compared with older age groups.[239] Swedish Standardbreds with RER, which do not begin racing until 3 years of age, did not show the same age association with RER as Thoroughbreds.[215] Temperament has a strong effect on the expression of RER in both Standardbreds and Thoroughbreds, with nervous horses, particularly fillies, having a higher incidence of rhabdomyolysis than calm horses.[187,215,239] Young fillies are more likely to have a nervous temperament than mares or male horses. Diet also has an impact, with Thoroughbred horses fed more than 2.5 kg of grain per day being more likely to show signs of RER.[241,242] One study also found a higher prevalence of rhabdomyolysis among Thoroughbred horses with lameness.[243] A few days of rest before exercise increases the degree of elevation on serum CK activity with the next exercise session and in practice predisposes horses to an episode of ER.[242]

Genetics

A genetic susceptibility to RER has been suggested for Thoroughbred horses.[190,251-253] Standardbred trotters with a history of RER actually have faster racing times from a standstill start than those without a history of RER, suggesting the trait may have beneficial and deleterious effects.[215] The variable penetrance of RER, however, and other potential modifying genes have made a genetic basis for RER suspected but difficult to identify.[254]

Diagnosis

A presumptive diagnosis of RER is based on clinical signs of muscle pain and the presence of risk factors commonly associated with RER. Muscle histopathology is nonspecific in RER horses; either no abnormalities or evidence of centrally located nuclei in mature fibers and potentially waves of myofiber degeneration or regeneration is found.[7] There is a notable absence of abnormal amylase-resistant polysaccharide, although increased subsarcolemmal amylase-sensitive glycogen may be present.[7] The value of a muscle biopsy as a diagnostic tool in horses with suspected RER is largely confined to particularly recurrent unmanageable cases where a need arises to rule in or out other forms of ER. Serum CK and AST activities serve as the basis for detecting muscle degeneration, and they often show intermittent abnormal elevations that return to normal relatively quickly during the course of training. If CK elevations are mild, there are a number of factors to consider. Timing of the sample with regard to the onset of ER and exercise are important. Reliability is improved by obtaining blood samples at a standardized time after exercise, preferably 4 to 6 hours when CK peaks, and consistently with regard to exercise on the preceding day because serum CK activity is higher on exercise days that are preceded by a day or more of rest.[186] In addition, normal values need to be adjusted for the age and sex of horses. Two-year-old

fillies generally have greater fluctuations in serum CK activity during race training than 3-year-old fillies or geldings.[186]

Management

Prevention of rhabdomyolysis in horses susceptible to RER is complex, and multiple factors need to be changed to decrease episodes. These factors include the environment, the exercise regimen, and diet. In addition, medication may be necessary at times to prevent further episodes of muscle damage.

ENVIRONMENT. Because excitement and nervousness often trigger rhabdomyolysis, stressful situations in the environment that can be modified need to be identified. This may involve a change to a smaller barn with fewer horses and fewer handlers, compatible companions, and a more consistent daily routine. Many stressed RER-susceptible horses respond to a regular routine, including feeding first before other horses and training first before other horses, especially if the horse becomes impatient while waiting. Other horses respond to being housed in a quiet area of the barn next to calm, companionable horses. The use of hot walkers, exercise machines, and swimming pools needs to be evaluated on an individual basis because some horses develop rhabdomyolysis when using this type of equipment. Horses that develop rhabdomyolysis at specific events, such as horse shows, may need to be reconditioned to decrease the stress level associated with such events or tranquilized as part of the accommodation process. Providing daily turnout with other horses seems to be beneficial for RER horses and may decrease anxiety and thereby the likelihood of rhabdomyolysis.

EXERCISE. Although a period of rest is recommended for sporadic forms of ER until serum CK normalizes, it is not recommended for horses with RER.[14] Daily exercise is important in preventing episodes of rhabdomyolysis, and therefore when serum CK is less than about 3000 U/L, horses are returned to regular daily exercise. Horses with more severe episodes of rhabdomyolysis may require additional time off in a paddock before gradually resuming exercise. Once back in training, some form of daily exercise is recommended. Avoiding fighting to hold racehorses to slower speeds during galloping may decrease rhabdomyolysis in RER-susceptible Thoroughbreds. Interval training and reduction of jog miles to no more than 15 minutes per session will benefit Standardbreds. For horses under saddle, a relaxed warm-up with intermittent periods of long, low stretching may be of benefit, and continued breaks to stretch between episodes of collection are recommended. Event horses may require training that incorporates calm exposure to speeds achieved during the steeplechase or cross-country phase, especially when used in an interval training program.

DIET. A nutritionally balanced diet with appropriate caloric intake and adequate vitamins and minerals are the core elements of managing RER. For RER Thoroughbreds and Standardbreds in training, the challenge is usually supplying enough calories in a highly palatable form to meet their daily energy demands. This is in part because they often require more than 30 Mcal of digestible energy (DE) a day (5 kg sweet feed, 1.5% of body weight in hay) and, due to their nervous temperament, they may be more discriminating in their eating habits. Out of the total daily calories required by RER horses, research suggests that less than 20% DE be supplied by NSCs (starch and sugar) and at least 20% of DE be supplied by fat.[242]

Selection of Forage. Thoroughbred horses do not appear to show the same significant increase in serum insulin concentrations in response to consuming hay with an NSC of 17% that is seen in Quarter Horses (Borgia L, 2010 PhD thesis, University of Minnesota). This fact combined with the high caloric requirements of racehorses may mean that it is not as important to select hay with very low NSC content in RER Thoroughbreds as it is in PSSM horses. Anecdotally, some trainers find that horses with RER have more frequent episodes on alfalfa hay. The nervous disposition of some RER horses may predispose them to gastric ulcers, and thus frequent provision of hay with a moderate NSC and mixed alfalfa content may be indicated.

Low-Starch, High-Fat Concentrates. When RER Thoroughbreds are fed a moderate caloric intake (24 Mcal/day) in the form of high-starch concentrates (2.5 kg of corn, oats, wheat middlings, and molasses), they show little elevation in serum CK activity with exercise.[241] Most Thoroughbred racehorses, however, are fed at least 5 kg of high-starch concentrate per day at 30 Mcal or more per horse per day, and at this level of feeding postexercise serum CK activity rises significantly.[242] The discovery that substitution of fat for starch in a high-calorie ration significantly reduces muscle damage in exercising RER horses was a major advance in nutritional management of RER.[242] Practically, however, it was difficult to achieve the desired caloric intake of racehorses because the maximum amount of fat that finicky Thoroughbreds will happily consume is limited often to 600 mL of vegetable oil or 5 lb/day of balanced rice bran. Management of RER horses was significantly improved when a palatable means to provide the amount of fat required by fit, finicky RER Thoroughbreds was developed. A controlled trial using a specialized feed developed for RER (Re-Leve: 13% fat by weight and 9% NSC) determined that NSC should be no greater than 20% of daily DE and that 20% to 25% of daily DE should be provided by fat for optimal management of RER horses fed 30 Mcal or more per day.[242] No beneficial effect on serum CK activity occurred when sodium bicarbonate (4.2% of the pellet) was added to a high-starch pellet feed.[242] The amount of fat in the diet of an RER horse depends on its caloric requirements. Over and above hay at 1.5% to 2% of body weight and 2.5 kg of grain, any additional calories should be supplied by fat.

The benefit of a fat diet does not appear to be a change in muscle metabolism. Muscle glycogen and lactate concentrations before and after exercise are the same in RER horses fed a low-starch, high-fat diet compared to those fed a high-starch diet.[242,255] Rather, low-starch, high-fat diets in RER horses may decrease muscle damage by assuaging anxiety and excitability, which are tightly linked to developing rhabdomyolysis in susceptible horses. Low-starch, high-fat diets fed to fit RER horses produce lower glucose, insulin, and cortisol responses and lead to a calmer demeanor and lower preexercise heart rates.[256] Neurohormonal changes may develop in response to high serum glucose, insulin, and cortisol concentrations, resulting in an anxious demeanor. Although a calm demeanor is desired during training, some racehorse trainers feeding low-starch, high-fat feeds prefer to supplement with a titrated amount of grain 3 days before a race to potentially increase liver glycogen and increase a horse's energy during the race.

Expectations. Studies in RER horses show that significant reductions or normalization of postexercise serum CK activity occurs within a week of commencing a low-starch, high-fat diet.[242] Days off training in a stall are discouraged because postexercise CK activity is higher following 2 days of rest compared with values taken when performing consecutive days of the same amount of submaximal exercise.

SUPPLEMENTS. Horses require daily dietary supplementation with sodium and chloride in the form of either loose salt (30 to 50 g/day) or a salt block. Additional electrolyte supplementation is indicated in hot, humid conditions. A myriad of supplements that are purported to decrease lactic acid buildup in skeletal muscle of RER horses are sold. These include sodium bicarbonate, B vitamins, branched-chain amino acids, and

VetBooks.ir

dimethylglycine. Because lactic acidosis is no longer implicated as a cause for rhabdomyolysis, it is difficult to find a rationale for use of these supplements.

MEDICATIONS. Low doses of tranquilizers such as acepromazine before exercise have been used in RER horses prone to excitement.[257] A dose of 7 mg IV 20 minutes before exercise is reported to make horses more relaxed and manageable. Reserpine and fluphenazine, which have a longer duration of effect, have also been used for this purpose. Horses given fluphenazine may occasionally exhibit prolonged bizarre behavior. Use of tranquilizers may be necessary only when horses are in their initial phase of training and accommodating to a new environment. Horses obviously cannot compete on these medications, and withdrawal times must be observed.

Dantrium sodium acts to decrease release of calcium from the ryanodine receptor in skeletal muscle and is used to treat malignant hyperthermia. Controlled and field studies have shown that oral dantrolene can significantly decrease signs of rhabdomyolysis in RER horses.[168,258,259] One study indicated that horses need to be fasted to achieve measurable blood levels of dantrolene,[168] but more recent controlled trials suggest that absorption of dantrium is superior in fed versus fasted horses.[258] Administration of 4 mg/kg of dantrium PO 1 hour before exercise to RER-susceptible horses fed high-grain diets resulted in significantly lower serum CK activity 4 hours after exercise compared with placebo.[168] A dose of 800 mg of dantrium was given to Thoroughbred horses in the United Kingdom 1 hour before exercise and resulted in significantly lower postexercise CK activity than a placebo.[259]

Phenytoin has been reported to be effective in preventing rhabdomyolysis in horses with RER.[260] Phenytoin acts on a number of ion channels within muscle and nerves, including sodium and calcium channels. Therapeutic levels vary, so oral doses are adjusted by monitoring serum levels to achieve 8 µg/mL, not to exceed 12 µg/mL.[260] Drowsiness and ataxia are evidence that the dose of phenytoin is too high, and the dose should be decreased by half. Initial dosages are 6 to 8 mg/kg PO twice a day for 3 to 5 days, and if the horse is still experiencing rhabdomyolysis but is not drowsy, the dose can be increased by 1-mg/kg increments every 3 to 4 days. Most horses require a dose of 10 to 12 mg/kg PO twice daily (bid). Phenytoin is a monoaminoxidase activator and can affect dosages of other medications. Unfortunately, long-term treatment with dantrolene or phenytoin is expensive, and these drugs must be withdrawn before competition.

HORMONE THERAPY. Various hormones, ranging from thyroxine to progesterone and testosterone, have been given to horses with RER. Initial studies linking low T3 and T4 concentrations in horses with ER have not been substantiated.[261-263] Some mares appear to exhibit signs of rhabdomyolysis during estrus, and it may well be of benefit in these horses to suppress estrous behavior using progesterone injections. Testosterone and anabolic steroids have been used at racetracks to prevent signs of RER, but their use is no longer permitted.

ADJUNCT THERAPIES. Massage, myofascial release, mesotherapy, stretching, aqua treadmills, and hot/cold therapy performed by experienced therapists may be of benefit in individual cases.[264-266] Their use may promote relaxation and normal muscle tension and build muscle strength.

Malignant Hyperthermia

Malignant hyperthermia (*RYR1* mutation) in Quarter Horses and Paints has also been linked to exertional rhabdomyolysis.[173,174] It is caused by an autosomal dominant mutation that exists in exon 46 of the skeletal muscle *RYR1* gene on ECA 10.

Prevalence and Risk Factors Malignant hyperthermia is a rare disorder in Quarter Horses and Paints, affecting less than 1% of the breed. Halter and pleasure horse lines have the highest prevalence. Rhabdomyolysis may be induced by exercise and anesthesia but can be extremely intermittent in nature.[173]

Clinical Signs Horses with the *RYR1* mutation may intermittently show signs of ER and high body temperatures.[173,174] Some horses affected with malignant hyperthermia have died suddenly after an episode of ER. Horses with the *RYR1* mutation may also have the *GYS1* mutation associated with PSSM1.[219] Such horses have more severe episodes of ER, higher serum CK activity after exercise, and a more moderated response to the diet and exercise regimens recommended for PSSM1.[219]

Diagnosis Genetic testing is recommended in Quarter Horses and Paints with difficult-to-manage forms of PSSM or a family history of postanesthetic complications. Muscle biopsy is not particularly useful for diagnosing malignant hyperthermia. Biopsies may contain mild myopathic changes, including increased variation in fiber sizes, centrally located nuclei, fiber necrosis, glycogen depletion, and ringbinden fibers.[174]

Treatment The nature of ER with horses positive for malignant hyperthermia is so intermittent that it is hard to justify premedication with dantrolene before exercise.

Hereditary and Congenital Myopathies

Stephanie J. Valberg

Mitochondrial Myopathy

A deficiency of complex I, the first step in the mitochondrial respiratory chain, has been identified in a young Arabian filly that was presented for veterinary attention with clinical signs similar to ER.[267] In contrast to cases of ER, however, this horse showed no changes in serum CK following exercise. A marked lactic acidosis developed even with light exercise, and maximum oxygen consumption was drastically reduced, resulting in marked exercise intolerance. Histopathologic evaluation of muscle biopsies showed an abnormal increase in mitochondrial density, and biochemical analyses revealed a complex I deficiency. The horse has shown slowly progressive signs of muscle atrophy but has otherwise remained healthy at rest.

Glycogen Branching Enzyme Deficiency

Glycogen branching enzyme deficiency (GBED) is a glycogen storage disorder causing abortion, seizures, and muscle weakness in Quarter Horse–related breeds.[268-270] It represents a separate glycogen storage disorder from PSSM. GBED is caused by a nonsense mutation in exon 1 of the *GBE1* gene at codon 102, which introduces a premature stop codon.[270] Nine percent of the breed is a carrier of this autosomal recessive mutation, and 3% of abortions are attributed to this disease in Quarter Horses.[268] The prevalence of carriers is particularly high in pleasure horses, with 26% of pleasure horses carrying the *GBE1* mutation.[56] Most foals diagnosed with GBED have presented with hypothermia, weakness, and flexural deformities of all limbs at 1 day of age. Ventilatory failure may also be a presenting sign in addition to recurrent hypoglycemia and collapse. All foals have died from either euthanasia because of muscle

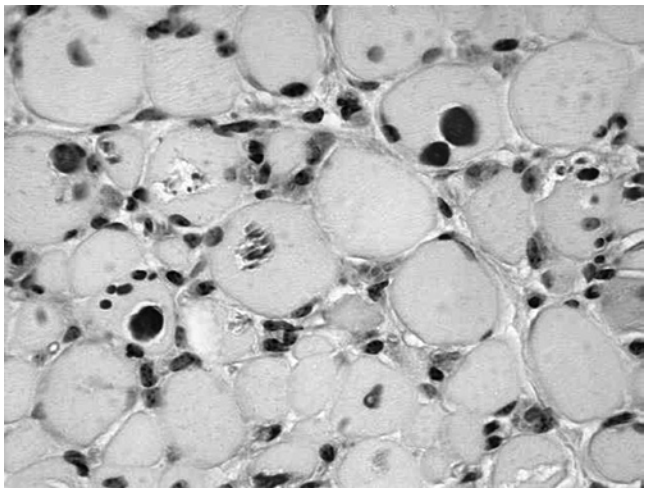

FIG. 42.20 Periodic acid–Schiff (PAS) stain of skeletal muscle from a foal with glycogen branching enzyme deficiency. Note the lack of normal diffuse dark staining for glycogen and the presence of globular and crystalline PAS-positive inclusions.

weakness or suddenly because of apparent cardiac arrhythmia. Persistent leukopenia, intermittent hypoglycemia, and high serum CK (1000 to 15,000 U/L), AST, and γ-glutamyltransferase (GGT) activities are features of affected foals. Gross postmortem changes are not evident, and routine hematoxylin and eosin stains of tissues may be normal or show basophilic inclusions in skeletal muscle and cardiac tissues. Frozen sections of muscle, heart, and liver show a notable lack of normal PAS staining for glycogen, as well as abnormal PAS-positive globular or crystalline intracellular inclusions (Fig. 42.20). Branching enzyme activity is minimal in skeletal and cardiac muscle, as well as in liver. A diagnosis is best obtained by confirming the presence of the genetic mutation in tissue samples or by identifying typical PAS-positive inclusions in muscle or cardiac samples.[269,270]

Centronuclear Myopathy in a Foal

Progressive muscular weakness, lameness and atrophy including ventroflexion of the neck, ptosis, and lip droop have been described in an Arabian-cross foal that died by 5 months of age.[271] Electromyography revealed fibrillation potentials, positive sharp waves, and complex repetitive discharges. Muscle biopsy findings were consistent with centronuclear myopathy that is associated with abnormal distributions of T-tubule and triad structures.

Phosphorylase Deficiency in Charolais Cattle

A deficiency of the enzyme myophosphorylase (McArdle's disease) has been identified in Charolais cattle in the United States and New Zealand and in sheep in Australia.[272-275] Cattle show exercise intolerance and often collapse when forced to exercise. Serum CK is elevated, and severe rhabdomyolysis clinically resembling white muscle disease may be present. Screening for myophosphorylase can be performed by histochemical staining for phosphorylase activity in frozen sections of muscle biopsies. Confirmation of the autosomal recessive disease is obtained by biochemical analyses or identification of the base pair sequence defect. In Charolais a C-to-T substitution, which changes an encoded arginine (CGG) to tryptophan (TGG) at codon 489, is present, and in sheep a splice-site mutation is present in intron 193. This disease should be considered a differential diagnosis for white muscle disease in animals that are found to have normal vitamin E and selenium status. An ovine form of myophosphorylase deficiency has also been described.[276]

Pseudomyotonia in Cattle

Chianina and a Dutch Improved Red and White crossbreed heifer that have a form of pseudomyotonia characterized by delayed relaxation of muscle have been identified.[277,278] Clinical signs include exercise-induced muscle stiffness with normal response to muscle percussion. In contrast to myotonia, electromyography and muscle histochemistry are normal. Missense mutations have been identified in the *ATP2A1* gene encoding the sarcoplasmic reticulum SERCA1 protein.

Porcine RN(-) Glycogen Storage Disease

The RN(–) (rendement Napole) phenotype is common in Hampshire pigs. Clinically, pigs appear normal; however, the 70% increase in glycogen content in skeletal muscle causes poor meat content at slaughter. It is due to an autosomal dominant mutation in the protein kinase AMP-activated gamma 3 subunit gene *(PRKAG3)*, which encodes the gamma 3 isoform of AMP-activated protein kinase.[279] The mutation affects meat quality of pigs by increasing the glycogen content of muscle.

Nonpathogenic Infertility

Breeding Season

Mares

The mare is a seasonally polyestrous animal, breeding during seasons of long day length. Annual breeding and nonbreeding seasons are divided by fall and spring transitional periods, which are characterized by erratic reproductive behavior and irregular estrous cycles.

Clinical Signs During the breeding season, mares ovulate every 21 days (range 19 to 22 days).[1] Estrus (5 to 7 days but variable) is characterized by the presence of an ovarian follicle, serum progesterone level of less than 1 ng/mL, and sexual receptivity. During estrus the cervix is palpably relaxed and the uterus is edematous. One or two follicular waves occur per cycle, and preovulatory follicles are 45 to 60 mm in diameter, often with a cone-shaped appearance on ultrasonography.[2] Ovulation occurs 24 to 48 hours before the end of estrus and may be accompanied by ovarian sensitivity.[1] The ruptured follicle is replaced by a corpus luteum (CL). Diestrus (luteal phase) is predictable in length because regression of the CL, caused by release of endometrial prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), occurs 14 to 15 days after ovulation.[3] During diestrus and early pregnancy the cervix is tight and the uterus has increased tone. Diestrous ovulations occur and may be fertile.[4] First postpartum estrus ("foal heat") begins in the week after foaling, and ovulation occurs in most mares 7 to 15 days postpartum.

Ruminants

COWS. Cows are polyestrous, but seasonal differences in fertility may be caused by climate. The estrous cycle averages 21 days (range 17 to 25 days), and the duration of estrus averages 12 to 16 hours (range 6 to 24 hours). Cows are unique among domestic animals in that they ovulate spontaneously after the end of estrus, 24 to 30 hours after the beginning of estrus.[5]

In the absence of a bull, estrus can be detected in cows by their homosexual (bisexual) activity. Cows that stand to be mounted by another cow are in estrus (standing heat). Secondary signs that may be helpful in detecting estrus include restlessness and increased activity, vulvar hyperemia and edema, and a clear mucous discharge. Errors in heat detection are a common cause of infertility on large dairy farms.[6] The optimum time for insemination of cows is between 16 and 24 hours after the onset of estrus. Insemination of cows based on standing to be mounted results in a higher pregnancy rate than if it is based on secondary signs of estrus. Well-managed dairy cows with uncomplicated periparturient experiences may ovulate approximately 20 to 25 days after calving, whereas beef cows with nursing calves usually do not ovulate until 40 or more days after calving. The presence of the calf appears to be responsible for the difference in return to cyclicity.[7]

SHEEP. Coarse-wooled breeds of ewes are seasonally polyestrous during the autumn and winter (short photoperiod) in temperate climates. Ovulation can be induced in seasonally anestrous ewes by artificial simulation of day length and temperatures characteristic of autumn (reduced photoperiod and reduced ambient temperature), but the long latency period required for response to manipulation of light and temperature makes the procedure impractical. Ewes of fine-wooled breeds may be polyestrous throughout the year if adequately nourished. The estrous cycle of ewes averages 17 days (range 14 to 19 days), and the duration of estrus averages 36 hours. Ovulation occurs spontaneously 24 hours after the onset of estrus. Ewes display few, if any, signs of estrus unless a male is present. The primary signs of estrus include seeking the ram and standing for mating. Secondary signs include restlessness and rapid tail switching; vulvar edema and discharge of clear cervical mucus may be observed occasionally. Lambing ordinarily occurs during the anestrous season; therefore ewes do not return to estrus until the next breeding season.

GOATS. Does in temperate climates are seasonally polyestrous from late summer until early spring (short photoperiod). Onset of the breeding season in yearling does can be advanced by exposing them to 19 hours of artificial light per day for 70

VetBooks.ir

days beginning in mid to late winter. Termination of artificial light results in a relative decrease in day length and stimulation of estrus and ovulation.[8] Alternatively, the breeding season may be hastened by exposing does to 14 to 18 hours of light per day for 3 months, followed by a reduction to 6 hours of light per day. The estrous cycle averages 21 days, and estrus lasts 18 to 36 hours. Ovulation occurs spontaneously 24 hours after the onset of estrus. An intact male or male pheromone is usually necessary for estrus detection. The primary signs of estrus are seeking the buck and standing for service. Secondary signs of estrus in does include rapid tail switching, restlessness, increased frequency of urination and vocalization, transient decrease in appetite and milk production, and edema and hyperemia of the vulva. As in sheep, parturition takes place during the anestrous season, and return to cyclicity in does is delayed until the next breeding season.[8]

CAMELIDS. South American camelids bred in North America are nonseasonal. In keeping with management decisions, they are often bred in a seasonal manner to avoid having newborn crias during the hottest or coldest months of the year. Some consider the South American camelids to be polyestrous, whereas others argue that they do not have a true estrous cycle.[9] These discrepancies arise from the fact that camelids are induced ovulators. Cyclic ovarian activity (e.g., transition from estrus to diestrus) is caused by coital activity. Unbred female camelids essentially exhibit estrous behavior continually, with perhaps short, occasional, unpredictive intervals of 1 to 2 days of decreased receptivity. Follicular waves in alpacas and llamas last around 17 days. Small follicles (<3 mm) are always present on the surface of the ovaries. After recruitment, follicles grow to approximately 5 mm in size. Dominance is established when one of the follicles reaches the size of 6 mm, and the female will show signs of receptivity to the male as long as a dominant follicle is present. The sizes of preovulatory follicles are 9 to 13 mm and 8 to 12 mm in the llama and alpaca, respectively. Females maintain fertile, dominant follicles for an average of 8 days before undergoing regression. Usually the next follicular wave has already produced the next dominant follicle before the previous preovulatory follicle begins to regress. For this reason, the female camelid usually maintains estrous behavior continually until she is mated.[9]

Cystic Follicular Degeneration

Cows

Ovarian cysts are follicle-like ovarian structures that arise because of failure of ovulation of a dominant follicle.[1] They are usually larger than 25 mm in diameter and persist in the absence of a CL for 10 days or more. Follicular cysts have thin walls and may be single, multiple, or multilocular structures on one or both ovaries. Partially luteinized cysts tend to be single, unilateral structures with thicker walls because of the presence of luteal tissue.

The mechanism by which ovulation fails and cysts develop is not known. Failure of ovulation may result from inadequate release of gonadotropins or ovarian dysfunction. Increased stress of conditions such as retained placenta, metritis, and hypocalcemia around the time of calving and postpartum ketosis has been associated with an increased prevalence of cystic follicular degeneration (CFD), as has a hereditary predisposition.[2] Negative energy balance in high-producing dairy cows, as well as prolonged suckling in beef cows, may inhibit lutenizing hormone (LH) release from the pituitary and subsequent failure of ovulation.

Clinical Signs and Diagnosis Approximately 70% to 80% of cows affected by CFD are anestrus, whereas 20% to 30% display frequent or intense estrus (nymphomania). Cystic ovarian disease affects 10% to 30% of dairy cows. The condition is rare in commercial beef cows because of rigid culling for reproductive failure.

The physical appearance of cows with CFD depends on the duration of the condition. No changes are apparent after a short time, but in long-standing cases relaxation of the pelvic ligaments may result in prominence of the tailhead and masculine characteristics such as a crested neck.

The diagnosis of CFD is based on an accurate history and clinical examination. A history of constant or frequent estrus, short interestrous intervals, or anestrus may suggest CFD. Examination of the ovaries by palpation per rectum reveals the presence of enlarged fluid-filled structures raised above the surface of the ovary that greatly increase total ovarian size. Ovarian cysts are larger (>25 mm) than preovulatory follicles (15 to 25 mm). Differentiation between a single large cyst and several smaller cysts on the same ovary may require ultrasonographic examination, as does recognition of the presence of partially luteinized cysts (based on peripheral progesterone concentrations). Ovarian cysts appear to be dynamic structures; those that develop early in the postpartum period may regress without treatment, and a normal estrous cycle may follow, or another cystic structure may develop.

During palpation of the ovaries, several normal structures may complicate the diagnosis of CFD. Normal preovulatory follicles may approach 25 mm in diameter and have palpable characteristics similar to those of small cysts. During the follicular phase of the estrous cycle, however, the uterus responds to palpation by becoming more turgid, whereas the uterus of a cow with CFD is typically flaccid and unresponsive. In neglected cases of CFD, mucometra may develop and must be differentiated from pregnancy. During the first 5 to 7 days of the estrous cycle, the developing CL may be smooth and soft and is commonly mistaken for an ovarian cyst. More mature CLs are solid and liver-like in consistency, often feature a palpable ovulatory papilla at the apex, and are more easily differentiated from ovarian cysts. However, 10% to 20% of mature CLs may lack an ovulatory papilla, making them more easily confused with ovarian cysts. Ultrasonography is generally more accurate in identifying subtle structural differences than transrectal palpation. Salpingitis, hydrosalpinx, oophoritis, ovarian abscesses, ovarian neoplasms, and cysts of the fimbria are other causes of enlargement of the ovary and surrounding structures that must be differentiated from ovarian cysts.[3]

Histories that may erroneously suggest CFD include apparently short interestrous intervals because of inaccurate detection of estrus. Oxytocin administered to stimulate milk letdown may result in short interestrous intervals that may spuriously be suggestive of CFD. The estrous cycle may be shortened by approximately 1 week by administering 100 IU of oxytocin per day on days 2 through 6[4] or on days 3 through 7 or 8.[5]

Clinical Pathology Plasma progesterone concentrations are low in cows with follicular cysts. Partial luteinization may occur, and progesterone concentrations may increase over time but remain lower than those of cows with normal CLs. Estrogen concentrations in the plasma of cows with CFD are variable.

Treatment and Prognosis The goal in treating CFD is to induce luteinization of the cyst and reestablish normal estrous cycles. Several methods have been recommended.

SPONTANEOUS RECOVERY. Spontaneous recovery from CFD occurs in up to 60% of cows that develop CFD before the first ovulation after calving but in only approximately 20% of cases that develop after the first postpartum ovulation. Evaluation of therapeutic agents for CFD may be confounded by spontaneous recovery.

VetBooks.ir

LUTEINIZING HORMONE. Recommended doses of human chorionic gonadotropin (hCG) range from 5000 IU either intravenously (IV) or intramuscularly (IM) to 10,000 IU IM. Among cows treated with a single dose of hCG, 65% to 80% establish a normal estrous cycle within 3 to 4 weeks; a second or third dose may be required in cows that do not respond after 3 to 4 weeks or in cases in which nymphomania persists. Anaphylaxis after repeated treatments with a larger protein hormone such as hCG can occur. Antibodies to hCG may reduce the effectiveness of sequential treatments. Therapeutic response to follicular cysts, both endocrinologically and clinically, is essentially equivalent between hCG and gonadotropin-releasing hormone (GnRH).

GONADOTROPIN-RELEASING HORMONE. Currently the most common treatment for ovarian cysts, especially follicular cysts, is an injection of GnRH (100 μg IM). Cows that respond to this treatment have an average interval to estrus of one estrous cycle or 18 to 24 days. The treatment to breeding interval can be shortened by administering GnRH at the time of diagnosis, followed by a luteolytic dose of prostaglandin 10 days to 2 weeks later. With this regimen, it is not critical whether the cyst is follicular or luteal or even whether it is a misdiagnosed large, smooth CL with or without a fluid-filled central cavity. Most veterinarians agree that accurate differential diagnosis by rectal palpation among follicular cysts, luteal cysts, and some CLs can be a problem.

PROSTAGLANDIN $F_{2\alpha}$. Luteal cysts can be treated with the luteolytic activity of $PGF_{2\alpha}$. The advantages are the quicker return to estrus for those cows able to respond and the lower cost of $PGF_{2\alpha}$. Cysts that luteinize in response to GnRH regress at a time similar to that of normal CLs. Treatment with $PGF_{2\alpha}$ may be used to reduce the interval from treatment with GnRH to estrus from 18 to 24 days to an average of 12 to 14 days by administering $PGF_{2\alpha}$ at 9 days after GnRH. Most clinicians are only approximately 50% accurate in determining the degree of luteinization of cysts by palpation per rectum; therefore measurement of concentrations of progesterone in milk or of plasma from affected cows allows the selection of GnRH or hCG for treatment of follicular cysts and $PGF_{2\alpha}$ for the treatment of luteinized cysts. Ultrasonography can also be used to make an accurate diagnosis.[6]

MANUAL RUPTURE. Thin-walled follicular cysts may be ruptured inadvertently during examination of the ovaries, and some practitioners intentionally may attempt cyst rupture. Recovery rates after manual rupture have rarely been studied in well-designed controlled experiments but are generally within the range reported for spontaneous recovery. Deliberate manual rupture of ovarian cysts is considered an obsolete form of treatment by some veterinary clinicians, but others routinely use the procedure—especially as an initial treatment for cysts found during the voluntary waiting period. Manual rupture of cysts may be followed by hemorrhage and adhesions between the ovary and surrounding structures. These complications appear to be much more common with the use of digital pressure to enucleate CLs (also no longer performed) than with manual rupture of ovarian cysts.

Ewes and Does

Cystic ovaries appear to be more common in goats than in sheep. In one study 12% of goats had cystic ovaries when examined at a slaughterhouse.[7] The condition is often overdiagnosed by owners observing nymphomania or abnormal cyclicity. Treatment typically consists of administering exogenous ovulation-hastening drugs (hCG and GnRH).[8] LH surge is noted usually within 2 hours of GnRH administration. Ten days later, $PGF_{2\alpha}$ may be administered to bring the doe into heat (roughly 2 to 2.5 days after administration).

Camelids

Hemorrhagic follicles are observed in nonbred llamas and usually regress within 22 days.[9] Follicles larger than 12 mm are considered by some authors as pathologic cysts. These structures may, however, be anovulatory follicles. They may have a negative influence on the emergence of other follicular waves, but this influence seems to last for only approximately 8 days.[10]

Poor Nutrition

As with other species, poor body condition, depressed energy intake, and decreased vitamin and mineral intake suppress reproductive activity in ewes and does. Lowered energy balance results in poor or weak signs of estrus, depressed ovulation, abnormal cycle, and delayed puberty. Deficiencies in energy, protein, vitamins A and E, phosphorus, and many trace minerals (iodine, copper) are commonly seen. These deficiencies are most commonly associated with irregular estrous cycles.

Ovarian Reserve and Anti-Mullerian Hormone

The mammalian ovarian reserve declines with age, and antral follicle count (AFC) is thought to be predictive of ovarian reserve and fertility.[1] Plasma levels of anti-mullerian hormone (AMH) have been directly correlated with AFC in multiple species, including mares.[2,3] Based on these findings, AMH has been suggested as a promising indicator of ovarian reserve (and therefore "reproductive age").[4,5] In the female, AMH is produced by granulosa cells in developing follicles and serves in the regulation of primordial follicular recruitment and development into primary follicles, preserving the ovarian reserve.[6-8] The mechanisms for the role of AMH in folliculogenesis are still being understood; however, it has been demonstrated that AMH restricts follicular development by decreasing the sensitivity to follicle stimulating hormone (FSH) in granulosa cells.[9,10] Finally, perhaps the more commonly known clinical application of AMH in mare reproductive health is as a reliable marker for the presence of granulosa cell tumors.[11]

Plant Toxicity

Ergot Alkaloids

The consumption of fescue infected with *Neotyphodium coenophialum* is associated with decreased reproductive efficiency (see Chapter 12). The ergot alkaloids have been shown to affect prolactin production in ewes and to increase the interval from introduction of the ram to conception.

Estrogen-Producing Plants

Sheep appear to be sensitive to the effects of phytoestrogens. Clinical observations include infertility, irregular and prolonged heat cycles, lowered conception rates, and early embryonic death.

Heat Stress

Fertility in lactating cows is decreased during the hot seasons of the year. Heat stress may cause decreased estrus detection, impair follicular development, disrupt function of the reproductive tract, affect oocyte competence, and lead to early embryonic death. Embryos develop resistance to heat shock as they age. Bovine morulae to blastocyst stages are unaffected by heat shock.[1]

Anestrus

The causes of anestrus are multiple and include diseases of the reproductive and other systems. In addition, the problem

is complicated by management factors that cause estrus to pass undetected, even though the animal's estrous cycles and estrous behavior are normal. Common causes of anestrus in mares are summarized in Table 43.1.

Mares

Puberty

The mare likely undergoes puberty between the ages of 12 and 24 months. Because the horse is not an agricultural production animal, there has been little interest in studying the onset of puberty as in other species, where hastening puberty increases production. Most mares are not bred until they are at least 3 years old, thus making prepubertal status an unlikely differential diagnosis for infertility.

Seasonal Anestrus

Clinical Signs and Diagnosis The mare is a seasonally polyestrous animal, showing anestrus during the shorter days of the year and cycling regularly during the longer days. Length of anestrus varies from one to several months, although some mares, particularly in the tropics, may cycle year-round.[1] In California, Australia, and South Africa 18% to 25% of mares cycle year-round.[2-4] Anestrous mares may be indifferent to teasing and do not show regular estrous behavior. Ovaries are small and firm on palpation, and the uterus is flaccid with a thin endometrium. The cervix has mild tone and may be indistinct. On speculum examination of the vagina, the vaginal mucosa is pale and dry, and the cervix usually appears closed but is occasionally open or may be easily opened. Mares that experience seasonal anestrus will go through a transition period in late winter and early spring, characterized by the development of waves of antral follicles that regress without ovulation because the ovulatory surge of LH is absent.[5] Transitional mares exhibit signs of estrus, including clitoral "winking," tail flagging, and urinating in the presence of the stallion. Eventually, increasing LH concentration coincides with a large follicle, resulting in ovulation. After the first ovulation of the season, the mare will continue to ovulate on successive estrous cycles. A transition period is also observed during the fall as the mare changes from a polyestrous condition to the winter anestrus. Differential diagnoses for seasonal anestrus are listed in Table 43.1.

Treatment and Prognosis As day length increases, most mares ovulate and begin regular cyclicity without treatment. Methods to advance the onset of regular ovulatory periods can be both managerial and pharmacologic and are discussed in the following sections.

ARTIFICIAL LIGHTING. The vernal transition can be moved but not shortened beyond its physiologic length of 6 to 8 weeks by exposure of mares to artificial light. A common artificial lighting regimen is to expose the mares to 16 hours of light and 8 hours of dark by extending the photoperiod in the evening starting in late November to initiate ovulation by February (in the northern hemisphere). Light should be added to the end of the day, or split between the beginning and end of the day, as opposed to adding light only at the beginning of the day.[6] An alternative regimen is to expose mares to 1 hour of artificial light 9.5 to 10.5 hours after the onset of darkness.[7] Use of one 200-watt incandescent bulb or two 40-watt fluorescent tubes at a height of 7 to 8 feet in a 12- × 12-foot box stall has been recommended.[8] Paddock lighting has been described.

Recently, research has evaluated the effectiveness of a mask fitted with a single low-intensity blue light as a method to induce the onset of cycling.[8] The masks were compared with mares not under lights and with mares stalled under lights using a conventional protocol. The study found that the masks were able to achieve the same results as the traditional protocol, bringing mares out of seasonal anestrous earlier than the control group.

EXPOSURE TO STALLIONS AND SOCIAL ENVIRONMENT. Alterations in social environment can alter the timing of ovulation in several species. Recent work has investigated social factors and the cessation of seasonal anestrus in mares. The group found that anestrus mares exposed to a stallion several times per week ovulated earlier and more frequently than anestrus mares never exposed to stallions.[9]

GONADOTROPIN-RELEASING HORMONE. Treatment with GnRH or a GnRH analog for mares in anestrus or spring transition has been shown to induce ovulation.[10-15] Twice-daily injections of a GnRH agonist induced ovulation in a majority of mares within 2 to 3 weeks.[14] Mares that are in deep anestrus (January and February, northern hemisphere) can be expected to return to anestrus after treatment.

DOPAMINE ANTAGONISTS. Domperidone and sulpiride have been reported to stimulate follicular activity and advance the first ovulation of the year in seasonally anestrous mares.[16] However, the efficacy of dopamine antagonists in advancing follicular growth and ovulation in anestrous mares has been questioned recently, and it has been suggested that adjustments in light and climatic conditions may influence the efficacy of the treatment.[17,18]

STEROIDS. Exogenous progestins suppress the release of LH from the anterior pituitary and may be used for estrous regulation during the vernal transition. After treatment of mares for 10 to 14 days, withdrawal of progestin may result in LH release from the pituitary and estrus beginning in 4 to 5 days, with ovulation within 10 days after cessation of treatment. Mares should be in mid to late transition and have a follicle at least 25 mm in size to respond to treatment. Progestins will not induce estrus or ovulation in anestrous mares.[19] The recommended dose of progesterone in oil is 150 to 300 mg daily by IM injection. The synthetic progestin altrenogest is administered orally (PO) at 0.044 mg/kg daily. Progestins may be used in combination with extended photoperiod and gonadotropins. Products that are ineffective or unavailable include repositol progesterone, melengestrol acetate, chlormadinone acetate, proligestone, medroxyprogesterone acetate, hydroxyprogesterone acetate, and norgestomet implants.

Synchronization of the first ovulation (or any ovulation during the cyclic season) can be accomplished by the administration of a combination of progesterone in oil (150 mg/day IM) and estradiol-17β (10 mg/day IM) once daily for 10 days.[20] Treatment is most effective if given after mares have been under lights for 45 to 60 days. $PGF_{2\alpha}$ should be given on the last day of steroid treatment. Treated mares will ovulate within 8 to 10 days after the last treatment.

GONADOTROPINS. At a dose of 2500 to 3000 IU, hCG may induce ovulation within 48 hours when administered to a mare with a follicle larger than 35 mm in diameter[21] and may reduce time to first ovulation in transitional mares, particularly when used in combination with lights and/or progesterone treatment. Ovulation response here is less predictable than that induced with hCG during the breeding season.

Based on a recent study, treatment of seasonally anestrous mares with recombinant equine FSH (reFSH) is effective in stimulating development of follicles and advancing the first ovulation of the year.[22] Treatment with FSH resulted in multiple ovulations but was not successful in inducing continued cyclicity.

TABLE 43.1

Differential Diagnosis of Anestrus in Mares

Cause	Uterus	Cervix	Ovaries	Peripheral Progesterone	Season	Other Laboratory Tests	Treatment
Pregnancy	Increased tone during early pregnancy; enlarged; positive signs of pregnancy by palpation or ultrasound	Tightly closed	Normal size during early pregnancy; out of reach of examiner in late stages	Elevated throughout pregnancy until just before term	Any season; may be more common in spring and summer	Equine chorionic gonadotropin; Cuboni test	Usually none required; therapeutic abortion if mismated
Prolonged diestrus	Normal size, increased tone and tubularity; may be similar to early pregnancy	Tightly closed	Normal size; prolonged corpus luteum is embedded within ovary	Elevated throughout prolonged life span (30-90 days)	Any season; may be more common in summer	Progesterone	$PGF_{2\alpha}$
Seasonal anestrus	Normal size; flaccid; difficult to palpate	Varies from tightly closed to open	Both are small and firm, may or may not have small follicles	Low until first corpus luteum develops	Late autumn, winter, early spring	Progesterone	Artificial lights; wait for normal breeding season
Unobserved estrus	Normal size	Characteristic cyclic changes; relaxed and open during estrus	Development of one (or more) follicles; ovulation	Elevated for ≈14 days; low for ≈7 days	Spring, summer, autumn		Improve management; tease with another stallion; sequential examinations; $PGF_{2\alpha}$
Pyometra	Variable enlargement	May be open, closed, or stenotic; purulent discharge may be present	Normal size, follicular development may be present	Erratic profiles; some are elevated for prolonged periods, others may have luteal regression	Any season	Endometrial cytology; bacterial culture; antibiotic sensitivity	Drain; systemic antibiotics; $PGF_{2\alpha}$
Undernutrition	Normal size	Varies from tightly closed to open; no cyclic changes	Bilaterally small and firm	Low	Any season	Hematology; clinical chemistry as indicated; fecal flotation	Improve nutritional status; parasite control; treat concurrent diseases
Granulosa-theca cell tumor	Normal size	Varies	One enlarged, multicystic; other small and atrophic	Low	Any season	Peripheral inhibin concentrations are elevated in ≈90%, testosterone in ≈50%, and AMH in >90% of mares with granulosa-theca cell tumor	Surgical removal of neoplastic ovary
Gonadal dysgenesis	Small	Varies	Small, firm, atrophic	Low	Any season	Karyotype	None

AMH, Anti-mullerian hormone; *$PGF_{2\alpha}$*, prostaglandin $F_{2\alpha}$.

VetBooks.ir

FOLLICULAR ASPIRATION. Ultrasound-guided transvaginal follicular aspiration of follicles less than 35 mm in diameter has been shown to hasten the onset of cyclicity in transitional mares.[23] Follicular aspiration resulted in the formation of an active CL, and subsequent treatment with $PGF_{2\alpha}$ resulted in estrous behavior and ovulation of a dominant follicle.

Prolonged Luteal Phase and Pseudopregnancy

Mares that experience embryonic loss in the presence of endometrial cups (days 35 to 150 of gestation) are said to be *pseudopregnant* (*pseudopregnancy* may also refer to the condition in which a conceptus was lost after maternal recognition of pregnancy and before the development of endometrial cups, resulting in prolonged luteal life). Despite the loss of the fetus and placental tissue, endometrial cups remain in place and continue to secrete equine chorionic gonadotropin (eCG) for a similar period to that in a pregnant mare, to 100 to 150 days of gestation.[24] The primary and secondary CLs may regress after embryonic loss, allowing the mare to return to cyclicity,[25,26] or remain during eCG secretion, maintaining high levels of peripheral progesterone and preventing the mare from cycling. Persistent endometrial cups throughout pregnancy and during the following breeding season have been described.[27]

Treatment and Prognosis

In untreated mares, cyclic activity is often reestablished after the cessation of eCG secretion. Repeated daily injections of $PGF_{2\alpha}$ products have been reported to cause luteal regression in pseudopregnant mares,[28] but only CLs older than 5 days respond to the treatment, which may prevent mares returning to estrus. Pregnancies have occurred in the face of high eCG,[29] but fertility of treated mares is usually low.

Lack of Behavioral Estrus (Silent Estrus)

Behavioral estrus may not be detected in otherwise normal mares as a result of inadequate estrus detection or a failure on the part of the mare to show obvious signs of estrus. The latter may occur in up to 15% of mares on well-managed farms.[1] Inadequate estrus detection may result from human apathy or ignorance or from use of a low-libido or inexperienced stallion. Teasing mares as a group may make detection of estrus more difficult, especially for nervous mares, mares with foals, and mares of low social rank. Use of anabolic steroids may suppress behavioral estrus.

Clinical Signs and Diagnosis

The mare fails to show estrus on adequate teasing with a stallion. Differential diagnoses are listed in Table 43.2.

Treatment and Prognosis

Management should be examined to ensure a competent teasing routine. When approached by a stallion, mares in estrus stand still with ears held forward; they may elevate the tail, rhythmically evert the clitoris ("winking"), assume a squatting posture, urinate, and lean against the teasing chute toward the stallion. Mares that are in diestrus move about and hold their ears back; they may strike, kick, squeal, swish their tails, and forcefully void small amounts of urine. Experienced personnel should handle both stallion and mare. The teaser stallion should have adequate libido without being aggressive. Transrectal palpation and ultrasonography should supplement teasing. Some mares are indifferent to teasing, and records of sequential palpation must be relied on for breeding. Progesterone concentrations of less than 1 ng/mL are consistent with estrus but may also occur in anestrous mares. Mares that fail to show behavioral estrus should be bred by artificial insemination (AI) if allowed by the breed register or with appropriate restraint used for natural cover.

TABLE 43.2

Irregularities of the Equine Estrous Cycle: Differential Diagnosis

Etiology	Distinguishing Features
Failure to Cycle With Low Progesterone	
Winter anestrus	Season; inactive ovaries
Gonadal dysgenesis	Small, hard, inactive ovaries; karyotype; underdeveloped tubular tract; small body
Pituitary adenoma	Systemic signs; inactive ovaries
Granulosa-theca cell tumor	See "Prolonged or Irregular Behavioral Estrus"
Behavioral	Intimidated by stallion; recently foaled; low social rank
Failure to Cycle With High Progesterone	
Pregnancy	Presence of embryonic vesicle or fetus
Persistent CL	CL fails to regress; responds to $PGF_{2\alpha}$
Diestrous ovulation	CL immature at time of endogenous $PGF_{2\alpha}$; responds to exogenous $PGF_{2\alpha}$
Pseudopregnancy	Conceptus loss after maternal recognition of pregnancy; responds to exogenous $PGF_{2\alpha}$
Iatrogenic	History of exogenous progestin or nonsteroidal antiinflammatory drug administration
Pyometra	Uterus palpably enlarged
Short Luteal Phase	
Uterine infection	Pyometra or endometritis causing premature endogenous $PGF_{2\alpha}$ secretion
Systemic endotoxemia	Systemic signs; endotoxin-mediated release of endogenous $PGF_{2\alpha}$
Iatrogenic	History of uterine manipulation, infusion, invasive procedure, or exogenous $PGF_{2\alpha}$
Prolonged or Irregular Behavioral Estrus	
Transitional period	Season; variable ovarian activity
Granulosa-theca cell tumor	Affected ovary large and multicystic, contralateral ovary small; elevated inhibin, AMH, and/or testosterone; anestrus, nymphomaniac or stallion-like behavior
Gonadal dysgenesis	Occasionally irregular cyclicity; as above
Behavioral nymphomania	Otherwise normal mare
Normal mare	Mares in winter anestrus and pregnancy may show estrous signs

AMH, Anti-mullerian hormone; *CL*, corpus luteum; *$PGF_{2\alpha}$*, prostaglandin $F_{2\alpha}$.

Behavioral Nymphomania

Abnormal estrous behavior and aggression may be demonstrated by otherwise normal mares at any stage of the estrous cycle. Ovarian tumors should be considered as an important differential diagnosis.[1]

Clinical Signs and Diagnosis Exaggerated signs of estrus occur, initially during estrus and then throughout the cycle. Mares may develop behavioral anomalies and become aggressive. Differential diagnoses are listed in Table 43.2. It is important to differentiate abnormal estrous behavior from unrelated systemic or behavioral problems.[2]

Treatment and Prognosis Exogenous progestins have been used to limited effect. Short-term dexamethasone treatment (5 to 10 mg) may alleviate signs for 3 to 4 days. The prognosis for resolution after bilateral ovariectomy is unpredictable, as it may be successful in some cases and exacerbate the undesired behaviors in others.[3]

Ruminants

Common causes of anestrus in cows are summarized in Table 43.3.

Unobserved or Silent Estrus

Cow

Failure of a cow to display, or a manager to observe, the signs of estrus contributes significantly to reproductive inefficiency. When the presenting history suggests anestrus (failure to have a normal estrous cycle), the clinician must determine if the cause is failure of the manager to detect estrus in normal cows or failure of the cow to cycle because of some abnormal process. In dairy herds approximately 90% of cows presented for examination because of a history of anestrus have evidence of normal cyclic ovarian changes, whereas only approximately 10% are affected by an abnormality that suspends the estrous cycle (i.e., only ≈10% are in true anestrus).

Nearly 90% of well-managed dairy cows have initiated normal-length estrous cycles by 60 days after calving, but only approximately 60% are detected correctly to be in estrus by that time.[1] Rates of estrus detection by twice-daily observation range from 50% to 73% depending on the skill of the observer.

Mounting activity and estrous behavior are reduced by hot and cold ambient temperatures and during the times of milking and feeding. More mounts are observed when cows are kept on dirt than on concrete. Estrous behavior varies with the time of day and may be an inverse reflection of extraneous activity interfering with cow behavior. In one study, 43% of

TABLE 43.3

Differential Diagnosis of Anestrus in Cows

Cause	Uterus	Ovaries	Peripheral Progesterone	Treatment
Pregnancy	Enlarged; positive signs of pregnancy	Corpus luteum in ovary ipsilateral to pregnant uterine horn	Elevated throughout	Usually none required; $PGF_{2\alpha}$ or $PGF_{2\alpha}$ + dexamethasone if unwanted pregnancy
Unobserved estrus	Normal; characteristic tone during estrus; postovulatory edema	Development and regression of corpora lutea and follicular waves diagnosed by sequential examinations	Elevated during diestrus and low for ≈3 days before ovulation and ≈4 days after ovulation	Improve estrus detection; estrus detection aids; synchronize estrus with $PGF_{2\alpha}$; teaser animals
Cystic follicular degeneration	Normal in acute cases; later flaccid mucometra may develop in chronic cases	Fluid-filled cyst(s) >25 mm in diameter; no corpora lutea; unilateral or bilateral; single or multiple cysts	Variable; low in cases of follicular cysts; slight elevation in cases of partially luteinized cysts	Spontaneous recovery; GnRH or hCG to induce luteinization of follicular cysts; $PGF_{2\alpha}$ for partially luteinized cysts; manual rupture
Pyometra	Variable enlargement; fluid movable from horn to horn, normal to thick uterine wall; no positive signs of pregnancy	Corpus luteum in one ovary, frequently contralateral to larger uterine horn	Elevated throughout	$PGF_{2\alpha}$
Mummified fetus	Leather-like fetus within involuted uterus; no positive signs of pregnancy	Corpus luteum in ipsilateral ovary	Elevated throughout	$PGF_{2\alpha}$; usually slaughter, advisable for economic reasons
Undernutrition	Normal	Small; static; no cyclic changes detected on sequential examinations	Low until corpus luteum forms	Improve quality and quantity of ration
Granulosa-theca cell tumor	Normal	One ovary enlarged; other low atrophic	Low	Surgical removal of neoplastic ovary
Freemartinism	Small to nonexistent	Small to nonexistent	Low	No possible treatment
Ovarian hypoplasia	Very small to near normal	Very small to near normal; unilateral or bilateral; partial or complete	Variable; depends on degree of hypoplasia	No possible treatment

GnRH, Gonadotropin-releasing hormone; *hCG*, human chorionic gonadotropin; *$PGF_{2\alpha}$*, prostaglandin $F_{2\alpha}$.

VetBooks.ir

cows showed heat between midnight and 6 AM; 22% between 6 AM and noon; 10% between noon and 6 PM; and 25% between 6 PM and midnight.[2]

Estrus in dairy cows averages 7 to 16 hours but ranges from 0.5 to 36 hours. Sixty-five percent of cows are in estrus for less than 16 hours, and 25% are in estrus for less than 8 hours.[3] The number of mounts per hour ranges from 2 to 8, and the total number of mounts during estrus ranges from 11 to 56. Total number of mounts per estrus increases with the number of cows simultaneously in estrus.

Clinical Signs and Diagnosis Dairy herds in which infertility is caused by inaccurate estrus detection are usually characterized by prolonged intervals from calving to first breeding and between services; insemination intervals of 10 to 15 days and 30 to 35 days; records of examinations that confirm cyclic ovarian changes but in which observation of estrus is not recorded; and finding more than 15% of cows presented for pregnancy examination to be nonpregnant. Insemination during the luteal phase of the estrous cycle may occur in 10% to 20% of cows and is not likely to result in conception; insemination of pregnant cows may be followed by abortion.

The diagnosis of unobserved estrus requires sequential examination of affected cows and accurate records. Other causes of anestrus are eliminated. Conditions such as cystic follicles, pyometra, mummified fetuses, granulosa-theca cell tumors, and segmental aplasia that cause anestrus affect individual animals. Anestrus caused by undernutrition is characterized by depressed milk production and low body condition score.

Treatment and Prognosis $PGF_{2\alpha}$ is widely used in clinical management of unobserved estrus. Mature CLs (≈day 6 through day 18 of the estrous cycle) are responsive to $PGF_{2\alpha}$-induced luteolysis. Estrus occurs an average of 3 days (range 2 to 5 days) after administration of $PGF_{2\alpha}$, depending on the follicular status of the ovaries at the time of injection. The endocrine events surrounding the controlled estrus are indistinguishable from those surrounding spontaneous estrus and ovulation. Treatment with $PGF_{2\alpha}$ shortens the intervals from treatment to first breeding and from treatment to conception but has no effect on fertility. The benefits of $PGF_{2\alpha}$ treatment are limited by inaccurate palpation of the temporary ovarian structures, injection during the wrong phase of the cycle, and failure of the manager to observe estrus in treated cows (timed AI can be used to overcome this problem).

Measurement of progesterone concentrations in milk samples taken on the day of breeding is useful in herds with a history of reduced fertility to confirm that cows being inseminated are not in the luteal phase of the estrous cycle. If more than an occasional cow presented for insemination has an elevated concentration of progesterone, the methods of estrus detection should be reviewed. Enzyme immunoassay kits for measuring concentrations of progesterone in milk and plasma of cows and other female animals have been described and are commercially available.

Various heat detection aids have been developed. Several of these use devices mounted on the tailhead that record when a cow has stood to be ridden. Pressure-sensitive devices that are glued to the tailhead and change color after sustained pressure by the weight of a mounting cow are commonly used. Similarly, pressure-sensitive devices glued to the tailhead can send a record of riding events directly to a computer. Chalk, cattle crayon marker, or paint applied to the tailhead are inexpensive aids that rub off when the animal is mounted when she is in heat. These methods require daily maintenance and twice-daily evaluation to function effectively. Detection aids that measure changes in activity (pedometers), mucous conductivity, or body temperature can be used successfully. Accuracy is enhanced when measurements are related to previous estrous activity and progesterone concentrations.[4]

Prevention and Control Because unobserved estrus is primarily a problem of management, efforts to reduce time lost from delayed breeding are directed at improving efficiency of heat detection. Accurate records are required to identify cows that have not been observed in estrus by 40 days after calving. Cows not observed in estrus by 40 days after calving should be examined, and abnormalities of the reproductive organs that cause anestrus treated as indicated. The time of estrus can be predicted by palpation of the temporary ovarian structures, or estrus can be controlled with $PGF_{2\alpha}$. The most significant benefit of a planned herd health program is stimulation of improvements in management that decrease the interval from calving to conception as a result of improved estrus detection.

Anestrus after insemination is frequently interpreted as a clinical sign of pregnancy. However, unobserved estrus in cows that have failed to conceive or have experienced early embryonic death (postservice anestrus) contributes significantly to increased calving intervals. Clinical management of postservice anestrus depends on diligent observation of cows 18 to 24 days after breeding and identification of nonpregnant cows as early as possible after the infertile service so that they may be reinseminated with minimum delay. Nonpregnant cows may be accurately identified by ovarian palpation or ultrasonography for absence of a mature CL, by low milk or plasma progesterone at the time of the first expected postservice estrus (≈21 days after breeding), or by palpation of the uterus per rectum before the second expected postservice estrus (30 to 42 days after breeding). Biochemical markers for pregnancy, such as pregnancy-associated glycoproteins (including pregnancy-specific protein B), have been validated as early as 28 days post insemination with a sensitivity and specificity of 93.9% and 95.5%, respectively.[5]

Ewe

The breeding season of most breeds of sheep maintained at temperate latitudes is restricted to late summer, autumn, and early winter, although some breeds cycle all year long. There is almost no homosexual interaction among ewes; therefore a male must be present to stimulate display of estrus.

Introduction of a ram (either intact or vasectomized) into a flock of ewes advances the breeding season. Most ewes ovulate by 3 to 6 days after introduction of rams. The induced ovulation is seldom accompanied by estrus, but the subsequent estrus approximately 17 days later is ovulatory and fertile. The "ram effect" is lost when rams are allowed to associate with ewes throughout the year.

Return to estrus after mating may be detected in a flock of ewes by fitting the ram with a brisket device that marks serviced ewes. Return of an excessive number of ewes to service after breeding alerts the owner to the possibility of infertility.

AI of ewes is rare in the United States but more popular in other countries. Laparoscopic AI is required due to the tortuous nature of the ewe's cervix and therefore is a more complicated procedure than in other species. Detection of estrus for AI depends on the use of teaser rams mingled with the ewes or led through the flock several times daily.

Doe

The breeding season of does is similar to that of ewes (i.e., it surrounds the autumnal equinox). During periods of short daylight, the normal estrous cycle of does is 20 to 21 days. Homosexual interaction among estrous does rarely occurs, so signs of estrus must be elicited by teasing. Signs of estrus may also be evoked by exposure to male pheromones by way of a "buck jar" prepared by rubbing a cloth over the scent glands

caudomedial to the horns of a mature buck during the breeding season and storing the cloth in a tightly closed container. If estrus is not observed in does exposed to a mature buck or to a buck jar during the physiologic breeding season, pregnancy or pseudopregnancy might be considered as possible causes of anestrus. Severely parasitized or inadequately nourished does do not have normal estrous cycles. Deficiencies of phosphorus, iodine, and manganese have been suggested as causes of anestrus in does.

Introduction of bucks into a flock of does early in the breeding season results in initiation of estrous cycles and some degree of synchrony of estrus approximately 10 days after introduction of the bucks. In contrast to ewes, however, the first ovulation after exposure to males is accompanied by estrus and fertile mating.

Camelids

Most female South American camelids, although showing signs of ovarian cyclicity as early as 5 months of age, have decreased fertility until approximately 15 months of age. A female camelid should be at least 60% of her expected adult weight before she is bred. Male camelids have a preputial attachment of the penis that is not separated until 2 to 3 years of age. However, some males may detach as early as 15 months of age. Before this time they will show mounting behavior but will not be capable of intromission.

Infertility Caused by Abnormalities of the Female Genital Organs

Abnormalities Caused by Problems With Sexual Differentiation

Sexual differentiation occurs in three stages, each stage dependent on the previous one:

1. Chromosomal (genotypic or genetic) sex is determined at fertilization in mammals by the type of sex chromosome contributed by the sperm (X or Y). In mammals, females are XX and males are XY.
2. Gonadal sex is regulated by the *Sry* (sex-determining region of the Y chromosome) gene, which produces a protein called the *HY antigen*, as well as other sex-linked and autosomal genes downstream of *Sry*. Activation of this pathway induces testis formation in the bipotential gonads. The X-linked *Dax1* gene suppresses testis formation.
3. Phenotypic sex is regulated by substances produced in the male testes to cause regression of the female tract and formation of the male tract or, in the absence of a testis, formation of the female tract.

Chromosomal sex is determined at fertilization. All normal mammalian oocytes contribute an X chromosome in addition to one of each representative autosomal maternal chromosome. Sperm cells contribute either an X or a Y sex chromosome in addition to one of each representative autosomal paternal chromosome. Abnormalities in chromosomal sex occur because of nondisjunctional errors during either mitosis or meiosis. Fig. 43.1 shows some examples of chromosomal sex anomalies.

Monosomy X (XO)

Monosomy X is also known as *Turner syndrome*. Owing to the lack of a Y chromosome and the consequent *Sry* gene, but the presence of the *Dax1* gene on the present X chromosome, the phenotype is female. Monosomy X is the most commonly reported chromosomal abnormality in mares. Animals with this syndrome often have a history of poor performance and lack of or sporadic reproductive cyclicity. Ovaries are typically

			Sperm					
			Normal		Abnormal			
			X	Y	XY	XX	YY	O
Eggs	Normal	X	XX	XY	XXY	XXX	XYY	XO
	Abnormal	XX	XXX	XXY	XXXY	XXXX	XXYY	XX
		O	XO	YO	XY	XX	YY	O

FIG. 43.1 Examples of chromosomal sex abnormalities.

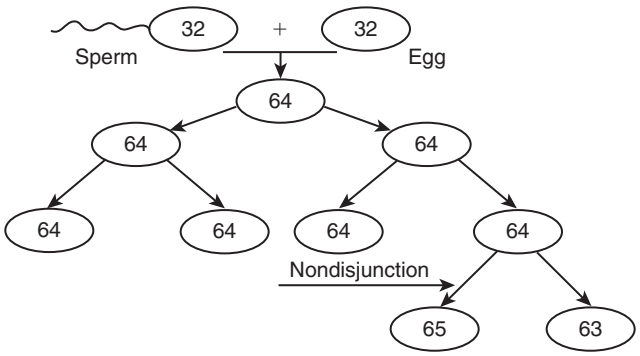

FIG. 43.2 Process of how a mosaic may occur. The haploid sperm and egg form a diploid zygote. Through the process of mitosis, diploid cells are replicated to always produce the same number of chromosomes. If, however, a chromosome pair does not separate during anaphase, called a nondisjunction event, cell lines that do not reflect a correct representation of the genome will be created and potentially propagated. If this happens with the sex chromosomes in the germ cell line, fertility of the individual or its offspring may be affected.

inactive, small, smooth, and firm. The uterus and cervix are usually hypoplastic. Externally the mare's genitalia may appear normal or underdeveloped.

XXY Syndrome

The genotype for XXY syndrome is part of Klinefelter syndrome. Because of the presence of a Y chromosome and the consequent *Sry* gene, affected individuals are phenotypically male, but probably owing to the presence of two copies of the *Dax1* gene on the two X chromosomes, they generally have hypoplastic genitalia and reproductive organs. It is thought that some factor (*Dax1* or some other) on the X chromosome must escape the inactivation process, which happens early in development (around day 7 or 8 in the horse). Testicular development and spermatogenesis are inhibited, resulting in small, flaccid testes and azoospermia. The testes may be retained or descended, but they are often small and soft. The penis may be normal or smaller than usual. Affected males often show normal libido and sexual behavior. Low testosterone concentrations may be noted. Infertility always accompanies this syndrome. Reports have been made in numerous species, including the horse.[1,2]

XXX

More is not better. A report of an infertile mare with the 65,XXX genotype confirms this.[3] The mare had bilaterally small, inactive ovaries and a hypoplastic uterus and cervix.

MOSAICS. Mosaics are individuals that have at least two cell lines with different karyotypes arising from the same zygote (Fig. 43.2).

Phenotypes vary in accordance with the degree of mosaicism. Varying degrees of hermaphroditism and pseudohermaphroditism have been reported in many domestic species. Mosaics

VetBooks.ir

often have mixed gonadal dysgenesis, with an ovary and a testis, or ovotestes, owing to sex chromosome mosaic cell lines.[4,5] These are true hermaphrodites.

Chimeras

Chimeras are individuals having cell lines from two different embryonic sources. This can occur experimentally or from the natural fusion of blastocysts in utero. The possibility has been reported from a suspected double ovulation and fertilization followed by blastomere fusion in the horse (64,XX/64,XY and 63,XO/64,XY genotypes reported). Freemartinism is a common occurrence in ruminants, resulting in chimeric twins.

Freemartins

Freemartinism is a phenomenon in ruminants in which an infertile female is twin to a male. The dizygotic occurrence happens when the blastodermic vesicles of the two zygotes fuse early in development (day 18 to 20 in cattle) and share embryonic tissue. The placentas fuse (day 30 to 50 in bovines), and they share blood throughout gestation. This occurs before gonadal differentiation at day 40 to 50. Both individuals are XX/XY chimeras. The *Sry* gene of the male twin causes the freemartin gonads to develop at least partially toward the male testis. The degree of differentiation varies with each freemartin, and many freemartin gonads remain undifferentiated. The shared circulation allows testosterone and AMH from the male twin, and possibly from the chimeric freemartin, to affect the freemartin genitalia, and so she lacks a cervix, uterus, uterine tubules, and cranial vagina. The vulva is fairly normal. The yearling freemartin fails to exhibit estrus, the udder and teats remain small, and the freemartin externally resembles a steer (only with a vulva). Clinical diagnosis can be made by establishing a blind end to the vagina (no cranial vagina, no cervix) and confirmed with genotyping or use of polymerase chain reaction (PCR) to detect the Y chromosome in a phenotypic female. Among heifers born co-twin to a male, 92% will be freemartins.[6]

The male twin may develop into a fertile adult, but these individuals show a higher incidence of infertility than bulls with a 60,XY genotype. Most male twins to freemartins become steers.

Freemartinism is less common in sheep than in cattle, but it does occur. It has also been reported in goats and pigs. With increased fecundity in modern animals, the authors observe the phenomenon more often than was reported in the past. This is because ovine freemartinism is rare with twins or triplets but much more common with quadruplets or quintuplets. A notable difference between ovine and bovine freemartinism is the marked masculinity of the ovine freemartin. Gonads within the inguinal canal resemble normal prepubertal testes, and those within the abdomen resemble cryptorchid testes from rams of normal XY gonadal sex. Many ovine freemartins also have epididymides, vasa deferentia, vesicular glands, and even cremaster muscles.

Gonadal Sex

Chromosomal sex determines gonadal sex. The Y chromosome has very few genes, and all of the ones studied play a role in sex differentiation. The gene located at the sex-determining region on the Y chromosome *(Sry)* has a DNA binding domain high-mobility group (HMG) box. It produces a protein called the *HY antigen*, and its action appears to be regulated by the transcription of other genes. Their actions initiate differentiation of bipotential embryonic gonadal tissue into testicular tissue. Other genes act downstream of *Sry* to support gonadal differentiation; these include *Sox9*, *Gata4*, *Wt1*, and *Sf1*, which act synergistically to promote testicular differentiation. *Sox9* is a powerful promoter of testicular tissue differentiation. It is hypothesized that *Sry* upregulates *Sox9*. In the absence of the *Sry* gene, the dual copies of the *Dax1* gene on the X chromosomes suppress the formation of testicular tissue by antagonizing the *Sry* gene and the synergy between *Sf1* and *Wt1*. Another gene, *Wnt4*, has been shown to support female development, and the absence of this gene in female mice results in masculinization.[7] This evidence refutes the notion that female development is strictly a default process caused by the absence of *Sry*. Further research is elucidating other factors that actively promote the formation of ovarian tissue (e.g., *Rspo1* β-catenin signaling). Factors affecting *Sry*, or any of the other genes downstream of *Sry*, or any factors governing female development will affect phenotypic sex.

Abnormalities of Gonadal Sex: Sex Reversals

Sex reversals occur when the chromosomal sex and gonadal sex do not agree with each other. XX sex-reversed males and XY sex-reversed females are reported in many domestic species. These individuals are either XX males (testicular tissue), XY females (ovarian tissue), or true hermaphrodites (both ovarian and testicular tissue on separate gonads or the same gonad [ovotestes]). Sex reversals are relatively common in the horse and are considered to occur both sporadically and with familial inheritance.

XY SEX-REVERSED FEMALES (GONADAL DYSGENESIS). XY sex-reversed females have been reported to arise because of an absent or mutated (and nonfunctional) *Sry* gene. It is believed that the Sry chromosome is missing because of an abnormal meiotic exchange with the X chromosome. It is thought that in the sire, two crossing-over events occur between X and Y chromosomes during spermatogenesis. The offspring are subsequently infertile, and their external genitalia have a normal female appearance. The ovaries and uterus tend to be hypoplastic or even completely undifferentiated ("streak gonads"). These animals may be true hermaphrodites (ovotestes) or XY females (only ovarian tissue).

***SRY*-POSITIVE XX SEX-REVERSED MALES.** XX sex-reversed males conversely may arise from a translocation of the *Sry* gene onto the X chromosome. These animals may be true hermaphrodites or XX males (only testicular tissue). This condition has been reported in ruminants but not in horses.

***SRY*-NEGATIVE XX SEX-REVERSED MALES.** There are reports in horses of *Sry*-negative XX sex-reversed males.[8,9] The exact mechanism of masculinization is still uncertain. Possibilities include Y-specific sequences other than *Sry* (which would require an XY individual with an inactivated or absent *Sry* gene), XX/XY chimerism within the testicular tissue, and a mutation in an autosomal or X-linked gene farther down the cascade of genes responsible for sex determination. XX sex-reversed males may have ambiguous sexual characteristics and may be true hermaphrodites or XX males (only testicular tissue).

Goats (especially Alpine, Saanen, and Toggenburg) present another classic, common example of *Sry*-negative XX sex-reversed males. Either the "polled" (hornless) gene is closely linked to an intersex locus or the polled gene itself is pleomorphic and controls both the hornless and intersex traits. This close linkage or pleomorphism is called the *polled/intersex syndrome* (PIS). A partial reason for the sex reversal is the deletion that affects a noncoding RNA (Pisrt1) and a transcription factor (FoxL2). The mechanism of testis induction has not been discovered yet. Elucidating this mechanism may be a big step in describing autosomal sex-determining factors in other species, including humans. The intersex gene is currently thought to work by mimicking the *Sry* gene and codes for the HY antigen.

VetBooks.ir

The polled gene shows a dominant autosomal inheritance pattern, whereas the intersex trait shows an autosomal recessive inheritance pattern. A single dose of the P polled gene is enough to cause the polled trait, but a double dose is required to cause intersexuality in XX individuals. Therefore PP animals are hornless and infertile (if XX; fertile if XY); Pp individuals are hornless and fertile, and pp individuals are horned and fertile. Intersex individuals are always sterile and have a shortened vagina, large clitoris, bucklike head and neck, buck odor, and buck behavior. The gonads are testes or ovotestes and may be scrotal, inguinal, or abdominal. Even very masculinized intersexes with scrotal testes are azoospermic. A PP polled goat that has an XY genotype is usually initially fertile but often develops sperm granulomas later in life. The only way to avoid the intersex condition is to always breed a polled individual to a horned individual.

Phenotypic Sex

Gonadal sex determines phenotypic sex. Initially each embryo has both mullerian (paramesonephric) ducts and wolffian (mesonephric) ducts. Within testicular tissue, *Sox9* triggers Sertoli cells to secrete mullerian-inhibiting substance (MIS; also known as *anti-mullerian hormone* [AMH]), which initiates the irreversible regression of the paramesonephric ducts. The action of MIS or AMH is further regulated by other genes and their proteins (Sf-1, Gata factors, Wt-1, Dax-1, and FSH). Wt-1 and Sf-1 synergistically enhance AMH transcriptional activity. Gata-4 enhances AMH promoter activity by directly binding to DNA and by synergistically interacting with Sf-1.

Leydig cells secrete testosterone that is converted by 5α-reductase to dihydrotestosterone. These two steroids promote the differentiation of male genitalia. Testosterone influences the differentiation of the wolffian ducts into the internal male genitalia (vasa deferentia and epididymides), whereas dihydrotestosterone stimulates the formation of the seminal vesicles and male urethra from the urogenital sinus, and the penis from the genital tubercle. In the absence of these testicular hormones, the wolffian ducts regress and the mullerian ducts become the female internal genitalia.

In the presence of two X chromosomes, the double dose of Dax-1 has an inhibitory effect on the synergistic relationships between Sf-1 and Wt-1 and Gata-4, preventing their support of AMH production.[10] The primitive sex cords (gonadal cords) degenerate in the medulla and remain in the cortex (opposite in the horse). Subsequently there is no communication between the gonad and the mesonephros. In the absence of AMH, the mullerian ducts persist as the oviducts and fuse to form the uterus and cranial vagina. In the absence of testosterone, the wolffian ducts regress. Vestigial traces of these are located in the mesentery of the ovary, the epoophoron, the paroophoron, and Gartner's ducts. The tissues that form the round ligament of the uterus are analogous to the male gubernaculum.

Abnormalities of Phenotypic Sex

Abnormalities of phenotypic sex occur when the chromosomal and gonadal sex agree (XX with ovaries or XY with testes) but the external and/or internal genitalia do not correlate or are ambiguous. Affected animals are the male and female pseudohermaphrodites. The condition can occur because of insensitivity of androgen receptors or because of any abnormality along the pathway that may affect the intervening hormones, such as the conversion of 5α-reductase to dihydrotestosterone.

TESTICULAR FEMINIZATION. Testicular feminization is reported in domestic species, including the horse.[11] Patients have external genitalia that are either female or ambiguous in appearance. The vagina may be blind-ending, or the uterus may be hypoplastic. The gonads are testicles, although they are usually abdominal or inguinal. Male behavior may be reported in horses. The problem lies in the gene for the androgen receptor, located on the X chromosome received from the dam. This X-linked recessive inheritance has been demonstrated in both humans and horses. Affected individuals are male pseudohermaphrodites. The condition has been diagnosed in multiple horse breeds. Serum testosterone concentration is often increased because of loss of negative feedback; a subnormal testosterone response to an hCG test is expected.

Abnormalities of the Ovaries

Mares

Abnormally Small Ovaries

The most common causes of bilaterally small ovaries in the mare are (1) seasonal anestrus, (2) hypothalamopituitary dysfunction, (3) severe malnutrition, (4) immaturity, (5) advanced age, (6) use of anabolic steroids, and (7) gonadal dysgenesis. Clinical signs and treatment of seasonal anestrus, hypothalamopituitary dysfunction, and malnutrition are discussed elsewhere in this chapter.

Immaturity and Advanced Age

The average age at which fillies reach puberty is 18 months, with a wide range of 10 to 24 months. Fillies younger than 2 years of age with inactive ovaries and a flaccid and relaxed reproductive tract may be too young to cycle and should be reexamined later. The condition should be differentiated from gonadal dysgenesis, and karyotyping may be indicated if puberty is delayed beyond 24 months.

Older mares (>20 years) not only frequently begin cycling later in the season than do younger mares but also often have a longer follicular phase and, subsequently, a longer interovulatory interval.[12,13] Equine serum AMH levels that are related to antral follicle count have been shown to increase with age.[14] Some mares reach ovarian senescence when they grow older [12,15,16] and typically have small, inactive ovaries (follicles <5 mm) and a flaccid uterus and cervix. Although senescent mares may still show behavioral signs of estrus (similar to those of anestrous or ovariectomized mares), ovarian function is completely absent.

Oocytes collected from aged donor mares, cultured, and transferred to young recipient mares were less likely to result in pregnancy than oocytes from young donor mares.[17] Furthermore, oocytes obtained from old mares and examined using transmission electron microscopy had more morphologic abnormalities than oocytes from young mares. Results from these studies suggest that oocyte quality declines as mares age, and this factor will contribute to poor fertility in older mares.

Treatment and Prognosis No treatment is available for age-related ovarian inactivity. Because aged mares often experience a delayed seasonal onset of ovarian activity, they benefit from an artificial light regimen starting 60 to 90 days before the breeding season. GnRH has been used to stimulate follicular growth in mares with poor follicular development attributable to anestrus or transition. Several researchers have examined the effects of GnRH administered at different doses and intervals to stimulate follicular development in mares. In general, the number of mares responding to GnRH therapy increases as the size of follicle increases or the time of year at the onset of therapy advances.

EXOGENOUS HORMONE TREATMENT. Anabolic steroids are derivatives from androgens that have been altered to provide

high anabolic activity with minimal androgenic side effects. A suppression of gonadotropin secretion has been documented when mares have been treated with these drugs.[18] Anabolic steroid administration may affect both estrous behavior and ovarian size and function. The treatment of mares with low doses of anabolic steroids can cause aggressive or stallion-like behavior, whereas high doses can inhibit ovarian activity and result in failure of follicular development and ovulation.[18] Prolonged treatment of prepubertal mares with anabolic steroids results in hypertrophy of the clitoris.[19] Ovarian inactivity in mares treated with anabolic steroids is often reversible, and pituitary and ovarian function eventually return to normal in most mares after withdrawal of the treatment. However, mares intended for breeding should not be treated with anabolic steroids.

Progestins are commonly given to cycling mares for the suppression of estrus or synchronization of ovulation. Mares may continue to ovulate during progestin administration, especially if treatment is started late in the luteal phase. A high incidence of persistent CL formation has been observed in mares that ovulate during progestin treatment.[20] Administration of the potent GnRH agonist deslorelin acetate to induce ovulation has been associated with delayed follicular development and a prolonged interovulatory interval.[21,22] Deslorelin acetate is effective in inducing ovulation, but treatment appears to cause a temporary downregulation of FSH secretion. The low FSH concentrations have been associated with a prolonged period of decreased follicular growth. Administration of $PGF_{2\alpha}$ 7 to 8 days after ovulation appears to increase the risk of delayed follicular development. It has been suggested that $PGF_{2\alpha}$ administration "resets" the timing of the estrous cycle during a period when limited follicular activity is present.

Treatment and Prognosis Removal of the deslorelin implant after ovulation has been detected to decrease the incidence of prolonged interovulatory intervals.[23]

GONADAL DYSGENESIS. Chromosomal abnormalities occur in all breeds of horses. Mares are usually small and phenotypically female. The ovaries are small, firm, smooth, and inactive. The tubular tract is thin and flaccid. Endometrial hypoplasia is a common finding. Diagnosis is confirmed by physical findings and karyotype. Mares with gonadal dysgenesis are sterile, and there is no treatment.

PITUITARY PARS INTERMEDIA DYSFUNCTION. Mares with hypertrophy, hyperplasia, or adenoma formation in the pars intermedia of the pituitary (pituitary pars intermedia dysfunction [PPID]) have been reported to have abnormal estrous cycles, infertility, or both.[24,25] The mechanisms by which PPID causes reproductive abnormalities have not been determined. Potential causes may be destruction of the gonadotrophs of the anterior pituitary owing to compression by the enlarged pars intermedia and/or suppression of gonadotropin secretion owing to elevated levels of glucocorticoids or androgens produced by the adrenal cortex.[26] In support of the glucocorticoid hypothesis, administration of dexamethasone to intact mares results in reduced estrous behavior, LH concentrations, follicular growth, and incidence of ovulation.[27] In addition, administration of dexamethasone to ovariectomized mares results in suppression of pituitary LH and FSH secretion,[28] and treatment of pony mares with dexamethasone during the winter eliminates estrous behavior.[29] However, others have shown that abnormally high levels of cortisol secretion has a minimal effect on fertility.[30] Many PPID horses are insulin resistant, and insulin is believed to play a role in the regulation of ovarian steroidogenesis and follicular development.[31] Obese mares with reduced insulin sensitivity have been shown to have prolonged interovulatory periods. Insulin resistance therefore may be one mechanism by which PPID mares exhibit abnormal ovarian function.[32] Most horses diagnosed with PPID are older, with the average age being approximately 20 years. Consequently the decrease in reproductive efficiency in mares with PPID may be partly a result of advanced age.

Clinical signs of PPID include hirsutism and abnormal hair-coat shedding patterns, polyuria, polydipsia, and hyperhidrosis.[33] Diagnostic tests for PPID include measurements of serum glucose, insulin, adrenocorticotropic hormone (ACTH), and cortisol levels; dexamethasone suppression; ACTH stimulation; and thyrotropin-releasing hormone response.[34] The measurement of single samples for basal cortisol or ACTH concentrations is of limited value in the diagnosis of PPID.

Treatment and Prognosis The medical management of PPID includes the administration of pergolide mesylate, a dopamine receptor agonist, at a dose of 0.002 to 0.01 mg/kg every 24 hours (1 to 5 mg/500 kg) in an adult horse. Because of its dopaminergic agonist effect, treatment with pergolide mesylate should be avoided in late pregnant and lactating mares. Treatment of pregnant mares can be discontinued at 30 days before expected foaling until 1 month postpartum, and the mares should be monitored for adequate milk production. Foals should be supplemented with a milk replacer when insufficient milk production is suspected in the dam. The serotonin antagonist cyproheptadine has also been used, but it may not be as efficacious as pergolide. The dose of cyproheptadine is 0.25 mg/kg every 24 hours, given once in the morning.

EQUINE METABOLIC SYNDROME. Equine metabolic syndrome (EMS) is not clearly defined, and intense research in this area is expected to shed further light on the understanding of this condition in horses. Altered circulating concentrations of leptin and adiponectin have been observed in horses with EMS, and an effect on reproductive cycles in mares has been suggested, but existing data are not conclusive.[35-37] In fact, moderately obese mares are more likely to cycle year-round compared to lean mares.[38]

EMS has been associated with regional obesity, insulin resistance, and laminitis.[39] A presumptive diagnosis is often based on body condition score and signs of regional obesity, history of laminitis, and insulin resistance.[40]

Treatment and Prognosis Controlled diet and exercise are important components in the management of mares with suspected EMS. Medical treatment with metformin at a dose of 15 to 30 mg/kg and levothyroxin sodium at a total dose of 48 mg has been suggested.[39] However, scientific evidence of the safety and efficacy of these drugs is insufficient in horses. Metformin has not been evaluated for safety in pregnant mares, but it is considered safe to use in pregnant women.[41] The effect of human maternal hyperthyroidism on the fetus should be considered before levothyroxin is used in pregnant mares.

Abnormally Enlarged Ovaries

The most common causes of enlarged ovaries in the mare are (1) tumors, (2) anovulatory follicles, (3) ovarian hematomas, and (4) pregnancy.

Ovarian Tumors

Most equine ovarian tumors can be categorized as sex cord–stromal tumors (granulosa-theca cell tumors), epithelial tumors (cystadenomas), or germ cell tumors (dysgerminomas and teratomas), and mares can present with more than one tumor type.[1]

GRANULOSA-THECA CELL TUMORS. The granulosa-theca cell tumor (GCT) is the most common ovarian tumor in the

FIG. 43.3 Granulosa cell tumor removed from a mare.

mare (Fig. 43.3),[2] and 10% of all neoplasms in horses are GCTs. It is usually slow growing, unilateral, and benign; however, malignant tumors have been reported.[3] It occurs in mares of all ages and parity[2,4] and is occasionally found in pregnant mares.[2,5] The tumor arises from the steroidogenic cells of the follicle, resulting in abnormal secretion of inhibin and testosterone.

Clinical Signs and Diagnosis Diagnosis of GCTs is made based on ultrasonographic findings, histologic evaluation, hormone profile analysis, and behavioral observations. Transrectal ultrasonographic examination of the affected ovary often reveals a multicystic or honeycombed structure, but the tumor may also occur as a solid mass or as a single large cyst. In most cases the GCT affects only one ovary, and the contralateral ovary is usually small and inactive, although mares with a GCT on one ovary and a functional contralateral ovary have been reported.[6]

GCTs are hormonally active, and clinical diagnostic assays for the detection of a GCT include the measurement of inhibin (α-inhibin), testosterone, progesterone, and AMH.[7-11] α-Inhibin is elevated in approximately 90% of the mares with a GCT.[8,10] It has been hypothesized that inhibin produced by the GCT is responsible for inactivity of the contralateral ovary through the suppression of pituitary FSH release,[12] but the poor correlation between dimeric inhibin and the presence of GCT raises questions about the mechanism by which the contralateral ovary is suppressed in affected mares.[10,13] Serum testosterone in a single blood sample can be expected to be elevated (100 to 200 pg/mL) in approximately 50% to 60% of affected mares. Daily fluctuations in testosterone concentrations have been reported, and repeated samples may have to be obtained on different days in order to detect elevated testosterone.[10] Progesterone concentrations in mares with a GCT are almost always below 1 ng/mL because normal follicular development, ovulation, and CL formation do not occur. Serum levels of AMH in mares with GCTs are consistently higher than in normal cyclic and pregnant mares, and this provides an excellent tool in the diagnosis of GCT.[11] As a result of hormone secretion from the tumor, mares may show anestrus, constant estrus, irregular estrus, or stallion-like behavior. Physical changes such as an enlarged clitoris, increased muscle mass, and the development of a crested neck have been associated with GCTs, and other clinical signs such as colic, lameness, and weight loss have been observed.[2]

Treatment and Prognosis Treatment for GCTs is removal of the affected ovary.[14] Surgical approaches for tumor removal include colpotomy, flank and ventral midline laparotomy, and laparoscopy. The prognoses for both life and reproductive use are good. The time from surgery to return to cyclicity varies, but most mares cycle in the year after ovariectomy.

CYSTADENOMAS. The most common tumor of the surface epithelium of the equine ovary is cystadenoma. They are rare, benign, normally hormonally inactive tumors from the surface epithelium of the ovulation fossa. The tumor is unilateral, and the contralateral ovary is normal.

Clinical Signs and Diagnosis Mares with cystadenomas cycle normally from the opposite ovary and may become pregnant if bred. Rectal palpation and ultrasonography reveal the presence of one enlarged multicystic ovary, which may appear similar to a GCT, and one normal ovary; however, final diagnosis is histologic.

Treatment and Prognosis Although cystadenomas are benign tumors and do not affect the reproductive performance of the mare, they are usually surgically removed if diagnosed. The prognoses for both life and reproductive performance are excellent.

GERM CELL TUMORS. Dysgerminomas and teratomas are rare ovarian tumors of germ cell origin. Both tumors are unilateral and hormonally inactive.

Clinical Signs and Diagnosis Both tumors make the affected ovary unilaterally enlarged and multicystic. Dysgerminomas are malignant and do often metastasize to the peritoneal and thoracic cavities. Teratomas may arise from all three germinal layers, and the neoplastic ovary may contain bone, cartilage, teeth, hair, muscle, and nerves. Teratomas do not cause clinical signs, interrupt the estrous cycle, or alter the behavior of the mare. Diagnosis of dysgerminomas and teratomas is made using ultrasonography and histologic evaluation of the affected ovary.

Treatment and Prognosis Surgical removal is recommended for both dysgerminomas and teratomas. The prognosis for teratomas is usually good, but it is poor for mares diagnosed with dysgerminomas.

Anovulatory Follicles

Clinical Signs and Diagnosis

Ovulation failure is a normal physiologic event for the mare during the spring and fall transition periods, but it may also occur occasionally during the physiologic breeding season. Persistent anovulatory follicles (PAFs) may be quite large (5 to 15 cm in diameter), persist for up to 2 months, and result in abnormal estrous behavior and prolonged interovulatory intervals.[15] The cause of ovulation failure is still being determined, but it has been suggested to be due to gonadotropic stimulation insufficient for ovulation,[16] reduced estrogen production by the follicle,[17] blockage of the ovulation fossa,[18] repeated use of ovulation-inducing drugs,[19] alterations of the matrix metalloproteinase system,[20] and defects in the normal ovarian proangiogenic activity.[21] PAFs have been reported to occur in approximately 8.2% of estrous cycles, and significantly more mares 16 to 20 years of age developed anovulatory follicles than mares 6 to 10 years of age.[22] The formation of an anovulatory follicle was preceded by development of normal endometrial folds or edema in 78.3% of these cases. Initial growth patterns of follicles destined to become anovulatory were usually normal, and the first indication of a problem was the detection of echogenic particles within the follicular fluid.[22]

PAFs may contain blood and have been called *hemorrhagic anovulatory follicles*. The hemorrhage can be detected ultrasonically

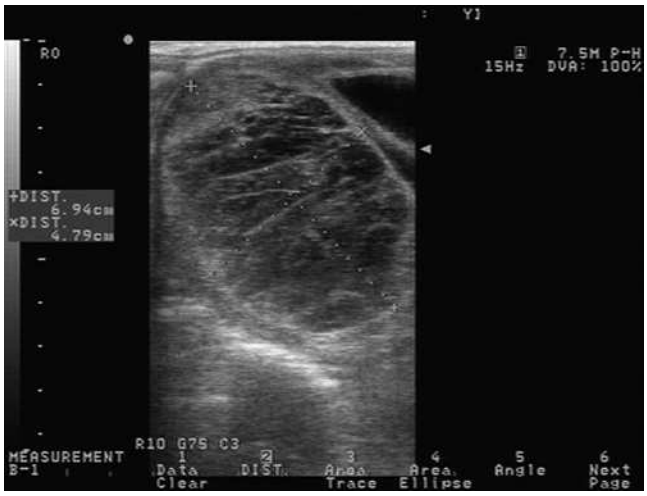

FIG. 43.4 Transrectal ultrasonographic image of a persistent anovulatory follicle in a mare.

as scattered free-floating echogenic spots within the follicular fluid. The follicular fluid may form a gelatinous, hemorrhagic mass within the follicular lumen. Ultrasonographically these structures may contain echogenic fibrous bands traversing the follicular lumen (Fig. 43.4).[23] A thickening of the follicular wall may be observed in anovulatory follicles. This thickening is often associated with luteinization of the follicular wall, and 85.7% of PAFs were found to be luteal structures based on elevations in plasma progesterone concentrations.[22]

Treatment and Prognosis Treatment with hCG or a GnRH agonist to induce ovulation or luteinization of the anovulatory follicle is generally not effective. The administration of prostaglandins may result in the destruction of the luteal cells in mares with luteinized PAFs. Most nonluteinized PAFs spontaneously regress in 1 to 4 weeks. Pregnancy does not usually occur if a persistent follicle eventually spontaneously ovulates or is induced to ovulate. This is likely a result of degeneration of the oocyte over time. Pregnancy obviously will not occur if the follicle becomes hemorrhagic or luteinized without ovulation.

Ovarian Hematoma

Clinical Signs and Diagnosis Hemorrhage into the follicular cavity is a normal occurrence at ovulation. Occasionally hemorrhage is severe, resulting in the formation of an ovarian hematoma that may be 10 cm in diameter or larger. Diagnosis can be made using transrectal palpation and ultrasonography, and the condition presents as an enlarged ovary that is initially irregularly hypoechoic and then echogenic with organization of the hematoma. Ovarian hematoma should not be mistaken for a GCT, since the ovulation fossa usually remains distinguishable on the affected ovary, and the contralateral ovary remains active.

Treatment and Prognosis Ovarian hematomas regress spontaneously over a period of weeks or months. The functional life span of the luteal tissue in a hematoma is normal, and ovarian activity is unaffected.[24] Because the affected ovary is not permanently damaged and the contralateral ovary is unaffected, the prognosis for fertility is undiminished.

Pregnancy

Multiple secondary CLs form in pregnant mares at 40 to 180 days of gestation, resulting in bilaterally enlarged ovaries that may be mistaken for ovarian pathology.

Clinical Signs and Diagnosis Ovarian enlargement is commonly bilateral. Pregnant mares may show stallion-like behavior associated with increased testosterone production from the fetus during midgestation. Pregnancy should always be considered in a mare with stallion-like behavior, elevated serum testosterone concentrations, and enlarged ovaries. Pregnancy is diagnosed by rectal palpation and ultrasonographic examination.

Persistent Corpus Luteum

The CL usually regresses 14 to 15 days after ovulation. Although luteal cells appear to be sensitive to $PGF_{2\alpha}$ almost immediately after ovulation, complete luteolysis and return to estrus in response to endogenous or exogenous $PGF_{2\alpha}$ will not occur until 5 days after ovulation. Because the functional CL is lysed by $PGF_{2\alpha}$ from the endometrium, the CL will continue to function in the following situations.

1. The equine conceptus produces a $PGF_{2\alpha}$ inhibitor factor, which is secreted as early as day 11 to 13 after ovulation.[25] The factor prevents $PGF_{2\alpha}$ from being synthesized and secreted from the endometrium. This results in a prolonged luteal phase of the primary CL until the development of endometrial cups and secretion of eCG ensure the presence of functional luteal tissue in the pregnant mare.
2. Embryonic loss after the time of maternal recognition of pregnancy can result in a persistent CL for a variable period of 35 to 90 days.[26]
3. Destruction of the endometrium in infectious and inflammatory conditions such as pyometra may cause insufficient synthesis of $PGF_{2\alpha}$ and prolonged luteal life.[27]
4. Late diestrous ovulation will result in a CL that is insufficiently mature to respond to endogenous $PGF_{2\alpha}$ release.
5. Nonsteroidal antiinflammatory drugs may inhibit endometrial $PGF_{2\alpha}$ synthesis, resulting in a prolonged luteal phase.[28]
6. Repeated treatment with oxytocin before upregulation of oxytocin receptors occurs (before day 13) has resulted in a prolonged luteal phase.[29,30]
7. Spontaneous CL persistence has been proposed as a clinical entity[26] but has not been adequately documented and is an area of controversy.[31]

Clinical Signs and Diagnosis A persistent CL may be suspected clinically in mares that are not expressing normal estrous behavior during the physiologic breeding season, and it must be differentiated from mares with silent heat. Diagnosis is made by transrectal ultrasonographic examination of the ovaries. The CL appears as a well-defined hyperechoic structure on the ovary. Mares with a persistent CL will have good cervical and uterine tone on palpation, and the cervix will appear tight and dry on vaginal speculum examination because of the influence of progesterone. The diagnosis may be confirmed by analysis of plasma progesterone concentrations or a clinical response to prostaglandin administration. Progesterone concentrations greater than 1 ng/mL are indicative of the presence of active luteal tissue. Differential diagnoses are listed in Table 43.4.

Treatment and Prognosis After pregnancy has been ruled out with sonographic examination, luteolysis can be achieved with administration of 5 to 10 mg of the α-progstaglandin product dinoprost tromethamine or similar prostaglandin analog. The mare must be at least 5 days post ovulation to respond reliably to treatment, although administration of the drug 3 days post ovulation can be effective.[32] If the mare is treated with $PGF_{2\alpha}$ in the presence of a mature diestrous follicle (≥35 mm), she may ovulate the follicle without signs of estrus in response to declining progesterone concentrations that allow LH to be secreted from the anterior pituitary. An

TABLE 43.4

Unilaterally Large Ovary: Differential Diagnosis

Etiology	Distinguishing Features
Granulosa-theca cell tumor	Sonographically multilocular, high inhibin, AMH and/or testosterone; small contralateral ovary
Other ovarian tumor	See text
Ovarian hematoma	Ovulation fossa still palpable, cycles normally
Ovarian abscess	Large, hard ovary; sonographically echogenic
Ovarian follicle	Normal cycling mare, ovulates
Anovulatory hemorrhagic follicle	Free-floating echogenic spots

AMH, Anti-mullerian hormone.

ultrasonographic or rectal examination of ovarian follicular activity should therefore always be performed before $PGF_{2\alpha}$ is administered to induce estrus.

Shortened Luteal Phase (Premature Luteolysis)

Premature (<15 days) luteolysis is associated with an early onset of estrus and a decrease in the interovulatory interval. The most common cause of premature luteolysis in the mare is endometritis. Inflammation of the endometrium results in an acute activation of inflammatory mediators. One of these mediators is $PGF_{2\alpha}$, which in addition to its inflammatory effect also may cause luteolysis and return to estrus. Consequently a mare that exhibits a shortened diestrus should be examined for endometritis. Manipulation of the reproductive tract for uterine biopsy has also been found to cause premature luteal regression.[33]

Luteal Insufficiency

Primary luteal insufficiency implies a deficiency in progesterone production. Luteal insufficiency has been suggested to be a cause of subfertility in mares.[34] Maintenance of pregnancy in some habitually aborting mares after administration of exogenous progestogens offers circumstantial evidence that progesterone insufficiency may be responsible for some cases of pregnancy loss. However, the concept of primary luteal insufficiency as a cause of early pregnancy loss is controversial and not supported by conclusive scientific data.

Luteal insufficiency secondary to $PGF_{2\alpha}$ release in mares with endotoxemia has been reported[35] and should be considered in pregnant mares with gram-negative infection and/or endotoxemia-associated colic. Reports on the effect of exogenous administration of $PGF_{2\alpha}$ during the periovulatory period suggest that $PGF_{2\alpha}$ can delay the formation of a functional CL. Suboptimal concentrations of progesterone were found in mares after treatment with $PGF_{2\alpha}$ during the first 2 days after ovulation.[36-39] Although the CL eventually became functional and progesterone concentrations had returned to normal levels at day 14, pregnancy rates were significantly lower in treated mares.[37,38]

Clinical Signs and Diagnosis The minimum concentration of progesterone required to maintain pregnancy in the mare has been suggested to be 2 ng/mL.[35] Repeated samples are necessary to diagnose luteal insufficiency because progesterone is released episodically.

Treatment and Prognosis The most common treatment for luteal insufficiency is supplementation with the synthetic progestogen altrenogest (Regu-Mate®) at a dose of 0.044 mg/kg PO once daily. Options for duration of altrenogest supplementation include treatment until day 80 to 120 of pregnancy or longer and measurement of endogenous progesterone level greater than 2 ng/mL (progesterone and altrenogest do not cross-react on radioimmunoassay [RIA]) or treatment until the end of gestation. It is important to emphasize the need to monitor fetal well-being when mares are kept on progestin supplementation to maintain pregnancy. A case of mummification of a 5-month-old fetus in a pregnant mare at term has been reported.[40] The mare had been maintained on altrenogest throughout gestation.

Ruminants

Prolonged Luteal Function

COW. Spontaneous prolongation of luteal function in the presence of a normal, nongravid uterus does not occur in cows. However, several conditions affecting the uterus do suspend the luteolytic mechanism, resulting in prolonged luteal function, persistently elevated progesterone concentrations, and anestrus. Common causes of prolonged luteal function in cows include pregnancy, pyometra, mummified fetus, and segmental aplasia, including uterus unicornis.

Clinical Signs and Diagnosis Pregnancy resulting from an unobserved or unrecorded breeding must always be considered as a possible cause of anestrus. Examination of the uterus by transrectal palpation or ultrasonography for one of the positive signs of pregnancy (fetal membrane slip, amnionic vesicle, placentomes, or fetus) must precede administration of $PGF_{2\alpha}$.

Pyometra is characterized by accumulation of variable amounts of mucopurulent exudate within the uterine lumen, failure of luteolysis, and subsequent anestrus. An enlarged uterus as a result of fluid accumulation and a thickened uterine wall in the absence of any positive signs of pregnancy can be used to differentiate uterine enlargement caused by pregnancy from that caused by pyometra. Fluid associated with pyometra is more viscous than fetal fluid and can be manipulated from horn to horn. Because the cervix is nearly always closed, there is generally no vaginal discharge.

Fetal mummification is occasionally encountered in dairy and beef cows and is characterized by fetal death, failure of expulsion, absorption of fetal fluids, and persistence of the CL. Cows with fetal mummification are usually presented when they do not deliver a calf at the expected time. The condition can be differentiated from pregnancy by palpation per rectum of a dried, leather-like fetus within the involuted uterus. Fetal membranes cannot be slipped, and fetal fluids and placentomes are absent.

Clinical Pathology No remarkable changes in hematology and clinical chemistry are associated with pregnancy, mummified fetus, or pyometra in cows. In all three conditions, peripheral concentrations of progesterone remain elevated above 1 ng/mL of plasma until spontaneous luteolysis occurs or the condition is treated.

Treatment and Prognosis Unwanted pregnancy is seldom encountered in dairy cows, but when cows or heifers are mated by accident or to an undesired sire, abortion may be reliably induced with $PGF_{2\alpha}$ products (25 mg of dinoprost tromethamine or 500 µg of cloprostenol, two injections 8 to 12 hours apart) after 7 days and before 150 days of gestation or with a combination of $PGF_{2\alpha}$ and dexamethasone (20 mg) beyond 150 days of gestation. The $PGF_{2\alpha}$ products are also

VetBooks.ir

VetBooks.ir

the treatment of choice for pyometra in cows. Mummified fetuses are usually expelled 3 to 5 days after treatment with $PGF_{2\alpha}$. The mummy may pass through the cervix, but the vagina is likely to be dry and may not dilate sufficiently, so the mummified fetus may be retained. If the mummified fetus is not expelled by 5 days after treatment, a vaginal examination should be performed and the mummy delivered by gentle traction if necessary. The prognosis for fertility after delivery of a mummified fetus is fair, but slaughter is often recommended for economic reasons.

Ovarian Hypoplasia

Ovarian hypoplasia occurs sporadically as an autosomal recessive trait in the cow. The condition has incomplete penetrance; therefore it may be partial or complete and unilateral or bilateral. The affected gonad varies in size from a cordlike thickening in the cranial edge of the mesovarium to a bean-sized structure. The tubular genital organs remain infantile in animals with complete bilateral hypoplasia or may develop to near normal size in heifers with unilateral or partial hypoplasia. Individuals affected with complete bilateral ovarian hypoplasia are sterile, whereas those affected by partial or unilateral hypoplasia may be subfertile. With partial hypoplasia the uterine pole of the ovary is typically affected. On direct observation by laparotomy or laparoscopy or on slaughter, the uterine pole is flat and triangular and shows converging striations. The affected part is devoid of follicles. Animals with partial ovarian hypoplasia can be expected to have a reduced superovulatory response to gonadotropin treatment. Heifers with abnormal karyotypes are also affected by ovarian hypoplasia. The condition should be differentiated from nonfunctional ovaries and anestrus associated with malnutrition or debilitating diseases. Treatment of ovarian hypoplasia is not successful.

Ovarian Tumors

Granulosa Cell Tumor

COW. Although rare, various ovarian neoplasms have been described in cows; granulosa cell tumors appear to be most common.[1]

Clinical Signs and Diagnosis Granulosa cell tumors are characterized by unilateral ovarian enlargement, with the affected ovary being greater than 10 cm in diameter. The surface may be smooth or coarsely lobulated. Function of the contralateral ovary may be suppressed. The behavior of affected cows ranges from anestrus to nymphomania to bull-like behavior. Udder development and lactation may occur in affected heifers. Hormonal profiles, including estrogen and testosterone, may be variable among cows with granulosa cell tumors. Although inhibin has not been validated for use in cows, AMH is secreted by neoplastic granulosa cells and can be a useful diagnostic measurement.[1] Few bovine granulosa cell tumors are malignant, and they rarely metastasize. Among the other ovarian neoplasms that have been reported in cattle are dysgerminomas, interstitial cell tumors, and teratomas. Causes of ovarian enlargement that must be differentiated from ovarian neoplasia include ovarian cysts, oophoritis, ovarian abscesses, and parovarian cysts.

Treatment and Prognosis The treatment for ovarian neoplasia in cattle is surgical removal of the affected ovary; however, cows may not be as fertile as mares after removal of the tumor.

EWE. Granulosa cell tumors have been reported, but tumors of the genital organs of ewes appear to be rare. Animals with ovarian tumors may exhibit all types of behavioral and physiologic abnormalities (nymphomania, inappropriate lactation). Diagnosis is based on transabdominal or transrectal ultrasonographic evaluation of the ovaries. Treatment is ovariectomy.

DOE. Ovarian neoplasia appears to be rare in does as well. Granulosa cell tumors and dysgerminomas have been reported.

Ovarian Hemorrhage

Cow

Ovulation tags develop after ovulation, resulting from blood loss associated with rupture of the follicle. Fine adhesions may develop between the ovarian surface and surrounding structures. Most ovulation tags resolve spontaneously and have no effect on fertility. Severe ovarian hemorrhage may follow attempts to manually enucleate the CL. Adhesions between the ovary and its bursa interfere with their normal function. Enucleation of CLs for treatment of anestrus and pyometra has been superseded by treatment with $PGF_{2\alpha}$ products.

Oophoritis

Cow

Inflammation of the ovary may follow traumatic manipulations, such as enucleation of CLs and attempts to drain fluid from ovarian cysts, and ascending infections from the uterus. Oophoritis may also accompany brucellosis, mycoplasmosis, and tuberculosis.

Infertility Caused by Abnormalities of the Female Tubular Genitalia

Salpingitis

Inflammation of the oviducts is characterized by macroscopic enlargement. Lesions are frequently bilateral and consist of infiltration by lymphocytes, plasma cells, and neutrophils, and desquamation of epithelial cells.

Most cases of salpingitis follow infections of the uterus. Necrotizing and granulomatous salpingitis may follow infection by *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), *Mycobacterium tuberculosis*, and *Brucella abortus*. Mild inflammation of the uterine tubes that does not usually result in permanent damage accompanies uterine infection caused by *Campylobacter fetus* subsp. *venerealis* and *Tritrichomonas foetus*. Salpingitis may be a sequela to manipulations of the ovaries and uterine tubes by palpation per rectum, transvaginal ovum pickup, aggressive irrigation of an infected uterus, and inappropriate treatment with estrogenic hormones. Migrating larvae of *Strongylus edentatus* have been proposed as a possible cause of nonobstructive infundibulitis in mares, but their role is speculative.

Pyosalpinx is characterized by segmental accumulation of pus within the lumen of the oviduct after mechanical blockage of either end. Pyosalpinx frequently follows severe cases of uterine infection and may be complicated by perimetritis and localized peritonitis.

Hydrosalpinx is characterized by accumulation of thin mucus within the lumen of the oviduct. Hydrosalpinx and adhesions to perisalpingial tissues are common sequelae to chronic salpingitis.

Clinical Signs and Diagnosis The usual history associated with diseases of the uterine tubes is one of infertility. Additional history may include uterine infection or traumatic therapy such as uterine irrigation, enucleation of CLs, or administration of exogenous estrogen during CL function. Salpingitis is an uncommon clinical finding in the mare.

VetBooks.ir

However, in one study up to 88% of mares were found to have macroscopic lesions in the oviduct, including adhesions, fibrous bands, and parovarian cysts, which may or may not have affected fertility.[1] Accumulations of cells and debris may form intraluminal masses; however, their role in infertility has not been adequately tested.[2] Similarly, moderate lesions of uterine tube disease may escape diagnosis by physical examination in cows, but the results of abattoir studies suggest that lesions of the oviducts are not uncommon. In cows, lesions involving adhesions among the ovary, ovarian bursa, oviduct, and surrounding tissues may be identified per rectum by inserting two or three fingers into the ovarian bursa and rolling the oviduct between the fingers and thumb. Easy identification of the oviduct by palpation per rectum is sometimes considered indicative of abnormalities. Diagnosis of diseases of the oviducts in ewes and does is impossible by physical examination. Although a history of infertility after one of the predisposing causes might suggest oviductal lesions, diagnosis is made by exploratory laparotomy, peritoneoscopy, or necropsy.

Lesions of the oviductal or perisalpingial tissues must be differentiated from other causes of abnormal enlargements such as ovarian neoplasia, parovarian cysts, cystic ovarian disease, and ovarian hematomas. Neoplasia of the oviducts in domestic animals is extremely rare.

Clinical Pathology Several tests that determine oviductal patency of mares[3,4] and cows[5] have been described, but neither the starch test nor the phenolsulfonphthalein dye test is reliable or consistently diagnostic. For suspected unilateral blockage, each uterine horn may be catheterized individually with a Foley catheter placed at the base of the horn on different days.[6]

Embryo Recovery Embryo recovery after either a single ovulation or superovulation is objective evidence that one or both uterine tubes are patent and functional. Improved reproductive performance of cows may follow uterine lavage; therefore embryo recovery as a diagnostic test may have therapeutic benefits as well.[7]

Treatment and Prognosis Treatment of diseases of the oviducts is not likely to be successful. Appropriate treatment for concurrent uterine infections should be instituted. A period of sexual rest may be beneficial and is indicated in valuable animals. The prognosis for reproduction in cases of bilateral obstruction of the oviducts is poor. In vitro fertilization of ova harvested from affected females is a therapeutic option. Affected females can also serve as embryo recipients.

Prevention and Control Traumatic manipulation of the ovaries, irrigation of the endometrial cavity with large volumes of fluid (>100 mL in heifers or 150 mL in cows) or irritating chemicals, and administration of estrogenic hormones to luteal phase females should be avoided. Because abnormalities of the oviducts are frequently associated with uterine infections, reduction of the prevalence of uterine infections results in fewer tubal infections as well.

Uterine Abnormalities

Retained Fetal Membranes

MARES. Retention of the fetal membranes beyond a period of 3 hours is an abnormal occurrence in the mare. The mare has an epitheliochorial placenta characterized by diffuse microvilli that interdigitate with endometrial crypts. After delivery, blood flow through the placental vessels is reduced. Placental microvilli shrink and disengage from endometrial crypts. The pathophysiology of the disease is poorly understood but may involve disturbances of normal prepartum endocrine events or myometrial contractility. The condition is more common after abortion, dystocia, cesarean section, and fetotomy. Partial placental retention may be localized to well-defined areas of continued placental attachment. The most common site of partial retention is the previously nongravid horn.

Equine placentas should be spread on a flat surface after expulsion and examined to ensure that the complete membrane is present. Areas of placental necrosis are common near the tips of the uterine horns, and the fragile area may be incarcerated by the rapidly contracting uterus.

Clinical Signs and Diagnosis Retained fetal membranes (RFMs) are usually visible at the vulva. However, small tags of placental tissue may remain attached to the uterus without being apparent and may be a nidus for infection, resulting in severe metritis, endotoxemia, and laminitis hours to days postpartum.

Treatment and Prognosis The severity of sequelae makes early intervention essential. Treatment should begin if fetal membranes are not passed within 3 hours of foaling. Most instances respond to vigorous early pharmacologic treatment. Occasional cases require several days of persistent treatment.

MANUAL REMOVAL. Manual removal should be avoided because trauma induces placental tearing, leaving microvilli in endometrial crypts.

OXYTOCIN. Oxytocin induces myometrial contractions, which may aid placental expulsion. Oxytocin may be administered by IV injection (5 to 20 IU every 30 to 60 minutes) or IM injection (10 to 20 IU every 30 to 60 minutes), or it may be infused slowly (30 to 80 IU in 500 mL of warm saline IV over 30 to 60 minutes). Care should be taken to avoid higher doses, which may result in signs of abdominal pain and will cause tetanic rather than orchestrated uterine contraction.

ALLANTOCHORIONIC INFUSION. If the allantochorion is intact, the allantochorionic cavity may be filled to distention with 3 to 4 gallons of warm saline or water through the cervical star.[1] The opening in the placenta is held closed manually until the mare exerts abdominal pressure. Oxytocin may be used in conjunction with this treatment.

UTERINE LAVAGE. If the allantochorion is not intact, uterine lavage with an isotonic saline solution will clear debris, will trigger myometrial contractions, and may help free the retained fragment of the fetal membrane. The isotonic saline solution may be infused into the uterus through an equine nasogastric tube (dedicated to reproductive use) manually held in place. Approximately 5 L may be placed in the uterus of a full-grown, postpartum mare at one time, but care should be taken to observe the mare for signs of discomfort and to gauge the amount of fluid felt within the uterus. During fluid infusion the operator may carefully explore the uterus manually, searching for RFM remnants. Once the uterus is relatively full of fluid, the fluid is siphoned out. Care must be taken to protect the fragile endometrium from damage incurred by the strong suction force of the siphon. The operator's hand should guard the end of the tube from direct contact with the endometrium. This process should be repeated until the effluent is clear. Uterine lavage should be performed at least once daily until 12 to 24 hours after the RFM remnants are retrieved.

ADJUNCT THERAPY. Concurrent therapy directed at controlling or minimizing common sequelae to retained placenta is often indicated.

1. *Antimicrobials.* Bacterial infections are commonly associated with prolonged (>6 to 8 hours) retention of the fetal

membranes. The bacterial population is frequently mixed and likely to include β-hemolytic streptococci and coliforms. In prolonged cases, bacterial culture and sensitivity should be performed. Broad-spectrum antibiotics known to be effective against commonly isolated organisms are indicated. Drugs that have been recommended for systemic administration include amikacin, ampicillin, gentamicin, kanamycin, penicillin, ticarcillin (with gentamicin for *Pseudomonas* infection), and trimethoprim-sulfamethoxazole. Intrauterine administration of antibiotics and antiseptics depresses phagocytic activity of uterine neutrophils, and many chemicals irritate the endometrium. Drugs that have been suggested include those recommended for systemic administration.

2. *Antiinflammatory drugs.* Laminitis may be a sequela to metritis and is commonly associated with RFMs. Treatment with administration of antiinflammatory drugs such as phenylbutazone or flunixin meglumine is indicated to reduce the likelihood and severity of laminitis. Polymyxin B may also be indicated in cases in which preliminary signs of laminitis are noted because of its antiinflammatory and antiendotoxic effects. Additional therapy for laminitis should be administered as indicated.
3. *Other treatments.* Caslick's surgery may be indicated in some cases of RFMs to control aspiration of air. Tetanus may complicate RFMs, and prophylaxis with tetanus antitoxin in unvaccinated animals or tetanus toxoid in previously vaccinated animals is indicated.

Some cases of RFMs are refractory to treatment, and membranes may remain firmly attached to the endometrium for several days. Aggressive attempts at manual removal should be eschewed because severe endometrial damage may follow. Persistent treatment with uterine lavage antibiotics, antiinflammatory drugs, and oxytocin is indicated until the placenta is expelled and bacterial infection of the uterus is controlled.

The prognosis for RFMs is generally good but is reduced if treatment is delayed or if retention is accompanied by infection with virulent pathogens. Sequelae to RFMs include metritis, endometrial fibrosis, invagination of a uterine horn, uterine prolapse, and laminitis.

Ruminants

Cow

The cotyledonary placenta of cows is usually expelled within 3 to 8 hours after calving and is considered retained if not expelled by 12 hours. RFMs are more commonly seen in dairy than in beef breeds. In dairy cattle the reported prevalence ranges from 8% to 12% after spontaneous delivery of single calves. RFMs are more likely after deliveries of male calves or twins and deliveries complicated by dystocia. Parturition after a shorter- or longer-than-normal gestation is accompanied by an increase in the incidence of RFMs.[2]

The cause of RFMs in cattle is failure of fetal cotyledons to separate from crypts of maternal caruncles; the process of separation normally begins during the last months of pregnancy. Villi shrink after blood flow is interrupted by rupture of the umbilical vessels. Strong myometrial contractions continue during the third stage of labor, and changes in the size and shape of maternal caruncles contribute to separation of the placenta from the endometrium. In addition to mechanical factors, elevated collagenase, in response to increasing relaxin and estrogen prior to parturition, promotes collagen breakdown at the cotyledon-caruncle interface. A number of factors have been associated with separation failure, including induced parturition, abortion, dystocia, cesarean section, twinning, and nutritional deficiencies (selenium, vitamin E, vitamin A). The precise reasons for separation failure are unknown.

Clinical Signs and Diagnosis

The majority of affected cows show no serious clinical signs other than a transient decrease in appetite and milk production. However, 20% to 25% of cows affected by RFMs develop moderate to severe metritis. The most overt clinical signs are malodorous discharge and placental tissue hanging from the genital tract. RFMs are usually expelled by 4 to 10 days after calving when the caruncular tissue has become necrotic and is sloughed. Some affected cows show signs of endotoxemia, including depression, fever, ruminal stasis, and inappetence, as a result of RFMs.

Treatment and Prognosis

A variety of treatments have been suggested for RFMs in cows, including aggressive attempts at manual removal, myometrial stimulants, intrauterine and systemic antibiotics (alone or in combination with other approaches), and no therapy whatsoever. Because the processes that culminate in RFMs begin during late gestation, it is expected that treatment initiated at calving has little effect on the loosening process. Most treatments for RFMs are directed toward controlling the intrauterine bacterial population.

MANUAL REMOVAL. Manual removal of the placenta is indicated only when gentle traction is sufficient to withdraw the membranes in a short time. Attempts at manual removal are contraindicated if the patient shows clinical signs of septicemia. Trauma caused by manual removal inhibits phagocytosis by uterine neutrophils and predisposes to severe sequelae, including endometritis, septic metritis, peritonitis, and a delay to first ovulation.[3]

MYOMETRIAL STIMULANTS. Administration of a single dose of oxytocin does not reduce the prevalence of RFMs in cows that calve spontaneously or in cows that require assistance at delivery.[4,5] Cows with RFMs have an elevated plasma concentration of estrogen during the period of retention; therefore administration of additional estrogen for treatment of RFMs may be of questionable value.[6] Intravenous calcium solutions are indicated in cases of RFMs secondary to hypocalcemia. Because a relatively small proportion of RFMs are due to myometrial atony, myometrial stimulants may not be beneficial in many cases.[3]

PROSTAGLANDIN. In one trial, treatment with fenprostalene (a prostaglandin) resulted in a shorter period of retention in treated cows, reduced the number of treatments subsequently required for metritis, and slightly reduced the intervals to first service and conception.[7] However, other researchers found that fenprostalene produced no changes in myometrial activity between days 1 and 4 after calving and concluded that uterotonic agents are unlikely to hasten placental expulsion, because uterine effort is already increased in animals that have RFMs.[8] An imbalance between synthesis of $PGF_{2\alpha}$ and Prostaglandin I_2 (PGI_2) between 30 and 60 minutes after parturition has been demonstrated in cows affected by RFMs.[9] Prostaglandin at the time of calving does not reduce the incidence of RFMs or improve reproductive performance.[10]

ANTIBIOTICS. Intrauterine tetracycline may reduce fertility,[11] or the reproductive performance of treated cows may be as good as that of untreated herdmates. Intrauterine treatment with 4 to 6 g of oxytetracycline per day until the placenta is expelled may reduce the prevalence of metritis associated with RFMs, but pyometra may develop in treated cows.[12] The placenta is released only after necrosis of the caruncles, which may be delayed by the presence of intrauterine antibiotics. Systemic antibiotics are indicated in cases of RFMs in which the cow has a fever, is off feed, or has a drop in milk production. Multiple studies have demonstrated that the effects of systemic antibiotics are just as good as intrauterine antibiotics alone or

VetBooks.ir

VetBooks.ir

a combination of systemic and intrauterine antibiotics in terms of systemic health and future fertility. Ceftiofur (2.2 mg/kg IM or subcutaneously [SC] q24h for 3 to 5 days) given to febrile cows with retained membranes has shown a beneficial effect in future reproductive parameters and may reduce the incidence of acute metritis.[3,13,14]

Cows that retain their membranes for more than 12 hours after calving are more likely to develop metritis than are cows that promptly expel the membranes. However, reproductive performance of cows that rapidly return to normal after RFMs is similar to that of their unaffected herdmates, indicating that in the absence of a secondary reproductive abnormality, RFMs have a minimum effect on future fertility.

COLLAGENASE. An alternative approach to the treatment of RFMs is the injection of collagenase into the umbilical arteries of the retained membranes.[15] This treatment is aimed directly at the lack of cotyledonary proteolysis, and although effective, it is expensive and often not economically justifiable. Intrauterine infusion of collagenase is not effective.

Ewe and Doe

Fetal membranes are considered retained in ewes and does if not expelled within 12 hours after delivery of the last fetus. The prevalence in does is approximately 6% after spontaneous delivery but may be higher when delivery is complicated by dystocia or abortion. Selenium deficiency has been suggested as a cause.

The clinical signs of RFMs in ewes and does are usually obvious. Does may ingest their placentas, complicating identification of cases of partial retention. RFMs may accompany retention of a fetus within the uterus, and does and ewes should be carefully examined.

Other tissues that may be exposed from the vulva in association with parturition are a prolapsed uterus, a prolapsed or everted urinary bladder, prolapse of some portion of the digestive tract through a uterine rupture, prolapsed rectum, prolapsed vagina, or a twin fetus.

Treatment and Prognosis Manual separation of cotyledons from caruncles is impossible in ewes and does; therefore manipulative attempts to remove the placenta are limited to gentle traction on exposed membranes at daily intervals. Treatments with broad-spectrum systemic antibiotics, oxytocin (10 to 20 IU) at 12-hour intervals until the placenta is expelled, and antiinflammatory drugs have been suggested. Prophylaxis against tetanus is indicated.

Camelids

The placenta is usually passed within 1 to 2 hours of parturition. Camelid placentas resemble equine placentas (diffuse, microcotyledonary, epitheliochorial), with the exception that the left horn is almost always the pregnant horn. RFMs in camelids are most commonly seen as sequelae to dystocia or other disorders of parturition. Treatment is similar to that described for the mare.

Uterine Infections

Mare

Endometritis

A failure of the uterine defense mechanisms to effectively eliminate an antigen (bacteria or spermatozoa) and inflammatory products from the uterus results in persistent endometritis, which is a major cause of reduced fertility in broodmares.[16] In the normal mare the uterus is well protected from external contamination by physical barriers consisting of the vulva, vestibule, vagina, and cervix, and any compromise of these barriers may predispose the mare to a chronic uterine infection.[17] Breeding is another source of uterine contamination. Intrauterine deposition of semen causes an inflammatory reaction resulting from bacterial contamination of the ejaculate or from spermatozoa.[18] Approximately 10% to 15% of a normal population of Thoroughbred broodmares developed persistent endometritis after breeding.[19] AI with frozen semen resulted in 16% to 25% persistent inflammation after breeding.[20,21] Natural resistance to experimentally induced bacterial contamination has been demonstrated in young mares, whereas a population of multiparous and barren mares developed persistent endometritis after bacterial contamination of the uterus.[22,23] On the basis of these studies, mares have been classified as either susceptible or resistant to persistent uterine infection.[22] Endometritis has severe effects on the fertility of affected mares. A persistent inflammation may interfere directly with the survival of an embryo or may cause premature luteolysis and embryonic loss because of increased $PGF_{2\alpha}$ concentrations.[24]

Several classes of immunoglobulins have been isolated from the equine uterus. Although antibody-mediated uterine defense may be important for effective elimination of bacterial contaminants from the uterus in susceptible mares, concentrations of immunoglobulins in uterine secretion are similar or even elevated compared with those of resistant mares.[25-29] Polymorphonuclear neutrophils (PMNs) are the first inflammatory cells to enter an inflamed site. Chemoattractive properties of uterine fluid have been described in vitro in horses, and the uterus responds quickly to an antigen with release of PMN-chemotactic mediators, which results in a rapid migration of PMNs into the uterine lumen.[30] Complement products and leukotriene B4 (LTB4), Prostaglandin E (PGE), and $PGF_{2\alpha}$ may all serve as chemoattractants for PMNs in the uterus.[30-34] Studies on the role of local uterine factors in PMN function suggested that an impaired phagocytosis by uterine PMNs in susceptible mares is the result of insufficient opsonization in uterine secretion rather than a primary dysfunction of the PMNs.[35]

Recent work by researchers at the University of Kentucky found that breeding, as well as a bacterial infection with *Escherichia coli*, resulted in an upregulation of both proinflammatory and inflammatory modulating cytokines in the endometrium. A transient upregulation of proinflammatory cytokines was observed in resistant mares, whereas a sustained expression of proinflammatory cytokines coupled with an altered ratio of proinflammatory and modulating cytokines was observed in susceptible mares.[36] An imbalanced cytokine expression was also observed in susceptible mares following breeding. Inflammatory modulating cytokines were expressed at a significantly lower level at 6 hours after breeding in susceptible mares when compared with resistant mares, leading the authors to conclude that susceptible mares may have a deficiency in their ability to regulate endometrial inflammation.[37]

Mechanical aspects of the uterine defense system are currently believed to be a major contributor in uterine clearance of bacteria and inflammatory products.[38-40] Through use of intrauterine inoculations of a combination of radioactive-labeled microspheres and bacteria, impaired uterine clearance was demonstrated in susceptible mares but not in resistant mares.[38] Studies using scintigraphic measurements of intrauterine clearance of radioactive colloids further defined a delayed physical clearance in susceptible mares.[39] Through use of electromyography (EMG) to register myometrial activity, it was observed that the impaired uterine clearance in susceptible mares was caused by reduced myometrial activity in response to the inflammation.[39] This may be explained by an accumulation of nitric oxide (NO) in susceptible mares following breeding.[41] NO is an inflammatory mediator that causes smooth muscle relaxation. The dependent position of the mare's uterus may also interfere with effective clearance.

Based on pathogenesis, persistent endometritis can be divided into (1) sexually transmitted diseases (STDs), (2) persistent uterine infection, and (3) persistent breeding-induced endometritis.

VetBooks.ir

SEXUALLY TRANSMITTED DISEASES. Contagious equine metritis (CEM) is an example of a true STD.[42,43] The disease is caused by *Taylorella equigenitalis*, a highly contagious and pathogenic microorganism. Although the present status of a mare's uterine defense mechanism is important for the manifestation of the disease, this bacterium is highly resistant and capable of overcoming the mare's normal disease barriers.

PERSISTENT UTERINE INFECTION. Bacteria most commonly isolated from the uterus of the mare are β-hemolytic streptococci (*Streptococcus zooepidemicus* and *Streptococcus equisimilis*), *E. coli*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae*. Other aerobic bacteria isolated from the reproductive tracts of mares include α-hemolytic streptococci, *Corynebacterium* spp., *Staphylococcus* spp., *Enterobacter* spp., *Actinobacter* spp., *Proteus* spp., *Citrobacter* spp., *Candida* spp., and *Aspergillus* spp. and are the organisms most commonly associated with yeast or fungal endometritis. The role of viruses, mycoplasmas, ureaplasma, and anaerobic bacteria in endometritis is poorly understood. *P. aeruginosa*, *K. pneumoniae*, and possibly *S. zooepidemicus* and *E. coli* can be sexually transmitted in horses, but the consequences of exposure to these microorganisms are determined by the particular strain involved and active participation of all facets of the mare's uterine defense mechanisms. In contrast to a true STD, persistent infectious endometritis is often the result of contamination of the uterus by the mare's fecal and genital flora in combination with compromised uterine defense.[44,45] It has been proposed that endometrial biofilms are responsible for chronic infectious endometritis that appears to be nonresponsive to conventional treatment.[46] A bacterial biofilm is a complex aggregation of microorganisms. They are characterized by structural heterogenicity, genetic diversity, complex community interactions, and an extracellular matrix of polymeric substances, which greatly increases resistance to antibiotic therapy.[47] Although uterine biofilms have not yet been identified in the clinical setting in horses, an experimental model to study biofilms in the equine endometrium has recently been developed. Workers inoculated mares with a uterine infusion of *P. aeruginosa* and later successfully identified biofilms within the mares' endometrial folds.[48] An alternative explanation for persistent bacterial endometritis has been offered by Petersen and colleagues.[49] The authors suggested that bacteria can persist in the endometrial glands and the uterine wall in a dormant state. This would increase their resistance to antibiotic therapy. Another study investigated potential mechanisms of persistent uterine infections with *S. zooepidemicus* and hypothesized that the bacteria can enter epithelial cells and evade diagnosis and attempts to treat and resolve the infection.[49] More work needs to be done to further understand the ways in which bacteria infect and survive in the equine endometrium.

PERSISTENT BREEDING-INDUCED ENDOMETRITIS. Intrauterine deposition of semen causes an inflammatory reaction resulting from spermatozoa.[50,51] The mechanism of the induced inflammation is similar to endometritis caused by bacteria, involving activation of the complement cascade.[51] The role of spermatozoa in breeding-induced endometritis implies that a transient uterine inflammation is a physiologic reaction to semen, and it appears to be a normal process by which excess sperm and bacterial contamination are eliminated from the mare's reproductive tract.[45,52] Transport of spermatozoa from the uterus to the oviduct is completed within 4 hours after breeding, and only a small portion of the ejaculated or inseminated semen reaches the oviduct.[53,54] The rapid transport of spermatozoa to the oviduct coincides with increased uterine activity.[52] Increased myometrial contraction in response to breeding is also responsible for rapid sperm elimination from the uterus through the cervix.[55] Not all excess spermatozoa are removed from the uterus through this mechanism. The remaining spermatozoa have to be eliminated by means of other uterine clearance mechanisms, such as PMN-phagocytosis of spermatozoa.[45] However, the condition may develop into a persistent inflammation in mares with impaired uterine clearance.[38,39] If sperm elimination and all physical and chemical reactions that are involved in the induced inflammation persist beyond the time when the embryo enters the uterus at 5 days after ovulation, embryonic loss will occur because of an incompatible inflammatory uterine environment. The incidence of persistent breeding-induced endometritis has been reported to be approximately 10% to 15% in a normal population of Thoroughbred broodmares and up to 25% in mares bred by AI with thawed frozen semen.[19,20]

In contrast to spermatozoa, seminal plasma has a suppressive effect on complement activation, PMN-chemotaxis, and phagocytosis.[56] A function of seminal plasma may be to act as an inflammatory inhibitor or modulator in the uterus, which may be of importance with regard to the transient nature of breeding-induced endometritis. The duration of breeding-induced uterine inflammation was shown in a study to be shorter when seminal plasma was included in an insemination dose, compared with when all seminal plasma was removed and replaced by a commercial semen extender.[57] Although the peak numbers of PMNs were the same for both groups, significantly fewer PMNs were recovered from the uterus at 24 hours compared with 6 and 12 hours after insemination when seminal plasma was included. In contrast, there was no significant difference in the number of uterine PMNs at 6, 12, and 24 hours of insemination in the absence of seminal plasma. Another function of seminal plasma in breeding-induced endometritis may be to protect spermatozoa from being phagocytosed and destroyed in an inflammatory environment. PMNs are present in the uterine lumen by 0.5 hours after breeding, but sperm transport is not completed until 3 to 4 hours later.[53] In addition, when mares are inseminated twice within a 24-hour period, semen from the second insemination is introduced into an inflammatory environment. This environment is detrimental to sperm motion characteristics, and motile sperm cells appear to bind to PMNs, forming large clusters of PMNs and spermatozoa. Addition of seminal plasma has been shown to reduce the binding between spermatozoa and inflammatory cells in vitro.[58] Recent data suggest that a specific protein in equine seminal plasma, CRISP-3, selectively protects viable but not dead spermatozoa from PMN-binding and phagocytosis.[59,60] Selective protection of viable spermatozoa from PMN-binding and phagocytosis increases their survival in a hostile uterine environment and ensures that a sufficient number of spermatozoa reach the oviduct for fertilization while effective sperm elimination of nonviable spermatozoa can be maintained.

Diagnostic Approach

History compatible with endometritis includes infertility after breeding to a fertile stallion. Mares with severe endometritis may have shortened interestrous intervals and may show vaginal discharge. Physical and speculum examination may show anatomic defects of the vulva or cervix. Excessively easy passage of a vaginal speculum may indicate loss of integrity of the vestibulovaginal sphincter. Discharge from the cervix and vaginal inflammation may be apparent. Transrectal palpation and ultrasonography may reveal accumulations of luminal fluid (Fig. 43.5). Diagnostically, it may be difficult to identify susceptibility to breeding-induced endometritis before breeding. Some mares have free fluid present in the uterine lumen before breeding, but most mares are not diagnosed until after they have been bred. If susceptibility to persistent breeding-induced endometritis is suspected, the mare should be monitored closely by ultrasonography per rectum at 6 to 12 hours after breeding, if possible, and at a minimum within 24 hours after breeding. If free fluid is present in the uterine lumen, the mare should be considered to have persistent

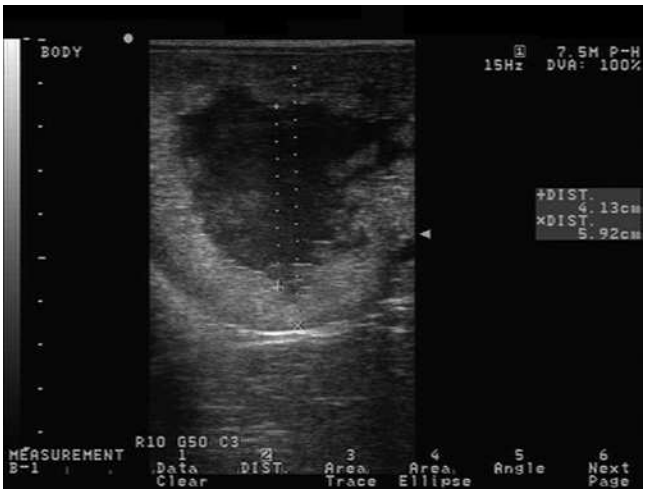

FIG. 43.5 Transrectal ultrasonographic image of uterine intraluminal fluid accumulation in a mare with endometritis.

mating-induced endometritis. Clearance of charcoal particles from the uterus within 48 hours of inoculation and the use of scintigraphy to measure uterine clearance have been suggested to be useful in identifying mares that are susceptible to persistent breeding-induced endometritis.[39,61] However, these methods may not be practical under field conditions. Recent attempts to identify genetic markers for susceptibility to persistent endometritis are encouraging and may aid clinicians in identifying susceptible mares in the future.[62]

MICROBIOLOGY. Quantitative aerobic bacterial culture of the uterine lumen is necessary to identify potential pathogens and for antibiotic sensitivity testing. Samples can be obtained using a swab, low-volume uterine lavage, or an endometrial biopsy, and they should be taken during estrus. If a uterine swab is used, the swab should be transported in a nonnutritive medium to the laboratory. Inadvertent contamination of cultures with bacteria from the lower reproductive tract is common, so the culture instrument should be guarded until it is within the uterus.[63] A false-positive bacterial sample result may be obtained as the result of contamination (even when double-guarded swabs are used), and culture results should always be interpreted together with results from endometrial cytology. Samples obtained through a vaginal speculum may decrease the risk of contamination. The use of low-volume lavage (50 to 100 mL) has been suggested to be a sensitive method to obtain an endometrial sample for culture.[64,65] It is important to use a closed system to infuse and recover fluid from the uterus in order to avoid environmental contamination when this method is used. False-negative results are frequently obtained even under optimal circumstances, and laboratory results should always be interpreted with consideration given to clinical findings. Use of culture and histologic interpretation of an endometrial biopsy appears to be the most accurate method to diagnose persistent infectious endometritis.[66] Cultures may also be performed on endometrial biopsy samples. Culture samples for *T. equigenitalis* should be taken from the endometrium, cervix, clitoral fossa, and sinuses. Samples should be placed in Amies medium with charcoal or Stewart medium and be kept refrigerated until delivered to the laboratory.

ENDOMETRIAL CYTOLOGY. PMNs migrate into the uterine lumen in response to inflammation, so endometritis is rapidly and accurately diagnosed by examination of exfoliated endometrial cells. A sample may be taken with a guarded swab, with a cytology brush, or by low-volume lavage. Air-dried smears are stained with new methylene blue or modified Wright-Giemsa stain. Epithelial cells may be shed singly or in rafts. Arbitrary definitions of endometritis have been established based on relative numbers of PMNs or numbers of PMNs per high-power field. Using these criteria, more than one PMN per 10 epithelial cells is consistent with endometritis. Evaluating the number of PMNs per microscopic field, Riddle and colleagues observed that mares with more than two PMNs per 100× magnification microscopic field had significantly lower pregnancy rates than mares with fewer than two PMNs per 100× field.[67] Mares with more than five PMNs per 100× field had the greatest reduction in pregnancy per cycle. The authors also found that bacterial infection with *E. coli* was less likely to be associated with a positive cytology compared with mares infected with *S. zooepidemicus.* Presence of bacteria on a cytology slide may indicate infection but can also be the result of a contaminated slide or staining fluid. Bacteria phagocytosed by PMNs are true indicators of an infection. Endometrial cytology from normal mares may contain PMNs and spermatozoa for 24 to 36 hours after breeding. It has been suggested that eosinophils are associated with fungal endometritis and pneumovagina, but the importance of this finding is unclear. Urine crystals indicate urovagina.

TABLE 43.5

Endometrial Biopsy Grade and Fertility Prognosis (Kenney and Doig)

Biopsy Category	Degree of Change	Predicted Foaling Rate (%)
I	None	80-90
IIA	Mild	50-80
IIB	Moderate	10-50
III	Severe	<10

From Kenney and Doig: Equine endometrial biopsy. In Morrow DA, ed: *Current therapy in theriogenology*. W.B. Philadelphia, 1996, Saunders, pp 723-729.

ENDOMETRIAL BIOPSY. Endometrial biopsy is an accurate diagnostic and prognostic tool for endometritis. The biopsy sample should be taken during the breeding season, should be of adequate size, and should be either fixed in Bouin solution for 24 hours and then transferred to 10% formalin or immediately put in 10% formalin. Chronic endometritis is characterized by infiltration of the endometrium with mononuclear cells and deposition of layers of fibrosis around endometrial glands. Fibrosis of the endometrium is a degenerative change and is permanent. This pathology has been associated with susceptibility to persistent endometritis and delayed uterine clearance.[68,69] The severity of endometrial changes is inversely related to reproductive performance. A system to classify histologic changes has been described and is widely used (Table 43.5). Special stains such as periodic acid–Schiff and Gomori methenamine silver may be used to identify the presence of fungi in endometrial biopsies. Special staining can be used to detect degenerative vascular changes such as elastosis.

TRANSRECTAL ULTRASONOGRAPHY. The presence of free intraluminal fluid before breeding strongly suggests susceptibility to persistent endometritis.[70] Ultrasonographic examination of the uterus is helpful to assess both the quantity and the quality of accumulated fluid in the uterine lumen. Normal mares may retain fluid for up to 6 to 12 hours after mating. If fluid is present at 12 hours or more after breeding, the mare should be considered to have a persistent mating-induced endometritis.[71] Increased echogenicity of the fluid is associated with the presence of inflammatory cells and debris.

VetBooks.ir

Hysteroscopy. Examination of the uterine lumen with an endoscope provides information about the degree of inflammation in addition to evidence of foreign bodies, transluminal adhesions, intraluminal masses, and endometrial cysts.

Treatment

SEXUALLY TRANSMITTED DISEASES. Mares with CEM should be treated with intrauterine infusions of antibiotics based on sensitivity tests, in combination with local treatments of the clitoral fossa and sinuses. Best results can be expected when treatment is initiated when the mare is in estrus and is combined with uterine lavage if inflammatory debris or intraluminal fluid is present. Cleansing of the vulva and the clitoris daily for 5 days with a 4% chlorhexidine or nitrofurazone ointment has been recommended.[72] Sinusectomy can also be performed.[73] Import regulations in countries free from CEM serve to prevent outbreaks of the disease. The spread of CEM on farms in endemic countries is best prevented by implementation of strict hygiene, screening of breeding stallions before the breeding season, and the use of AI, if allowed by the breed registry.

PERSISTENT UTERINE INFECTION. Treatment of mares with persistent uterine infections needs to be directed toward the underlying breakdown of the uterine defense and against the microbial agent. The first therapeutic concern should be to remove predisposing causes, such as a breakdown of external genital barriers. Persistent uterine infection frequently follows degenerative or traumatic anatomic changes and loss of integrity of the barriers of ascending infection. Therefore Caslick's surgery, repair of cervical damage and perineal lacerations, and correction of urovagina should precede specific endometrial treatment. All potential sources of contamination, including intrauterine passage of diagnostic and treatment implements, should be minimized. In some mares, recovery follows with sexual rest and no further treatment. Mares that are susceptible to persistent uterine infections should be bred using minimal contamination techniques to avoid bacterial contamination of the uterus.[74] Antibiotics may be administered by either local or systemic routes. Intraluminal fluid and inflammatory debris should be removed by uterine lavage before local treatment. Drugs and doses are summarized in Table 43.6. Treatment should be based on sensitivity. Mares should be treated during estrus when natural defense is maximal, and strict aseptic technique should be used. The volume of fluid used for antibiotic therapy depends on the size of the uterus. A total volume of 30 to 60 mL is usually sufficient. Treatment should continue daily for 4 to 6 days during the duration of estrus. Repeated contamination may indicate an unsuccessfully resolved predisposing cause. The clitoral fossa should always be considered as a primary location of bacteria grown in these cases. If culture results from the endometrium and clitoral fossa match, the clitoral fossa should be cleaned and treated locally with antibiotics. Removal of the primary microorganism may result in overgrowth of a second bacteria or fungus (superinfection). Critical studies of the efficacy of systemic antibiotics are limited, although effective concentration of amikacin has been measured in the endometrium after systemic administration.[75] Parenteral administration may be easier, and the opportunity to introduce uterine contamination or cause uterine irritation with treatment is eliminated. Treatment of fungal infections is generally more challenging than treatment of bacterial infections. Culture and sensitivity will determine the choice of antifungal drugs (see Table 43.6). Fungal endometritis may require daily intrauterine infusions for 7 to 10 days to effectively resolve the infection. To avoid intrauterine infusions in the presence of high circulating concentrations of progesterone, treatment can be initiated 1 or 2 days after an injection of PGF2α in diestrual mares and continued until 1 or 2 days after ovulation. A single dose of a benzoylphenyl urea (lufenuron) has been suggested to effectively treat mares with fungal endometritis.[76]

Antimicrobial Alternatives and Supplemental Treatments. Although suitable antibiotics are the most effective treatment against infectious endometritis, recent research has focused on situations where this treatment alone is not sufficient to eliminate bacterial growth from the uterus. Suggested presence of biofilms, dormant bacteria in the deeper layers of the endometrium, and other barriers may prevent antibiotics from reaching their target and effectively eliminating bacteria.[77-79] Although further evidence may be needed to conclusively confirm some of these hypotheses, their suggestive presence

TABLE 43.6

Antibacterial Drugs Used for Intrauterine Administration for Treatment of Uterine Infections in Mares

Drug	Dose (Intrauterine Administration)	Comments
Amikacin sulfate	2 g	Gram-negative spectrum; buffer with equal volume of 7.5% bicarbonate
Ampicillin	3 g	Gram-negative spectrum; may irritate the endometrium
Carbenicillin	2-6 g	Gram-negative spectrum; may irritate the endometrium; buffer with equal volume of 7.5% bicarbonate
Gentamicin sulfate	1-3 g	Gram-negative spectrum; buffer with equal volume of 7.5% bicarbonate
Kanamycin sulfate	1-3 g	*Escherichia coli*, spermatocidal
Neomycin sulfate	3-4 g	Useful against sensitive *E. coli*
Potassium penicillin G	5000-10,000 U	*Streptococcus zooepidemicus*
Polymyxin B	1 million U	*Pseudomonas*
Ticarcillin	6 g	Broad spectrum
Ticarcillin/clavulanic acid	6 g/200 mg	Broad spectrum
Ceftiofur	1 g	Broad spectrum *(S. zooepidemicus)*
Antimycotics		
Nystatin	500,000 U	Dissolve in 30 mL 0.9% saline solution; daily for 7-10 days
Clotrimazole	500 mg	Suspension or cream; daily for 1 week
Miconazole	500 mg	Effective against yeast
Amphotericin B	200-250 mg	Daily for 1 week
Vinegar	2%	20 mL wine vinegar to 1 L 0.9% saline solution; used as uterine lavage
Lufenuron	540 mg (single dose)	Suspend in 60 mL sterile saline solution

VetBooks.ir

in the uterus have given rise to multiple treatment options to accompany or replace traditional antibiotics. The medical value of most of these treatments is often anecdotal rather than evidence based.

N-*acetylcysteine (NAC):* This mucolytic substance has been used to reduce the viscosity of mucus in the uterus. In addition, NAC has been suggested to have antiinflammatory, antioxidant, and antibacterial activity.[80] Typically, 30 mL of a 20% solution NAC (200 mg/mL) is diluted in 150 mL of saline and infused into the uterine lumen during estrus, followed by ecbolic treatment or uterine lavage 12 hours after treatment. The treatment protocol has been suggested to be beneficial both 24 to 48 hours prior to breeding and 24 hours prior to antibiotic treatment. Repeated lavage may be indicated if the effluent fluid is cloudy.[81] When used together with antibiotics, the interaction with antimicrobials should be kept in mind. NAC enhances the efficacy of β-lactams but reduces the antibacterial activity of aminoglycosides, fluoroquinolones, and erythromycin. Oral treatment with NAC at 10 mg/kg did not reduce viscosity of uterine mucus; however, an antiinflammatory effect was observed in one study.[82] NAC was also suggested to decrease biofilm biomass and reduce bacteria within biofilms of *E. coli* isolates in vitro.[79] The same effect, however, was not observed for other bacteria. Intrauterine treatment with NAC is sufficiently proven to be safe and has been suggested to improve pregnancy rates, although the pregnancy data were not supported by controlled experimental conditions.[77]

EDTA-Tris: Tricide® (a third-generation chelator) chelates calcium and magnesium within the bacterial cell wall, which may potentiate the effect of the antibiotic.[83] It has been suggested to potentiate the effect of antibiotics on some bacteria, but its effect to disrupt gram-negative biofilms is less clear.[79] Treatment protocols often consist of intrauterine infusions of 250 to 750 mL Tricide followed by uterine lavage with a buffered saline solution the next day. The treatment is repeated until the effluent fluid is clear, at which time the mare is treated with local antibiotics for 5 days. Tricide can also be added to antibiotics but is not recommended for use together with ceftiofur, penicillin K, or Timentin due to precipitation in the solution.[81]

Cationic steroid antimicrobial (CSA): Ceragyn® belongs to a class of peptides that cause depolarization of bacterial cell wall membranes and activate apoptotic pathways. These peptides have been used for various conditions in human medicine because of their biofilm breakdown and broad-spectrum antimicrobial activities. Ceragyn (60 mL; 1 vial) is labeled for use up to 24 hours before or 12 to 48 hours after breeding. The drug has become increasingly popular among equine practitioners, but the authors have not been able to find conclusive data from controlled studies to support its effect on equine endometritis.

Hydrogen peroxide: H_2O_2 has a bactericidal effect on most uterine pathogens. A 1% solution (20 mL of a 3% H_2O_2 solution diluted in 60 mL lactated Ringer's solution [LRS]) has been suggested to be effective on biofilms in vitro.[79] Information regarding the efficacy of H_2O_2 treatment is anecdotal and needs to be supported by controlled in vivo studies.

bActivate: A proprietary substance marketed as bActivate® has been shown to activate dormant *Streptococcus* spp. from the equine endometrium.[78] Dormant bacteria are not sensitive to antibiotics, but after confirmed activation with bActivate, evidenced by a positive culture, mares can successfully be treated with intrauterine infusion of antibiotics. However, fertility data from controlled studies are needed to confirm claims of improved fertility following treatment.

Immune Modulators. The immune response of the equine endometrium has been investigated following bacterial inoculation, and treatment protocols aimed at restoring a normal immune response in susceptible mares have been reported.[84]

Bacterial cell wall extracts: Cell wall extracts of *Mycobacterium phlei* (MCWE) as well as *Propionibacterium acnes* have been investigated regarding their effect on the uterine immune system and reproductive performance. Fumoso and colleagues[85] found that MCWE treatment of susceptible mares at the time of breeding resulted in an endometrial immune environment similar to that of resistant mares at 24 hours after AI. In a follow-up study,[86] the authors concluded that MCWE treatment was effective in eliminating inoculated bacteria from the uterus in 70% of treated mares at 7 days after infusion. In another study,[84] the immune response between 3 and 72 hours after intrauterine inoculation of *E. coli* was characterized; cytokine expression in MCWE-treated mares was not different from that of untreated mares, but messenger RNA (mRNA) expression of serum amyloid A was suppressed in treated mares. Clinically, MCWE had a favorable effect on the clearance of pathogens and fluid retention.[84] These results supported a comprehensive clinical study in which problem mares were treated with *P. acnes* extract (Settle®); the authors found a 10% increase in pregnancy rates compared to untreated controls.[87] However, the mares received additional treatments and the effect of stallion fertility was not considered in that study.

Plasma: Intrauterine infusion of autologous or heterologous plasma has been used to treat mares with infectious endometritis.[88] The rationale for the treatment was to add immunoglobulins and complement to assist the mares in eliminating pathogens from the uterus. Supplementation of fresh or cryopreserved PMNs into the uterine lumen in mares with persistent endometritis has also been proposed as an alternative treatment to antibiotics.[89-91]

PERSISTENT BREEDING-INDUCED ENDOMETRITIS. Management of mares susceptible to persistent breeding-induced endometritis should include limiting uterine exposure to semen and bacteria and assisting the uterus to physically clear contaminants and inflammatory products after breeding.[30,92] Preexisting uterine infections should be resolved before the mare is bred. Exposure to semen should be limited to a single breeding per cycle, if possible. This can be accomplished by closely monitoring follicular development and hormonal treatment to induce ovulation of mature follicles.

Woodward and colleagues[37] found that the imbalance of proinflammatory cytokines and inflammatory cytokines in response to semen in susceptible mares is present already within 3 to 6 hours after insemination. This information should serve as a guideline for timing of treatments in susceptible mares after insemination.

Uterine lavage: Infusion of 1 to 2 L of buffered saline solution after breeding is effective in removing accumulated fluid and inflammatory products from the uterus. Because sperm transport to the oviduct is completed within 4 hours after breeding, uterine lavage 6 to 24 hours after breeding will not have a negative effect on fertility.[53] The uterine lavage is typically repeated until the recovered effluent fluid is clear. The treatment is often combined with an ecbolic drug in order to facilitate recovery of the infused fluid.[81,90,92]

Manual dilation of the cervix in mares with poor cervical dilation may help these mares more effectively clear the uterus of fluid.

Ecbolics. The administration of ecbolic drugs after breeding is effective in overcoming impaired myometrial contractility in susceptible mares.[93-95]

Oxytocin: Low doses of oxytocin appear to be more effective than high doses.[96] A common treatment protocol is 10 to 20 IU of oxytocin 4 to 6 hours after breeding, repeated

VetBooks.ir

every 6 to 8 hours until the intraluminal fluid has disappeared. The half-life of oxytocin is relatively short, resulting in approximately 50 minutes of myoelectric activity after the administration of 10 IU.[97]

Carbetocin: Carbetocin is a long-acting oxytocin analog with an extended half-life after administration of 0.175 mg IV.[98] Limited data are available on the efficacy of carbetocin versus oxytocin.

Prostaglandin: $PGF_{2\alpha}$ has considerably longer duration on uterine contractility compared to oxytocin.[95] Treatment is not recommended after ovulation, since $PGF_{2\alpha}$ and its analogs can cause a delay in the formation of a functional CL when administered within 2 days after ovulation.[36-39] It is the authors' observation that luteolytic doses of $PGF_{2\alpha}$ are excessive and may cause myometrial "cramp" initially rather than a physiologic contraction that would be more suitable for removing fluid from the uterus. A suitable dose of $PGF_{2\alpha}$ and its analogs for treatment of equine endometritis has not been established. In severe cases of persistent breeding-induced endometritis, ecbolic treatment is often combined with uterine lavage with 1 to 2 L of buffered saline 6 to 12 hours after breeding.[81]

Social interaction with a stallion: Social interaction with a stallion may facilitate normal uterine clearance following breeding. Audio, visual, and physical exposure of mares to a stallion stimulated pituitary oxytocin release and caused uterine contractions.[100] This observation was confirmed in a subsequent report.[101] Housing susceptible mares close to a tease stallion after breeding may therefore enhance normal uterine activity and clearance.

Immune Modulators. The immune response of the equine endometrium has been investigated following insemination,[37] and treatment protocols aimed at restoring a normal immune response in susceptible mares after breeding have been reported.

Corticosteroids: Several studies support a positive clinical effect of corticosteroids on persistent breeding-induced endometritis. A single dose of dexamethasone (50 mg at the time of breeding) was found to improve pregnancy rates in mares with more than three risk factors for susceptibility to persistent breeding-induced endometritis.[102] Researchers from Belgium did not observe a positive effect of treatment with 10 mg or 20 mg of dexamethasone 6 to 12 hours after AI in a large group of unclassified mares,[103] emphasizing the importance of correctly identifying mares as susceptible to persistent endometritis before implementing treatment regimens. Furthermore, mares with a history of excessive postbreeding inflammation had significantly higher pregnancy rates when treated with acetate 9-α-prednisolone (0.1 mg/kg) twice daily compared to control cycles.[104]

Although the immune modulation appears to favor resolution of inflammation, it does not mimic that of resistant mares.[105] Recent observations suggest that dexamethasone suppresses the proinflammatory cytokine interleukin-1β (IL-1β) in susceptible mares at 6 hours after breeding.[106] However, no effect was observed for modulating cytokines, which previously had been suggested to differ between susceptible and resistant mares.[37]

Nonsteroid antiinflammatory drugs (NSAIDs): Because of its modulating effect on inflammation, treatment of susceptible mares with NSAIDs has been studied.[107] Oral administration of Vedaprofen (2 mg/kg) the day before AI, and of 1 mg/kg twice daily until one day after ovulation, had no effect on fluid accumulation or uterine cytology but resulted in higher pregnancy rates. It should be noted that the mares were also treated with oxytocin (20 IU) three times per day. More research is needed to determine the potential value of this treatment protocol.

Bacterial cell wall extracts: Studying the immune response to semen, Woodward and colleagues[105] found that MCWE downregulated mRNA expression of IL-1β in susceptible mares at 6 hours after AI, supporting previous observations by Fumuso and colleagues.[108] As noted under infectious endometritis, a comprehensive clinical study suggested that treatment of problem mares with *P. acnes* extract (Settle®) resulted in a 10% increase in pregnancy rates compared to untreated controls.[87] However, the mares received additional treatments and the effect of stallion fertility was not considered in that study.

Plasma: The use of plasma products has recently been directed toward immunomodulation rather than elimination of pathogens from the uterus. Platelet-rich plasma (PRP) was shown to modulate the uterine inflammatory response to semen,[109,110] including downregulation of mRNA coding for proinflammatory cytokines and NO.[111] The protocol for treatment with PRP entails separation of 180 mL of whole blood by a special centrifugation system (Angel Cytomedix, Inc., Gaithersburg, Md.) followed by resuspension of the PRP in 10 mL plasma before the mix is being infused into the uterus at 24 to 36 hours prior to breeding.

Lactoferrin: Recombinant human lactoferrin (rhLF) has been demonstrated to be safe to administer in the equine uterus and modulates breeding-induced inflammation.[112] It was concluded that intrauterine treatment with 250 μg/mL rhLF may assist susceptible mares to resolve the breeding-induced inflammation in a timely fashion. Clinical trials are needed to confirm this observation.

Electroacupuncture has been used clinically to increase uterine contractility in mares with delayed uterine clearance. Anecdotal reports are encouraging, and further research is necessary.

It is important for the clinician to keep in mind that a transient inflammatory response to semen is normal. Postbreeding treatment of these mares most likely will not improve fertility but may cause even further contamination and interfere with pregnancy. Only 10% to 25% of all broodmares develop a pathologic, persistent form of breeding-induced endometritis.[19-21] Attention should be given to identifying and managing these mares appropriately in order to optimize reproductive efficiency.

CHRONIC DEGENERATIVE ENDOMETRITIS (ENDOMETRIOSIS). Degenerative changes of the endometrium such as periglandular fibrosis and glandular dilation are often seen in older multiparous mares. The condition is associated with susceptibility to persistent endometritis[68] and may result from repeated uterine inflammation. However, the condition has also been observed in older mares without any known history of endometritis, suggesting that degenerative fibrosis of the endometrium can be a process of aging rather than inflammation.[113] Because of the possibility of a noninfectious cause of the disease, it was suggested that the condition should be called endometriosis, rather than degenerative endometritis.[113] It is not clear why mares with fibrotic degenerative changes to the endometrium have an impaired physical uterine clearance mechanism. Sclerotic changes in the uterine vascular bed impair blood flow to both the endometrium and the myometrium, which may explain the effect on uterine clearance.[114]

Several treatments have been suggested for degenerative fibrosis of the endometrium, but consistent results have not been reported. Infusion of dimethyl sulfoxide (DMSO) into the uterine lumen has produced inconsistent results in mares with chronic degenerative endometritis.[115,116]

The use of mesenchymal autologous stem cells and autologous conditioned serum has been explored in experimental models as potential treatment alternatives for susceptible mares and mares with degenerative endometrosis.[117-119] A modulation

of the inflammatory response to semen was reported as was an indication that regenerative treatment strategies have the potential to restore degenerative changes to the endometrium.

Prognosis and Prevention. Prognosis for fertility after endometritis varies with the severity of inflammation and fibrosis and the inciting cause. Prognosis should take into account the age of the mare, the level of reproductive management, the cause (if known), and the most probable response to treatment.

Metritis

Metritis is classically defined as inflammation of all layers of the uterine wall. Metritis occurs in the first 2 weeks after foaling and commonly follows abortion, dystocia, and RFMs. Equine metritis is often accompanied by endotoxemia and laminitis. Transluminal adhesions between endometrial folds may follow severe metritis.

Clinical Signs and Diagnosis Metritis is characterized by uterine accumulation of postpartum secretions, bacteria, and the products of inflammation, with discharge from the cervix and possibly the vulva. Discharge is usually fluid and red-brown and may be fetid. Systemic signs of depression accompanied by neutropenia and leukopenia are apparent with development of endotoxemia. Differential diagnoses include normal lochia and causes of profound depression in the postpartum period as a result of uterine tears and acute abdominal disorders.

Treatment and Prognosis Treatment is directed toward removing contamination and microorganisms from the uterus while providing systemic treatment for endotoxemia. Broad-spectrum systemic antibiotics, antiinflammatory drugs, and fluid therapy are indicated. Uterine contamination may be removed by gentle intraluminal infusion of warm water or saline and siphoning off of uterine contents. Vigorous lavage should be avoided, particularly during acute systemic disease. Prognosis depends on severity of clinical signs. If metritis is diagnosed quickly and treatment is instituted, prognosis for fertility and systemic health is good. Prognosis is guarded once endotoxemia and laminitis develop.

Pyometra

Pyometra in mares is an accumulation of purulent exudate in the lumen of the uterus. Impedance to mechanical uterine outflow, such as cervical fibrosis and adhesions of cranial parts of the tract ventrally into the abdomen, often contributes to the development of pyometra. If endometrial irritation causes release of endogenous endometrial $PGF_{2\alpha}$, diestrus will be shortened. In some mares, endometrial destruction is so severe that $PGF_{2\alpha}$ release is inadequate and luteal life is prolonged.[27] A variety of bacteria may be involved, including *E. coli*, *Pseudomonas* spp., and *Streptococcus* spp. Cultures may also be negative.

Clinical Signs and Diagnosis A purulent vaginal or cervical discharge may be seen. The mare may demonstrate a short diestrus, a normal interestrous interval, or a prolonged diestrus. Some mares with pyometra have mild leukopenia and normocytic-normochromic anemia, secondary to mild suppression of erythropoiesis. Transrectal palpation and ultrasonography reveal a fluid-filled uterus. The uterine wall may be thin and flaccid or thick.

Treatment and Prognosis Treatment should involve correction of predisposing causes, fluid evacuation, and local antibiotic treatment. Evacuation of large amounts of fluid from the uterus may result in redistribution of fluid and circulatory shock. The mare should be monitored for signs of circulatory shock, and intravenous fluid may be administered during evacuation of large amounts of fluid from the uterus. The prognosis for life is excellent; however, the prognosis for return to normal fertility is guarded to poor because the conditions that predispose to development of pyometra in mares (cervical stenosis and adhesions) are difficult to treat and because severe endometrial destruction may develop. Endometrial biopsy should precede vigorous treatment. Hysterectomy should be considered if treatment is unsuccessful and if discharge is unacceptable or if adhesions impair athletic ability.

Ruminants

Bovine Uterine Infection

Deliveries complicated by dystocia or RFMs may be followed by severe bacterial infections of the uterus. The most sanitary environment possible should be provided for calving. The use of a clean pasture may be most appropriate on some farms, whereas the use of roomy, well-bedded, indoor maternity pens that are cleaned after each delivery may be appropriate on others.

Cows with abnormalities such as hypocalcemia, dystocia, and RFMs around the time of calving are more likely to develop uterine infections than are cows that calve normally. Routine treatment of cows with antibacterial drugs and chemicals has not been shown to be beneficial and may in fact reduce fertility. Postpartum uterine infections may be prevented, or the number of such infections reduced, by strict attention to sanitation in the calving environment and during assistance with delivery, along with proper management during the dry period.[1]

Bovine uteri are normally contaminated by a wide variety of microorganisms during the puerperium. Most of the organisms are transient residents of the reproductive tract and are soon eliminated from the involuting uteri of normal cows. *T. pyogenes* can persist in the uteri of cows and act with *Fusobacterium necrophorum* and *Prevotella* (formerly *Bacteroides*) spp. to cause uterine infections. Coliforms, *P. aeruginosa*, hemolytic streptococci, and gram-positive and gram-negative anaerobic bacteria are also frequently isolated from animals with postpartum uterine disease. *T. pyogenes* and *Clostridium* spp. occasionally colonize the postpartum uterus synergistically, causing severe gangrenous metritis. Other organisms that appear to have little effect on fertility may colonize the uterus and produce penicillinase, thus influencing the selection and route of administration of drugs used to treat uterine infections.[2,3]

Clinical Signs and Diagnosis Lochia is normally expelled during the first 2 weeks after calving and may range from dark red or brown to white to clear. If uterine involution is delayed, discharge of lochia may continue until 30 days after calving. Discharge of lochia is not abnormal unless the fluid is fetid or the cow develops other abnormal clinical signs. Abnormalities of uterine involution cannot be diagnosed by palpation per rectum during the first several days after calving when both normal and abnormal uteri are out of reach and cannot be safely retracted. By 10 to 15 days after calving, the entire uterus can be palpated if involution is normal. Fluid should not be palpable within the uterine lumen by 14 to 18 days after calving. Gross reduction in size and histologic repair of the endometrium are complete in dairy cows by 40 to 50 days after calving.

Postpartum metritis in cows is characterized by the presence of variable amounts of lochia within the uterine lumen that may be discerned by palpation per rectum. A vaginal discharge is usually present, but it may become obvious during palpation. Septic or puerperal metritis is characterized by clinical signs of toxemia that may include fever, depression, partial or complete anorexia, and laminitis. Milk yield is depressed, and cows may be unwilling or unable to rise. Some cases may be complicated by tenesmus. Vaginitis and cervicitis may accompany metritis. Discharges associated with septic metritis vary from scanty white mucus to copious amounts of red to red-black, watery, malodorous fluid. In some cases inflammation may spread through the uterine wall and cause perimetritis and

peritonitis.[4] Septic metritis in ewes and does is characterized by fever, depression, anorexia, and tenesmus.

Endometritis in cattle is usually observed between 2 and 8 weeks after calving. Discharge can range from white pus to estrual mucus. Purulent exudate may be observed only with palpation or may be found in the cranial vagina and cervical canal on examination with a speculum. The history may indicate that the cow has failed to conceive after several services but the patient is otherwise healthy.

Culture of endometrial fluid is not usually done in individual cases of bovine uterine infection but may be indicated to determine the antibiotic susceptibility of microorganisms on a particular farm or as a part of the diagnostic plan when the incidence of postpartum metritis or endometritis increases suddenly.

Endometrial biopsies are rarely used in cows but have been recommended when complete evaluation is required of the reproductive tracts of cows that do not conceive or that conceive but do not complete their pregnancies.

Treatment and Prognosis To be useful in treating uterine infections in cows, an antibiotic must be active against the primary uterine pathogens (*T. pyogenes* and gram-negative anaerobes), in the presence of organic debris, and in the anaerobic environment of the postpartum bovine uterus.[5] Oxytetracycline is active against many of the microorganisms that infect the bovine uterus, and its activity is only slightly reduced by organic debris and absence of oxygen. Intrauterine treatment with administration of 4 to 6 g of oxytetracycline per day has been used; however, some preparations of oxytetracycline irritate the endometrium, cervix, and vagina. Intrauterine antibiotic treatment of dairy cows results in residues in their milk.[6] For example, oxytetracycline has been found in milk from 44[7] to 96[8] hours after intrauterine administration, and thus an appropriate withdrawal period should be enforced and milk residue testing should be conducted.

Penicillin by systemic administration is effective for treatment of uterine infections in cows. Doses of penicillin required to reach the minimum inhibitory concentration of *T. pyogenes* are 10,000 to 20,000 IU/kg/day. Systemic ceftiofur (2.2 mg/kg IM or SC q24h for 3 to 5 days) achieves adequate concentrations in the uterus and is effective in treating bovine metritis.[9,10]

Treatment of septic or puerperal metritis should be directed toward controlling septicemia. Large doses of broad-spectrum systemic antibiotics are indicated, along with fluids and other supportive therapy. Attempts to remove RFMs or irrigate the uterus are contraindicated during the acute phase of the disease. After the patient has recovered from acute septicemia, intrauterine therapy may be considered.

ANTISEPTIC CHEMICALS. A variety of antiseptic chemicals have been infused into the uterine lumen of cows in attempts to treat metritis and endometritis, but few controlled trial evaluations are available. The potential for endometrial damage by these chemicals needs to be considered carefully.

UTERINE LAVAGE. Lavage of the uterine lumen with large volumes of warm saline (40° to 45° C [104° to 118° F]) removes accumulated fluid and debris. Uterine lavage has been used as an adjunct to antibiotic, antiseptic, and plasma treatment. Catheters designed for nonsurgical embryo recovery are suitable for uterine lavage. Saline is infused into the endometrial cavity in 0.5- to 1-L increments, allowed to reflux through the catheter, and collected for inspection. A milk hose and larger fluid volumes may be used in cattle with larger postpartum uteri, but care must be taken not to enter far into the uterus because it is friable and easily perforated. Massage or partial retraction of the uterus by palpation per rectum may be necessary to increase fluid recovery. The uterine lumen is lavaged repeatedly until the fluid returning through the catheter is no longer turbid.

PROSTAGLANDINS. In cows, repeated administration of $PGF_{2\alpha}$ results in shortened estrous cycles and may mimic the shortened luteal phase of patients with acute endometritis. $PGF_{2\alpha}$ therapy alone may be sufficient in mild cases of endometritis, or it may be used in combination with intrauterine or systemic therapy. In cases of chronic bovine endometritis, treatment with $PGF_{2\alpha}$ one or two times at 10- to 14-day intervals decreased the number of days open.[11]

The prognosis in cows for recovery from endometritis is usually good if the condition does not progress to a more severe form of uterine disease. Septic metritis after dystocia or RFMs may result in permanent impairment of reproductive function, laminitis, or death of the patient despite aggressive therapy.

Pyometra

In dairy cows, pyometra is likely to develop in cows that ovulate before microorganisms that infect the uterus during the postpartum period are eliminated. The CL that develops after the first postpartum ovulation at approximately 15 to 18 days after calving persists, possibly because the abnormal uterine contents suspend release of $PGF_{2\alpha}$ from the endometrium or sequester it within the uterine lumen. The uterus is brought under the influence of progesterone, which depresses phagocytic activity of uterine neutrophils and closes the cervix, allowing the bacterial infection to persist.[12] Pyometra rarely endangers the general health or life of affected cows. Postcoital pyometra may be caused by *T. foetus* in natural breeding dairy and beef herds.[13]

$PGF_{2\alpha}$ is the treatment of choice for bovine pyometra. Treatment is followed in 3 to 6 days by uterine evacuation in 85% to 90% of treated cows. Response to $PGF_{2\alpha}$ treatment may be bolstered with a repeat injection in 6 to 12 hours. After endometrial lesions are allowed to heal for 30 days, fertility is restored in most patients.

Treatment of cows with GnRH after calving is controversial. In herds with a high prevalence of postpartum uterine infections, treatment with GnRH may decrease fertility by inducing ovulation and CL development; thus the uterus is brought under the influence of progesterone before contaminating bacteria are removed, leading to pyometra.

Perimetritis

Perimetritis may occur in all species as a sequela to severe uterine infections, uterine rupture, penetration of the vagina during mating, traumatic insemination or obstetric procedures, and cesarean section.[14] Perimetritis is characterized by inflammation of the peritoneal surface of the uterus and may be accompanied by localized or diffuse peritonitis. Adhesions then develop between the uterus and other pelvic and abdominal organs.

Clinical Signs and Diagnosis The clinical signs of perimetritis are those of peritonitis and may include fever, depression, partial or complete anorexia, stasis of the gastrointestinal tract, and evidence of abdominal pain. Abdominal pain is typified by colic in mares and by grinding the teeth (odontoprisis) in cows. In cows the condition should be differentiated from traumatic reticuloperitonitis, displacements of parts of the digestive tract, abomasal ulcers, postpartum metritis, and abdominal fat necrosis. Perimetritis in mares must be differentiated from other causes of colic. Antemortem diagnosis of perimetritis is difficult in sheep and goats that are presented mainly with fever, depression, anorexia, and odontoprisis.

Clinical Pathology Cases of acute perimetritis are accompanied by leukopenia, neutropenia, and a degenerative

left shift. Further evidence of peritonitis is obtained when peritoneal fluid is obtained by paracentesis and examined for its cellular and microbiologic content.

Treatment and Prognosis The cause of perimetritis should be treated if possible. Cases of severe metritis should be treated appropriately, and uterine ruptures sutured if possible. Repair of uterine ruptures inaccessible by flank incisions may be facilitated by intentional prolapse of the uterus after administration of epinephrine, provided the tear is not too close to the cervix (see next section). Treatment with broad-spectrum systemic antibiotics is indicated. Lavage to remove peritoneal exudate has been recommended but is difficult to accomplish, especially in cows in which the rumen, abomasum, and greater omentum make ventral drainage almost impossible and in which fibrinous peritonitis with loculation of infection occurs rapidly. Other supportive treatments such as intravenous fluids and antiinflammatory drugs should be administered.

The prognosis depends on the severity of lesions. Fatalities can occur despite prompt treatment, and surviving animals may be infertile because of mechanical interference with gamete transport caused by adhesions between the genital organs and other pelvic and abdominal tissues. In general, the prognosis for fertility in affected animals is fair at best.

Prevention and Control Perimetritis occurs sporadically in individual animals; therefore prevention depends on avoiding the causes. Immature females, especially heifers and fillies, should not be allowed at pasture with adult males to prevent undesired mating complicated by penetration of the vagina. Traumatic obstetric, insemination, and uterine lavage procedures must be avoided. Uterine tears that occur at parturition must be sutured immediately. Postpartum metritis must be treated promptly and appropriately before it progresses to perimetritis.

Small Ruminants Uterine infections may follow dystocia and RFMs in sheep and goats, but these infections are not frequently a cause of infertility because in most cases parturition is followed by a few months of sexual rest before the next breeding season. In ewes, RFMs and metritis follow abortion caused by *Listeria monocytogenes*, *Campylobacter* spp., and *Chlamydophila abortus*.

Ewes and does affected with metritis are usually treated with systemic antibiotics such as penicillin, sulfamethazine, oxytetracycline, or ceftiofur. Early and aggressive treatment is indicated.

Camelids

Metritis and Endometritis

When camelids breed, the penis is inserted through the cervix and deep into the uterine horns. Unnecessary mating, or overbreeding, is the most important factor causing damage to and contamination of the uterus.[15] Other major contributing factors include RFMs, rectal vaginal tears, and unsanitary obstetric manipulations.[15]

Chronic endometritis will often not cause evident clinical signs, whereas acute, postpartum endometritis may cause fever, depression, and signs of shock. A thick, mucoid lochial discharge is normal in the postpartum female for up to a week postpartum. In contrast, thin, watery, fetid discharge is a sign of endometritis.[15]

Transrectal ultrasonography and vaginoscopy are helpful in diagnosing endometritis and metritis. Inflamed, thickened uterine walls and hyperechoic, intraluminal fluid may be present on ultrasound examination. Vaginoscopy may reveal cervical discharge. Transrectal ultrasonography may usually be performed in llamas. In alpacas, because of smaller size, an extension probe is necessary to facilitate transrectal ultrasonographic evaluation.

Uterine culture and cytology samples from the llama may be obtained using methods similar to those used in the mare and cow. A double-guarded swab prevents environmental contamination. In the alpaca, the swab should be passed through the cervix via visualization using a vaginoscope. These diagnostics should be performed during the peak follicular phase to ensure ease of passage through the open cervix and more reliable test results.[15] The most common bacteria isolated from the uteri of camelids with endometritis are *E. coli*, *S. zooepidemicus*, β-hemolytic streptococci, *Enterococcus*, coagulase-negative *Staphylococcus*, *Proteus* spp., *Enterobacter aerogenes*, *K. pneumoniae*, and *T. pyogenes*.[15]

Uterine biopsy can be a useful diagnostic tool for evaluation of metritis and endometritis in camelids. Endometrial biopsy samples in llamas may be obtained as in the mare. The left horn is perhaps better to target unless a particular pathology is suspected in the right horn, because camelid pregnancies almost always occur in the left horn.[15] Pathologic changes, evaluation, and prognosis are all assumed to be similar to those in the mare.

Treatment for endometritis and metritis is also similar to that described for the mare. Uterine lavage with a warm, isotonic saline solution and oxytocin injection (5 to 10 IU) are the major components of treatment. Intrauterine antibiotic infusion is done after uterine lavage. The most common antibiotics used are penicillin K (1.5×10^6 U), gentamicin sulfate (200 to 300 mg), and ceftiofur sodium (250 to 500 mg).[15] Antibiotics should be diluted in sterile water or saline (saline should not be used with ceftiofur) and given once daily for 5 to 7 days. Females should be evaluated after cessation of treatment and completion of 2 weeks of sexual rest.

Prevention of endometritis often requires a "minimum contamination breeding technique."[15] This entails monitoring follicular growth via transrectal ultrasound until the follicle is of preovulatory size, breeding only once, following breeding with an injection of hCG (750 IU) or GnRH, and administering an intrauterine infusion of antibiotics 24 hours after breeding. Females should be evaluated for pregnancy 12 to 14 days after breeding.

Further preventative measures include performing prebreeding examinations on all maiden animals to avoid breeding animals that are too young or do not have follicular activity; breeding only females that exhibit strong receptive behavior (as opposed to mere submissive behavior); performing complete gynecologic examinations on all females with a history of infertility, obstetric problems, or postpartum complications; and observing strict rules of hygiene during breeding and obstetric manipulations.[15]

Pyometra

Pyometra caused by delayed uterine involution may be observed shortly after parturition. Chronic pyometra is often associated with vaginal or cervical adhesions that may be sequelae to trauma after dystocia or aggressive obstetric manipulation.[15]

Anatomic Defects as a Cause of Uterine Infection

The most common anatomic defect associated with genital infections in camelids is pneumovagina. Other defects include urovagina and perineal lacerations. These defects should be corrected to prevent contamination with environmental and fecal organisms.

Endometrial Cysts and Lacunae

Mares Endometrial cysts and lymphatic lacunae are common degenerative changes of the endometrium that are more prevalent in mares older than 11 years of age than in

VetBooks.ir

younger mares.[16] Endometrial cysts can originate from endometrial glands or obstructed lymphatics. Glandular cysts are small (<10 mm) and believed to be the result of periglandular fibrosis. Lymphatic cysts can reach several centimeters in diameter. The cause of lymphatic cysts is not fully understood, but lacunae are thought to arise after interference with normal lymph drainage from the genital tract.

Clinical Signs and Diagnosis Endometrial cysts can be visualized by ultrasonography or hysteroscopy. Cysts may mimic pregnancy when mares are examined per rectum by palpation or ultrasonography.[17]

Sequential examination reveals that the size of endometrial cysts remains static, whereas amniotic vesicles enlarge. Large, discrete, fluid-filled cysts may be identified by palpation of the uterus per rectum. Smaller cysts and lacunae may be observed in endometrial biopsy sections. Uteri affected by lymphatic lacunae are enlarged and have a thicker wall than normal.

Treatment and Prognosis Endometrial cysts do not require treatment unless they are suspected to interfere with pregnancy. Endometrial cysts have been suggested to cause embryonic death and abortion if large or numerous. However, there is no proven association between the presence and number of cysts and fertility.[16] Obliteration of endometrial cysts using endoscopic-guided laser surgery or electrocoagulation removes the cysts permanently, but the long-term effect on fertility has not been critically evaluated. Needle aspiration, mechanical rupture of the cyst, uterine curettage, and intrauterine infusion of hypertonic saline solution have all been suggested to effectively remove endometrial cysts. However, the cysts often recur after treatment.

Uterine Prolapse

Uterine prolapse occurs when the previously gravid uterine horn becomes invaginated after delivery of the fetus(es) and protrudes from the vulva.

Mares Uterine prolapse is an uncommon sequela to normal foaling, dystocia, or RFMs in the mare. The tip of the previously gravid horn invaginates to form uterine eversion. Eversion is accompanied by pain and abdominal straining. The myometrium may contract around the ring of invaginated tissue. Transrectal palpation confirms the diagnosis, and the everted tissue may be replaced manually. Eversion may progress to complete uterine prolapse, accompanied by rapid onset of systemic signs.

Treatment and Prognosis The prolapsed uterus should be washed with clean saline and replaced manually in the standing mare as rapidly as possible. Replacement is aided by sedating the mare and administering epidural anesthesia. The uterus should be supported on a clean sheet held at the level of the pelvis. The uterus should be replaced, beginning with the uterine body and working gradually, replacing the tip of the horns last. Correct positioning of the uterus is important to prevent the prolapse from recurring. Replacement should be followed by treatment with broad-spectrum antibiotics, antiinflammatory drugs, and intravenous isotonic fluids. Treatment with oxytocin (10 to 20 IU IM) facilitates uterine involution. Prognosis is related to development of sequelae such as uterine tears, metritis, and endometrial damage.[18]

Ruminants In cows, most cases of uterine prolapse occur within a few hours after calving. The condition is invariably associated with hypocalcemia, which results in lack of uterine tone and delayed cervical involution. In addition, dystocia frequently precedes uterine prolapse.

Elective uterine prolapse can be induced within 6 to 12 hours after calving by administering epinephrine to relax the uterus for the repair of uterine tears. A 10-mL amount of epinephrine (1:1000) is diluted to 250 mL in sterile saline and administered slowly IV. After 100 mL of the solution has been given, the operator reaches through the cervix, grasps the uterine wall and caruncles, and everts the uterine horn toward the cervix. When sufficient uterine tissue has entered the cervical canal, the patient responds by straining, which assists in completion of the prolapse. Epidural anesthesia is administered to abolish further straining after the prolapse is complete.

Uterine prolapse in does has been associated with dystocia, hypocalcemia, and lack of exercise. The predisposing factors are probably similar for ewes.

Clinical Signs and Diagnosis Clinical signs of uterine prolapse are obvious, with maternal caruncles exposed on the uterine endometrium. The membranes may remain attached. Immediately after prolapse occurs the tissues are nearly normal, but within a few hours they become enlarged and edematous. The endometrium is usually contaminated with feces and bedding material. In some cases the prolapsed tissue may be lacerated or severely traumatized and may contain loops of intestines.

Clinical signs that may accompany uterine prolapse include straining, abdominal pain, restlessness, anorexia, and increased pulse and respiratory rates. Parturient paresis is common in affected dairy cows. In most patients these signs are transitory, but shock may complicate some cases.

Clinical Pathology Uterine prolapse in cows is frequently accompanied by hypocalcemia and a significant increase in the packed cell volume.[19]

Treatment and Prognosis The prolapsed tissue should be protected from further damage by wrapping it in wet towels or covering it with a plastic bag. Beef cows should be restrained where they are found, to prevent trauma to the uterus or rupture of the large uterine vessels should an animal try to escape on arrival of the clinician. Treatment of hypocalcemia is usually indicated before replacement of the uterus if the cow is recumbent and semicomatose; otherwise calcium gluconate is administered after replacement. Epidural anesthesia (3 to 5 cc of 2% lidocaine) is frequently, but not always, required.

The prolapsed tissue is washed with a mild presurgical scrub. The membranes are removed if they can be easily separated from the endometrium but are left in place if removal is difficult. Some clinicians recommend that cows stand during replacement, whereas others have found that the organ can be replaced in recumbent cows if the patient is placed on her sternum with the hind legs drawn straight out behind. The prolapse is placed between the extended limbs. In fresh cases, replacement is relatively easy and is begun at the cervical pole of the organ; the dorsal and ventral parts are massaged alternately back into their normal position. After the ovarian pole has been replaced, the previously prolapsed horn must be straightened and eversion of the uterus corrected; this can be done manually or by intrauterine infusion of warm saline. Administration of clenbuterol is reported to relax the uterus, facilitate replacement, and reduce the need for epidural anesthesia, but its use is illegal in the United States. If the patient has been neglected, accumulated fluid must be reduced by lubricating the tissue with an emollient ointment and then carefully but vigorously massaging the tissue from the ovarian pole toward the cervical pole. The hygroscopic action of sugar when applied liberally to prolapsed uteri is of questionable value.

Oxytocin (5 to 40 IU IM or IV) is frequently administered to stimulate myometrial contractions after the uterus has been

VetBooks.ir

replaced. Metritis is a frequent sequela, and appropriate antibiotic treatment is indicated in most cases. Temporary closure of the vulva with heavy sutures after replacement may not be necessary but is practiced by many clinicians. If replacement of the prolapsed uterus is impossible or the tissue is severely traumatized, amputation may be indicated; in this case it is important that the uterine arteries be double ligated.[20] Euthanasia may also be considered in such instances.

The prognosis varies but is generally favorable if there has been no serious damage to the uterus. Fatalities can occur in cases complicated by shock or by rupture of large uterine vessels. The culling rate from infertility of cows with uterine prolapse is higher than that of their herdmates, and the calving interval is prolonged in affected cows. Barring hypocalcemia, the risk of uterine prolapse at a subsequent calving is no greater than for other cows in the herd.

Prevention and Control Because the condition is associated with hypocalcemia in cows, provision of a properly balanced ration before calving is indicated. Although uterine prolapse can occur after an apparently normal delivery, it is more commonly associated with dystocia and forced extraction; therefore prolapse should be anticipated, and the dam observed so that affected patients may receive prompt treatment. Oxytocin (5 to 40 IU IV or IM) may be administered after a dystocia to increase uterine tone and potentially prevent prolapse.

Camelids Uterine prolapse in camelids is usually a consequence of dystocia, RFMs, or excessive obstetric manipulation. Treatment is the same as described for other species.

Uterine Tumors

Neoplasia uncommonly affects the uterus of domestic animals. Leiomyomas are usually benign and arise from the outer smooth muscle of the uterus without need for a preparatory event. Leiomyomas are not necessarily associated with reproductive failure, and tumors and fetuses can coexist.

The multicentric form of lymphosarcoma may affect the uterus of cattle. Lymphosarcoma also affects does, but a predilection for the uterus is not apparent. Uterine walls affected by lymphosarcoma may contain discrete neoplastic nodules or be diffusely infiltrated.

Carcinomas, chorionepitheliomas, fibromas, fibrosarcomas, rhabdomyosarcomas, and adenosarcomas are rarely reported. Regardless of tumor type, tumors must be differentiated from normal fetuses, mummified or macerated fetuses, placentomes, abscesses, and fat necrosis.

Segmental Defects

Segmental aplasia (white heifer disease) occurs sporadically in all breeds of cattle. In most cases the cranial parts of the genital tract (ovaries, uterine tubes, and cranial part of the uterine horns) are normal, and endometrial secretions from the parts of the uterine horns accumulate because normal drainage through the cervix is impeded. Various defects may be found in affected animals, ranging from nearly complete absence of tubular genital organs to an imperforate hymen that blocks secretion drainage from a normal genital tract.

Clinical Signs and Diagnosis Segmental aplasia may be associated with a history of anestrus if fluid accumulation within the uterine horns interferes with release of $PGF_{2\alpha}$ and luteolysis. Other presenting history may involve infertility or difficulty in AI. On palpation per rectum, various degrees of aplasia may be recognized. Fluid-filled parts of the uterine horns may suggest pregnancy, from which they must be differentiated. An imperforate hymen may bulge from the vulvar cleft and may be confused with vaginal prolapse, prolapse or eversion of the urinary bladder, cystic vestibular glands, or neoplasia of the vulva or vagina.

Treatment and Prognosis The only form of segmental aplasia amenable to treatment is that in which an imperforate hymen occludes an otherwise normal tract. Incision of the hymen is followed by drainage of accumulated secretions and may allow the tract to function normally.

Paramesonephric Duct Aplasia

Aplasia of one paramesonephric duct leads to development of one uterine horn (uterus unicornis). The condition is found in cattle but is rare. Subfertility is the result of prolonged periods of anestrus caused by a persistent CL on the ovary ipsilateral to the missing uterine horn (no local luteolytic signal). The condition can be managed with exogenous $PGF_{2\alpha}$ in the hope that ovulation will occur on the intact side. Alternatively, the unaccompanied ovary can be surgically removed.

Uterus Didelphis

The caudal parts of the paramesonephric ducts may not fuse properly in cattle, causing duplication of various parts of the caudal tubular tract. Abnormalities of fusion are most common in and around the cervix. The entire cervix may be duplicated, or the cervix and vagina may be normal, with the exception of the presence of a band of tissue extending dorsal to ventral across the external os of the cervix. Partial failure of fusion may involve a part of the cervix, and the affected animal may possess a single uterine body and internal cervical os, duplication of a part of the cervical canal, and a doubled external cervical os. Uterus didelphis results when the cervix and uterine body are completely duplicated. Affected cows may conceive after natural service or if artificially inseminated through the cervix and uterine horn ipsilateral to the ovary about to ovulate. Affected animals may be unable to carry a pregnancy to term because of lack of placental attachment in the nongravid horn.

Hydrometra (Pseudopregnancy in Small Ruminants)

Hydrometra occurs sporadically in sheep and goats and is characterized by accumulation of several liters of clear fluid within the uterus, abdominal distention, persistence of a CL, and subsequent anestrus.[20] Previous breeding is not necessary, but the condition may develop after mating, and does are frequently assumed to be pregnant. It can also occur after early embryonic loss in goats or sheep. The cause of hydrometra is unknown, but a deficiency in production or release of $PGF_{2\alpha}$ from the endometrium has been postulated, as has exposure to phytoestrogens. The clinical signs of hydrometra mimic those of pregnancy. The diagnosis is suspected if the goat fails to show estrus when it cannot possibly have been bred but is in a herd where heat detection is good. Serum progesterone concentrations are elevated, and abdominal enlargement suggestive of pregnancy may occur. Blood-based biochemical pregnancy markers will be negative. Amplitude-depth ultrasound for pregnancy is positive because of fluid in the uterus. Transabdominal ultrasound reveals anechoic fluid but no fetus or caruncles in the uterus. The animal should be rechecked if fewer than 40 days have elapsed since the last possible breeding, as early pregnancy is possible in such cases. In advanced hydrometra, large anechoic fluid-filled compartments are seen separated by undulating tissue walls, which represent the uterus coiled back on itself. Spontaneous correction is common and varies from red discharge suggestive of early abortion to expulsion of accumulated fluid approximately 150 days after

VetBooks.ir

an infertile mating, so-called cloudburst. No fetus or placenta is passed. Treatment of false pregnancy is with prostaglandin. The clinician needs to keep in mind that this will induce abortion if the ewe or doe has a true pregnancy. An initial dose of 5 to 10 mg of dinoprost (Lutalyse) or 125 to 250 µg of cloprostenol (Estrumate) is given and repeated in 12 days. Estrus and emptying of the uterus occur in 1.5 to 4 days. Oxytocin (50 IU bid for 4 days) is normally reserved for females that retain fluid in the uterus after prostaglandin therapy. The doe frequently becomes pregnant within a few days to weeks after termination of a false pregnancy if a buck is available. Sometimes hydrometra recurs. Suggestions for prevention have included selenium supplementation and breeding on the first heat of the season. The prevalence is surmised to be increased in herds where breeding is delayed in order to obtain winter milk and in does manipulated hormonally to breed out of season.[20] Routine pregnancy diagnosis of sheep and goats with transabdominal ultrasound should be advised to permit rebreeding during the same season.

Cervical Abnormalities

Cervicitis

Inflammation of the cervix usually accompanies endometritis and vaginitis and is frequently secondary to trauma associated with dystocia and obstetric operations. The mucus-secreting epithelium of the cervix is more resistant to bacterial infection than is the epithelium of the uterus and vagina.

Mares The equine cervix is a straight tube made up of layered circular and longitudinal muscle. During estrus it relaxes, and the external os lies on the floor of the anterior vagina. During diestrus or pregnancy, under the influence of progesterone, the cervix is closed and the external os is elevated off the vaginal floor. Cervicitis or inflammation of the cervix may be iatrogenic or may occur secondary to trauma associated with parturition or dystocia or as an extension of vaginitis or endometritis. Endometritis and infertility follow if the cervix lacks anatomic integrity.

Clinical Signs and Diagnosis Infertility and history of an inciting cause such as urine pooling or dystocia may be the only signs of cervicitis in the mare. Cervical hyperemia and edema may be apparent on speculum examination in acute cervicitis. In more chronic injuries, direct digital examination of the cervix of the mare in diestrus may reveal transluminal adhesions or anatomic defects.

For treatment and prognosis in mares, see discussion under Ruminants.

Ruminants Similarly, in cows cervicitis is secondary to uterine infections and follows trauma associated with parturition and obstetric manipulations. Infection is usually caused by microorganisms normally present in the cranial vagina such as *E. coli*, streptococci, staphylococci, and *T. pyogenes*.

Cervicitis in does and ewes is uncommon but may occur secondary to vaginal and uterine infections and obstetric trauma.

Clinical Signs and Diagnosis Examination of cows with a vaginal speculum reveals swelling and edema of the external cervical os. The mucous membrane is hyperemic and inflamed. Mucopurulent exudate may be present in the cervical canal or in the cranial vagina. Hypertrophy of the cervix is common in Bos indicus breeds and their crosses and may be a normal finding; therefore cervical size as detected by palpation per rectum may or may not indicate inflammation. Inflammation of the cervix without contemporary endometritis may not affect fertility. Cervicitis may occur in pregnant cows.

The clinical signs of cervicitis in does and ewes are similar to those in cattle and must be observed with a small vaginal speculum.

Treatment and Prognosis Most cases of cervicitis resolve spontaneously when coexisting endometritis and vaginitis improve. Exudate can be flushed from the cervical canal and cranial vagina with warm saline lavages, and a nonirritating antibiotic ointment applied to the affected tissue. Caustic chemicals should not be placed in contact with the cervical mucosa. Aggressive treatment with systemic antibiotics is indicated in cases complicated by infection with anaerobic bacteria.

The prognosis for most cases of simple cervicitis is fair to good. However, inflammation of the cervix in mares may progress to more severe cervical abnormalities. Cervical damage is a serious threat to future reproductive performance in mares. Anaerobic infections of the cervix may be fatal.

Prevention and Control Obstetric manipulations and operations must be temperate. When the cervix does not dilate properly during parturition, a cesarean section is preferred over forced extraction.

Cervical Lacerations

Mares Cervical lacerations are most often seen after dystocia. The condition may result in adhesions and a nonpatent cervix or in failure to seal the uterus during diestrus or pregnancy. Cervical adhesions in combination with endometritis are a common cause of pyometra in the mare.

Clinical Signs and Diagnosis Cervical lacerations can be diagnosed by vaginoscopy and digital examination of the cervix. A digital examination of the cervix is often necessary to evaluate the degree and severity of the laceration. Evaluation of the ability of the cervix to close adequately is best performed during diestrus.

Treatment and Prognosis If cervical lacerations are diagnosed shortly after parturition, antimicrobial ointment should be applied frequently to the lesion. Early signs of adhesions should be broken down until the tissue is healed. If the laceration results in an incompetent cervix, it should be corrected surgically. Although surgical repair of cervical lacerations has resulted in restored fertility in many mares, the condition is likely to recur at the time of the next parturition. Embryo transfer should be considered if allowed by the breed registry.

Vaginal Abnormalities

Pneumovagina

MARES. Pneumovagina is characterized by aspiration of air, often containing microorganisms, into the vagina. Pneumovagina is secondary to changes in perineal conformation, which include cranioventral displacement of the reproductive tract, loss of integrity of the vestibulovaginal sphincter, and loss of integrity of the vulvar labia. These changes occur more commonly in older, multiparous mares and those that have had perineal lacerations. Pneumovagina is a common antecedent to infertility.

Clinical Signs and Diagnosis In the normal mare, the anus is positioned directly dorsal to the vulva. The perineal body between the dorsal vulva and the anus is thick, muscular, and well formed. The vestibulovaginal sphincter is well formed, and the vulva has a vertical alignment, with 80% of the vulval labia situated below the floor of the pelvis. The vulvar labia form a seal in the normal mare.

VetBooks.ir

Mares prone to pneumovagina are those in which the vulva tilts horizontally at its dorsal aspect, the perineal body is thin, the vulval labia do not form a seal, and the anus lies cranial to the vulva. A scoring system has been developed to evaluate the perineal conformation in mares.[1] The system uses Caslick's index, which equals the distance (in cm) between the dorsal commissure of the vulva and the pelvic floor multiplied by the degrees of declination of the vulvar lips. Mares with a Caslick's index above 150 were found to have subnormal pregnancy rates. Affected mares aspirate air on exercise or when the vulval labia are parted. Aspirated air may be noted on transrectal palpation or vaginal speculum examination. Signs of secondary changes such as vaginitis, cervicitis, or endometritis may be apparent.

Treatment and Prognosis Treatment of pneumovagina should be directed toward correcting defective perineal conformation. Cranioventral displacement of the reproductive tract in aged mares may be irreversible. Perineal confirmation in thin mares is often improved by increasing the mare's body condition. Pneumovagina is often successfully corrected by surgical closure of the dorsal vagina via Caslick's surgery. Secondary changes should be treated as described elsewhere. Prognosis for correction of pneumovagina is excellent; however, prognosis for fertility depends on the extent of secondary changes.

Urovagina

MARES. The normal vagina in young mares slopes craniodorsally and is largely contained within the pelvis. With aging and repeated pregnancy, the cranial vagina may slope cranioventrally and fall below the level of the pelvic floor. Under these conditions urine collects in the anterior vagina. Urine is spermicidal, and the condition is often associated with subfertility.

Clinical Signs and Diagnosis In mild cases, a history of infertility may be the only indicator of urovagina. In more severe cases, urine dribbles from the vulva at rest or during exercise and may accumulate on the skin of the hindlimbs. Speculum examination reveals a cranioventral slope of the vagina, variable inflammation of the cranial vagina and cervix, and a pool of urine in the ventral vaginal fornix. Urovagina may occur intermittently or only during estrus.

Treatment and Prognosis Surgical procedures to prevent the anterior flow of urine include urethral extension[2] and vaginoplasty.[3] Prognosis depends on the severity of secondary endometritis and the success of surgery.

Vaginitis

Vaginitis may occur as a result of ascending infection or exposure to irritants, or secondary to pneumovagina, urovagina, perineal laceration, rectovaginal fistulas, breeding, endometritis, abortion, parturition, or dystocia. Occasionally, traumatic wounds may be infected with clostridial or anaerobic organisms; however, most infection is nonspecific.

Clinical Signs and Diagnosis Signs may vary from hyperemia evident on speculum examination to mucopurulent exudation from the vulva. Severe trauma and infection may be followed by necrotic vaginitis with tenesmus, fetid discharge, elevated tail, swollen vulva, and systemic signs. Rapid formation of adhesions follows necrotic vaginitis. Metritis, RFMs, and uterine tears also may show systemic signs and vaginal discharge.

Treatment and Prognosis The inciting cause should be treated. Animals with mild vaginitis may recover spontaneously, whereas moderate cases require lavage with dilute antiseptic or antibiotic solutions. Fertility is unaffected in mild vaginitis without extension, and prognosis is good. Severe, necrotic vaginitis is treated with systemic antibiotics, analgesics, and antiinflammatory agents. Caslick's surgery may be necessary to prevent aspiration of air. Local application of antibiotic and steroid-impregnated ointments may help prevent adhesions. Prognosis for severe vaginitis is guarded. Vaginal stenosis and adhesions may follow vaginitis.

Prevention and Control Nonspecific vaginitis may be prevented by reducing trauma to the vagina during foaling. Clinicians should elect appropriate methods for relief of dystocia and apply extractive force to fetuses judiciously.

Infectious Pustular Vulvovaginitis

COWS. Infectious pustular vulvovaginitis (IPV) affects cattle and is caused by bovine herpesvirus 1, also the cause of infectious bovine rhinotracheitis (IBR), although the two strains are genetically distinct.[4] Therefore the respiratory and genital forms of the disease rarely occur concurrently, and abortions usually do not follow an outbreak of the genital form of the disease. IPV is spread by coitus and mechanical means and may affect unbred heifers. The incubation period of IPV is short (1 to 3 days), and the infection spreads rapidly through the herd, affecting 60% to 90% of the animals.

Clinical Signs and Diagnosis Early in the course of the disease, IPV is characterized by a mucopurulent vaginal discharge, inflammation of the vaginal and vulvar mucosa, and painful urination. Pustules develop over lymphoid follicles and progress from small (<3 mm) ulcers to coalescing erosions. The virus also causes inflammation of the penis and prepuce (balanoposthitis), leading to considerable pain. Therefore animals of both sexes with IPV are reluctant to mate. The clinical signs subside in 10 to 30 days, leaving the recovered animals with transient immunity. Early in the course of IPV, lesions may be similar to those of granular vulvitis (see later section), but the lesions of IPV rapidly become more severe. Vulvovaginitis caused by *Histophilus somni* (formerly *Haemophilus somnus*) should be a differential diagnosis.

Treatment and Prognosis Treatment of IPV is usually not required, although lavage of the vagina with dilute antiseptic solutions and emollients has been recommended. Mating among infected animals should be suspended until the disease subsides. The prognosis for recovery is excellent.

Prevention and Control Vaccination against IBR is not likely to be beneficial in the face of an outbreak, but cattle may be protected if they are vaccinated before exposure. The IPV virus may survive in cryopreserved semen used for AI; therefore semen donors and semen should be free of the virus. Genital carriers may be responsible for sporadic outbreaks of IPV.

Vaginal Varicose Veins

MARES. Vaginal varicose veins are common in older mares. In most cases the condition is not associated with clinical signs, but affected mares may exhibit vaginal hemorrhage. A thorough examination of the reproductive tract is necessary to determine the origin of the bleeding.

Clinical Signs and Diagnosis Clinical signs of varicose veins vary from no signs to persistent and profuse vaginal hemorrhage. Vaginoscopy or fiber endoscopy of the vagina reveals varicose veins in the vagina or the vestibulovaginal transverse fold. Fiberoptic endoscopic examination may be necessary to diagnose lesions that are present in the cranial aspect of the vestibulovaginal transverse fold. Vaginal hemorrhage from varicose veins should be differentiated from vaginal

trauma and premature separation of the placenta in periparturient mares.

Treatment and Prognosis Most mares with vaginal varicose veins do not require treatment. Surgical ligation, treatment with phenylephrine HCl cream,[5] or laser surgery of the veins may be necessary in cases of severe bleeding. The short-term prognosis after surgery is good, but the condition often recurs.

Vestibular and Vulvar Abnormalities

Coital Exanthema

MARES. Coital exanthema is caused by equine herpesvirus 3 (EHV-3) and is a venereally transmitted dermatitis of the genital region of mares and stallions.[6,7]

Clinical Signs and Diagnosis The disease is recurrent, is usually mild and transient, and affects the vulva and perineum of mares and the penis and prepuce of stallions. Lesions are initially small papules that rapidly progress to pustules and then ulcers. Lesions may rarely appear on the conjunctiva, lips, nares, and mucosa of the upper respiratory tract. Rare secondary bacterial infection and systemic signs occur. Intranuclear inclusion bodies are apparent in epithelial cells on histologic sections taken from the active edge of ulcers. Coital exanthema does not affect fertility in mares, but libido may be decreased in affected stallions because of pain during coitus.

Treatment and Prognosis Lesions usually heal spontaneously within 14 days, leaving depigmented spots. Treatment is not necessary unless secondary bacterial infection occurs. There is no available vaccine for EHV-3. Sexual rest until the lesions are healed is recommended to prevent further spread of the disease. The prognosis is excellent.

Granular Vulvitis

COWS. Granular vulvitis may occur in females of all domestic species but is most often seen in cattle. The disease is characterized by development of granules or papules in the vulvar mucosa accompanied by genital discharge. Infertility may or may not be a feature of the syndrome. Vulvitis may be secondary to nonspecific vaginitis. *H. somni*[8] and *Mycoplasma bovigenitalium* have been isolated from cattle with vulvitis, but their role in infertility is not well defined, and there may be differences in pathogenicity among strains of the organisms. *Ureaplasma diversum* has been isolated from cases of granular vulvitis in cows and ewes and may be associated with infertility when the organism is transferred into the uterus during AI.[9]

Clinical Signs and Diagnosis Granular vulvitis is characterized by the formation of raised granules or papules in the vulvar mucosa and around the clitoris with variable amounts of mucopurulent exudate. In the mild form of granular vulvitis associated with *U. diversum*, only a few granules develop and the infection has minimal effect on fertility. However, acute severe cases are characterized by hyperemia of the vulva, a profuse mucopurulent discharge, and depressed fertility. Purulent discharge during the acute phase persists for 3 to 10 days, after which the disease becomes chronic. In chronic cases the lesions are reduced in severity, and there is little or no purulent discharge. The chronic form may persist for several months, and the disease may become enzootic in some herds. The clinical signs of granular vulvitis may be similar to the early signs of IPV.

Clinical Pathology Samples for microbiologic culture should be obtained from the vulva, cervicovaginal mucus, and uterus. Use of a transport medium for submission of samples to a laboratory is mandatory. The organisms may be eliminated before the samples are obtained, yielding false-negative results. Conversely, microorganisms incriminated as causing granular vulvitis may be isolated from the genital tracts of normal animals.

Treatment and Prognosis Most cases of nonspecific vulvitis resolve spontaneously. Infertility associated with *U. diversum* infections is treated by preventing transfer of organisms to the uterus by using double-sheathed AI instruments. Natural breeding should be suspended. In addition, infusion of 1 g of tetracycline or spectinomycin in a nonirritating vehicle into the uterus 24 hours after breeding has been recommended to reduce the population of organisms that may have been transferred to the uterus. Local treatment of vulvar lesions with tetracycline or spectinomycin has also been suggested.

Prevention and Control In chronically infected herds, fertility rates may approach normal if double-sheathed AI instruments are used and affected cows are treated with appropriate antibiotics.

Ulcerative Dermatosis Genital Lesions

SMALL RUMINANTS. Ulcerative dermatosis is a venereal disease of sheep caused by a parapoxvirus similar to but distinct from the virus that causes contagious ecthyma.[10] The disease is characterized by ulceration of the skin and mucous membranes of the vulva of ewes and the penis and prepuce of rams. Lesions also occur on the lips, nares, feet, and legs. The lesions are painful, and affected animals avoid coitus. The disease subsides in 7 to 10 days.

Because of its viral cause, no specific treatment is available for ulcerative dermatosis. Symptomatic treatment with local astringent and antiseptic ointments has been suggested. Mortality is low if the animals are otherwise healthy.

No vaccine is available. Males with the disease should not be used for breeding.

Abnormal Labial Approximation

MARES AND COWS. The most common anatomic defect of the vulva of mares and cows is abnormal labial approximation, which leads to pneumovagina and subsequently to infertility. The defect may be the result of imperfect conformation or traumatic insult to the vulva. Abnormal labial approximation is treated with Caslick's surgery or one of its modifications.

Persistent Hymen

In the developing embryo, failure of cannulation of the urogenital sinus by the mesonephric duct system results in absolute or partial occlusion of the vestibulovaginal junction. Total occlusion causes accumulation of endometrial and cervical secretions cranial to the obstruction, and occasionally the membrane may appear at the vulva. Partial occlusion may be noted only as an obstruction to breeding or during speculum examination. The membrane may be manually ruptured or incised. Prognosis is excellent.

Clitoral Hypertrophy

Clitoral hypertrophy may be a feature of intersex conditions, may occur in filly foals whose dams received progestins during pregnancy, or may follow administration of anabolic steroids.[11] Hypertrophy may persist after cessation of steroid treatment. In cows it may be associated with freemartinism.

Vulvar wattles in cattle may superficially appear similar, but the elongated epithelial structure does not involve the clitoris.

Neoplasia

Melanomas and squamous cell carcinomas (SCCs) are the most common neoplasms affecting the perineum, anus, and vulva of gray- and light-skinned horses, respectively. Lesions are

VetBooks.ir

usually proliferative and may have surface ulceration, hemorrhage, and infection. Lesions should be differentiated from habronemiasis, granulation tissue, and sarcoids. Treatment is surgical removal. Sarcomas and melanomas may metastasize. Viral fibropapillomas are the most common tumors affecting the vulva of cattle. SCCs may be seen in all species and may be more common in white-skinned animals exposed to long periods of solar radiation.[12]

Vulvar neoplasia is characterized by variable degrees of tissue proliferation. The surface of SCCs and fibropapillomas may be ulcerated, necrotic, and fly-blown. In cows, squamous metaplasia of the nonpigmented skin of the vulva is frequently a precursor of SCCs of the vulva. Vulvar neoplasia must be differentiated from other causes of tissue proliferation, habronemiasis in mares, and ectopic mammary tissue in does. Neoplasia of the vulva and vestibule is diagnosed by biopsy of the tumor.

Surgical excision is the treatment for most neoplasms of the vulva. Viral fibropapillomas regress spontaneously after a period of several months. Recurrence and metastasis may occur.

Ectopic Mammary Tissue

Ectopic mammary tissue has been described in does and is characterized by swelling of the vulvar lips. The abnormal enlargement begins before each parturition and persists for approximately 2 months. The condition is benign unless the tissue enlarges sufficiently to interfere with evacuation of feces or urine. Milk may be aspirated from the mammary tissue, and the condition may be confirmed by biopsy; however, this may introduce infection and lead to complications.

Abortion

Mares Information on the major causes of abortion in horses is summarized in Table 43.7.

Noninfectious Causes

Twin Pregnancy

Despite the overall decrease in the number of twin-related abortions, twinning remains an important noninfectious cause of abortion in the mare.[1] The mare is unable to successfully support two fetuses to term and only in rare cases (<2%) is able to carry both fetuses to term and deliver without dystocia.[2] It is much more common for the mare to have a natural reduction to a singleton pregnancy during the embryonic stage or to abort the pregnancy after the fetal stage.[3,4] Some breeds are more commonly diagnosed with twins during the embryonic stage (e.g., Thoroughbreds have 20% to 30% double ovulations and 10% to 15% diagnosed twin pregnancies).

Clinical Signs and Diagnosis Mares should be evaluated with transrectal ultrasound 13 to 15 days after documented ovulation during a breeding cycle. The ovaries should be examined for more than one active CL, and the uterus should be carefully scanned from the tip of one horn to the other and along the uterine body to the cervix. Equine embryos at this stage are highly mobile within the uterus and may be located anywhere within the uterus. Twin pregnancy should not be ruled out until the entire uterine tract has been scanned for the presence of embryos. After one embryo is found, the remainder of the uterus still must be visualized to ensure the absence of a twin. The embryo proper per se is not visible at this stage of pregnancy, but the embryonic vesicle is easily visualized. Care must be taken not to confuse endometrial cysts with embryos, which sometimes can look deceptively similar. It is helpful to have scanned the mare's uterus using ultrasound before breeding to document the size and location of endometrial cysts.

Treatment and Prognosis If twins are confirmed before 16 days of pregnancy, the best way to treat the mare is to manually crush one of the vesicles. This is done by visualizing the twins using transrectal ultrasound and spatially separating them from each other within the uterus. One twin is moved away from the other to the tip of a uterine horn, where it is crushed manually. The remaining embryo should be evaluated 1 to 2 days later to determine its status. Manual reduction of an embryo fixed in the contralateral horn from its twin between days 16 and 20 should be performed at the base of one uterine horn, because embryos are typically "fixed" at this site after day 16. Survival of the remaining embryo is greater than 90% when twin reduction is performed in this manner before day 20.[5]

TABLE 43.7

Major Causes of Infectious Equine Abortion

Cause and Common Names	Usual Stage of Gestation	Major Fetal Lesions	Diagnostic Tests
Equine herpesvirus 1 (EHV-1)	Seventh month to term	Pulmonary edema, multifocal hepatic and pulmonary necrosis, intranuclear inclusions	Histopathology, virus isolation, fluorescent antibody test, fetal serology, PCR
Equine viral arteritis (pestivirus)	5-10 months	Myocardial arteritis	Histopathology, virus isolation, PCR, serology
Nocardioform actinomycetes, *Crossiella equi*, *Amycolatopsis* spp.	Mid to late gestation	Characteristic placentitis located ventrally in the uterine body and at the base of the uterine horns	Culture, PCR
Streptococcus zooepidemicus	Any stage	Placentitis with or without inflammation in fetal tissues	Histopathology, culture
Mycotic abortion, *Aspergillus*, and other species	Latter half (often near term)	Placentitis, fetal bronchopneumonia	Histopathology, fungal culture
Leptospirosis	Seventh month to term	Icterus and autolysis	Culture, immunofluorescence, serology, PCR

PCR, Polymerase chain reaction.

VetBooks.ir

It is the established practice of some veterinarians to treat mares with a nonsteroidal antiinflammatory agent (e.g., flunixin) and/or altrenogest after a twin-crush procedure. The reasoning behind this practice is that manual stimulation of the uterus may cause a release of oxytocin, signaling a prostaglandin cascade that will result in luteolysis and complete pregnancy loss. No studies have been performed to support this theory; to the contrary, other studies have shown that the release of prostaglandin after the routine twin-crush procedure does not cause a drop in progesterone and that supplementation with antiinflammatory drugs or progesterone makes no difference in the outcome.[5,6]

Twins fixed next to each other at the base of the same horn between days 16 and 20 cannot be separated from each other. Manual reduction can still be reliably performed at this stage but will result in the loss of both embryos and the need to breed the mare again on a subsequent cycle. If twins are discovered fixed ipsilaterally between days 16 and 20, the practice of "benign neglect" may be followed for a short time. Since most of these situations will resolve naturally with the resorption of one twin and the persistence of the other, it is a responsible practice to simply monitor the situation to note if one twin regresses. If both twins continue to develop approaching the formation of endometrial cups (day 37 to 38), a decision must be made either to terminate the pregnancy or to refer the mare for advanced, selective twin reduction, which includes transvaginal, ultrasound-guided fetal aspiration[7]; transcutaneous, ultrasound-guided fetal intracardiac injection of procaine penicillin or potassium chloride[8]; or craniocervical dislocation.[9] The success of these techniques is lower than that of manual crush, and they are performed later in gestation, after the window for manual crushing has been missed. These are all specialty techniques and are beyond the scope of this chapter.

Other Noninfectious Causes of Equine Abortion

In a survey of causes of equine abortion in the United Kingdom from 1988 to 1997, nearly 39% were caused by umbilical cord pathology.[10] Most of the cases (35%) resulted from torsion of the umbilical cord. Twisting of the umbilical cord is common in equine fetuses and often is not pathologic. A diagnosis of abortion caused by umbilical torsion should be made only if localized swelling and discoloration accompany the twisting. Congenital abnormalities may cause abortion. The most common congenital abnormality in equine fetuses is contracted tendons, accounting for 5% of abortions in a study from the United States.[1] Fetuses that implant in the uterine body instead of the base of one of the horns develop placental villous atrophy and usually abort, accounting for 2% of abortions in the same study.

Infectious Causes

Placentitis

Placentitis is the leading cause of equine late-term pregnancy loss in the United States.[1] Bacterial organisms most commonly cultured from aborted fetuses include *Streptococcus* spp., *E. coli*, *Pseudomonas* spp., *Klebsiella* spp., *Staphylococcus* spp., and *Leptospira* spp. Nocardioform actinomycetes are an important cause of placentitis in central Kentucky and have also been reported in Florida.[11-13] *Aspergillus fumigatus* and *Mucor* spp. are the most commonly diagnosed causes of mycotic abortion in mares, causing 5% to 30% of infectious equine abortions.

The route of placental infection is believed to most commonly be ascending via the cervix, which results in loss of chorionic villi around the cervical star. In addition to loss of chorionic villi, additional allantochorionic lesions may include nodular cystic allantoic masses, edema, necrotic areas of chorion, and necrotic mucoid exudate coating the chorion. Hematogenous placentitis shows a more generalized, diffuse loss of villi.[1] Infection of the placenta results in subsequent infection of the fetus and release of proinflammatory cytokines and prostaglandins from the inflamed placenta, which ultimately leads to mid- to late-term abortion or delivery of a premature foal.[14] The distribution of the avillous chorionic lesion classically noted in mares with ascending or hematogenous placentitis does not fit the pattern noted with nocardioform placentitis. Mares with nocardioform placentitis classically show a loss of chorionic microvilli, covered by brownish, thick, and tenacious exudate in a focal area around the ventral aspect of the uterine body and base of the uterine horns.

The pathogenesis of nocardioform placentitis is still unresolved. It has been hypothesized that the pathogen is present in the environment or introduced into the mare at the time of breeding and settles in the ventral aspect of the uterus, where infection ensues. Various nocardioform organisms have been reported in soil across the globe, although the pathogenicity of most of these organisms has not been determined. Nocardioform organisms isolated from equine placentas include *Amycolatopsis* spp. and *Crossiella equi*.[11,13,15,16] These bacteria have been diagnosed only from clinical cases of placentitis and not from the environment.[17] Nocardioform placentitis often results in abortion or premature delivery.[1] Bacteria and resulting inflammation are limited to the interface between the chorion and the endometrium. Because no bacterial invasion or signs of inflammation have been observed in the placental and fetal tissues, the abortion is postulated to be due to nutritional deprivation of the fetus resulting from separation between the chorion and endometrium.

Clinical Signs and Diagnosis Premature udder development and vaginal discharge are common signs of pending abortion caused by ascending placentitis. However, when these signs are present, the prognosis is poor even when mares are treated. Transrectal ultrasonography of the allantochorion in an area close to the cervix is useful to detect early signs of placentitis and impending abortion (Fig. 43.6).[18] Ultrasound evaluations may reveal hyperechoic fetal fluids, placental separation, increased or decreased fetal heart rates (normal range 75 ± 7 bpm[19]), and thickening of the combined thickness of the uterus and placenta (CTUP). Consistently low or high fetal heart rates are associated with fetal stress. Foals experiencing fetal distress often become bradycardic initially and then become tachycardic in the terminal phase of life.[20,21] Serial examinations should be performed to verify fetal well-being or distress. Mares considered "at risk" for pregnancy loss are often examined daily. Fetuses experiencing distress are often evaluated several times a day. Normal measurements of CTUP have been established (Fig. 43.7).[18,22] Mares with placentitis may show increased CTUP, edema of the allantochorion, and separation from the endometrium. A 5-MHz linear transducer should be used for transrectal ultrasonography. The transducer should be positioned 1 to 2 inches cranial to the cervical-placental junction and then moved laterally until a major uterine vessel is visible at the ventral aspect of the uterine body.[22] The CTUP should then be measured between the vessel and the allantoic fluid (see Fig. 43.6). It is important to obtain all CTUP measurements from the ventral aspect of the uterine body, because physiologic edema of the dorsal aspect of the allantochorion has been noted in normal pregnant mares during the last month of gestation.[22] In addition, care should be exercised to be certain that the amniotic membrane is not adjacent to the allantochorion because this may result in a falsely increased CTUP. To examine the placenta from a transabdominal approach, a 3.5-MHz sector transducer is used most frequently. All four quadrants of the placenta should be examined: right cranial, right caudal, left cranial, and left caudal. Measurements of the CTUP can be made with this technique

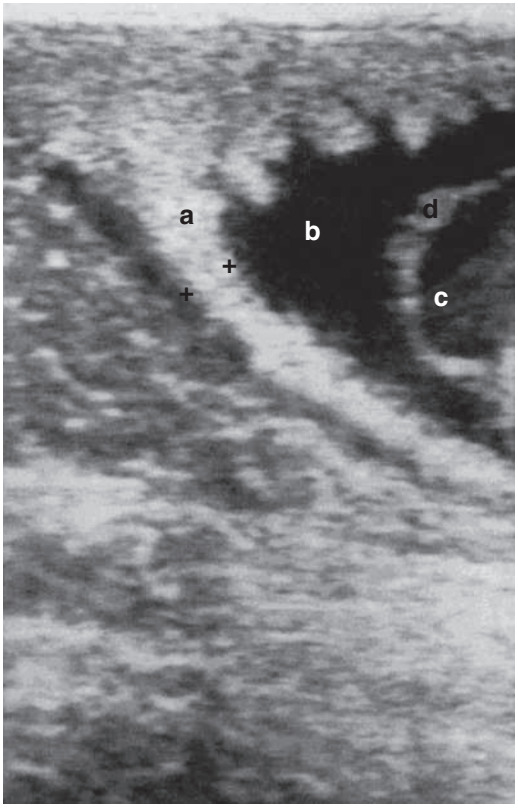

FIG. 43.6 Transrectal imaging of the combined thickness of the uterus and placenta (CTUP). Measurements of the CTUP (distance between + and +) were recorded from the ventral part of the uterine body, close to the cervix. *a*, Placenta adjacent to the cervix; *b*, allantoic fluid; *c*, amniotic fluid; *d*, the amnion. *(Modified from Renaudin CD, Troedsson MH, Gillis CL, et al.: Ultrasonographic evaluation of the equine placenta by transrectal and transabdominal approach in the normal pregnant mare.* Theriogenology, *47:559, 1997.)*

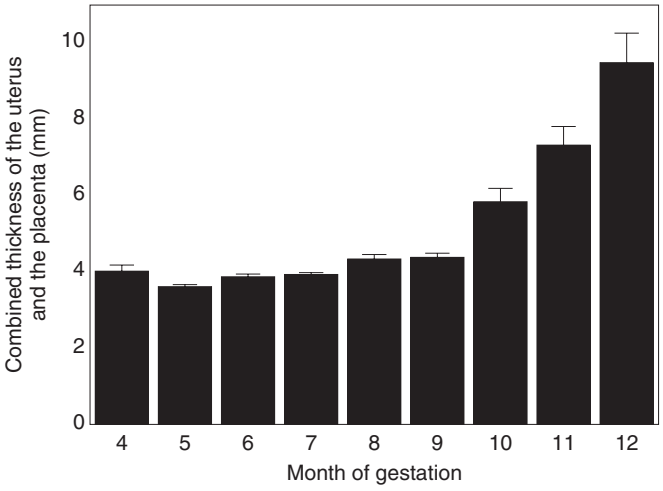

FIG. 43.7 Monthly recordings of transrectal ultrasonographic measurements of the combined thickness of the uterus and placenta (CTUP) in normal mares from 4 months of gestation and throughout the pregnancy. Month 4 is 91 to 120 days; month 5 is 121 to 150 days; month 6 is 151 to 180 days; month 7 is 181 to 210 days; month 8 is 211 to 240 days; month 9 is 241 to 270 days; month 10 is 271 to 300 days; month 11 is 301 to 330 days; month 12 is 331 to 360 days. *(Modified from Renaudin CD, Troedsson MH, Gillis CL, et al.: Ultrasonographic evaluation of the equine placenta by transrectal and transabdominal approach in the normal pregnant mare.* Theriogenology *47:559, 1997.)*

if the fetus is not in close apposition with the uterine wall. Mares with normal pregnancies should have a minimum CTUP of 7.1 ± 1.6 mm and a maximal CTUP of 11.5 ± 2.4 mm.[23] Pregnancies with an increased CTUP have been associated with the delivery of abnormal foals.[23] False-positive results have been reported, and clinical judgment should be exercised before treatment is implemented. Placental separation and purulent material at the ventral aspect of the base of the gravid horn and the uterine body can be observed in mares with nocardioform placentitis. This finding can be identified only by using transabdominal ultrasound.

The gross lesions of the fetus are not specific. An increased amount of fluid in the thoracic and abdominal cavities and an enlarged liver are frequently observed in aborted fetuses. Placental lesions in cases of ascending placentitis are most severe on the chorionic surface at an area from opposite the cervix ("cervical star") to the body of the placenta. The affected area is edematous, thickened, and discolored or brown with a mucoid or fibronecrotic exudate on the surface. The placenta is characteristically thickened and leathery in cases of mycotic placentitis, with lesions well demarcated from the rest of the chorionic surface. Microorganisms can be isolated from the placenta and several fetal organs, most consistently from the stomach.

Mares with nocardioform placentitis may have premature mammary development but will not have vulvar discharge, owing to the location of the infection. Placental lesions in mares infected with *Amycolatopsis* spp. and *C. equi* are located ventrally in the uterine body and at the base of the uterine horns. Affected areas are avillous, thickened, and covered by thick brown or reddish exudate. Differential diagnoses for this clinical presentation include twins and *Cellulosimicrobium cellulans* placentitis.[15]

Prevalence of fungal abortions varies greatly with region. The most common route of fungal infection is ascending via the cervix, and fungal infections may be seen with a mixed bacterial infection. Abortions are observed from mid to late gestation. The chorion generally shows marked evidence of placentitis with edema, thick plaques, and a thick, mucoid exudate. In rare cases, amniotic thickening may be noted. The aborted fetus is often small and emaciated owing to chronic placental insufficiency. Culture of the chorion may be diagnostic but takes time. Culture of the fetus is rarely rewarding. Impression smears of the chorion, as well as sometimes the fetal stomach, may reveal hyphae.

PROGESTERONE. The equine placenta is part of an endocrine fetal-placental interaction that synthesizes and metabolizes progestagens.[24] This endocrine function of the placenta is important for maintenance of pregnancy after the endometrial cups and the secondary corpora lutea disappear at approximately day 120 to 150 of gestation. Fetal-placental progesterone is rapidly metabolized to 5α-pregnanes. Mares with placental pathology may have increased plasma concentrations of progestagens as a result of stress to the fetal placental unit.[25,26] Unfortunately, 5α-pregnanes are not readily assayed in a commercial setting, so diagnosis of placental disease using 5α-pregnane concentrations is not possible. There is cross-reactivity between 5α-pregnanes and progesterone using some commercial radioimmunoassays for progesterone. Using an experimental model to induce placentitis, it was found that mares that develop a chronic form of placentitis also develop increased plasma progesterone concentrations.[26,27] Conversely, mares that developed acute placentitis and abortion soon after infection experienced a rapid drop in plasma progesterone concentrations. It has been suggested that serial measurement of plasma progestin concentrations in mares with placentitis might be a useful method to identify mares that may abort or deliver prematurely.[26] However, in a recent prospective study

VetBooks.ir

of 700 mares in central Kentucky, with blood collected weekly until the end of pregnancy, progesterone concentrations in the sample obtained during the week preceding abortion were not significantly different from those in mares with normal pregnancy outcome.[28] Sensitivity of progesterone assays can be improved when they are combined with evidence of placental thickening as detected using transrectal ultrasonography.[27]

ESTROGEN. Serum estrogen concentrations are deviated in pregnant mares between 150 and 310 days of gestation.[29] The predominant estrogens in pregnant mares are estrone, equilin, equilenin, estradiol-17β, and estradiol-17α. Douglas[29] observed that mares aborting from placentitis had serum estrogen concentrations below those normally detected in pregnant mares. These observations were supported by results from a recent prospective study, in which low estradiol-17β sulfate serum concentrations were significantly associated with abnormal pregnancy outcome.[28] Based on these findings, it was suggested that supplementation with estradiol cypionate (ECP) or estradiol-17β may prevent abortion in mares with placentitis, but this has not been supported by later research.[30]

RELAXIN. Relaxin is produced by the equine placenta and can be detected in peripheral blood plasma from day 80 of gestation and then throughout the pregnancy. The role of relaxin during pregnancy is not fully understood, but there is some evidence that placental relaxin production is compromised in mares at risk of aborting their fetuses.[31] There currently is no commercial test available for equine relaxin.

ADDITIONAL MARKERS FOR PLACENTITIS

Acute Phase Proteins. Serum amyloid A (SAA) remains low throughout gestation but shows a significant increase within 12 hours of parturition and returns to baseline within 60 hours postpartum.[32] Interestingly, levels of SAA in peripheral blood have also been reported to increase in mares with experimentally induced placentitis.[33] However, SAA is a nonspecific marker of inflammation with significant increase observed during other sources of inflammation and even after vaccination. Furthermore, only a weak association was detected between pending abortion and elevated SAA concentrations in a prospective clinical study.[28]

Serum Alpha-Fetoprotein (AFP). Elevated AFP has been associated with abnormal pregnancy outcome under clinical conditions, and this protein may be used as a marker for mares with placentitis and/or at risk of aborting.[28] In summary, no single test appears to have sufficient specificity, sensitivity, or practicality to accurately detect early subclinical cases of placentitis. A panel of estradiol-17β, AFP, and SAA may serve as the best available method to screen mares for unhealthy pregnancies as well as predict the outcome.

Treatment and Prognosis Treatment efforts should be directed at combating infection, reducing inflammation, and controlling myometrial activity. Pregnant mares with clinical signs of placentitis should be treated with systemic broad-spectrum antimicrobials and antiinflammatories. Commonly used antibiotics such as penicillin G sodium or potassium (22,000 IU/kg IV q6h), gentamicin (6.6 mg/kg IV q24h), and trimethoprim-sulfadiazine (30 mg/kg PO bid) cross the placenta and reach therapeutic concentrations in both placental tissues and the allantoic fluid.[34] However, the duration of these elevated concentrations was short and below that in blood plasma. This may explain why more than 60% of mares that had been treated for placentitis still cultured positive on endometrial biopsy after foaling.[35] It may also explain why antibiotic treatment appears to be necessary for the remainder of gestation in mares with placentitis. Flunixin meglumine (1.1 mg/kg IV or PO q12h) and pentoxifylline (8.5 mg/kg PO bid) have been used to control proinflammatory cytokines associated with placentitis. Treatment with progestins has long been advocated to promote uterine quiescence in mares with uterine pathology. Presumably the anti-prostaglandin effect of progestins contributes to reduced myometrial activity by interfering with upregulation of prostaglandin and oxytocin receptors.[36] Altrenogest at twice the recommended dose (0.088 mg/kg PO q24h) is commonly used.

The efficacy of multimodal, long-term therapy for equine placentitis has been investigated in a large-scale clinical trial.[37] Investigators examined records of 477 mares over 6 years. Fifteen mares were diagnosed with placentitis. Criteria for treatment included increased thickness of the uteroplacental unit using transrectal ultrasound, placental separation, and/or vulvar discharge and udder development. The average gestational age at diagnosis was 8.6 months. Mares were treated until abortion or delivery of foal with a combination of systemic antibiotics (trimethoprim-sulfa, ceftiofur, or penicillin and gentimicin); pentoxifylline; altrenogest; and nonsteroidal antiinflammatory agents. Twelve of 15 treated mares (80%) carried their foals to term, and 11 of 15 (73%) delivered live foals. Birth weights of surviving foals from mares treated for placentitis were similar to those of foals from nonaffected mares. The benefit of this treatment strategy is supported by more recent data from a controlled study on experimentally induced placentitis.[38] Therefore long-term antibiotic, antiinflammatory, and progestin treatment may positively affect pregnancy outcome in mares with placentitis.

Although most mares are capable of conceiving and successfully carrying a foal to term in subsequent breedings, reproductive performance may be negatively affected after placentitis, be it induced by the ascending or hematogenous route. Treatments for endometritis, such as uterine lavage and intrauterine infusions of appropriate antibiotics, should be implemented after abortion. Most mares affected by nocardioform placentitis do not require subsequent treatment and show no signs of infertility the following breeding season.

Equine Herpesvirus 1 Abortion

The most prevalent viral cause of equine pregnancy loss is equine herpesvirus 1 (EHV-1), which causes abortion, paresis, and neonatal foal death. EHV-4 causes abortion in rare cases. The primary route of transmission of EHV-1 is via the respiratory tract. The virus invades the respiratory epithelium and establishes a leukocyte-associated viremia. EHV-1 establishes a chronic, possibly lifelong, latent infection. During the initial infection, placental endothelial cells are infected by the virus and transiently present targets to the immune system as the cells present viral particles. The virus eventually inactivates the major histocompatibility complex 1 (MHC-1) ability of the cells to present viral particles, thus evading the immune system.[39] After respiratory infection, EHV-1 causes an episode of viremia and infects the fetus via transplacental migration of virus-bearing leukocytes. Respiratory clinical signs in infected mares may be subclinical. The time between infection and abortion varies greatly from less than 2 weeks to several months.[40] Abortion occurs as a result of a rapid separation of the placenta, causing suffocation of the fetus.[41] Near-term fetuses may be born alive but will die within days. Aborting mares clear the virus quickly from the reproductive tract, and subsequent fertility is often not affected by the disease. Clinical signs and fetal lesions of abortion caused by EHV-1 and those caused by EHV-4 are indistinguishable from each other.[40]

As with all herpesviruses, EHV-1 establishes a latent infection that may recrudesce after stressful events, such as weaning, translocation, introduction of a new animal, or other illnesses. It is unclear whether a reactivation event will cause an abortion, but this is considered likely.[42] Recrudescent infections are certainly transmissible. Aborted, infected fetal materials are also highly contagious. Both of these sources may be responsible

for abortion epizootics. Although epidemic abortions occur, losses may be confined to only a few mares in a herd.

Clinical Signs and Diagnosis The primary lesion of EHV-1 is necrotizing vasculitis and thrombosis resulting from lytic infection of the capillary endothelium. The fetus may become infected or remain uninfected, depending on whether the virus crosses the uteroplacental barrier. If transplacental fetal infection occurs late in gestation, a live, infected foal may be born but will not usually survive. Stage of pregnancy during which abortions may occur varies, but the vasculitis is most pronounced from the fifth to ninth months of gestation, and 95% of abortions occur in the last trimester of pregnancy.[43]

Abortions occur suddenly as sporadic abortions or "abortion storms" without maternal clinical signs. The aborted fetus is fresh, with minimal signs of autolysis. Gross lesions in the fetus include increased fluid in the thoracic and abdominal cavities; congestion and edema of the lungs; hepatomegaly with multifocal, small (~1 mm), yellow-white necrotic foci; subcutaneous edema; and icterus. Histologically, the most characteristic lesion consists of areas of necrosis in lymphoid tissue, liver, adrenal cortex, and the lung, with large intranuclear eosinophilic inclusion bodies. In addition, a hyperplastic necrotizing bronchiolitis is often found. Lymphoid tissues are most commonly affected (nodes, thymus, spleen, and Peyer's patches). Other histopathologic lesions may include mild, multifocal, necrotizing lesions in the liver and adrenal cortex and a hyperplastic, necrotizing bronchiolitis. The placenta may be grossly normal or edematous with no specific microscopic lesions.[44]

Laboratory diagnosis of EHV-1 abortion is done by either direct demonstration of virus (virus isolation or viral antigen) or viral nucleic acid detection (PCR) or indirectly through serologic evidence of recent infection. The placenta, lung, liver, spleen, and thymus should be collected aseptically in suspected cases of EHV-1 abortion for virus detection. Tissue samples for virus isolation should be kept at 4° C, not frozen at –20° C, until inoculated into cell culture. Samples that cannot be processed within a few hours after collection should be stored at –70° C. The identity of virus isolates recovered from tissue specimens must be confirmed by PCR, indirect immunofluorescent assays using EHV-1 specific antisera or monoclonal antibodies, or neutralization assays using EHV-1 specific antisera or monoclonal antibodies. Serologic tests are not considered reliable in EHV-1 diagnosis. It should be kept in mind that serum from mares that aborted may already contain peak levels of antibodies, and no increase in titers will be detectable in subsequently collected sera. Equine fetuses have been found to be capable of producing antibodies to EHV-1 at 200 days of gestation. Maternal serology is of limited diagnostic value because mares may abort several weeks after infection. The rise in serologic titer may have disappeared by the time of the abortion.

Treatment and Prognosis Most studies do suggest a beneficial effect of vaccination, and the current recommendation is to vaccinate during the fifth, seventh, and ninth months of gestation.[39,43] Both killed and modified live vaccines are available. The vaccines are not fully protective, and abortion may occur in vaccinated mares. However, consistent vaccination of pregnant mares should be expected to decrease the incidence of abortion storms and sporadic abortions in a herd.

For the effectiveness of a vaccination program to be maximized, it needs to be combined with a management strategy that minimizes exposure of mares to the virus and prevents activation of a latent viral infection. All horses—young, adult, nonpregnant, and pregnant—should be vaccinated to restrict shedding of the virus. Unnecessary stress such as transportation and overcrowding should be avoided. Pregnant mares should be kept separate from other horses on the farm. Newly arrived horses should be isolated from the resident population for 3 weeks, during which time they should be monitored daily for signs of respiratory disease.

After abortion, the fetus and fetal membranes should be transported away from the area without contaminating the surrounding environment. The stall in which the mare aborted should be disinfected with a phenolic or iodinophoric compound, and the bedding should be prevented from contaminating other areas on the farm. All pregnant mares on an infected farm should remain on the farm until they have foaled. No horse should leave the farm until 3 to 4 weeks after the last abortion.

Equine Viral Arteritis

Equine viral arteritis (EVA) is caused by equine arteritis virus (EAV). The primary target of EAV is the vascular endothelial cells and macrophages. Shortly after infection EAV can be found in the macrophages and later in the lymph nodes. The virus infects circulating monocytes and becomes systemic in distribution by 3 days after the primary infection, resulting in a carrier state (important in stallions). About a week after the primary infection, EAV infects the blood vessel endothelium and causes enough damage by 10 days after the primary infection to cause abortion. Abortion is likely caused by myometritis and vasculitis. Serum progesterone concentrations (produced exclusively by the placenta in the last half of equine pregnancy) fall to baseline levels before the abortion because of placental hypoxia.

Although the pathophysiology is not well established, fetal death may occur by fetal anoxia secondary to compression of myometrial vessels by edema and decreased progesterone production by the placenta.[45]

History and Clinical Signs Clinical signs may be absent or highly variable and may include pyrexia, depression, anorexia, leukopenia, limb edema, stiffness of gait, rhinorrhea and epiphora, conjunctivitis, rhinitis, urticarial rash, localized or diffuse edema, and abortion. Abortion typically occurs at 3 to 10 months of gestation and follows the onset of clinical signs by several days up to 2 months. Abortion rates in outbreaks of EVA have varied from less than 10% to 71%. Less frequently, severe respiratory distress, ataxia, mucosal papular eruptions, submaxillary lymphadenopathy, and intermandibular and shoulder edema may be observed.[46] Infection is rarely fatal in adults but is more frequently fatal in neonates due to interstitial pneumonia and secondary bacterial infections. Clinical pathologic findings are variable, inconsistent, and nonspecific and include hypoxia, hypercapnia, respiratory or metabolic acidosis, lymphocytosis or lymphopenia, neutrophilia or neutropenia, thrombocytopenia, and hyperfibrinogenemia. Gross and histologic lesions differ in severity with the virulence of the viral strain. Edema, congestion, and hemorrhage of the subcutaneous and lymphoid tissues and viscera are the most common gross lesions. Histologic lesions may be found in the vasculature, lymphoid tissues, lungs, intestines, adrenal glands, kidneys, and skin.[46] Abortion may occur without any clinical signs in the mare, and the fetus may be fresh or autolyzed. Fetal lesions are uncommon. The infected stallions may serve as long-term carriers, and virus may be transmitted in the semen.

Laboratory Diagnosis Laboratory diagnosis of EVA is currently based on any combination of virus isolation, viral nucleic acid or antigen detection, and serology. The most appropriate specimens for virus isolation from live horses include nasopharyngeal swabs or washings, conjunctival swabs, and citrated or ethylenediaminetetraacetic acid (EDTA) blood samples for separation of buffy coat cells. Placenta, fetal fluids, lung, spleen, and lymphoid tissues should be collected for virus

VetBooks.ir

VetBooks.ir

isolation to confirm cases of EAV-induced abortion. Reverse transcription PCR (RT-PCR)–based assays (standard and real time) have several potential advantages over the current virus isolation procedure. Serologic diagnosis of EVA is based on virus microneutralization and is standardized by the World Organization for Animal Health (still known by the French abbreviation OIE for Office International des Epizooties) and described in the OIE manual. There are no characteristic lesions of EVA infection in the fetus, although autolysis and myocardial arteritis have been reported. An avidin-biotin complex (ABC) for immunoperoxidase staining using monoclonal antibodies to individual EAV proteins has been used successfully to detect viral antigens in formalin-fixed paraffin-embedded samples, as well as in frozen tissue sections.

Epidemiology and Control Transmission may occur venereally from persistently infected stallions to mares. Reproductive performance of venereally infected mares is not affected, but contact transmission from venereally infected mares to late gestational mares may cause abortion. Major outbreaks of EVA were reported in 1953, 1984, and 2006 in the United States. Apart from these incidents, occasional outbreaks have occurred, with abortion occurring at low incidence.[47] Mares may be isolated after infection but usually do not become carriers. A proportion of naturally infected stallions become persistently infected with EAV and shed the virus constantly in semen. Incidence of seropositive animals is higher in Standardbreds than in Thoroughbreds, and regulatory guidelines may govern the use of seropositive Thoroughbred stallions. Carrier stallions may be the reservoir for the disease between outbreaks and should be isolated and bred only to immune mares. Mares bred in this way should be isolated for 3 weeks. A modified live-virus attenuated vaccine and a killed-virus vaccine are available for prevention of EAV infection in mares and stallions, although some local regulatory restrictions on use may exist. Vaccination of mares up to 3 months before foaling or in the postpartum period appears to be safe. Vaccinating pregnant mares in the final 2 months of gestation is associated with an increased risk of abortion, and decisions to vaccinate in this period must be weighed against concerns for widespread disease in naturally infected herds.[48] Control in stallions involves vaccination of seronegative stallions under the guidance of regulatory authorities.

Leptospirosis Abortion

Leptospirosis causes bacterial abortions in some areas and was reported to be responsible for 2.2% of abortions in a Kentucky study.[49] The serovar responsible shows regional variability. Serovar *Leptospira pomona* has most commonly been associated with leptospirosis abortion in mares, but *Leptospira grippotyphosa*, *Leptospira hardjo*, *Leptospira bratislava*, and *Leptospira icterohemorrhagiae* have also been isolated from sporadic abortions.[49] Wet environmental conditions are considered important in the dissemination of the disease from wildlife to horses. Infected animals shed the spirochete in their urine, which contaminates groundwater and serves as a source for further infections. Many horses are seropositive for leptospires but are subclinical.

Clinical Signs and Diagnosis Clinical signs may include pyrexia, hemoglobinuria, jaundice, and abortion. Aborted chorioallantoic lesions are similar to those of other bacterial placentitis cases (nodular cystic allantoic masses, edema, necrotic areas of chorion, and necrotic mucoid exudate coating the chorion) but may show a diffuse pattern of distribution, indicating a hematogenous source of placental infection. Funisitis has been reported in leptospiral cases of abortion, and examination, both gross and histologic, of the umbilical cord should always be a part of every abortion investigation.[50] Serologic antibody conversion lasts for years, so serologic diagnoses are not helpful. Gross lesions are nonspecific. Diagnosis is best done by fluorescent antibody (FA) tests or Warthin-Starry (WS) silver stain of the allantochorion and umbilical cord. Demonstration of leptospirosis could aid in rapid diagnosis and have important clinical and therapeutic indications in the case of live-born, weak foals.[50]

Treatment and Control Horses may shed spirochetes in urine for up to 90 days; therefore affected animals should be isolated and treated with antibiotics. Aborting mares should be isolated, and the stalls should be disinfected. Infected mares may be treated with streptomycin (10 mg/kg twice daily), penicillin (22,000 to 44,000 IU/kg IM twice daily), or oxytetracycline (5 to 10 IV mg/kg) for a period of 1 week. Because *L. pomona* is the most common isolate in the United States, mares should be separated from other leptospiral hosts such as ruminants and pigs. A vaccine against *L. pomona* is available for horses. Vaccines for cattle are not effective in horses.

Protozoal Abortion

Pregnant mares with equine monocytic ehrlichiosis (Potomac horse fever), caused by the protozoa *Neorickettsia risticii*, may abort. Abortions caused by *N. risticii* have been documented in both natural and experimental cases.[51,52] Mares were infected at 90 to 180 days of gestation and aborted at around 217 days of gestation.

Clinical Signs and Diagnosis Abortions have been observed 2 to 3 months after clinical signs of ehrlichiosis.[53] Abortions were associated with placentitis and RFMs. Fetal histologic lesions include enterocolitis, periportal hepatitis, myocarditis, and lymphoid hyperplasia with necrosis of the mesenteric lymph nodes and spleen. Recovery of the protozoan may be from fetal bone marrow, spleen, lymph node, colon, or liver.[51,52] The diagnosis can be confirmed by identifying a small number of rickettsiae by PCR assay.

Treatment and Prevention Treatment with oxytetracycline (6.6 mg/kg IV once daily) for 5 days in pregnant mares with clinical signs of ehrlichial colitis may prevent or reduce the incidence of abortion. Commercial vaccines against equine ehrlichiosis are available, but the protective effect of vaccines against abortion is unknown.

Neospora caninum is a known protozoal abortifacient in cattle. This protozoan has not been definitively shown to cause abortion in the mare, but its presence has been documented in aborted foals, suggesting the need for further investigation.[54]

Insect-Related Abortion

In the equine breeding season of 2001, central Kentucky horses experienced pregnancy losses estimated to have affected more than 3000 mares (>60% of mares on some farms[55]) and to have resulted in more than $330 million in losses.[56] The syndrome was named *mare reproductive loss syndrome* (MRLS). On a much smaller scale, MRLS was documented in mare abortions in north central Florida during the 2006 breeding season. Epidemiologic studies noted abnormal weather patterns (sudden freezing in mid-April followed by unusually warm springtime temperatures) and positive correlations with the presence of black cherry trees *(Prunus serotina)* and abnormally large numbers of the eastern tent caterpillar *(Malacosoma americanum)*.[57] Pregnancy loss was later linked to ingestion of the caterpillars themselves, with the toxic agent related to the larval exoskeleton.

Clinical Signs and Diagnosis Clinical signs preceding early embryonic death or abortion are typically not observed. Both early (40 to 150 days' gestation) and late (near-term) pregnancies are affected. Hyperechoic amniotic and allantoic

fluids can be noted on ultrasonographic examination, along with a dead or dying fetus (slow heart rate, <75 bpm), which would then be expelled within several days.[58,59] Characteristic histologic lesions are noted in the placenta and umbilical cord (funisitis). In many cases, endometrial cultures are positive for non-β-hemolytic streptococci and actinobacilli. *Actinobacillus* spp. identified in cases of MRLS are identical to commensal organisms found in the oral cavities and alimentary tracts of healthy horses.[60] Larval hairs (cetae) are hypothesized to migrate through the gastrointestinal system and translocate commensal organisms from the oral cavity and intestines to other sites.[57]

Treatment and Prevention Because clinical signs are absent in the mare before fetal death, treatment is not possible. Prevention is aimed at limiting exposure to *M. americanum* larvae. Applying insecticides, physically removing caterpillar nests from trees, removing black cherry trees, muzzling mares in pasture, and supplementing hay feeding in pastures to minimize grazing have all been used.

Salmonella Abortion

Salmonella abortus equi (*Salmonella abortivoequina* or "contagious abortion") was a common cause of abortion in the early 1900s but is now rare. Non–host-specific species, including *Salmonella typhimurium*, currently cause most equine *Salmonella* abortions. Abortion caused by *Salmonella* is discussed in the Ruminants section.

Trypanosomiasis (Dourine)

The protozoan parasite *Trypanosoma equiperdum* causes a venereally transmitted genital infection that may be followed by fatal systemic dissemination in horses. Systemic illness may cause abortion. It occurs in tropical and subtropical regions and has been eradicated from North America. Dourine is diagnosed by isolation of trypanosomes in uterine discharge. Exposed animals can be detected by serology (complement fixation). Control strategies require identification and treatment or euthanasia of infected animals.

Abortion Caused by Endotoxemia

Gram-negative septicemia and endotoxemia associated with intestinal disorders that alter the integrity of the mucosal barrier (e.g., intestinal obstructions, acute enteritis, colitis, grain overload) result in the release of vasoactive metabolites including $PGF_{2\alpha}$. Endogenous release of $PGF_{2\alpha}$ during an episode of experimental endotoxemia has been shown to cause luteolysis and abortion during the first 2 months of pregnancy in mares.[61] The equine pregnancy is dependent on ovarian sources of progesterone for the first 80 days of gestation. After this time, the fetoplacental unit takes over progesterone production, which is necessary for maintenance of the pregnancy.

Clinical Signs and Diagnosis Abortions follow a recent episode of stress induced by endotoxemic shock or gram-negative endotoxemia. Pregnancy loss at early stages of gestation may go undetected unless fetal membranes or parts are found in the stall. Abortions during later stages of the pregnancy may be observed as vaginal discharge or the detection of an expelled fetus.

Treatment and Prevention Daily administration of a progestagen (altrenogest 0.044 mg/kg PO) has been shown to effectively prevent experimental endotoxin-induced abortion.[61] If the animal is treated while the pregnancy is still CL dependent (approximately before day 80), analysis of serum progesterone concentrations after the acute episode of the disease helps in deciding if the supplementation needs to continue. Serum progesterone concentrations of less than 1 ng/mL indicate the loss of an active CL, and supplemental progestagen treatment should continue until the fetoplacental unit is known to be capable of maintaining the pregnancy. For practical reasons, supplementation until day 100 is commonly recommended. Serum progesterone concentrations greater than 2 ng/mL are compatible with a functional CL, and the progestin treatment can gradually be discontinued. Treatments with flunixin meglumine or other prostaglandin inhibitors have not been proven to effectively prevent endotoxin-induced fetal losses unless the agents are administered before clinical signs appear.

Ruminants Information on the major causes of abortion in cows, sheep, and goats is summarized in Tables 43.8 and 43.9.

In large commercial operations a low percentage of intermittently occurring abortions is considered acceptable; such abortions are considered "background abortions." In beef and dairy operations 2% to 3% and 10% are considered acceptable, respectively. Abortion levels beyond these are considered abnormal and are usually investigated. When investigating bovine abortions, it is important to determine commonalities among abortion events, including stage of pregnancy affected, sire used, heifers versus cows affected, dates of new arrivals to the herd, season of year, vaccination protocols, presence of dogs, and management practices among different groups. Cows and heifers on the farm presumed to be pregnant should be evaluated to detect unobserved pregnancy losses. These examinations should document apparently normal, open animals who had previously been documented as pregnant, those with mummified fetuses, and those with pyometra. If possible, an entire fetus (or more than one) should be submitted for culture, serology, and histopathology. If the placenta is available, this should be submitted as well. If it is not practical to submit the entire animal and placenta, tissues including lung, stomach and contents, liver, spleen, and placenta should be collected and appropriately submitted for culture (chilled), viral isolation (frozen), and histopathology (formalin fixed).

Noninfectious Causes

Noninfectious causes of abortion in ruminants include the following:

- Heat stress
- Other stress
- Nitrate toxicity
- Malnutrition (rare)
- Pine needle toxicity
- Drug induced (corticosteroids)
- Physical

Infectious Causes

Bovine Herpesvirus 1

Bovine herpesvirus 1 causes IPV and IBR. The latter disease is the major cause of bovine viral abortion.[1] IBR manifests as upper respiratory disease and abortion, and naive herds may experience abortion rates as high as 25% to 60% when exposed. The virus causes clinical signs in both dam and fetus. Immune dams exposed to the virus do not experience abortions. In naive animals the virus is carried in leukocytes and can become localized in placental tissues. Fetuses exposed to the virus usually die within 24 hours of placental infiltration. Although other stages of pregnancy may be affected, 5 to 6 months' gestation is the most susceptible stage. Fetal lesions include renal hemorrhagic edema; acute general necrosis in the liver, spleen, kidneys, lungs, and adrenal glands; widespread hemorrhage; petechia; epithelial destruction; and hepatic necrosis with intranuclear inclusion bodies. The amnion may be thickened without obvious signs of inflammation.

Diagnosis of IBR is by virus isolation from the placenta, identification of intranuclear inclusion bodies in fetal tissues,

TABLE 43.8

Major Causes of Bovine Abortion

Cause and Common Names	Usual Stage of Gestation	Major Fetal Lesions	Diagnostic Tests
Bovid herpesvirus 1, IBR	Fifth to ninth months	Multifocal necrosis with intranuclear inclusions (liver, lung, spleen, kidney)	Histopathology, virus isolation, FA test of frozen fetal kidney
Bluetongue (orbivirus)	Any stage	Anomalies of skeletal and nervous systems	Pathology, virus isolation, fetal serology
BVD virus, pestivirus	Any stage	Anomalies of skeletal, nervous, cardiovascular, respiratory, or other systems	Pathology, FA test on fetal tissues, fetal serology (virus neutralization, ELISA), serologic survey in herd
EBA, foothill abortion, deltaproteobacterium	Third trimester	Lymphadenopathy, splenomegaly, hepatopathy	Pathology, PCR
Brucella abortus, brucellosis, Bang's disease	Third trimester	Placentitis, fibrinous serositis, bronchopneumonia	Culture, maternal serology (card test, plate, or tube agglutination)
Campylobacter fetus subsp. *venerealis*, campylobacteriosis, vibriosis	Usually early embryonic death	Placentitis, fibrinous serositis, bronchopneumonia, hepatitis	Pathology, dark-field examination, culture (Clark media), smegma (Clark media)
Histophilus somni (formerly *Haemophilus somnus*)	Any stage	Placentitis	Histopathology, culture
Leptospira interrogans, leptospirosis	Fifth to ninth months	Icterus, edema, renal degeneration and inflammation	Fetal and maternal serology, FA in urine
Leptospira interrogans, listeriosis	Eighth or ninth month	Placentitis	Histopathology, culture
Salmonella Dublin, *Salmonella* Typhimurium	Third trimester	Placentitis	Culture
Aspergillus fumigatus and all fungal species, mycotic abortion	Third trimester	Placentitis, bronchopneumonia, dermatitis	Histopathology, fungal culture
Sarcocystis cruzi	Third trimester	Protozoa in caruncles	Histopathology or FA of caruncles
Tritrichomonas foetus, trichomoniasis	First half	Placentitis, bronchopneumonia	Microscopic demonstration of organism, culture (Diamond media), PCR
Bovine neosporosis	Mid-gestation	Similar to those found in toxoplasma-aborted sheep fetuses	Histopathology, seroepidemiology

BVD, Bovine virus diarrhea; *EBA*, epizootic bovine abortion; *ELISA*, enzyme-linked immunosorbent assay; *FA*, fluorescent antibody; *IBR*, infectious bovine rhinotracheitis; *PCR*, polymerase chain reaction.

TABLE 43.9

Major Causes of Abortion in Sheep and Goats

Cause and Common Names	Usual Stage of Gestation	Major Fetal Lesions	Diagnostic Tests
Bluetongue, orbivirus	Any stage	Anomalies of skeletal or nervous systems	Pathology, IFA, serology
Border disease, pestivirus, hairy shaker disease	Any stage	Dysplasia of skeleton, CNS, and fleece	Pathology, virus isolation, serology (cross-reacts with BVD)
Coxiella burnetii, Q fever	Near term	Necrotizing placentitis	Histopathology, microscopic demonstration of rickettsiae, complement fixation, ELISA
Chlamydia psittaci, EAE	Fourth or fifth month	Necrotizing placentitis	Histopathology, microscopic demonstration of organism, fluorescent antibody on fetal tissues or cultures, paired sera
Campylobacter fetus subsp. *fetus*, vibriosis	Last 6 weeks	Placentitis, serositis, multifocal hepatic necrosis	Pathology, microscopic demonstration of organism, culture
Toxoplasma gondii, toxoplasmosis	Any stage	Necrosis and calcification in cotyledons	Pathology, demonstration of organism, serology (e.g., agglutination, ELISA)

BVD, Bovine virus diarrhea; *CNS*, central nervous system; *EAE*, enzootic abortion of ewes; *ELISA*, enzyme-linked immunosorbent assay; *IFA*, immunofluorescent antibody.

immunohistochemistry, or serum neutralization testing. If the latter is to be used, at least two samples must be taken days apart. The first must be negative and the second positive, or the first must be positive and the second titer must show a fourfold increase. Serum testing may not be helpful because the dam may have been infected months before the abortion and the titer after the abortion may actually be falling.

Prevention of disease is by vaccination (though infection and latency may occur despite vaccination). It is recommended to vaccinate heifers at 6 months and administer a booster 3 to 4 weeks before breeding. Vaccination too close to breeding can result in lowered conception rates due to normal, transient inflammation of the reproductive tract. A modified live virus is commonly used in pregnant cows from the third to eighth months of gestation, but its safety is questionable. A killed viral vaccine is available for pregnant cow use; a modified live virus vaccine labeled for intranasal administration is also available.[1]

Bovine Viral Diarrhea Virus

Bovine viral diarrhea virus (BVDV) is a pestivirus that can produce early embryonic death, fetal anomalies, or abortion (see Chapter 32 for complete discussion).[1]

History and Clinical Signs Although fetal death is most common during the first trimester, abortion can occur at any stage of gestation.[2,3] Pathogenicity of the disease depends on gestational time of infection, the viral strain, viral biotype (cytopathic or noncytopathic), and fetal immunocompetence.[4] Often there is a history of repeat breeding and a recent episode of febrile disease in the herd before the onset of abortions.

Laboratory Diagnosis Fetal loss generally occurs 10 to 27 days after exposure, with expulsion of the fetus up to 50 days later.[4] As a result the fetus is most often autolyzed, although in some cases it may be mummified or fresh. The aborted fetus may have a variety of dysplastic lesions, including cerebellar hypoplasia; cerebral malformations (hydrencephaly, porencephaly, microencephaly); cataracts; brachygnathia; arthrogryposis; alopecia; thymic hypoplasia; and intrauterine growth restriction.[2,5] Microscopic lesions include a mild nonsuppurative placentitis. Nonsuppurative vasculitis may be observed in the placenta, liver, or lymph nodes.

Virus isolation from fetal tissue is seldom successful, likely because of the protracted time before fetal expulsion generally occurs after infection. Viral antigen may be detected by FA test on kidney, lung, or lymph node. Virus neutralization and enzyme-linked immunosorbent assay are used to detect antibodies in fetal thoracic fluid, which indicate prenatal exposure to the virus but do not necessarily incriminate BVDV as the cause of abortion. Maternal titers are seldom of diagnostic value because a rise in titer generally occurs before abortion.

Pathophysiology BVDV may be shed in most body secretions. The effects of exposure to BVDV vary greatly depending on the gestational time during which exposure occurred (Fig. 43.8).[6] In seronegative cows, exposure to BVDV at the time of breeding prevents conception. Placental attachment at approximately 35 days' gestation seemingly must precede fetal infection. During the first 4 months of gestation, infection usually causes fetal death and abortion. Fetuses that survive infection with noncytopathic strains between 18 and 125 days of gestation will be persistently infected (PI), are typically seronegative at birth, and subsequently shed BVDV continuously.[4] They may develop mucosal disease later in life from superinfection with cytopathic BVDV.[7,8] Fetuses infected at between 100 and 150 days of gestation, considered congenitally infected (CI), are at risk for the development of dysplastic lesions, including teratologic defects in the brain, skin, or bronchioles. Fetuses infected after 150 days usually recover without dysplastic lesions.[2] Recent evidence, however, suggests that those fetuses born with neutralizing titers to BVDV are more likely to develop a serious illness within the first 10 months of life and less likely to conceive as heifers than those calves born without neutralizing titers to BVDV.[9,10]

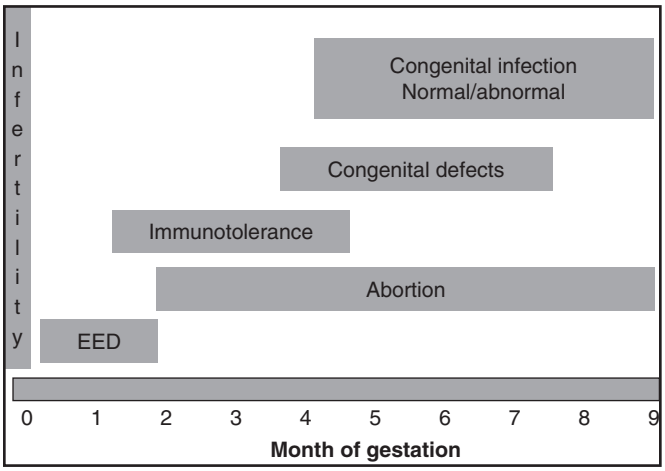

FIG. 43.8 Potential clinical reproductive outcomes after infection with bovine viral diarrhea virus. *EED*, Early embryonic death. *(From Smith KC, Blunden AS, Whitwell KE, et al.: A survey of equine abortion, stillbirth and neonatal death in the UK from 1988 to 1997.* Equine Vet J *35:496, 2003.)*

Epidemiology Most cattle have serum antibodies to the virus. The abortion rate may approach 25% with new infection of a susceptible herd.

Control Killed and modified-live vaccines are available and are an important component of BVDV control, but BVDV is not fully controlled with vaccination. Herd health plans must focus on elimination of PI animals and prevention of new PI animals being introduced into the herd.

Leptospirosis

Leptospirosis is a spectrum of diseases caused by multiple serovars of *Leptospira interrogans*. *Leptospira hardjo* is the major serovar associated with bovine leptospiral abortion, although isolations of serovars *pomona*, *canicola*, *icterohemorrhagiae*, *grippotyphosa*, and *szwajizak* have also been reported.[11] Two serologically indistinguishable but genetically distinct types of serovar *hardjo* have been identified: *L. interrogans* serovar *hardjo* (type *hardjo-prajitno*) and *Leptospira borgpetersenii* serovar *hardjo* (type *hardjo-bovis*). Serovar *hardjo* type *hardjo-bovis* is cosmopolitan in cattle populations, whereas type *hardjo-prajitno* is isolated primarily from cattle in the United Kingdom.

History and Clinical Signs In cattle, infection with serovar *hardjo* is associated with infertility, early embryonic death, abortions from 4 months of gestation to term, and birth of weak calves. Abortion rate is usually less than 10% but may approach 50% in some areas.[12] *L. interrogans* serovar *pomona* abortion usually occurs in the last 3 months of gestation, with an abortion rate as high as 50%. Clinical signs of leptospirosis in the cow may include icterus, hemoglobinuria, anemia, fever, and mastitis that is characterized by a flaccid udder and thick ropy secretions from all four quarters, but usually cows abort without clinical illness. Dead or weak calves may be delivered at term.[12] Abortions caused by serovar *hardjo* tend to occur sporadically rather than in storms (as may be seen with serovars *pomona* and *grippotyphosa*).

VetBooks.ir

Laboratory Diagnosis The aborted fetus is usually autolyzed, icteric, and edematous. Histologically, renal tubular necrosis is accompanied by lymphocytic interstitial nephritis, pneumonia, and placentitis.

Leptospires are rapidly destroyed by autolysis or freezing. Isolation from fetal liver, kidney, or brain is possible but slow and impractical. Leptospires may be isolated or demonstrated by dark-field microscopy, FA staining, or histologic techniques in fetal or placental tissues or in the urine of the aborting dam within approximately 2 weeks after abortion.

Diagnosis is usually based on serology. A few infected fetuses develop microagglutination titers of 1:10 or more. It is difficult to distinguish among vaccinated, acutely infected, and recovered animals, but titers to serovar *pomona* greater than 1:12,800 in the dam suggest leptospiral abortion. Maternal titer has usually peaked by the time of abortion. Single titers of 1:800 or more in unvaccinated animals, seroconversion, or fourfold changes in titers in paired sera indicate leptospirosis in the herd. Titers to serovar *hardjo* are often less than 1:100 in affected cows and seldom exceed 1:1600.

Pathophysiology Hematogenously spread leptospires colonize the gravid uterus up to 142 days after infection. Abortion occurs 1 to 6 weeks after acute disease with *L. pomona* infection and 1 to 3 months with *L. hardjo*. *L. hardjo* remains in the oviducts of infected cows for up to 22 days after calving.[12]

Epidemiology *Leptospira* organisms are ubiquitous and an important cause of abortion in all cattle-producing regions. *Leptospira* organisms persist in the genital tract and kidneys. The organisms localized in the kidneys of infected animals are shed in the urine and serve as a source of infection for other animals. The organisms localized in the female reproductive tract are responsible for abortions. Aborted tissues are infectious to other animals and humans and should be handled with caution.[13,14]

Treatment and Control In abortion outbreaks, pregnant cows can be vaccinated with killed bacterin and treated with oxytetracycline (antibiotic treatment can be limited to sick cows in dairy herds).[15] Aborting cows should be isolated from the rest of the herd, and aborted fetuses and placentas should be removed from the premises.[16] Preventing exposure to swine, rodents, and contaminated water lessens the opportunities for infection. *L. interrogans* serovar *pomona* usually has no permanent effect on fertility, but infection with serovar *hardjo* has been associated with persistent herd infection and recurring abortions.

Herd vaccination is recommended at 6-month intervals or more frequently in areas with heavy exposure to leptospires, such as dairies or beef operations with wet environments. Vaccination programs are aimed at reducing urinary shedding of leptospires and decreasing fetal loss. Vaccination is discussed in detail in the Leptospirosis section in Chapter 34.

Epizootic Bovine Abortion (Foothill Abortion)

Epizootic bovine abortion (EBA), or foothill abortion, is a syndrome of late abortions in cattle in the foothills bordering the central valley of California.[17] Once thought to be caused by *Chlamydia psittaci* or a spirochete-like organism, studies have demonstrated that EBA differs from chlamydial abortion.[17] After decades of research, a novel deltaproteobacterium, *Pajarellobacter abortibovis*, was identified as the causative agent of EBA in 2005.[18,19]

History and Clinical Signs Late abortion or delivery of weak calves occurs in affected herds. Many fetuses in the sixth to seventh month of gestation may be aborted, especially from naive heifers that have not had natural exposure to the causative agent. Older native cows show no clinical signs of infection.

Laboratory Diagnosis A 3-month period is required for full development of pathologic changes in the fetus. Superficial cervical lymph nodes are enlarged up to 16 g, the spleen is enlarged up to 250 g, the thymus is slightly smaller than normal, and the liver may be enlarged and nodular.[17,20] Histologically there is loss of thymic cortical lymphocytes; remaining lymphocytes are enlarged and poorly differentiated. Follicular hyperplasia, histiocytosis, vasculitis, necrosis, and pyogranulomas occur in lymph nodes and spleen. Lymphohistiocytic proliferation may also occur around vessels in the liver, lung, and meninges.

EBA has been diagnosed mainly by pathologic examination of the fetus along with a compatible clinical scenario. Studies have demonstrated high levels of immunoglobulin G (IgG; 3 mg/mL or more) in fetal blood.[17] This deltaproteobacterium is detectable in fetal tissues with PCR, with reported sensitivity and specificity values of 88% and 100%, respectively.[18] Recent advances in real-time PCR assays are promising for diagnosis and may become the standard in the future.[21] Currently, serologic testing for EBA has promising results for identifying fetal infection, especially with fetal serum or precolostral serum in live calves. It may be difficult to distinguish immunity and recent exposure in adult cows and heifers.

Pathophysiology Infection is transmitted by the soft-shell tick *Ornithodoros coriaceus* (pajaroello tick).[20,22] The disease can also be transmitted with fresh or frozen fetal tissue.[17] Transformation and proliferation of fetal lymphocytes and macrophages occur by 50 days but are not severe enough for diagnosis until 100 days after maternal exposure to the tick vector. IgG and IgM are deposited in vascular lesions, but an increase in fetal serum immunoglobulin is not detectable until at least 80 days after tick exposure.[17,21] Repeated superinfection may be necessary to result in fetal death.[20] Because at least 90 days are required for development of fetal lesions, infection after 6 months' gestation is not likely to result in abortion.

Epidemiology EBA was limited to the range of the tick vector in the foothills bordering the central valley of California; however, it has also been identified in regions of Oregon and Nevada.[17,19] Of the annual calf loss in California, 5% to 10% is attributed to EBA.[22] The prevalence of infection by the spirochete is far greater than the prevalence of abortion.[20] Abortion occurs 3 to 4 months after exposure to ticks but almost always late in gestation, regardless of the time of tick exposure.[23] Older native cows from enzootic areas usually do not abort, and introduced cows and heifers generally abort only once.[17] The abortion rate may be 30% to 80% in susceptible animals.[23]

Treatment and Control Currently no commercially available vaccine exists for EBA, but abortions can be controlled by exposing heifers to the tick vector before breeding or by changing from spring to fall calving, which takes advantage of limiting exposure to the last trimester of gestation in some management systems. Therefore exposure of susceptible pregnant cattle to the tick only after the sixth month of pregnancy is a practical solution for ranchers using summer foothill pastures and fall calving. The tick lives in ground duff (e.g., leaves) and is not found on cattle that graze in irrigated pastures and most other areas outside of brushy foothills. Although chlortetracycline in feed has been used previously to reduce the rate of abortion,[22] such off-label use of antimicrobials in feed for cattle is no longer legal in the United States.

VetBooks.ir

Brucella abortus Abortion

Brucella abortus is a gram-negative coccobacillus that is a facultative intracellular pathogen. Infection (Bang's disease) causes abortion in cattle and, less commonly, in sheep and goats.[24] Horses may be infected with *B. abortus*, which has been associated with fistulous withers, but usually experience no infertility or abortion. Bang's disease is an important zoonotic disease worldwide, particularly in developing nations.[24]

History and Clinical Signs Abortion is the chief clinical sign of bovine brucellosis and usually occurs in the last trimester of gestation. Because of its highly contagious nature, outbreaks of abortion can occur in grouped pregnant cattle. Lameness, mastitis, epididymitis, and/or orchitis may be present in infected herds.[24] A foul-smelling, yellow to brownish exudate containing fibrin and necrotic debris may be expressed from the uterine lumen. Placentitis is a consistent finding. Cotyledons are necrotic; the intercotyledonary placenta is thickened and opaque with accumulation of odorless, flocculent, yellow-brown exudate between maternal and fetal membranes. Importantly, the affected placenta may show some normal placentomes and others with severe necrosis and hemorrhage.[24]

Laboratory Diagnosis Histologically there is suppurative placentitis (and endometritis in the dam). Suppurative bronchopneumonia, serositis, and lymphoreticular hyperplasia are frequent histologic findings in the fetus.

Diagnosis depends on culture of *B. abortus* from fetal lung, abomasum, or placenta or from maternal uterine or mammary secretions. Organisms and *Brucella* antigen can be detected in fetal tissues or placenta by immunofluorescent techniques. PCR and culture can be applied as well. Fetal abomasal fluid may be the optimal sample for PCR diagnosis.[25,26] A variety of serologic tests can be used to diagnose the disease in clinically or latently infected adults, including serum agglutination, card and buffered plate agglutination, complement fixation, and direct and indirect enzyme-linked immunosorbent assay (ELISA); the performance of these tests in infected and vaccinated herds has been reviewed recently.[26]

Pathophysiology Initial replication of *B. abortus* occurs in regional lymph nodes. Bacteremia is followed by colonization of supramammary lymph nodes, the mammary gland, and the gravid uterus. Uterine infection occurs during the second trimester.[27] In the placenta the bacteria appear first in phagosomes of erythrophagocytic trophoblasts. Replication occurs in the rough endoplasmic reticulum of chorioallantoic trophoblasts.[27] Preferential replication in chorioallantoic trophoblasts has been attributed to their erythritol content.[24,28] The organism also occurs in fetal placental endothelial cells and capillary lumina, where it is associated with vasculitis and destruction of chorionic villi. Placental inflammation spreads along the allantochorion to involve additional cotyledons with resultant chorioallantoic ulceration, necrosis of trophoblasts, and ulcerative endometritis. Fetal death results from placental disruption and endotoxemia.[27] The fetus is frequently retained 1 to 3 days in utero. Numerous bacteria are expelled from the genital tract at parturition, but shedding usually stops by 3 weeks after abortion.

Epidemiology Infection with *B. abortus* occurs naturally by inhalation or ingestion of bacteria present in aborted fetal membranes, fetuses, or postabortion vaginal discharge.[24] Contaminated materials are infectious for humans and should be handled with caution. Infection is not easily transmitted between cattle separated by fences or roads. Most calves infected at birth clear the infection, but persistent congenital infection has been documented.[29-31]

Bovine brucellosis has been nearly eradicated in the United States by test and slaughter of seropositive cattle and vaccination. However, a reservoir remains in bison and elk, especially in the greater Yellowstone area.

Treatment and Control Treatment of brucellosis is usually not effective. Combination therapy with long-acting oxytetracycline and streptomycin has been shown to reduce shedding in most cows and potentially eliminate infection in some,[32] but because eradication is typically a priority in most countries, infected cows are rarely treated. In the United States, infected individuals are destroyed, and exposed herdmates are quarantined to the herd until slaughter or the herd is recertified as brucellosis free.

In the past, strain 19 vaccine was used as part of the eradication program. However, vaccinated and field strain–infected cattle could not be differentiated. A newer vaccine for *B. abortus*, vaccine strain RB51, was developed to overcome the serologic problems associated with the strain 19 vaccine.[33] Animals vaccinated with RB51 lack antibodies to the *O*-polysaccharide chain and can thus be differentiated from field-infected cattle. Strain RB51 is also less abortifacient for cattle than strain 19, although vaccination of pregnant heifers may result in abortion and subsequent zoonotic exposure if obstetric assistance is necessary,[34] so the vaccine is to be administered only to young heifers before pregnancy.

Campylobacter fetus subspecies *venerealis* Abortion

C. fetus subsp. *venerealis* is a gram-negative flagellated bacterium that is the main cause of bovine campylobacteriosis (vibriosis, bovine genital campylobacteriosis).[35] The organism is an obligate parasite of the bovine genital tract and is not known to cause disease in other species.[35]

History and Clinical Signs Infection with *C. fetus* subsp. *venerealis* mainly causes temporary infertility or early embryonic death, but sporadic abortions from the fourth to eighth months of gestation are possible.[1] The usual history includes a high percentage of cows exposed for the first time returning to estrus or found nonpregnant after the breeding season and cows calving late because they returned to estrus one or more times.

Laboratory Diagnosis Autolysis is usually minimal, and the lungs of the term fetus may be partially inflated. Dehydration, fibrinous serositis, and necrotizing placentitis may be apparent grossly. Histologically, bronchopneumonia and hepatitis may also be evident. Diagnosis is based on demonstration or isolation of the organism. Using dark-field microscopy, the bacterium appears as a curved rod with darting corkscrew motility and can be differentiated from other *Campylobacter* spp. by immunohistochemistry.[1] Cows that abort may have serum antibody titers; however, they may not be diagnostic because they are not specific for *C. fetus* subsp. *venerealis*. Culture from placenta or fetal abomasal contents requires at least 72 hours. The vaginal mucus agglutination test is used to survey herds for infection. Alternatively, the penis and preputial mucosa of infected bulls may be swabbed and cultured, although culture is difficult because the organism is slow growing and often overwhelmed by saprophytes.

Pathophysiology The bull is the primary reservoir of the organism; it resides subclinically in the crypts of the penis and prepuce.[35] Transmission is venereal. Within a week of vaginal infection the organism is established in the uterus, causing mucopurulent endometritis, which persists 3 to 4 months. Intrauterine infection either prevents conception or causes embryonic death, and infected heifers typically return

to estrus by 40 days. Less commonly, abortions occur at up to 8 months of gestation.

Epidemiology *C. fetus* subsp. *venerealis* is ubiquitous. Venereal transmission from infected bulls to virgin heifers approaches 100%. Cows with previous exposure to infected bulls develop immunity and therefore are less likely to experience infertility than heifers. The abortion rate can range from 10% to 50%.[35] Because persistent vaginal infection can occur, vaginal carriage into the next breeding season is possible.[35]

Treatment and Control Infected cows usually recover spontaneously within 5 months and resist reinfection. Recovery is hastened by intrauterine infusions of streptomycin and penicillin. Infertility may be permanent if endometritis or salpingitis is severe. Heifers should be vaccinated with a bacterin before breeding. Most vaccines are administered 1 month before breeding and require a booster vaccination 2 weeks later. Cows and bulls must be vaccinated annually. Exclusive use of *C. fetus* subsp. *venerealis*–negative semen via AI controls the disease by preventing transmission.

Histophilus somni Abortion

Histophilus somni (formerly *Haemophilus somnus*) has been associated with vulvitis, vaginitis, endometritis, weak calf syndrome, stillbirths, and occasional abortion in cattle.[36-41]

Laboratory Diagnosis Aborted fetuses have been free of gross lesions. Necrotizing placentitis is associated with fibrinoid necrosis of placental arteries. Diagnosis is based on recovery of large numbers of the organisms in relatively pure culture from placenta or fetus, histologic evidence of placentitis, and lack of other apparent causes.

Interpretation of maternal titers to *H. somni* is difficult, and it is best to take paired serum samples. Titers between 1:256 and 1:512 in nonvaccinated herds may be the result of early active or chronic infection. Titers between 1:1040 and 1:4096 indicate recent active infection. A fourfold change in titer in paired sera is the best indicator of active infection.

Pathophysiology Although *H. somni* can be isolated from the genital tract of clinically normal cows, the rate of isolation is higher in cows with endometritis or cervicitis.[41] Experimentally, *H. somni* can adhere to zona pellucida–intact embryos and cause degeneration.[38] Vaginitis can be induced by inoculation with *H. somni*,[39] and abortion has been induced by intraamniotic, intravenous, or intrabronchial challenge with the organism.[40]

Treatment and Control Antibiotic treatment and vaccination anecdotally increase fertility in herds affected with *H. somni*–induced vulvovaginitis.

Listeria monocytogenes Abortion

Listeriosis is caused by *Listeria monocytogenes*, a ubiquitous, gram-positive, facultative intracellular bacterium.[42] Encephalitis, abortions, uveitis, and septicemia are other manifestations of infection in ruminants.

History and Clinical Signs Bovine abortions usually occur in the last 2 months of gestation. Infected ewes and does typically abort in the last month. Fever, depression, RFMs, or endometritis may occur, but often the dam shows no clinical signs of infection.

Laboratory Diagnosis In less severely autolyzed fetuses, fibrinous polyserositis may be apparent. Most aborted fetuses have gray-white hepatic foci up to 2 mm in diameter. Similar foci may be visible in cotyledons; exudation occurs between cotyledons. Abomasal erosions have been reported in aborted lambs. Histologically, suppurative placentitis and endometritis are consistent findings.

Listeria is readily cultured from abortuses without cold enrichment. *Listeria* appears in impression smears as gram-positive pleomorphic coccobacilli.

Pathophysiology Listerial abortion can be induced experimentally in cattle 6 to 8 days after infection and in sheep 3 to 11 days after infection. Fetuses die from placentitis and septicemia and are often retained in utero several days before expulsion.

Epidemiology Listerial abortion is usually sporadic, and incidence seldom exceeds 15%. Many outbreaks of abortion and encephalitis have been associated with feeding of silage.[42] The elevated pH of spoiled silage enhances multiplication of the organism.[42] However, nonensiled forages can be contaminated by *L. monocytogenes* originating in soil, wildlife or bird feces, or livestock manure, so exposure to silage should not be considered a necessary cause of this disease.[42] Aborted tissues are infectious for humans and should be handled with care.

Treatment and Control The effect on fertility is usually transient, and aborting animals tend to resist reinfection. Tetracycline may be used in remaining pregnant animals in the herd. Aborting animals should be segregated, and fetuses and placentas should be removed from the premises with strict hygienic protocols to limit human risk. Treatment and prevention of listeriosis is covered in detail in Chapter 8.

Mycoplasma Abortion

Mycoplasmal isolations from the bovine genital tract have been mainly *M. bovigenitalium* and *Mycoplasma bovis*. *M. bovis* is probably the more important cause of abortion.[43] *Mycoplasma mycoides* subsp. *mycoides* (see Chapter 31 for complete discussion) and *Mycoplasma capricolum* subsp. *capricolum* have been associated with caprine abortions.[44]

History and Clinical Signs *M. bovigenitalium* is associated with granular vulvovaginitis and less commonly with endometritis, especially in heifers. Infertility is more common than abortion. *M. bovis* causes mastitis and abortion.[43] In goats, mycoplasmal infection is associated with septicemia, arthritis, pneumonia, mastitis, and abortion.[44,45]

Laboratory Diagnosis Placentitis and fetal pneumonia have been associated with bovine mycoplasmal abortion.[43,45] Isolation of *Mycoplasma* from the genital tract, milk, placenta, or fetus indicates infection. However, mycoplasmosis should not be considered the cause of abortion unless placentitis or fetal inflammation is present and other more likely causes of abortion have been eliminated.

Pathophysiology *M. bovigenitalium* can be isolated from the vagina in up to 12% of clinically normal cows, but *M. bovis* is isolated from less than 1%. Vulvitis can be induced by inoculation with mucosal scarification with *M. bovigenitalium;* therefore venereal transmission may be the natural route of infection.[43] Experimental inoculation with *M. bovis* induces abortion with placentitis and fetal pneumonia.[43,45] *M. bovigenitalium* is rarely isolated from abortuses or normal fetuses.

Epidemiology *Mycoplasma* spp. are ubiquitous, but mycoplasmal abortions are not commonly documented.

Treatment and Control Tetracycline, florfenicol, or macrolide antibiotics may limit losses in pregnant animals when

Mycoplasma is implicated as the cause of abortion or granular vulvitis in herdmates.

Salmonella Abortion

A variety of *Salmonella* serotypes have been isolated from aborted fetuses of cattle, sheep, goats, and horses. A complete discussion of salmonellosis is presented in Chapter 32. Infection is acquired by ingestion or inhalation. Maternal septicemia is followed by localization of salmonellae in tissues, including the pregnant uterus, where placentitis and fetal septicemia occur. Salmonellosis accompanied by endotoxemia causes early pregnancy loss without colonization of the uterus because the infection and endotoxemia cause endogenous prostaglandin release.

History and Clinical Signs The animal may show systemic signs before abortion. Although abortion may occur at any stage of gestation, it typically occurs in the second half and is characterized by placental necrosis, edema, and hemorrhage. RFMs and fetal autolysis may occur. Abortion may be accompanied by diarrhea, fever, or vaginal discharge, particularly in the ewe, but often infection is not clinically apparent in the dam.[46,47] Fetuses also may be lost as a result of stillbirth or perinatal septicemia.

Laboratory Diagnosis The fetus is frequently autolyzed. Placentitis is usually present. Diagnosis is based on isolation of the organism and evidence of placentitis or inflammation of fetal tissues. Immunofluorescent techniques can identify the bacteria in impression smears or sections of placenta or fetal tissue. The dam can be tested serologically for evidence of recent active infection.

Pathophysiology Infected adult animals are often short-term carriers and shed salmonellae in the feces or milk. True long-term asymptomatic carriers occur mainly with the host-adapted serotypes: *Salmonella dublin* in cattle, *Salmonella abortus ovis* in sheep, and *S. abortivoequina* (or *Salmonella abortus equi*) in horses. Salmonellosis caused by *S. abortus equi* has been eradicated in the United States. Occasionally long-term carriers of other serotypes are seen; these are usually intestinal carriers and fecal shedders. Infection usually occurs by ingestion; there is no evidence of venereal transmission.[46] Maternal septicemia is followed by localization of the organism in a variety of tissues, including the pregnant uterus. The bacteria multiply in and cause necrosis of connective tissues of the cotyledon. The incubation period between infection and abortion varies from approximately 1 week to 1 month. Fetal death results from placentitis and fetal septicemia.[48] In most cases, maternal shedding of the organism in cattle ceases by 5 weeks after calving,[46] although longer-term shedding may occur with certain serotypes.

If infection and the resulting endotoxemia induce release of endogenous $PGF_{2\alpha}$, luteolysis and abortion will occur, but the fetus and placenta will not culture positive for *Salmonella* spp.

Epidemiology Bovine abortion resulting from salmonellosis is caused mainly by *Salmonella dublin* and *Salmonella typhimurium*. Abortion is sporadic and most common in the summer and fall.[46]

Ovine abortion is associated with *S. typhimurium*, *S. dublin*, *Salmonella arizona*, and *S. abortus ovis*. *S. abortus ovis* is enzootic in parts of England and Europe but is not reported in the United States. Young ewes in late gestation are most susceptible, and the abortion rate may approach 50%.[47]

Treatment and Control Aborting animals should be isolated; the fetus, placenta, and contaminated material should be removed from the premises. *Salmonella* spp. are infectious for humans; therefore aborted tissues should be handled with caution. Metritis is a rare complication of salmonellosis that can be fatal. Usually there is no lasting effect on fertility, but animals infected with host-adapted serotypes may become carriers and should be cultured and tested serologically and culled if positive. Salmonellosis can be controlled by hygiene and by avoiding the introduction of carrier animals.

Ureaplasma Abortion

Ureaplasma is a small, ureolytic bacterium that lacks a cell wall. *U. diversum* has been associated with granular vulvitis and abortion in cattle.

History and Clinical Signs Granular vulvitis appears as reddish nodules in the vulvar mucosa, with mucopurulent discharge in the early stages. The discharge is usually more copious and protracted than with IPV induced by herpesvirus.[43] Affected cows are not systemically ill. The organism has been recovered from embryo flushing media and can adhere to the zona pellucida, resisting removal by washing. It may reduce the pregnancy rate in embryo recipients when the transfer medium contains the organism.

Laboratory Diagnosis Gross lesions include thickening of placental membranes with foci of hemorrhage and fibrinous exudate. Gross lesions are seldom apparent in the fetus. Microscopically the placenta is fibrotic, with heavy mononuclear cell infiltration, multifocal necrosis, fibrin deposition, and mineralization. Cuffs of lymphocytes surround fetal intrapulmonary airways. Diagnosis is based on isolation of the organism from genital mucosa, placenta, or fetal stomach or lung and the presence of genital or fetal inflammation.

Pathophysiology *Ureaplasma* can be isolated from the genital tract of normal cows and from normal fetuses.[49] Vulvitis has been induced by inoculation of virgin heifers with *U. diversum*.[49] Intraamniotic inoculation of *U. diversum* caused placentitis, abortion, and fetal alveolitis in two of four experimental cows.[49] One cow delivered a weak calf at term. Experimental infection in ewes did not decrease fertility.[50]

Epidemiology Bovine infection is common, but documented abortions caused by *Ureaplasma* are rare.[43] Infertility is more common in heifers than in cows.

Treatment and Control Nonirritating tetracyclines by intrauterine infusion are recommended for treatment. Uterine contamination can be avoided by use of the double-rod technique of AI.

Miscellaneous Bacterial Abortions

In addition to the aforementioned bacteria, other bacteria occasionally produce maternal septicemia and hematogenous abortion, as well as potential ascending infection of the gravid uterus. Many of these bacteria are ubiquitous, frequently contaminate aborted fetuses and placentas, and should not be considered the cause of abortion unless (1) they are isolated from the placenta and fetus in large numbers and relatively pure culture, (2) placentitis or fetal inflammation is evident, and (3) other more likely causes of abortion have been eliminated.

Tritrichomonas foetus

Trichomoniasis is a venereal infection of cattle caused by the flagellated protozoan *T. foetus*, which subclinically inhabits the prepuce, penis, and occasionally the urethral orifice of infected bulls; transmission to cows results in clinical disease.[51-53]

VetBooks.ir

History and Clinical Signs Infertility characterized by a high percentage of cows returning to estrus or found nonpregnant after the breeding season and cows calving late plus occasional pyometras and abortions are the most common clinical signs of trichomoniasis. Pyometra in postcoital heifers or cows suggests that trichomoniasis may be the cause and should be ruled out first. Abortions generally occur in the first half of gestation at a rate of 5% to 30%.[51] The placenta may be expelled or retained.

Laboratory Diagnosis Diagnosis in the female is made by culturing trichomonads or using PCR to detect *Tritrichomonas* from cervicovaginal mucus, uterine exudate, placental fluids, or fetal abomasal contents.[53] Preputial smegma collected from bulls by using a plastic pipette or commercially available sampling device run against the mucosa can also be cultured for trichomonads (sensitivity is 84% to 96% under experimental conditions[53]). Diamond's medium (or modified Pastridge medium) is recommended for cultures from cows, bulls, or aborted fetuses. The organism is sensitive to environmental conditions, and thus samples should be transported at ambient temperature, kept out of sunlight, not refrigerated, and delivered promptly to the diagnostic laboratory. The organisms are identified microscopically by their size (10 μm × 15 μm), the presence of three anterior flagellae and an undulating membrane, and a characteristic jerky, rolling motion. PCR and quantitative PCR (qPCR) are often used now for identification of *T. foetus* because of their ability to differentiate *T. foetus* from contaminant, nonpathologic trichomonads. Due to the ability of *T. foetus* to degrade its DNA postmortem, improper sample handling may lead to false-negative results on both culture and PCR testing.[54] Diagnostic testing of bulls using both culture and PCR may maximize sensitivity and specificity.[53]

There are no specific gross lesions in aborted fetuses. However, placentitis is a consistent microscopic lesion, and trichomonads can frequently be recognized in the placental stroma in histologic sections. Organisms may also be observed in the fetal lung in association with pyogranulomatous bronchopneumonia.[55]

Pathophysiology Trichomoniasis is transmitted venereally from infected bulls to cows or vice versa. The organisms colonize the vagina, cervix, uterus, and oviducts; cervicitis and endometritis ensue. Embryonic death frequently occurs within the first 2 months of infection, followed by a 2- to 6-month period of immunity to reinfection. Clearance of infection in cows commonly occurs within 95 days; infection rarely persists for as long as 6 months.[51] However, infection in bulls older than 3 to 4 years of age is typically permanent and the main source of carryover from one breeding season to the next in beef cattle. Infection in younger bulls may be transient and related to the development of deeper mucosal folds in the prepuce as bulls age.[53]

Treatment and Control Systemic treatment of infected animals with imidazole compounds (ipronidazole, dimetridazole) is effective, but these compounds are prohibited in food animals in the United States.[56,57] Infected cows should be either culled or given at least 3 months of sexual rest. The use of AI with semen from *T. foetus*–negative bulls controls the disease once infected natural service bulls have been removed from the herd. In natural breeding situations, use of young virgin bulls and testing and culling of positive bulls older than 3 years of age will allow herd owners to gain control over the incidence of trichomoniasis. Vaccination of bulls and cows has shown some experimental benefit in limiting infection risk, but when all current research is evaluated extensively, vaccination appears to have very limited effect in reducing the risk of abortion.[53]

Neospora caninum Abortion

Abortion in cattle caused by *N. caninum* is relatively common and of economic importance, especially in dairy cattle. Congenital infection with limb paresis or dysfunction at birth as a result of encephalomyelitis may also occur. Canids are the definitive hosts and shed oocysts in their feces after ingestion of infected tissues from intermediate hosts (Fig. 43.9). Both the domestic dog and the coyote have been shown to transmit the oocysts in their feces.[58-60] Along with cattle, deer have been shown to serve as intermediate hosts.[60] The role of birds and wild rodents as intermediate hosts is suspected but has not yet been definitively demonstrated.[60] Aborted, infected fetal tissues ingested by canids will also result in massive shedding of oocysts in feces.[61] Transmission may be vertical (dam to fetus in utero) or via point-source horizontal transmission (ingestion of feed contaminated with feces containing oocysts).[62,63] Horizontal transmission from cow to cow does not occur. Bovine fetal lesions are distinctive and may include nonsuppurative encephalitis with foci of necrosis and gliosis, nonsuppurative myositis, hepatitis, and, most consistently, myocarditis.[37] Most abortions occur in the early second trimester, but they may occur throughout gestation. Diagnosis is based on characteristic lesions in aborted fetuses and seroepidemiologic study of an equal number of aborting and nonaborting herdmate cows if the proportion of seropositives is statistically higher in those that have aborted.[64] Finding one aborting cow to be seropositive does not confirm *N. caninum* as the cause, and cows that abort once because of *N. caninum* are not protected from future abortion caused by this organism.

Sarcocystis Abortion

Sarcocystosis may cause abortion in cattle, sheep, and goats. Cattle are infected by *Sarcocystis cruzi*, sheep by *Sarcocystis ovicanis*, and goats by *Sarcocystis capracanis*.

History and Clinical Signs Most cattle are infected with *Sarcocystis* but do not show clinical signs of infection; however, massive or repeated infections may elicit depression, anorexia, weight loss, lameness, hair loss, emaciation, or death. Abortions occur in late gestation, usually in severely affected animals.[65,66]

Laboratory Diagnosis There are no specific gross lesions in the aborted fetus. Histologically, protozoa may be observed in villi and small arteries of the cotyledon or (more likely) the caruncle but are seldom seen in the bovine, ovine, or caprine fetus. Parasites are more likely to be observed in the fetal brain than in other tissues.[65] Nonsuppurative inflammation may occur in the placenta or, less commonly, in fetal tissues, particularly the brain, heart, lung, liver, or kidney.[65,66]

FA demonstration of numerous developing protozoa in the cotyledon or caruncle is considered diagnostic. Caruncles are atrophied.[65]

Pathophysiology The pathogenesis of abortion in sarcocystosis is unclear. Generally, numerous spores are required to induce abortion experimentally. Fetal invasion by *Sarcocystis* is rare, and abortion may result from maternal fever, anemia, or placental insufficiency.[65] Pregnant does apparently have diminished immunity to *Sarcocystis*, because low doses of *S. capracanis* result in fetal death without maternal illness if given in early pregnancy.[67]

Epidemiology Ruminants are infected by consumption of canid feces that contain oocysts. *Sarcocystis* occurs in the skeletal and cardiac muscle of most cows without associated lesions or clinical evidence of illness.

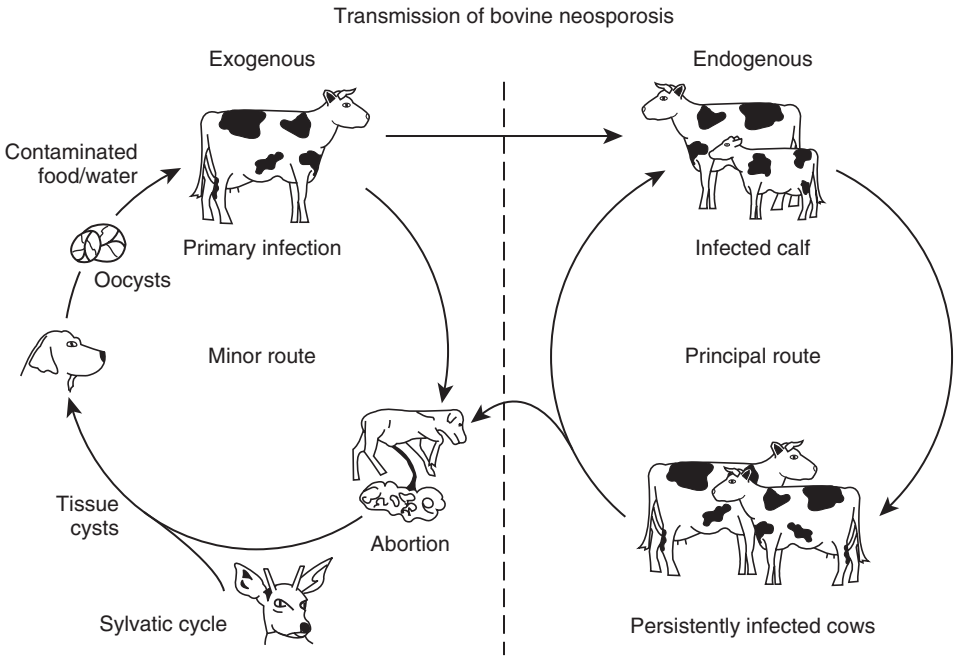

FIG. 43.9 Transmission of bovine neosporosis. Oocysts are produced by the canine definitive host, and their subsequent ingestion by a susceptible pregnant cow leads to infection of the fetus (exogenous transplacental transmission). Liveborn infected heifer calves would be expected to remain infected into adulthood, when they in turn may pass infection to their fetuses (endogenous transplacental transmission). Spread of *Neospora caninum* in this second way is the principal route whereby the parasite is propagated in a herd.

Control Effective therapeutic regimens for clinically ill animals have not been developed. For the life cycle of *Sarcocystis* to be broken, feeds should be kept free of dog or cat feces. These carnivores should not be allowed to eat aborted fetuses, placentas, or other ruminant carcasses.

Fungal Abortions

Mycotic Diseases That Cause Abortion

Fungal causes of bovine abortion include *Aspergillus*, *Absidia*, *Mucor*, *Rhizopus*, *Candida*, and *Mortierella*.[68,69] Mycotic abortion is uncommon in sheep and goats.

History and Clinical Signs Mycotic abortions usually occur in the latter half of gestation (often near term) and seldom are associated with prodromal or postabortion clinical signs in the dam.

Laboratory Diagnosis The most consistent lesion is placentitis with necrosis and thickening of fetal membranes. In ruminants, both cotyledons and the intercotyledonary placenta are affected. Histologically, necrotizing inflammation of the chorionic villi is associated with vasculitis and thrombosis. Gross lesions may not be apparent in the fetus, but granulomatous bronchopneumonia is frequently observed histologically.[69] In bovine aspergillosis the fetus is often near term with minimum autolysis and partially inflated lungs. Emaciation and dehydration with multifocal dry, scaly skin lesions occur in approximately 25% of affected fetuses. The fungus can be isolated from the fetus and placenta or demonstrated on histologic sections with special stains.

Pathophysiology The route of fungal infection in the bovine uterus is thought to be hematogenous.

Epidemiology Mycotic abortion generally affects only one or two animals in a herd and is more common in the winter. Fungi cause 3% to 10% of bovine abortions.[70,71] *Aspergillus* spp. appear to be the most common fungal agent identified in mycotic abortion of cattle.

Control The only means of control of mycotic abortion is reduction of exposure to fungal agents.

Does and Ewes

Infectious Causes

See Table 43.9.

Bluetongue Abortion

Bluetongue is an orbivirus infection that can result in embryonic death, abortion, and fetal anomalies in sheep, cattle, or other ruminants. Twenty-six serotypes of bluetongue virus have been recognized; five of these (serotypes 2, 10, 11, 13, and 17) occur in the United States (see Chapter 32 for complete discussion).[72]

Border Disease (Hairy Shaker Disease)

Border disease or hairy shaker disease is an ovine pestivirus infection that causes embryonic and fetal death; stillbirths; dysplasia of the central nervous system, skeleton, and fleece; and birth of weak lambs with low viability.

Coxiella burnetii (Coxiellosis)

Coxiella burnetii is an obligate intracellular, pleomorphic bacterium that is related to the rickettsial family of bacteria.[73,74] It is the causative agent of Q fever, which is the disease in human beings; the disease in livestock is called coxiellosis.[74] Late-term abortions in sheep and goats, and rarely in cattle, are the primary clinical manifestation of disease. It is an important zoonosis worldwide. Subclinically infected ruminants are considered the primary reservoir of the agent.[73,74] A variety of domesticated animals, including dogs, cats, and pigs, can also be infected, most often subclinically.

History and Clinical Signs Late-term abortions or delivery of stillborn or weak kids and lambs may occur in an

affected herd or flock. Affected dams show little to no clinical signs of infection and are typically not ill prior to or after abortion. In cattle the most common manifestation of infection is conception failure and abortion.[74]

Laboratory Diagnosis Hygienic measures, including barrier gowns, eye protection, and respiratory protection, are prudent when handling suspect animals, fetuses, fetal membranes, and contaminated bedding. There are no specific gross lesions in the fetus, but the placenta is thickened with white, chalky plaques and red-brown exudate, especially in intercotyledonary areas. Diagnosis of Q fever abortion should be based on gross and histologic evidence of severe placentitis with large numbers of organisms visible using modified Koster stain, Stamp's modified Ziehl-Neelsen stain, or Gimenez stain. Culture of the organism is difficult; therefore PCR (ideally qPCR) can be used to detect the organism in the fetus, placenta, milk, or vaginal discharge.[73] It is important to note that *C. burnetii* can be shed in the birthing fluids of normal ruminants; however, it is present in numbers far lower than encountered when this agent causes these animals to abort.[74] Therefore, ideally, the diagnosis of *Coxeilla* abortion includes demonstration of compatible placental lesions, quantification of *C. burnetii* by qPCR, and documentation of the absence of other abortigenic agents. Serologic testing of aborting ewes and does (by ELISA, immunofluorescence assay, or complement fixation) typically shows seropositivity in aborting individuals, although titers may decline over time.[74] Importantly, both seropositive and seronegative small ruminants may shed the organism, so the use of serology in determining infection status is problematic.[74]

Pathophysiology *C. burnetii* infection can be transmitted by infected ticks or by inhalation or ingestion of infected material. The organism replicates in trophoblasts, resulting in placentitis with late-stage abortion, stillbirth, or birth of weak offspring. Fetuses, fetal membranes, and uterine fluids from aborting animals contain massive numbers of the agent. The agent can persist in the environment as a durable sporelike particle called a small cell variant (SCV). These SCVs can persist in the contaminated environment and serve as a source of infection for naive animals.[74]

Epidemiology Coxiellosis is reported in many countries worldwide. Abortions typically occur over a 2- to 4-week period and may affect 5% to 50% of the flock. Because of the agent's zoonotic potential, pregnant women, immunosuppressed individuals, individuals with preexisting illness, and those with vascular grafts should not handle *Coxiella*-infected animals or tissues or be exposed to contaminated environments, as risk of Q fever is increased in such individuals. Aerosolization and inhalation of SCVs appears to be the most common means by which humans become infected during ruminant abortion outbreaks.

Treatment and Control As mentioned above, appropriate personal protective equipment is prudent when a suspected or confirmed abortion from *C. burnetii* is encountered. Aborting does and ewes should be segregated, and abortuses and placentas should be removed from the premises to prevent oral transmission. Farm cats and dogs should be kept out of contact with affected animals and their environment, as they may disperse the organism if allowed to feed on aborted materials. Affected animals should be situated on the premises so as to mitigate the risk of airborne transmission of SCVs to animals and people downwind of the area; an enclosed environment is ideal. Pregnant animals can be treated with tetracycline to reduce the chance of abortion, but further research on the efficacy of this measure is needed.

Vaccination of small ruminants is used in certain countries as a control measure. At present, no licensed vaccine is available in the United States or Canada, although provisional use in Canada may be allowed when the need is demonstrated.[74] In a recent meta-analysis of the scientific literature conducted by Canadian investigators, use of inactivated vaccine containing a specific phase I antigen of *C. burnetti* reduced the risk of shedding of the organism in previously exposed goats and reduced the number of organisms shed in birthing fluids in previously unexposed goats.[75] No effect on shedding risk was evident in vaccinated sheep.[75]

Cleaning and disinfection require removal of contaminated bedding and disposal by burial, burning, or composting. Soap and water scrubbing, followed by rinsing and application of an appropriate disinfectant (quaternary ammonium, 1% peroxygen, or 1:100 dilution of bleach), may reduce the environmental burden of SCVs. Appropriate personal protective equipment should be used by the personnel conducting cleaning and disinfection.

The potential for repeated reproductive loss and long-term carriage of the organism is a topic of active ongoing research. In one study goats were demonstrated to be capable of repeated reproductive failure and shedding of *C. burnetii* in two successive birthings.[76] Strategies to manage abortion and mitigate further risk of abortion in affected herds and flocks are included in a recent review.[74]

Campylobacter fetus subspecies *fetus* Abortion

C. fetus subsp. *fetus* is one agent of ovine campylobacteriosis (vibriosis) that causes abortion in sheep and sporadic abortion in cattle and goats.[35,77]

History and Clinical Signs Infection of ewes causes abortion in the last 6 weeks of pregnancy, stillbirths, and birth of premature lambs. Infected ewes may have fever, diarrhea, depression, and vaginal discharge several days before parturition.[35,77] In cattle the infection is not associated with infertility (unlike infection with *C. fetus* subsp. *venerealis*), but sporadic abortions can occur.[35]

Laboratory Diagnosis *Campylobacter* causes necrosuppurative placentitis and multiorgan infection of the fetus. The fetus is edematous and may be pot-bellied in appearance. Multifocal, circular, pale foci—resembling donuts or targets—may be visible in the liver of roughly 25% of aborted ovine fetuses, and although these lesions are not pathognomonic, their presence is strongly suggestive of campylobacteriosis.[35,77] Diagnosis is based on culture, PCR, or microscopic demonstration of the organism. Dark-field microscopic examination of wet mounts of fetal stomach contents or placenta may demonstrate the organism, which has a characteristic corkscrew shape.[35] Histologic changes include suppurative necrotizing placentitis and pneumonia, gastroenteritis, hepatitis, and serositis in the fetus.[35]

Pathophysiology *C. fetus* subsp. *fetus* is transmitted by ingestion. It then translocates across the intestinal mucosa into the bloodstream, ultimately infecting the placenta and fetus.[35] The incubation period is highly variable, ranging from 13 to 113 days (most commonly 14 to 21 days). The timing of initiation of infection appears to influence the incubation period.

Epidemiology Infection with *C. fetus* subsp. *fetus* is important in sheep in the United Kingdom, the United States, and New Zealand. Fetal infection is most common during the last 2 months of gestation. Outbreaks of abortion tend to occur in 4- to 6-year cycles.[77] Infection is highly contagious in confined ewes, and the abortion rate may approach 70%.

VetBooks.ir

VetBooks.ir

Treatment and Control Abortion outbreaks due to *C. fetus* subsp. *fetus* may be treated with tetracyclines or macrolides. Tetracycline-class antimicrobials may not be effective against North American strains of *Campylobacter jejuni*, which is clinically indistinguishable from *C. fetus* subsp. *fetus*. Thus speciation of the isolate and antimicrobial susceptibility testing are critical to appropriate antimicrobial treatment.[35,77] The efficacy of vaccination prior to the breeding season, as well as in the face of an abortion outbreak, appears to be quite variable and may depend on the degree of similarity between the vaccine and the abortigenic strain of *C. fetus* subsp. *fetus*.[35]

Campylobacter jejuni Abortion

C. jejuni is the other agent of ovine *Campylobacter (Vibrio)* abortion. *C. jejuni* is an enteric pathogen that causes enteritis and diarrhea in many species. Only in sheep is placental and fetal infection common. This organism has been associated occasionally with abortion in cattle and goats.[77-79]

History and Clinical Signs Ovine infection with *C. jejuni* is clinically indistinguishable from that with *C. fetus* subsp. *fetus*.

Laboratory Diagnosis Lesions in placental and fetal tissues and diagnostic testing strategies are identical to those for *C. fetus* subsp. *fetus*.

Pathophysiology Intravenous inoculation of pregnant ewes with *C. jejuni* at 114 and 123 days of pregnancy consistently induced abortion 7 to 12 days later.[80]

Epidemiology and Control *C. jejuni* is ubiquitous and can be identified in the gastrointestinal tract of normal sheep.[35] Abortion rates in excess of 25% are common, although the rate of abortion appears to vary among strains of this organism.[77] Aborted tissue is infectious for humans and should be handled with caution. Treatment and control of ovine infection with *C. jejuni* are similar to those for *C. fetus* subsp. *fetus*. It should be reiterated, however, that most isolates of *C. jejuni* in North America are tetracycline resistant, so treatment of the remaining pregnant animals with macrolides or florfenicol is advisable.[81] The protection afforded by commercially available *C. jejuni* vaccines appears variable and is not complete.[35,81a]

Brucella melitensis Abortion

Brucella melitensis causes abortion in goats and sheep and less commonly in cattle.[81b] Infection is associated with late abortion, stillbirth, or birth of weak kids or lambs. Necropsy findings include severe placentitis and fetal serositis. The disease is diagnosed by culture or demonstration of the organism in tissue or by maternal serology, although immunization is practiced in some countries, and this can interfere with interpretation of serologic tests.[81b] Infection with *B. melitensis* is important in Mediterranean countries and in Central and South America. Suspected cases should be reported to state and federal authorities, as this is currently exotic to the United States. Human infection with *B. melitensis* can be severe.

Brucella ovis Abortion

Brucella ovis infects only sheep. Epididymitis in rams is the most common manifestation of infection.[82] Ewes seldom show clinical evidence of infection; late abortions, stillbirths, and delivery of weak lambs can occur but are very rare.[82] Fetal and placental lesions resemble those induced by *B. abortus*. Notably, *B. ovis* has not been documented to be a zoonotic pathogen.

Chlamydophila abortus Abortion (Enzootic Abortion of Ewes)

Chlamydophila abortus (formerly known as *Chlamydia psittaci*) is a gram-negative, obligate intracellular bacterium that is a major cause of abortion in sheep and goats.[77,83] Ovine chlamydial abortion is called *enzootic abortion of ewes*.

History and Clinical Signs Late-term abortions or stillbirths with placentitis are characteristic findings. Offspring may be born alive but weak.[77] The dam seldom shows signs of illness but may have serosanguineous vaginal discharge several days before and after parturition.

Laboratory Diagnosis Placentitis is the most consistent necropsy finding in chlamydial abortion. The placenta is markedly thickened with necrosis in the cotyledon and intercotyledonary areas; hemorrhagic exudate may be evident at the edges of these lesions.[77] The fetus has no specific gross lesions and may be fresh, necrotic, or, rarely, mummified.[77]

Diagnosis of *Chlamydophila* abortion should be based on identification of the organism and the presence of typical placental lesions. Organisms appear in placental impression smears stained with Giemsa, Gimenez, or modified Ziehl-Neelsen stain as spheric bodies in the cytoplasm of trophoblasts. The organism can be positively identified by FA tests or by PCR.

Pathophysiology *Chlamydophila* spp. reside in the intestinal tract and are also shed from the genital tract of infected animals before and after parturition. Ingestion is the main form of transmission, resulting from exposure to aborted tissues, contaminated environment, or vaginal discharge. Transmission by infected rams and bucks appears possible. The incubation period appears to be long (60 to 100 days).[77]

Epidemiology *Chlamydophila* abortion has been reported in most major sheep- or goat-producing countries. The abortion rate in sheep is usually approximately 5% to 10% but may be up to 30% or more in goats. *C. abortus* also may infect other animals, including human beings.[77,83] Pregnant women or immunosuppressed individuals should not handle infected animals or tissues, and personal protective equipment appropriate for *C. burnetii* exposure should be considered for individuals handling infected animals, aborted tissues, or contaminated bedding.

Treatment and Control Aborting does or ewes should be segregated, and abortuses and placentas should be removed from the premises to avoid oral transmission. Oxytetracycline therapy (80 to 450 mg/head every day in feed or water) has been used where allowed by law.[84,85] Long-acting oxytetracycline injected subcutaneously at a dose of 20 mg/kg and repeated every 2 to 3 weeks may prevent further abortions.[77] Vaccination may confer variable levels of protection, with the temperature-sensitive mutant vaccine available in Europe appearing to be more promising than the inactivated vaccines currently available in North America.[77] Vaccination is described further in Chapter 48.

Toxoplasmosis Abortion

Toxoplasma gondii is a ubiquitous protozoan that is a major abortifacient in sheep and goats but only rarely causes abortion in cattle or horses. Exposure to kittens is an expected component of the history, either through direct contact or fecal contamination of feed or water. The organism is transmitted to sheep and goats by ingestion of oocysts present in feline feces.[77] Cats shed heavy numbers of oocysts in the first 2 to 4 weeks after becoming infected by ingestion of infected rodents, birds, carrion, or aborted fetuses and tissues.[77]

History and Clinical Signs Infection does not cause clinical illness in the adult but may result in embryonic death, fetal death and abortion, stillbirth, or birth of weak, nonviable lambs or kids. Mummification of fetuses may occur, and

mummified fetuses may be aborted along with stillborn or weak but live newborns.[77]

Laboratory Diagnosis The most characteristic gross lesion of toxoplasmosis is the presence of white, chalky foci of necrosis and calcification up to 2 mm in diameter in cotyledons.[86,87] The intercotyledonary areas of the placenta are grossly normal. Specific gross lesions may not consistently exist in the aborted fetus, but histologically most have nonsuppurative encephalomyelitis,[87] and many also have pneumonia, myocarditis, or hepatitis. Tachyzoites may be found in placenta or other fetal tissues but are not numerous.[88,89] The tachyzoites are oval (2- to 4-mm × 4- to 8-mm) with a central nucleus and appear larger in impression smears than in paraffin sections. Several serologic tests, including the modified agglutination test, indirect FA test, Sabin-Feldman dye test, indirect hemagglutination test, and ELISA, reliably detect toxoplasmosis in pleural or amniotic fluid or presuckling serum from nondecomposed fetuses.[90,91] The modified agglutination test is commercially available, safer, and more sensitive than the dye test. Fetal antibodies to *T. gondii* can be detected 35 days after infection.[86] Absence of fetal antibody does not always preclude a diagnosis of toxoplasmosis. High maternal titers are not diagnostic of toxoplasmal abortion, but lack of titer eliminates toxoplasmosis as the cause for abortion.[86] The peroxidase-antiperoxidase method for detecting *Toxoplasma* antigen in fetal tissues or placenta is reliable even in autolyzed fetuses. Fetal heart, lung, brain, spinal cord, skeletal muscle, and placenta are the preferred specimens for the peroxidase-antiperoxidase method and should not be held in formalin more than 2 days before paraffin embedding.[89]

Pathophysiology Placental infection occurs approximately 14 days after ingestion of oocysts.[89] Infection acquired before 50 days' gestation may result in embryonic death and resorption. Infection between 60 and 100 days' gestation usually causes fetal death or birth of weak lambs. Infection during the last month of gestation often has no apparent effect on the fetus.[86] In experimental infection of ewes between 6 and 14 weeks of pregnancy, abortions occurred 1 to 2 months after inoculation.[91] In natural infections, most abortions occur 1 month before parturition.[86]

Epidemiology Toxoplasmosis is a major cause of ovine abortion in many sheep-raising countries, including the United States.[87,88] Sheep are infected by ingestion of oocysts from feed, water, or grass contaminated with cat feces. Aborted tissues may be infectious for humans and should be handled with caution.[92]

Control Infected ewes or does seldom abort from toxoplasmosis in subsequent pregnancies.[87] The prevalence of abortion can be reduced by avoiding contamination of foodstuffs with feline feces. Cats should not be allowed to eat placentas or carcasses that may contain tachyzoites or tissue cysts. Farm cats should be spayed or neutered to limit birth of young, susceptible kittens. In endemic areas, exposing replacement ewes to aborting ewes or cat feces before breeding age may induce immunity.

Camelids The incidence of abortion in llamas and alpacas is low. Infectious causes in North America include leptospirosis, toxoplasmosis, chlamydophilosis, and other nonspecific uterine infections. Bovine virus diarrhea is considered an emerging disease in alpaca herds and may be responsible for some of the early pregnancy losses and abortions in some herds. Diagnostic work-up for abortion in camelids is similar to that described in this chapter for other species.

Male Reproductive Disorders

Infertility Caused by Diseases of the Penis and Prepuce

Penile Injury

Stallion

Definition and Etiology

If the penis is injured while erect, it may swell rapidly and massively from vascular rupture and hemorrhage. Hemorrhage usually originates from the superficial penile vessels in the plexus external to the tunica albuginea.[1] The stallion may be kicked during mating, or hematomas may follow breeding a mare with a tightly sutured vulva or may be induced if the mare moves suddenly during mating.[2,3] Injuries can also occur during semen collection if proper techniques are not used.

Clinical Signs and Differentials Cutaneous abrasions, lacerations, and visible hemorrhage may be present. Paraphimosis occurs when enlargement is sufficient to prevent retraction of the penis through the preputial ring.[1] Edema may extend to the scrotum and interfere with thermoregulation of the testes.[4] Venous thrombosis, lymphatic occlusion, excoriation, and swelling accompany chronic inflammation.[1] Hemorrhage from the corpus cavernosum penis (CCP) is uncommon. Rupture of the surrounding tunica albuginea, when healed, may develop fibrous adhesions that lead to penile deviation during erection.

Treatment and Prognosis Immediate treatment is directed toward reducing edema and inflammation, as well as controlling infection. Treatment is similar to that described in the Paraphimosis section later in this chapter. Sexual rest is indicated until the lesions have healed.[5] If treatment is initiated early and paraphimosis does not occur, the prognosis for recovery is good.[1,3]

Bull

Definition and Etiology The penis of bulls is susceptible to injury during mating. The vigorous thrust that accompanies copulation predisposes the penis and prepuce to excoriations, lacerations, and bruising. Rupture of the tunica albuginea (penile hematoma or "broken penis") occurs if the penis is misdirected during copulation.[6] Penile hematomas most commonly occur in young, sexually aggressive bulls. Injuries occur when these bulls attempt to breed heifers or cows that are not receptive, when females falter or collapse under the weight of the bull, or when the bull slips because of poor footing.[2] During copulatory thrusting in which the penis is bent, the tunica albuginea

VetBooks.ir

ruptures on the dorsal or dorsolateral surface of the penis opposite the attachment of the retractor penis muscle. Presumably, CCP pressure rapidly increases as the functionally closed system is compressed during bending to rupture the tunica albuginea. Experiments with fresh postmortem specimens indicated that a CCP pressure of 1180 to 1720 psi was required to rupture the tunica albuginea. Tearing virtually always occurred at the site described in naturally occurring cases. Mean peak CCP pressure recorded during normal coitus (275 psi) occurs when cavernous spaces fill with a relatively small volume of blood, perhaps as little as 110 mL.[6] Blood escapes from the CCP into the surrounding tissue.[1] The size of penile hematomas may be related to the number of repeated trials made by the bull before cessation of attempts at mating. Larger hematomas restrict full retraction of the penis and result in prolapse of the prepuce from the sheath. Secondary preputial injury is common.[1]

Clinical Signs and Differentials Diagnosis of penile hematoma is made based on the presence of a swelling immediately cranial to the scrotum. Initially it is soft, fluctuant, and painful, and it becomes firm as clot organization and fibrin formation progress.[2] The main differential diagnosis is extensive preputial laceration. If a distance of more than two handbreadths is present between the scrotum and the enlargement, the swelling is more likely to be a preputial laceration. Other differential diagnoses include rupture of the urethra, abdominal hernia, and chronic, fibrous adhesions. Dysuria usually does not occur in conjunction with penile hematoma. Other signs of urethral rupture or blockage, such as extensive preputial cellulitis and "water belly," elevated blood levels of urea nitrogen and creatinine, and tissue necrosis, do not occur. Abscess formation of penile hematomas sometimes occurs. A soft, fluctuant center is characteristic of an abscess. Occasionally, differentiation between blood clot and abscess may be difficult. An aseptic tap can be done to determine the character of the fluid, but the risk of inducing an abscess in a sterile hematoma is high and a tap should be used only as a last diagnostic resort or just before surgery.

If penile hematoma has been present for longer than 2 weeks, fibrous adhesions may form that prevent penile extension. Adhesions are frequent sequelae to an abscess and have also been reported to occur secondary to infiltration of local anesthetics to block the dorsal nerves of the penis.[2] Another sequela is the development of venous shunts that communicate between the CCP and either peripenile vasculature or the corpus spongiosum penis (CSP).[1,7] Such vascular shunts result in rapid drainage of blood from the CCP and impotence caused by failure to achieve or maintain full erection. If the dorsal nerves of the penis are damaged, sensation of the distal penis is lost or deficient and results in failure of the bull to successfully seek out the female's vagina and/or ejaculate. Organization of the portion of the blood clot (thrombosis) within the body of the CCP may result in functional blockage of engorgement of the more distal cavernous spaces, preventing full erection.

Treatment and Prognosis Treatment of penile hematomas should be aimed at not only restoring the bull to usefulness but also preventing recurrence. Approximately 50% of bulls with hematomas that are treated conservatively (i.e., nonsurgically) are reported to return successfully to breeding.[1] Some theriogenologists believe that small hematomas (less than football size) do not require surgery.[8] However, surgical correction has the advantages of (1) removing the blood clot before extensive fibrous adhesions develop; (2) permitting removal of a blood clot from within the body of the CCP itself, thereby reducing the chance of blockage of cavernous filling; and (3) suturing the tunica albuginea, which should reduce the chance of recurrence of the condition after return to service and the likelihood of developing vascular shunts that will prevent complete filling of the CCP. Surgical intervention is not recommended before coagulation of the extravasated blood. Once significant fibrin formation is present, the prognosis for successful correction is greatly reduced and should be attempted only in valuable bulls.[1]

Additional recommendations before electing surgical intervention include extending the penis manually. Cases in which the penis can be extended from 6 to 8 inches or more beyond the sheath orifice, and in which penile sensation remains, carry a better prognosis.[9] If engorgement of the distal penis does not occur after careful stimulation with the electroejaculator, blockage of the CCP should be suspected and reduces the prognosis. Finally, cases with abscesses are poor risks because severe restrictive adhesions usually develop.[1]

Regardless of whether surgical or conservative intervention is selected for a penile hematoma, the bull should be treated with high levels of systemic antibiotics in an attempt to prevent abscess formation. Penicillin is a good choice because abscesses are usually caused by *T. pyogenes.* Postsurgical complications are much the same as those that may occur without surgery, but these adverse consequences are reported to occur less frequently after surgery. Bulls should not be returned to service for 2 to 3 months after treatment.[1,2]

Ram and Buck Adhesions of the penis and prepuce caused by trauma are uncommon in adult small ruminants. The penis does not separate from the prepuce until puberty and cannot be extended before this time (4 to 5 months of age in bucks).[10] Most traumatic lesions of the penis or prepuce in sheep and Angora goats are from shearing injuries.[11] Blockage of the urethral process by calculi can cause necrosis and sloughing of tissue that may extend into the glans penis.[11] Fighting among horned animals may result in injury to the external genitalia, including the penis. In dairy goats the intersex condition can result in congenital malformation of the penis and prepuce (hypospadias).[12]

Phimosis and Injury to the Prepuce

Stallion

Definition and Etiology

Stenosis of the preputial orifice can prevent extension of the penis. The defect is likely to be a sequela to an injury that results in cicatrix formation but may rarely be congenital.[1,2] Tumors (such as melanoma or squamous cell carcinoma) or *Habronema* granulomas may encroach on the preputial cavity, thereby preventing penile extension.[13]

Clinical Signs and Differentials Acute posthitis often accompanies injuries to the prepuce or infections such as equine coital exanthema and dourine.[1,2] Edema is common with acute posthitis, particularly after trauma. Gravitational effects typically worsen the preputial edema, which may induce prolapse of the external prepuce, trapping the penis in the swollen internal prepuce with a constricting preputial ring.[1] Cicatricial scar formation may follow, narrowing the diameter of the preputial orifice. Transpreputial ultrasound examination may be of benefit in differentiating tumors or abscesses from inflammatory edema or hemorrhage. Containment of the penis within the prepuce causes preputial urine accumulation, worsening balanoposthitis and secondary bacterial infection. The extended chronic inflammation leads to cicatrix formation with phimosis.

Treatment and Prognosis Preputial edema can be relieved by administration of diuretics and exercise. Application of crushed ice in plastic bags, or preputial immersion in cold water, may reduce inflammatory edema if applied soon after injury. Subsequently, application of emollient antibiotic preparations and hydrotherapy can be used to massage injured tissues

VetBooks.ir

and reduce edema. Systemic antibiotics and nonsteroidal antiinflammatory drugs are indicated to control secondary infection and inflammation. Sexual rest is indicated until the lesions have healed.[5]

A biopsy can be procured from encroaching tumors to identify cell types and improve prognostic capability.[5] Cicatricial scars can sometimes be successfully removed surgically. Once inflammation and infection are resolved with local or systemic antibiotic and antiinflammatory drug treatment, incision of the ventral aspect of the preputial orifice (preputiotomy) may be necessary to enlarge the opening sufficiently to permit penile extension. Large tumors or granulomas of the prepuce can sometimes be successfully removed surgically if sufficient elastic and membranous tissue remains to permit normal penile extension and retraction.[5] The prognosis for return to breeding soundness, however, is guarded when surgery must be performed. Postsurgical adhesions may develop that result in continued phimosis or penile deviation. In cases of habronemiasis, treatment with systemic insecticides or ivermectin may be indicated to kill remaining parasitic larvae.[13] Congenital abnormalities can seldom be corrected surgically.

Bull

Definition and Etiology

Trauma to the prepuce involving the elastic lamellar layers may prevent the required flexibility of the prepuce to permit penile extension. Breed predisposition to preputial injuries corresponds to genetic differences in pendulousness of the sheath and development of the muscles responsible for retraction of the prepuce. The polled gene is linked to weak or failed development of the preputial muscles, leading to habitual preputial eversion, which predisposes to injury. Brahman-blooded cattle have the added predisposition of a loose, pendulant sheath. With their tendency to partially evert the preputial membrane through the sheath orifice, they are at greater risk of damaging the prepuce accidentally than are those breeds of cattle in which the sheath is held in close apposition to the abdominal wall.[1,2,14]

Inability of the bull to extend the penis most commonly follows injury to the penis and prepuce that culminates in strictures or adhesions that restrict normal penile movement.[15,16]

Other causes of phimosis include congenital anomalies such as a short penis, a short retractor penis muscle, and developmental abnormalities of the reproductive tract such as occurs in pseudohermaphrodites.[2]

Clinical Signs and Differentials The more common preputial injuries are contusions, abrasions, lacerations, and frostbite. When the injured prepuce can be retracted, the injury may not be suspected unless hemorrhage is noted from the sheath or the bull is observed having difficulty during breeding. Although minor injuries may spontaneously resolve, more extensive injuries commonly progress to abscess formation and fibrous stricture formation.[1,8,15,16] Extension and examination of the penis may result in further injury if the case is complicated by phimosis. In such cases an attempt to extend the penis to facilitate examination is contraindicated because forcibly stretching the prepuce will extend the laceration and spread infection to uncontaminated areas.[1]

Treatment and Prognosis Treatment of preputial injuries in the bull may be either medical or surgical. With few exceptions, such as fresh avulsive lacerations in the fornix area, surgical intervention carries a better prognosis when medical treatment is first carried out to control inflammation and infection.[15] The healing leaves more normal tissue to be identified and salvaged during surgery. In cases in which the injured prepuce is retracted into the preputial cavity, digital, speculum, or endoscopic examination can be done in an attempt to locate lesions and determine the extent and depth of tissue involvement. Systemic administration of antibiotic is necessary to reduce the incidence of abscess formation preoperatively, and antibiotic should be administered through the surgical and postsurgical periods if surgery is elected. When the injured prepuce remains prolapsed in presented bulls, the first consideration is to attempt to return the prepuce to the preputial cavity.[1,15] The exposed epithelial covering of the prepuce is easily injured and becomes quite edematous and friable because of its pendent location. Hydrotherapy for 20 to 30 minutes may be helpful in cleansing the exposed prepuce and reducing edema. After gently cleansing the prepuce and determining the degree of patency of the lumen, a protective emollient preparation is used to massage edematous swelling upward out of the prolapse.[15] Massage for 15 to 30 minutes may be required to reduce swelling sufficiently to permit the prepuce to be returned to the preputial cavity. If the prolapsed prepuce can be returned to the sheath, a retention technique should be used to prevent reprolapse. With the prepuce in place, a tube can be inserted just beyond the swollen internal portion of the prepuce to avoid urine retention. The tube is taped in place at the external preputial orifice. Tape should not extend past the proximal end of the tube or urine retention and migration into peripreputial tissue will occur. If this technique will not retain the prepuce, a purse-string suture in the skin of the sheath orifice can be used.[1] It should be tight enough to retain the prepuce but leave sufficient space for urine to pass freely. To avoid suture abscesses and stricture formation, the sheath should be clipped and prepared aseptically for suture placement, and sutures should be removed as soon as swelling and inflammation subside. If the prolapsed prepuce cannot be returned to the preputial cavity, the prognosis for correction without surgery is guarded. After cleansing as described previously, a portion of stockinette is coated in ointment and applied over the prepuce. A diaper constructed from heavy canvas, netting, or burlap with straps and centrally located perforations for urine drainage is applied under the prepuce and tied up over the back to hold the prepuce gently next to the abdominal wall to decrease gravitational edema. It is changed daily until infection and swelling are controlled and the prepuce is either returned to the sheath or surgery is performed. Alternatively, the prolapsed portion of the prepuce can be wrapped in medicated gauze followed by application of a gentle but firm pressure wrap around a section of tubing. The pressure wrap is left in place temporarily to reduce edema, at which time the wrap is removed and the prepuce is replaced into the sheath.[15]

Once sufficient healing has occurred, the need for surgery is determined by extending the penis.[1] Adhesions most commonly take the form of encircling cicatricial strictures that must be removed surgically. Guidelines suggested for predicting successful outcome of surgery include the following: (1) a minimum of 5 cm of normal prepuce should be present on either side of the surgical site or proper unfolding may not be possible after surgery, and (2) free prepuce remaining after surgery should be at least twice the length of the free portion of the penis or the prepuce may be too short to permit full penile extension. Presurgical and postsurgical considerations, as well as surgical techniques used to correct phimosis, are described by Walker and Vaughan.[1]

Congenital anomalies contributing to phimosis are diagnosed based on physical examination of the entire reproductive tract. Abnormal karyotypes may be helpful in determining causes. If the penis cannot be extended using the techniques described and evidence of injury or adhesions is not present, congenitally short penis or retractor penis muscles should be suspected.[2]

Accompanying history may provide information that the bull could copulate when young, but as he aged his abdomen progressively enlarged, causing the penis to be of relatively insufficient length to effect copulation.[2]

VetBooks.ir

Ram and Buck Phimosis is uncommon in small ruminants. It may be congenital or acquired as a result of adhesions or preputial scarring associated with trauma or balanoposthitis.[11] Acquired phimosis can be the result of ulcerative posthitis due to the presence of *Corynebacterium renale*, *Corynebacterium pilorum*, or *Corynebacterium cystitidis*. These bacteria normally inhabit the prepuce and transform urea to ammonia, which is highly irritating to the prepuce. High urine urea levels, which are noted in animals fed high-protein diets, may increase the risk of ulcerative posthitis.[17,18] This condition is diagnosed during the physical examination and/or by observing the animal during the breeding process. If phimosis is due to acute inflammation of the prepuce (posthitis), it may resolve when the preputial swelling reduces. However, the prognosis is guarded until scarring can be evaluated.

Paraphimosis

Stallion

Definition and Etiology

When injury of the penis and the laminae of the prepuce is attended by hemorrhage and edema, paraphimosis (the inability to retract the penis into the prepuce) is likely to occur.[1] Prolonged penile prolapse, caused by debility or paralysis after the use of some tranquilizers, usually culminates in extensive penile irritation.[19,20] Protracted priapism (persistent erection) can lead to penile trauma and complications similar to penile prolapse.[21] Penile paralysis and priapism are distinctly different conditions. Penile paralysis likely develops secondary to insufficient tone of the retractor penis muscles.[22] Motor innervation of the retractor penis muscles in stallions is believed to be solely supplied by α-adrenergic fibers. When α–adrenergic blocking drugs such as phenothiazine-derivative tranquilizers are administered, paralysis of these muscles can cause penile prolapse.[23] The prolapsed penis is flaccid and cannot be maintained in the retracted position.[1,22] Priapism is a persistent erection without sexual arousal and is initially unassociated with penile paralysis. It develops from engorgement of the CCP with blood, and although the horse may not achieve a full erection, its penis is not flaccid.[24,25] When the penis fails to detumesce, CO_2 tension in the CCP increases, resulting in increased blood viscosity and subsequent venous occlusion where collecting veins join the cavernous spaces. Edematous swelling of corporeal trabeculae further reduces venous outflow, thus increasing the likelihood of irreversible venous occlusion, fibrosis of the cavernous trabeculae, and arteriolar occlusion. Disruption of the arteriovenous supply and fibrosis of the CCP prevent subsequent erections.[5,26]

Clinical Signs and Differentials Penile paralysis has been reported in exhausted or debilitated horses, in horses with myelitis or spinal injury, and in horses with severe injury to the penis.[1,19] Traumatic inflammatory edema often results in severe swelling of preputial membranes that prevent retraction of the penis into the prepuce. The inability to retract the penis results in further gravitationally induced edema, and, as the problem worsens, edematous fluid eventually oozes through the increasingly fragile penile and preputial integument. Cellulitis develops, and the integument becomes thickened, inelastic, desiccated, necrotic, and irreversibly damaged.[1,5] In cases of long-standing priapism, the distal end of the penis becomes cool to the touch, and the clot may become palpable in the body of the CCP as fibrin organization occurs. The organized clot may be visible on ultrasound examination.[21]

Treatment and Prognosis Prognosis for recovery becomes guarded to grave as the chronicity of the problem increases. Principles of treatment are similar to those described for the bull. The key to success is early aggressive intervention to reduce the edema via compression so that the penis can be placed within the prepuce.[27] To maintain the penis within the prepuce, a temporary purse-string suture of heavy nonabsorbable suture can be placed near the preputial orifice; however, dehiscence is common following this procedure. Alternatively, a padded plastic bottle from which the bottom has been removed can be used to support retention of the penis within the sheath. After the injured penis is dressed, the bottle is placed over it and pushed back into the sheath. The bottle is held in place with flexible straps or tubing running over the lumbar area and on either side of the scrotum up over the tailhead. Voiding of urine occurs through the bottle. The apparatus should be cleaned and replaced twice daily until the penis can be self-retained in the retracted position. Another effective method for maintaining the penis within the prepuce is the use of a 2-inch outer-diameter probe made of polyvinyl chloride (PVC) or other plastic tubing that is secured to the stallion's abdomen using elasticated bandage tape.[28] If the penis cannot be returned into the prepuce, an external support for the prolapse should be applied. Prolonged penile prolapse may result in excess gravitational pull that damages smooth muscle cells, the retractor penis muscle, and the pudendal nerves[1,22]; such sequelae decrease the prognosis for recovery and return to a successful breeding career. Chronic, refractory penile prolapse results in severe balanoposthitis that may require circumcision or penile amputation. Surgical penile retraction (the Bolz technique) is described by Walker and Vaughan.[1] A simple amputation technique that can be performed in the standing horse, using a modified Vinsot procedure, has also been described.[29]

Medical treatment of horses with priapism has generally been unsuccessful.[5,24] In cases of drug-induced priapism seen within 2 to 4 hours of occurrence, slow IV injection of 8 mg benzotropine mesylate may cause detumescence and penile retraction to occur.[30] If not seen immediately, treatment is the same as for traumatic paraphimosis. Rapid detumescence can be induced by injecting 10 mg of phenylephrine into the CCP, even in long-standing cases. However, the detumescence may be transient, especially in chronically affected cases. Flushing the CCP with heparinized lactated Ringer's solution through 12-gauge needles to remove sludged blood has been recommended for horses with priapism of 12 to 24 hours' duration that have not responded to medical treatment.[5] If a blood clot forms in the CCP, the prognosis is poor, and amputation may even be necessary. Some stallions, if severe nerve damage does not occur, may regain the ability to breed and ejaculate when assisted with placement of the penis into either the vagina of the mare or an artificial vagina. When the stallion does not regain the ability to completely retract the penis into the sheath, continued penile trauma is likely to result in damage to the sensory nerves to the glans penis. Such horses may achieve an erection but may have difficulty in seeking the mare's vulva for intromission and ejaculation. Ultrasonography of the CCP to detect cavernosal fibrosis may be useful in assessing prognosis for recovery from priapism. Prognosis for recovery is good once penile retraction occurs, but breeding should not be permitted until healing is complete.

Bull

Definition and Etiology

Paraphimosis is less common than phimosis in the bull. Causes may be the same for both conditions, but for paraphimosis include penile tumors, parasitic invasion, traumatic or spinal disease affecting innervation of structures responsible for penile retraction, inadvertently severed retractor penis muscles, or physical trapping of the penis by a constricted prepuce after injury. Penile paralysis and paraphimosis sometimes occur as a result of spinal injury or disease and in rabies cases as well.[1,2]

Clinical Signs and Differentials Persistent exposure of the penis results in congestion, inflammation, and necrosis of the penile integument.[2]

VetBooks.ir

Treatment and Prognosis

Management of the prepuce has been discussed. Exposed portions of the penis should be frequently cleansed and protected by a bandage soaked in oily antibiotic preparations. The prolapsed penis should be supported close to the abdomen to reduce edema. The penis should be returned to the sheath as soon as possible and mechanically restrained if necessary. If the ability to retract the penis does not return in a few days, prognosis for recovery is poor.[1]

Ram and Buck

Paraphimosis is uncommon in small ruminants. The diagnosis is obvious, although the etiology may not be. Treatment involves the same principles as in the bull. Prognosis is guarded and correlates with the degree of injury and necrosis at the time the condition is discovered.

Urethral Injury and Urethritis

Stallion

Clinical Signs and Differentials

Traumatic injuries to the urethral process are usually obvious and are characterized by hemorrhage. *Habronema* granulomas are firm and friable. Ulcers of the urethral process often become secondarily invaded with bacteria such as *Pseudomonas* spp. Parasitic lesions tend to regress during winter, but if untreated they may mineralize and result in recurrence of hemospermia during the following breeding season.[31]

Lesions can occur throughout the urethra, including the pelvic urethra in the area of the ejaculatory ducts. Diagnosis is based on demonstration of the lesions by fiberoptic examination.[5] Ultrasonography and fractionation of the ejaculate may be helpful in eliminating involvement of the accessory sex glands.[32]

Urethral inflammation and lacerations may result in fibrous strictures.[33] Strictures are often painful and may separate and bleed during urination and ejaculation. Bacteriologic culture of the urethra, urine, and semen; fiberoptic examination; and histologic examination of biopsies of lesions are helpful in making a diagnosis.[1] Strictures in the distal urethra may be identified by contrast radiography of the extended penile urethra.[1,33]

Clinical signs of uroliths include dribbling of urine with chronic cystitis, dysuria and stranguria, occasional hematuria, recurrent colic, and a stilted, painful gait in the hindquarters. Penile protrusion is frequent or constant in cases of chronic, involuntary escape of urine.[1] Diagnosis is by urinalysis, revealing the characteristic crystals, red and white blood cells, and bacteria. Urethral calculi typically restrict the passage of urethral catheters. Bladder calculi may be palpated per rectum or visualized by ultrasonography.[1,31]

Treatment and Prognosis

Treatment of urethral injuries involves first removing inciting factors such as a tight stallion ring. Sexual rest is indicated while palliative therapy is given. The ability to void urine should also be established. Systemic treatment with antibiotics that are eliminated in the urine may be useful as a prophylactic measure or in cases in which secondary bacterial invasion has occurred. More severe cases of urethritis may be treated locally either by infusion of oily antibiotic preparations through sterile, rubber urethral catheters passed to the area of the seminal colliculus of the pelvic urethra or by inserting soluble suppositories through a perineal urethrostomy. After resolution of the urethritis, the urethrostomy is allowed to heal by granulation.[33] Lacerations or rents of the proximal urethra that result in hemospermia can be treated by perineal incision into the corpus spongiosum and underlying urethra (CSU) or by perineal corpus spongiotomy where the CSP is incised, but the incision is not extended into the urethral lumen. These surgeries are believed to prevent stretching of the urethra when engorgement of the corpus spongiosum occurs during urination or erection. Repeated tissue stretching and bleeding through the site at the time of urination are thought to prevent urethral lacerations from healing without these forms of surgery.[34]

Inflammation of the urethral process may respond to local antibiotic salves. Treatment of parasitic granulomas with ivermectin speeds resolution of these cases.[13,35,36] Larger, nonresolving granulomas with mineralization may require surgical removal.[37] The skin of the urethral process should be rolled inward when sutured to the mucous membrane to prevent eversion that predisposes it to reinjury after healing. Remaining hemorrhagic or ulcerative lesions can be lightly cauterized with silver nitrate.[31] More proximally located nonresolving urethral strictures, prolapsed subepithelial vessels, or ulcers can be removed surgically.

Calculi lodged within the lumen of the pelvic urethra can be removed via perineal urethrostomy. Treatment for urethral calculi is described in the discussion of diseases of the urinary system (Chapter 34).

Bull

Definition and Etiology

Urolithiasis is the primary problem affecting the urinary system that may interfere with normal function of the reproductive tract of the bull. It is of less importance in bulls than in steers but occasionally occurs and may result in hematuria or urethral obstruction.[1,2] Urolithiasis is thoroughly discussed in Chapter 34.

Balanoposthitis

Stallion

Definition and Etiology

Inflammation of the glans penis (balanitis) and prepuce (posthitis) often occur together (balanoposthitis). Traumatic injury resulting in inflammation of the penis and prepuce has been discussed. Balanoposthitis may also be caused by dourine, equine herpesvirus 3 (EHV-3), miscellaneous bacteria, and parasites.[3]

Equine Coital Exanthema

Equine coital exanthema is caused by EHV-3.[38,39] The occurrence of neutralizing antibodies to EHV-3 primarily in horses of breeding age suggests that spread of this infection may be primarily by genital contact.[40] Typically an inapparently infected mare transmits the virus to a stallion at the time of breeding. The stallion then transmits the infection to other susceptible mares before developing clinical signs of the disease. Clinical signs in the stallion are sometimes more severe than those observed in the mare and may include systemic manifestations such as dullness, anorexia, and fever.[40] Vesicles up to 1.5 cm in diameter develop first on the penis and then on the prepuce 2 to 5 days later. The vesicles progress to circumscribed pustules with raised borders and depressed centers, which slough and ulcerate.[41] Scabs are seldom noted on penile lesions because they are rubbed off by extension and retraction of the penis during breeding.[41] Some affected stallions may refuse to breed mares, whereas others breed willingly, even while extensive penile lesions are present. Healing occurs in a few weeks, often leaving depigmented spots.[41]

Some immunity to the virus is acquired, as recurrence of clinically apparent disease is uncommon. It is probable that the virus remains in the genitalia in a latent form. Recurrent coital exanthema usually occurs in aged broodmares but may also occur in stallions.[41] The relationship between viral recrudescence and recurrent coital exanthema in the equine is unknown but may mimic that which occurs in human genital herpes infections.

Diagnosis usually can be made based on the characteristic clinical signs. During the acute stage, the virus can be isolated

from swabs or scrapings taken from the edge of erosions, inclusions in lesion specimens, or confirmed by using an electron microscope to visualize typical herpesvirus particles in fluid or tissue samples. Probably the most sensitive, specific, and accurate tool for the detection of EHV-3 is PCR testing. Demonstration of antibody titers in serum may be useful in establishing time of exposure to the virus.[42]

Infection with EHV-3 is self-limiting. Local treatment with antibiotic ointments will not speed healing but may minimize secondary bacterial infection and soreness.[41] Care should be taken to avoid iatrogenic transmission of the infection (e.g., through contamination of sleeves, water, and examination or insemination equipment) to susceptible animals. Attending veterinarians may choose to refrain from breeding affected stallions until the lesions heal. One method that may be helpful in circumventing transmission of the infection while still breeding the stallion is to collect semen in an open-ended artificial vagina as soon as lesions are no longer painful. Collecting the semen as it directly exits the urethra reduces the chance of viral contamination from the penile and preputial lesions.

Bacterial Infections

Stallion The external genitals of stallions harbor potentially pathogenic bacteria, fungi, and yeasts, yet balanoposthitis caused by bacterial agents is uncommon.[43-45] These organisms are usually considered to be surface contaminants, and the stallion is a lesionless carrier in most instances in which venereal transmission occurs.[20] Sperm motility, however, may sometimes be adversely affected by bacteria and their products in semen.[44] Offensive odors may occasionally be associated with heavy colonization of the penis and sheath with *Pseudomonas* spp. or *Proteus* spp.[2] Documentation of a bacterial infection is dependent on serial isolation of a pathogen, preferably in large numbers and relatively pure culture.[45] A single isolation of *Taylorella equigenitalis* is considered diagnostic for contagious equine metritis.[20] Samples for bacteriologic culture should be retrieved from the fossa glandis, free portion of the penile body, and folds of the external prepuce before washing the genitals of a stallion presented to a mare in behavioral estrus.[45]

If there is evidence of horizontal transmission of *Pseudomonas* or *Klebsiella* to mares, or if longevity of sperm is reduced in association with these organisms, the preferred method of management is to breed mares artificially with semen mixed with an antibiotic-containing semen extender.[46] Antibiotic selection is based on trials comparing extended semen with and without antibiotic. Extenders containing antibiotics that control the offending bacteria and permit maintenance of sperm motility are then used to breed mares.[47] Bacteria are usually not recovered after 5 to 30 minutes of incubation at room temperature.[44,46,47] Penicillin G (1000 to 1500 U/mL), streptomycin sulfate (1000 to 1500 µg/mL), polymyxin B (100 to 1000 U/mL), reagent grade gentamicin sulfate (100 to 1000 µg/mL), amikacin sulfate (100 to 1000 µg/mL), and ticarcillin (100 to 1000 µg/mL) are usually the most suitable antibiotics.[5] Gentamicin sulfate and amikacin sulfate should be buffered with 8.4% sodium bicarbonate solution to adjust pH to approximately neutral before mixing with semen extender. A suitable volume of extender can be infused into a mare's uterus immediately before cover when natural service is necessary.[46]

Colonization of the external genitals with *P. aeruginosa* and *K. pneumoniae* can be treated by thoroughly washing the penis and prepuce, including the fossa glandis and diverticulum, daily with an iodine-based surgical scrub. The genitals are then rinsed with copious quantities of tap water with dilute disinfectants added (10 mL concentrated HCl per gallon of water for *Pseudomonas* colonization, or 40 mL of 5.25% sodium hypochlorite bleach per gallon of water for *Klebsiella* colonization). Drying of the penis can be followed by generous application of 1% silver sulfadiazine cream. The procedure is repeated daily for 1 to 2 weeks followed by serial cultures to determine if treatment was successful.[48] The clinician should be cognizant that recolonization with these organisms may occur and that routine scrubbing and disinfection may predispose to infection of the genitals with potential pathogens by displacing commensal organisms.[43] While not tested in a research setting, individual clinicians have used a tranfaunation procedure to replace normal flora by rubbing the penis and preputial areas of the affected stallion with smegma of a stallion with normal penile and preputial flora.

Bull Balanoposthitis in the bull is caused by traumatic injury and infections. Whereas injury of the prepuce is more common, penile inflammation often accompanies the traumatic posthitis. A multitude of potentially pathogenic organisms inhabit the prepuce, and injuries predispose to infection, particularly when deeper tissues are exposed. Pain and preputial discharge may be evident. Because of the presence of the many organisms in the preputial cavity, culture to identify a specific offending organism is likely to be misleading. When injury results in infection of the penis and prepuce, sexual rest in conjunction with local antibiotic treatment is indicated; systemic antibiotics are indicated if the injury is extensive or involves the full thickness of the prepuce. Treatment should be performed as previously outlined for the penis and prepuce until inflammation is corrected.

Balanoposthitis unassociated with trauma has been associated with infections caused by infectious bovine rhinotracheitis–infectious pustular vulvovaginitis (IBR-IPV) caused by bovine herpesvirus 1 (BHV-1), tuberculosis, and screwworm infestation.[2,49] Acute lesions associated with IBR-IPV infections are numerous small pustules that progress to ulcers and erosions in a few days. Purulent preputial discharge is present, and lesions may become confluent. The prepuce and penis may become quite inflamed and swollen. Healing is commonly spontaneous and rapid, beginning in 1 week and usually complete in 2 weeks. Severe cases may take longer to resolve.[49] Virus is shed from the prepuce for 2 weeks or longer, during which time venereal spread is possible. Sexual rest for 6 to 8 weeks has been recommended to prevent spread and to avoid abrasions that may aggravate inflammation.[2] Enlargement of the lymphoid follicles may be present along with a seromucoid exudate for several weeks. Histologic changes include the transient appearance of eosinophilic intranuclear inclusions in degenerating epithelial cells. Infusion of the preputial cavity daily may be of benefit in treatment, particularly in more severe cases. Vaccination with attenuated intranasal products has been reported as a method to prevent viral shedding into semen in bulls from AI studs.[2] Bulls infected with BHV-1 remain infected for life, as the virus remains latent in the sacral ganglia.[50,51] Viral shedding through the ejaculate occurs intermittently. Therefore valuable serologic-positive bulls could be tested for the presence of the virus in semen. Detection of BHV-1 in semen by real-time PCR is more sensitive than virus culture isolation. Two straws of extended processed ejaculate are necessary to detect the presence of the virus.[50,51]

Ram and Buck

Definition and Etiology

Balanoposthitis (also called "pizzle rot," "sheath rot," and "ulcerative posthitis") commonly affects the penis and prepuce of intact and castrated male small ruminants (see also Chapter 34).[11,12] In sheep, it is important to differentiate pizzle rot from ulcerative dermatosis. Ulcerative dermatoses, caused by a parapoxvirus, also present lesions in lips and legs, as well as in the genital area (see also Chapter 32). In goats, the caprine herpesvirus produces balanoposthitis in males and vulvovaginitis in females.[52,53] It is also a cause of caprine abortion.[54,55]

Persistent Penile Frenulum and Penile Deviations

Stallion

Definition and Etiology

Persistent frenulum is rare in the stallion. However, penile deviations can occur in older stallions, particularly those that have been subjected to semen collection through most of their breeding career. In the United States, most of the affected horses have deviations to the right. It is thought that repeated bending of the penis to the left to facilitate entry into the artificial vagina causes damage to the CCP/tunica albuginea on the right side, resulting in filling defects and fibrotic lesions that lead to penile deviation.

Treatment and Prognosis For most affected stallions, treatment is unnecessary, and the horse continues to ejaculate normally. Some stallions have such a severe deviation that attempts to collect semen result in pain and lack of ejaculation. For these stallions collecting semen on the side ipsilateral to the direction of deviation often alleviates the problem.

Bull

Definition and Etiology

Phallocampsis, or deviation of the erect penis, is a relatively common condition in the bull. The most common cause of penile deviation is persistent penile frenulum.[2] Other types of penile deviations include spiral, ventral, and S-curved deviations.[1] Less commonly, preputial or penile injury may result in scar tissue formation that subsequently leads to deviation of the erect penis.[1]

When the penile frenulum persists, it remains connected to the ventral surface of the tip of the penis and the prepuce and causes the penis to bend ventrally during erection by preventing complete extension.[56] Copulatory ability is interfered with except in some of the Zebu-influenced breeds that are endowed with a plentiful prepuce.[1] Diagnosis is based on physical examination of the extended penis.

Because spiraling of the penis is thought to be a normal physiologic event that occurs in the vagina during ejaculation,[57] care should be taken in making this diagnosis. Bulls affected with penile deviations often have a history of no problems in mating cows for some time, occasionally for several breeding seasons. If such bulls have been closely observed, it may have been noted that the condition did not occur on every mating attempt, but the frequency of occurrence gradually increased until bulls might require numerous mounts to successfully intromit and breed a cow in estrus.[2] Penile deviations occur at full erection when the CCP is maximally distended with blood. Caution should be exercised in diagnosing this condition during erection stimulated by electroejaculation. Such erections are not considered to be entirely physiologic and frequently result in penile deviations in bulls that have no deviations under natural mating conditions. The spiral deviations that occur with use of the electroejaculator may be a result of tension exerted by the retractor penis muscles.[1] Diagnosis is best based on observing occurrence of the deviation frequently in natural mating situations.

The ventral or rainbow deviation of the penis is less common than the spiral deviation and is a result of the apical ligament being too thin to support the engorged, stretched distal end of the erect penis.[1] The ventral curvature may be quite pronounced, preventing affected bulls from directing and inserting the penis into the vagina of the female.

The least common of the spontaneous penile deviations is the S-shaped curvature. It primarily occurs in older bulls with an apical ligament that is short in relation to an excessively long penis.[1] Penile deviations that result from adhesions that developed from penile or preputial injury are diagnosed by physical examination.

Treatment and Prognosis Persistent penile frenulum is easily corrected by severing the persistent band. Owners of affected bulls should be advised of the probable genetic basis and therefore the undesirability of retaining such bulls for breeding.[1] Treatment of spiral and ventral deviations is surgical.[1]

Tumors of the Penis and Prepuce

Stallion

Clinical Signs and Differentials

The most common neoplasm of stallion genitalia is squamous cell carcinoma (SCC). Generally, it is of low malignancy.[1,58] The tumor usually involves the glans penis but may also involve the shaft of the penis and prepuce and produce a fetid discharge. Large tumors may ulcerate and bleed, resulting in hemospermia. Carcinomas may resemble *Habronema* granulomas, which are more common and are diagnosed by histologic examination of affected tissue.[2,5] Carcinomas are usually well differentiated and surrounded by eosinophils. Necrosis and calcification may occur, but parasite larvae are usually not present unless secondary habronemiasis has occurred from flies feeding on the ulcerated tissue. Carcinomas may extend into the CCP or may metastasize to the inguinal lymph nodes or other abdominal or thoracic organs. The superficial inguinal lymph nodes lie midway between the prepuce and external inguinal ring; secondary tumors in this region often grow rapidly and develop necrotic centers with purulent sinuses that must be differentiated from bastard strangles.[1]

Tumors encountered much less frequently include melanoma, papilloma, angioma, lymphosarcoma, and sarcoid. Melanoma is a common equine tumor, especially of gray horses,[13] and occasionally involves the penis and prepuce[1,2,59] (see Chapter 40). Genital papillomas are rare in stallions but may occur on the glans or shaft of the penis. The lesions appear as multiple proliferative cutaneous growths and may become friable and result in hemorrhage during erection and ejaculation.[5] The lesions are generally thought to be caused by a papillomavirus, and papillomavirus antigens have been found in cutaneous and genital papillomas.[60] Angiomas and lymphosarcomas have occasionally been reported on the genitals of stallions.[3] Sarcoids may involve the skin of the prepuce or scrotum.[1,59]

Treatment and Prognosis When SCCs are relatively small and noninvasively attached to the skin, neoplasms may be successfully treated by cryosurgery or hyperthermia. Hyperthermic treatment (50° C for 1 to 2 minutes) appears to be most successful for SCC when lesions are small (less than ≈2 cm). If the tumor is extensive but superficial, cryosurgery may be attempted after the tumor is debulked and hemorrhage is controlled. The remaining base of the tumor is then frozen and thawed twice; healing occurs as necrotic tissue is sloughed. Successful treatment of small lesions has been reported with topical application of 5-fluorouracil.[61] If removal of tumors is unsuccessful or if neoplasia is extensive, penile amputation may be necessary.[1,62] If superficial inguinal lymph nodes are involved, euthanasia may be required.[1]

In contrast to nongenital squamous papillomas, genital forms are generally quite refractory to treatment.[5] Surgical removal and autogenous vaccine administration to treat fibropapilloma of the penis of two stallions did not effect a cure.[31]

Bull

Definition and Etiology

Fibropapilloma is the only tumor that frequently invades the bovine penis or prepuce. The tumor may be single or multiple

and usually affects young bulls. The cause is thought to be a papillomavirus antigenically similar to the virus that causes cutaneous papillomatosis in cattle.[63] Frequent mounting among young bulls is thought to result in damage to epithelial surfaces of the penis and prepuce that serves as a route of entry for the virus.[1,2]

Clinical Signs Small papillomas may be discovered during routine breeding soundness evaluations, but many become larger before they are discovered. Large fibropapillomas may prevent withdrawal of the penis into the preputial cavity. Fibropapillomas are pedunculated and attached at a narrow base in early cases. The surface becomes cauliflower-like and friable; hemorrhage is easily induced.

Treatment and Prognosis Many fibropapillomas regress spontaneously within a few months. Regression may be more likely in bulls approaching 2 years of age and usually occurs within 4 months of the appearance on the penis.[63,64] Several vaccines, including autogenous preparations, have been used for treatment, but vaccines may be more successful for prophylaxis.[2] Frequently surgical removal is indicated, but the fibropapillomas may recur. If only superficial attachment is present, surgical removal is easily accomplished. Catheterization of the distal urethra before surgery is helpful in identifying its location to avoid injury. If attachment has become extensive and sessile, amputation of a portion of the distal penis may be necessary.[1] Housing of young replacement bulls in individual pens, if possible, is recommended as a method to reduce the incidence of penile fibropapillomas.

Parasitic Infestations of the Penis and Prepuce

Stallion

Definition and Etiology

Habronema muscae, *Habronema microstoma*, and *Draschia megastoma* larvae commonly invade the urethral process, glans penis, and preputial ring of stallions.[1,13] Other terms for this condition are "genital bursatti" and "summer sores."

Clinical Signs Shallow irritations progress to irregular 1- to 3-cm granulomatous growths that may involve the entire circumference of the urethral process.[2] Lesions are friable and bleed when manipulated. Stretching of the infected urethral process during penile engorgement and ejaculation may result in hemospermia.[5] Pruritus associated with the lesions may be intense. Frequent micturition and dysuria may resemble urine spraying that accompanies accumulation of smegma in the urethral diverticulum ("bean"). Lesions subside during the colder months in northern areas but usually reappear and increase in size during subsequent warm weather.[2] Diagnosis is made by seeing yellowish granules (calcified larvae) in the lesion and by microscopic identification of larvae.[13]

Treatment and Prognosis See Chapter 40 for treatment and prognosis information.

Hemospermia (Blood in Semen)

Hemospermia refers to contamination of ejaculates with blood. Stallions with overt hemorrhage into ejaculates can be subfertile. Erythrocytes, rather than serum, have been implicated for the marked depression of fertility, although the precise factors involved are not known. A small amount of sanguineous contamination is compatible with good fertility, especially if the semen is quickly diluted with a suitable extender before insemination. The addition of 5% of blood (v/v) in extended semen did not affect the fertility compared to control mares artificially inseminated with extended semen containing no blood. However, if the extended semen contained 50% blood, no pregnancies were obtained. It was concluded that the level of blood rather the presence of blood affects the fertility.[65] A disproportionate number of leukocytes to erythrocytes suggests infection of the internal genital organs. Specific causes of hemospermia include lacerations of the penis, cutaneous habronemiasis, urethritis, urethral lacerations, and infection or inflammation of the accessory genital glands, which are discussed elsewhere in this chapter.

Urospermia (Urination During Ejaculation)

Definition and Etiology Urospermia is an uncommon but perplexing disorder of breeding stallions. Affected stallions generally exhibit normal libido and mating ability, but semen becomes contaminated with urine during the ejaculatory process. The problem may be incessant or unpredictably intermittent; urination can occur at any time or continuously during ejaculation. The amount of urine is up to 250 mL or more.[5]

The underlying cause or causes of urospermia are speculative. Closure of the bladder sphincter and seminal emission are controlled by the α-adrenergic sympathetic nervous system, and a disturbance in this pathway might contribute to urospermia.[66] Similarly, neuropathies that result in bladder paralysis (e.g., cauda equina neuritis or nerve damage secondary to EHV-3 or sorghum/Sudan grass poisoning) can create urinary incontinence that permits voiding during ejaculation. Most stallions with urospermia do not exhibit signs of a neurologic deficit.[5] In ruminants, urine can also contaminate semen collected by electroejaculation. To reduce this risk, it is recommended to avoid water ingestion 12 to 24 hours before semen collection.

Clinical Signs and Differentials Gross contamination of ejaculated semen with urine is easily detected by its color and odor. Contamination with significant quantities of urine adversely affects sperm motility and fertilizing capacity. Elevated concentrations (relative to serum levels) of urea nitrogen or creatinine in semen document the presence of urine in the ejaculate.[5,67]

Treatment and Prognosis Treatment options for urospermia vary, can be arduous, and are often unrewarding. Delay of semen collection (or breeding) until immediately after the stallion has voided urine may be a helpful management policy. Urination can be stimulated by administration of a diuretic drug (e.g., furosemide). Stallions may also void urine when provided access to feces of another stallion. Some stallions can be trained to urinate on command. Alternatively, the bladder can be catheterized to aid evacuation of urine before breeding, but urethritis or cystitis may result from routine use of this procedure. Fractionation of ejaculates using an open-ended artificial vagina can be used alone or in combination with any of the previously mentioned measures. When an open-ended artificial vagina is used, only the first three jets of the ejaculate are collected. These jets contain a majority of the spermatozoa in the ejaculate, and urination may not occur until the end of the ejaculatory process. Dilution of urine-contaminated semen in extender can restore sperm motility.[68] Semen may be centrifuged after initial dilution and the sperm pellet resuspended in extender before insemination[5]; however, centrifugation to remove urine may not provide a significant advantage to dilution in extender.[68]

Pharmacologic agents such as bethanechol chloride or flavoxate hydrochloride have been used in an attempt to correct urospermia, but usually without success.[5] Oral administration of imipramine (100 to 500 mg twice daily) has reportedly been useful for controlling urospermia in stallions, presumably by enhancing contractility of the bladder neck during emission.[66]

Infertility Caused by Diseases of the Scrotum and Testes

Scrotal Injury, Hydrocele, and Hematocele

Definition and Etiology Trauma to the scrotum can result in excoriation, lacerations, hemorrhage, and edema.[2] Systemic diseases such as hepatic disease and equine infectious anemia may result in scrotal edema.[2,20] Suppurative inflammation may develop as an extension of scrotal injury.[2] Adhesions often develop between the visceral and parietal tunics when inflammation, infection, or hemorrhage occurs. Adhesions are usually thin fibrous strands that become thickened with time. In such cases the testis and its tunics are not freely movable within the scrotum.

Hydrocele is an accumulation of serous fluid within the vaginal tunic. Ascites, anasarca, or local lymphedema may contribute to hydrocele because the vaginal tunic communicates with the peritoneal cavity. Accumulation of a significant volume of fluid around the testis may cause thermal degeneration and a decline in seminal quality.[69] In Texas, a seasonal hydrocele has been described in bulls submitted to breeding soundness examination during the fall and winter season.[70,71] This type of hydrocele was associated with ascites and intestinal edema and has been attributed to a hypersensitivity reaction to gastrointestinal nematodes.[71,72]

Hematocele occurs when trauma to the scrotum results in accumulation of blood within the testicular tunics. Hematoceles can be primary due to a testicular trauma or secondary to hemoperitoneum. Scrotal damage initially accompanies hematocele. Thermal degeneration of the testes follows, and a thick fibrous capsule encompasses the testis after the blood clot organizes.[73]

Clinical Signs and Differentials Diagnosis of scrotal injury, hydrocele, and hematocele is made by physical and ultrasonic examination of the scrotum. Testes remain freely movable within the scrotum if hydrocele is present. Ultrasonographic examination reveals variable amounts of anechoic fluid present surrounding the testes and epididymides, which are easy to visualize because of their echoic nature against the fluid background. With hematocele, evidence of trauma is often present, with thickening of the scrotal skin. Blood surrounding the testis and epididymides becomes progressively more echogenic as the clot organizes.[5,74] Extensive edema of the scrotal fascia next to the tunica dartos may be difficult to differentiate ultrasonographically from hematocele. Abdominal paracentesis is helpful in eliminating ascites or peritonitis as causes of hydrocele. Palpation per rectum of stallions and bulls may occasionally reveal that the internal inguinal rings are enlarged, readily permitting fluid transfer into the vaginal cavity.

An aseptic tap is useful to identify the character of this fluid and must be performed with care not to contaminate or penetrate the testis or its visceral vaginal tunic.[73] A modified transudate of low cellularity is typical of fluid drained from a hydrocele.[75] Fluid usually returns after drainage unless the initiating cause is corrected.[5] Determining and treating the cause of ascites could provide permanent cure of the ascites and hydrocele.[71,72]

Treatment and Prognosis Acute scrotal injury is treated with cold water or ice application to reduce edema (see earlier discussion on penile and preputial injuries). Lacerations and abrasions should be treated with topical antibiotic ointments. Systemic antiinflammatory drugs and antibiotics may reduce swelling, control infection, and prevent abscess formation.[5,73]

Scrotal thickening usually results in elevation of testicular temperature, causing degeneration and atrophy similar to that seen with experimental scrotal insulation.[76-78] Semen quality quickly deteriorates, and a rapid reduction in number and motility of spermatozoa occurs, with a concurrent increase in morphologic abnormalities of spermatozoa.[2,79] If swelling and edema resolve and adhesions do not develop among the testes, tunics, and scrotum, spermatozoa may gradually reappear in the ejaculate by 1 to 2 months after injury, but 4 to 5 months may be required for testes to return to normal size and sperm production.[4] One or both testes may remain atrophic and become firm because of fibrosis and loss of tubules. If only one testis is atrophied, the normal testis may eventually hypertrophy.

If hemorrhage occurs within the scrotum or testicular tunics, the prognosis for return of testicular function is poor. In unilateral cases, surgical removal of the clot and affected testis may minimize damage and speed recovery of the remaining testis.[80,81] Hydrocele is managed by correcting the underlying cause of fluid accumulation such as peritonitis or ascites.[73] Exercise may aid in control of fluid accumulation in some horses. Some stallions and bulls with persistent minor fluid accumulations within the tunics may continue to produce sufficient normal spermatozoa.[2] Permanent testicular degeneration may result in cases with extensive fluid accumulation that are unresponsive to therapy. If the condition is unilateral, removal of the affected testis may permit the animal to remain in service.[75] Because hydrocele and associated impairment of spermatogenesis may be transient (2 to 6 months),[70] caution should be exercised in recommending castration or culling of affected animals until demonstration that the disorder is long-standing.

Scrotal Dermatitis or Abscess

The scrotal skin is delicate and vulnerable to dermatitis. Causes include nonspecific environmental contaminants, bacteria, fungi, parasites, and frostbite. Scrotal abscesses are not uncommon in small ruminants and are due to shearing injuries and penetrating wounds.[11] Treatment is directed toward removing the affected testis. Bulls affected by frostbite should be provided a warm and dry environment.[82] Systemic and local antibiotics may be indicated. Abscesses should be drained. Thermal degeneration of the testes may follow dermatitis and may be temporary or permanent.[2] Semen quality should be evaluated at periodic intervals after skin lesions have resolved to gauge prognosis for improvement and return to fertility.

Testicular Aplasia and Hypoplasia

Definition and Etiology Complete absence (aplasia) of one or both testes is rare and usually occurs in conjunction with anomalous development of other organs.[2,83] Testicular hypoplasia may be unilateral or bilateral and affects both scrotal and abdominal testes. Testicular hypoplasia is thought to result from failure of germ cells to multiply in the gonad.[2] Causes of testicular hypoplasia may include transplacental infections and intoxications, zinc deficiency, hormonal insufficiency, impaired testicular descent, abnormal karyotype, and vascular disturbances.[11,12,79] Exogenous administration of hormones to prepubertal males can result in testicular hypoplasia. Testicular size of adult stallions is reduced after prolonged administration of exogenous steroids.[84-86] Scrotal circumference is diminished in bulls implanted with zeranol.[87]

Clinical Signs and Differentials Hypoplastic testes are usually smaller than normal, but they are occasionally normal in size.[88-90] Stallions 3 years of age should have a scrotal width greater than 8 cm.[20] Yearling rams with a scrotal circumference of less than 30 cm and mature rams with a scrotal circumference of less than 32 cm are not recommended for breeding.[91]

VetBooks.ir

The texture of affected testes varies from normal to soft in mild or moderate hypoplasia. Severely affected small testes are firm because of the relatively increased amount of stromal connective tissue. History is an important component in the clinical assessment in order to differentiate hypoplasia from atrophy. If uncertain, reexamination needs to be performed. Factors that influence the scrotal circumference in ruminants are breed, age, body condition score, and season.[92] In bulls, the minimum recommended scrotal circumference is 30 cm for 15 months old or younger and 34 cm for 2 years old or older according to the criteria established by the Society of Theriogenology.[93] Scrotal circumference in bulls is positively correlated with the number of normal functional seminiferous tubules and is negatively correlated with pathologic seminiferous tubules in bulls.[90] In bulls the heritability for scrotal circumference is medium to high.[92] In addition, scrotal circumference is negatively correlated with age at puberty of the female offspring. Bulls with higher scrotal circumference will produce females that acquire puberty earlier than females produced by contemporaneous bulls with smaller scrotal circumference.[92]

Depending on the number of seminiferous tubules affected, ejaculates from males with testicular hypoplasia may be azoospermic or contain a low concentration of spermatozoa with numerous morphologic defects.[2]

Treatment and Prognosis No successful treatment is available for severe hypoplasia. The useful breeding life of males with testicular hypoplasia may be shortened because affected bulls are thought to be predisposed to early testicular degeneration.[88] Because of the value of some individuals, particularly stallions, owners may elect to breed males with small testes. Effective management of such stallions is based on breeding a book of mares limited by the number of normal, motile spermatozoa present in ejaculates.

Cryptorchidism

Definition and Etiology Incomplete or abnormal testicular descent is thought to be a genetic abnormality. The inheritance pattern in horses is thought to be dominant,[1] although studies of offspring of some cryptorchid stallions suggest that inheritance of the condition may be multifactorial.[2] The relative risk for equine cryptorchidism also appears to be influenced by breed.[3] Other modes of inheritance have been suggested from studies of the offspring of cryptorchid rams, bucks, and bulls. These include a recessive gene with incomplete penetrance in Angora goats,[4] a dominant gene with variable expressivity in Hereford cattle,[5] and either an autosomal recessive gene or a dominant gene with incomplete penetrance in inbred sheep.[6]

Testes originate near the kidney and migrate to the inguinal rings before descending into the scrotum; the epididymis precedes the testis in descent. Retained testes are located at some point along the path of migration. Ectopic testes not associated with cryptorchidism may be found under the skin of the ventral caudal abdomen or elsewhere in bulls.

Clinical Signs and Differentials The majority of cases of cryptorchidism in stallions are unilateral.[7] Although testicular descent can occur in horses up to 2 years of age, the testes are normally descended at birth in large animals.[8] Testes are readily palpated in the scrotum of colts at 30 days of age. Spermatogenesis is inhibited in the abdominal testis because of the elevated temperature within the abdomen. The interstitial cells remain active and secrete testosterone, enabling even bilateral cryptorchids to maintain libido and copulatory activity. The descended testis may be hypertrophic; unilateral cryptorchids are fertile but are not considered sound breeders.[9]

Deep palpation of the superficial inguinal rings may reveal the testis in the canal ("high flankers"). If the testis is not located in the inguinal canal, transrectal palpation or ultrasonography can be performed in stallions and bulls in an attempt to locate a testis or to detect the vas or epididymis entering the superficial inguinal ring, thereby providing evidence of descent into the inguinal canal.[10]

Clinical Pathology Equine cryptorchids have high basal concentrations of testosterone (usually >100 pg/mL) and respond to human chorionic gonadotropin (hCG) administration (10,000 to 12,000 IU IV) with a significant elevation of circulating testosterone within 30 to 60 minutes if testicular tissue is present. Geldings and "false rigs" (geldings with malelike behavior) have low basal concentrations of testosterone (<40 pg/mL) and do not respond to hCG stimulation. Stallion testes contain a high concentration of conjugated estrogens, and a single measurement of high plasma conjugated estrogens (>400 ng/mL) is reported to be almost as reliable in diagnosing cryptorchidism as hCG stimulation.[11,12] Recent data suggest that anti-mullerian hormone (AMH) serum concentrations may serve as a useful marker for the presence of cryptorchid testes in the horse.[13] In some ruminants, measurement of testosterone concentrations before and after administration of hCG has also proved helpful in identifying cryptorchidism.

Treatment and Prognosis Stimulation of testicular descent with repeated injections of gonadotropin-releasing hormone (GnRH), sometimes combined with hCG or acupuncture, has been attempted, but the success has not been critically evaluated. Surgical removal of the abdominal and scrotal testes is often prescribed; however, many breed registries allow the breeding of stallions with unilateral cryptorchidism. Bilateral cryptorchidism results in sterility because of disrupted thermoregulation of both testes. Surgical placement of a retained testis into the scrotum is not considered an ethical procedure.

Testicular Degeneration

Definition and Etiology Testicular degeneration is an acquired condition with multiple etiologies.[1] Infections or traumatic orchitis may progress to permanent degeneration. Degeneration may be associated with thermal factors after elevation of body temperature by systemic infections; prolonged increase or decrease in ambient temperature; scrotal insulation from edema, dermatitis, scrotal hernias, or hemorrhage; or abnormal conformation resulting in an incompetent heat exchange system.[2-4] Degeneration results when testicular vasculature becomes occluded in torsion of the spermatic cord.[5] Obstruction of the proximal epididymis and malformation of the efferent tubules results in degeneration caused by pressure within the seminiferous tubules.[6] A variety of chemicals and ionizing radiation are capable of inducing testicular degeneration. Administration of steroid hormones may induce testicular degeneration by inhibiting secretion of gonadotropins.[7] Gradual degeneration also occurs with increasing age.[8]

Clinical Signs and Differentials Diagnosis of testicular degeneration is based on physical examination and semen evaluation. Testes are typically thought to be small, but they may be normal size. The testicular consistency and elasticity of the testes is also decreased. Semen examination reveals a low concentration of spermatozoa, a decreased number of spermatozoa in the ejaculate, and a high percentage of spermatozoa with morphologic defects, sometimes with premature (round) germ cells.[1] Without a history of normal testis size and function before atrophy, differentiation from testicular hypoplasia is usually not possible. Discrepancies between testicular size (measured by scrotal width in stallions and scrotal

circumference in ruminants) and daily sperm output may indicate testicular degeneration.[9,10]

Clinical Pathology The measurement of plasma hormone concentrations may be helpful in establishing a diagnosis of testicular degeneration in large animals. However, the relationship between the concentrations of various hormones and the parameters of testicular function appears to be quite variable. Measurements of hormone concentrations in subfertile stallions have demonstrated that serum gonadotropins can be abnormally low or high.[11] Hormonal criteria for confirming testicular degeneration in stallions typically include low concentrations of testosterone, with concurrent low LH concentrations in early cases of degeneration or with high FSH and low estradiol concentrations in cases of chronic (or irreversible) testicular degeneration. Less is known about hormone concentrations in other large animal species with testicular dysfunction. Scrotal insulation of rams resulted in an increase in plasma FSH concentrations and a decrease in plasma testosterone concentrations within 1 to 4 weeks.[12]

Testicular biopsy can confirm degeneration.[13] Excision of an amount of tissue sufficient for evaluation often results in hemorrhage, pressure degeneration, and necrosis.[2] Therefore testicular biopsy is usually undertaken only as a final recourse. However, testicular biopsy in the stallion appears to be a relatively safe procedure.[14]

Treatment and Prognosis Once testicular degeneration has occurred, treatment is usually of no benefit. However, any factors that might contribute to testicular degeneration (such as febrile conditions or systemic illness) should be corrected. Treatment of injuries of the scrotum and its contents is described earlier in this chapter.

Recent findings regarding variations in serum hormone concentrations in subfertile stallions have stimulated an interest in gonadotropin replacement therapy, including the use of GnRH. Although the hypothalamic-pituitary-testicular (HPT) axis of the stallion is remarkably refractory to GnRH-induced downregulation compared with other domestic species,[15] there are few controlled studies to evaluate the effectiveness of GnRH therapy. In one study, pulsatile or constant administration of GnRH for 20 weeks did not promote testicular growth or alter spermatozoa output in reproductively sound or unsound stallions.[16] In some cases, degeneration is temporary and improved semen quality is evident after 2 to 5 months. The prognosis for an animal recovering its fertility and the economic losses the client will sustain from treatment and decreased production must be considered when deciding whether treatment of testicular degeneration is warranted.

Orchitis

Definition and Etiology Orchitis is most commonly caused by infection or trauma. Bacterial infections may develop hematogenously or occasionally by retrograde movement from infected accessory sex glands. Periorchitis or epididymitis may coexist.[1] Testicular enlargement is due to edema that accompanies the inflammatory reaction. Contusion and inflammation of the testes occur in racing stallions, particularly Standardbreds. *S. zooepidemicus* is commonly isolated from infectious orchitis in stallions. In bulls, infectious orchitis is caused by *B. abortus*, *M. tuberculosis*, *T. pyogenes*, *Nocardia farcinica*, bovine herpesvirus 1 (IBR-IPV), and other miscellaneous organisms.[2] Epididymitis orchitis in rams may be associated with *B. ovis* or *Actinobacillus seminis* and *Actinobacillus*-like organisms.[3]

Clinical Signs and Differentials Acutely orchitic testes are hot, swollen, and painful. The swollen testis is turgid because of restriction by the tunica albuginea. Edema of the testicular parenchyma and concurrent presence of periorchitis or epididymitis may be detectable by ultrasound examination. Increased testicular temperature, congestion, and interference with circulation lead to ischemia and infarction. Abscesses sometimes develop, occasionally culminating in purulent liquefaction of testicular parenchyma. Testicular atrophy and fibrosis follow as the condition becomes chronic.

Acutely affected animals may refuse to mate. Ejaculates may contain numerous white blood cells. Variable mineralization of seminiferous tubules can occur as a chronic change. Decreased sperm motility and increased sperm morphologic abnormalities are evident. Standardbreds affected by acute orchitis may switch from a trot to a pace, whereas Thoroughbreds may suddenly develop a hopping gait.

Treatment and Prognosis Treatment consists of scrotal cryotherapy and systemic administration of antiinflammatory drugs. Bacterial orchitis is treated with antibiotics chosen by semen culture and in vitro sensitivity. Antibiotic therapy should continue for 1 to 2 weeks beyond resolution of testicular swelling and pain. Testicular atrophy and sterility are common sequelae to orchitis. Changes in the testes, including precise measurements of in situ testis size, are followed by sequential ultrasound examinations or caliper measurements. Serial semen analyses over a period of several months allow the clinician to monitor response to treatment and return of testes to normal production of spermatozoa.

Prevention and Control Support devices may aid in preventing recurrence of traumatic orchitis in racehorses. With *Brucella* or *Actinobacillus* orchitis in sheep, the presence of subclinical carriers in the flock must be considered.

Testicular Neoplasia

Definition and Etiology Primary testicular tumors are uncommon in large animals but may be slightly more frequent in older bulls than in stallions or rams. Testicular tumors originate from the interstitial (Leydig) cells, Sertoli cells, and the germinal epithelium. Testicular teratomas and lipomas of the testicular surface and lymphosarcoma also occur.[1-3] Although the incidence of testicular tumors is relatively greater in retained than in scrotal testes in dogs, this predisposition has not been confirmed in large animals, perhaps because most are castrated at an early age before the time of usual onset of testicular neoplasia. Retained testes in the horse, however, are thought to be more prone to neoplasia. Teratomas in particular are found more commonly in cryptorchid than in scrotal testes, probably because they are embryonal in origin and their size prevents migration of the testis into the scrotum.

Seminomas are the most common primary testicular tumor in the descended testes of adult stallions, with the majority occurring in stallions older than 10 years of age.[4] Seminomas are not hormonally active and are usually benign, but they may be malignant and invade inguinal and abdominal tissues.[5] Seminomas are rare and benign in bulls and are rarely seen in aged rams, in which they are occasionally highly malignant. The tumor arises from the germinal epithelium, occurs in retained and scrotal testes, and grows rapidly.

Interstitial (Leydig) cell tumors have been reported in stallions and bulls and can have a negative impact on semen quality and fertility.[6] Most do not produce androgenic hormones. They may be single or multiple in one or both testes and are commonly 1 to 2 cm in diameter.

Sertoli cell tumors are reported in horses, cattle, and sheep, but they are rare. Although metastasis is uncommon, extension of neoplastic tissue into the testicular vein and lymphatics can result in hydrocele. Because of the importance of Sertoli cells in spermatogenesis, these tumors are likely to exert an adverse

effect on semen quality and fertility. Tumors in newborn or young calves may be due to impaired embryogenesis.[3]

Teratomas are usually a benign tumor commonly found in cryptorchid testes of horses.[1,7] They are rare in other large domestic species. The tumors are often cystic and vary in diameter from 10 to 25 cm or more. Structures present in teratomas arise from all three embryonic layers and include hair, nervous tissue, salivary glands, adipose tissue, cartilage, and bone.[7]

Clinical Signs and Differentials Neoplastic testes are often larger than normal, with an affected scrotal testis often twice the size of the unaffected testis, especially in cases of seminoma. Abdominally located testicular tumors can be quite large. Neoplastic testes, particularly seminomas, are typically irregular and firm. Swelling may extend into the spermatic cord, and pain that interferes with breeding or is evident on palpation may be present. Ultrasonographic appearance of testicular tumors tends to be discrete, well-circumscribed hypoechoic areas within the usually homogeneous testicular parenchyma.[5] However, seminomas may involve so much of the testis at the time of diagnosis that differentiation between neoplastic and normal tissue can be difficult.

Swelling of the affected testis may interfere with thermoregulation of the contralateral testis, resulting in decreased sperm production. Semen examination, however, may reveal seminal parameters to be within normal limits, and fertility may be acceptable. A significant amount of normal testicular parenchyma may remain covering the tumor, and living spermatozoa may or may not be present in the epididymis on the same side.[8]

Treatment and Prognosis Testicular tumors should be surgically removed. Although metastasis is uncommon, early identification and removal of unilateral tumors prevents spread to other tissues. If semen quality is satisfactory in seasonal breeders, removal may be delayed until the breeding season is completed to avoid the transient decrease in semen quality associated with postsurgical swelling. If neoplasia is bilateral, surgical removal may be delayed until semen quality deteriorates sufficiently to negate the use of the animal for breeding.

Infertility Caused by Diseases of the Spermatic Cord

Torsion of the Spermatic Cord

Definition and Etiology Torsion of the spermatic cord occurs more commonly in stallions than in other large animals, possibly because of the horizontal position of the testes within the scrotum. Torsions may be transient or permanent and typically are of 180 to 360 degrees, but rotations may be greater.[1] Abnormal elongation of the caudal ligament of the epididymis (scrotal ligament), the proper ligament of the testis, or an excessively long mesorchium may encourage spermatic cord torsion.[1,2]

Clinical Signs and Differentials Torsion of the spermatic cord occurs in degrees that vary from those producing no pain or abnormality of semen to those involving vascular obstruction and acute colic. Torsion is often a transient condition that does not interfere with testicular function or cause pain.[2] In those cases the testis is usually rotated 180 degrees or less. If torsion is of sufficient degree to result in vascular compromise, acute pain results.[2,3] Diagnosis of torsion of the spermatic cord is aided when displacement of the tail of the epididymis and scrotal ligament is evident on palpation. The head of the epididymis is normally located craniodorsal to the testis, and the tail lies caudally, where it is attached to the testis by the proper ligament. The tail of the epididymis is most readily palpable, and its location is helpful in determining the degree of rotation. Torsions of 360 degrees or greater generally cause clinical signs that must be differentiated from strangulation of herniated contents into the scrotum. The primary method used to differentiate between the two conditions is palpation per rectum of the superficial inguinal ring to identify if herniation is present.

Clinical signs of vascular impairment with spermatic cord torsion include abdominal discomfort, elevated heart and respiratory rates, unilateral swelling and edema of the scrotum, and increased testicular temperature.[4] Affected testes are painful and quickly become soft and friable.[2,3]

Treatment and Prognosis Manual correction of spermatic cord torsion is sometimes possible, but recurrence is likely. To attempt manual correction, the horse is sedated and the testis is rotated in the direction opposite the torsion. Both hands are used to reposition the scrotum as the testis and its tunics are rotated. Surgical correction is indicated if manual correction is not possible. Nonsteroidal antiinflammatory drugs and analgesics may be administered to control pain.

The rapidity with which correction must occur is unknown; human testes may be salvageable if torsion is corrected within 6 hours. If hemorrhage or necrosis of the testis is evident, removal is indicated because the contralateral testis may become permanently damaged. The mechanism of the damage is probably immunologic, resulting from antibodies to spermatozoa liberated as a result of ischemia.[4]

Varicocele

Definition and Etiology Varicoceles are abnormally distended and tortuous veins of the pampiniform plexus.[1] Varicoceles are most often recognized in rams, where dilations in vessels may reach 15 cm and discourage movement and libido. Data from slaughterhouse necropsies show an increased incidence of varicoceles with age, reaching approximately 2% in rams 3 years and older. Varicoceles have been reported very infrequently in stallions.

Varicoceles may result from insufficiency of veins draining the testis or a deficiency of the fascia and connective tissue surrounding those veins that allows backflow and stasis of blood in the vessels. Infertility associated with varicocele is thought to be due to disturbance of the local thermoregulatory mechanism, causing increased testicular temperature and subsequent disturbance in spermatogenesis. In addition, the varicose veins could affect the level of oxygenation and normal interchange of hormones between the arteries and veins. In rams, bilateral varicoceles are more common than unilateral varicoceles.[1,2] This is in sharp contrast with men, in which 70% of varicoceles are unilateral and located on the left side.[2] Concomitant atrophy of the testis is common in rams. Bilateral varicoceles and atrophied testes have been reported in the ram.[3]

Clinical Signs and Differentials Diagnosis of varicocele is made by palpating the dilated tortuous veins ("bag of worms") within the spermatic cord. Confirmation of the varicocele has been accomplished by ultrasonographic examination in stallions. Large echolucent areas in the venous plexus of the spermatic cord, sometimes with concurrent distention of the central vein of the testis, are described as the identifying features. The ultrasonographic appearance of a suspected varicocele can be compared with the structures of a noninvolved contralateral testis and spermatic cord or with those of another nonaffected animal.

VetBooks.ir

VetBooks.ir

Thrombosis of the varicocele can occur. The large, organizing laminated thrombi can be mistaken as *Corynebacterium pseudotuberculosis* abscesses in the scrotal fascia of rams. Varicoceles might also be mistaken for sperm granulomas of the caput epididymis. Unless thrombosis has occurred, varicoceles are typically fluctuant and soft and fail to elicit pain when palpated.

Treatment and Prognosis Surgical removal of varicocele has improved semen quality and fertility of some human patients but has not been reported in large animals. Thrombosis of a varicocele necessitates unilateral castration, with transection of the spermatic cord proximal to the thrombus. Castration is also recommended for rams because of potential heritability risks.

Infertility Caused by Diseases of the Epididymis and Accessory Sex Glands

Epididymitis

Definition and Etiology Epididymitis is caused by infection or trauma and may occur separately but is commonly secondary to orchitis or infection of the accessory sex glands.[1] The tail of the epididymis is commonly involved, but the head and body may be affected. *S. zooepidemicus* is commonly isolated from equine epididymitis, although a number of other miscellaneous organisms, including *Proteus mirabilis*, have been incriminated.[2] In bulls, *B. abortus*, *A. seminis*, *T. pyogenes*, and other miscellaneous organisms cause epididymitis.[1] In mature rams the disease is commonly associated with *B. ovis*, whereas in ram lambs organisms from the *Actinobacillus*, *Haemophilus*, *Histophilus*, and *Corynebacterium* groups are prevalent.[3] Routes of infection have been postulated to be hematogenous, venereal, or ascending from genitourinary passages, similar to routes of infection proposed for orchitis. Injuries, such as penetrating wounds, especially during shearing, could compromise the scrotal sac, leading to epididymitis. All routes of infection are likely to occur to some degree, depending on the pathogen and species involved. In an interesting study performed in yearling rams, conjunctival inoculation of *B. ovis* culminated primarily in localized infections of the reproductive tract, which tended to first result in lesions of the distal tail of the epididymis.[4]

Clinical Signs and Differentials Diagnosis of epididymitis is based on detection of clinical signs that include pain when irregular swellings of the epididymis are palpated, changes in shape and texture of the organ, adhesions between the epididymis and scrotal tunics, and enlargement of the tail of the epididymis. The course of epididymitis varies from acute swelling and edema to chronic abscesses, periorchitis, and fibrosis. Granulomas may develop if sperm escape into surrounding tissue.[1,5] In rams, epididymal lesions may be palpable along the entire length. Abnormal sperm morphology (especially detached heads) and leukocytes in the ejaculate may be seen before lesions are palpable.[6]

Animals affected with the *Actinobacillus*, *Histophilus*, and *Haemophilus* groups of organisms may acquire an epididymo-orchitis syndrome.[7] Affected rams are usually younger than 1 year of age. They may be subclinical carriers or acutely ill with pyrexia, depression, pain as evidenced by an arched back, and unilateral or bilateral swelling and tenderness of the scrotal contents. If these animals recover from the acute phase, the disease may become chronic and is characterized by an enlarged, firm, and often irregular epididymis; palpable adhesions of portions of the epididymis to the testis and vaginal tunics; atrophic testes; abscess formation; and draining fistulas to the scrotal surface. Ultrasonographic examination of the epididymis may reveal dilated ducts, fluid accumulation around the tail of the epididymis, and cystic areas within the epididymis that contain purulent material.

Clinical Pathology Inflammatory cells may be present along with abnormal sperm in the ejaculate of affected animals. Seminal leukocytes correlate positively with epididymitis lesions and correlate negatively with seminal quality.[6] Bacteriologic culture or PCR analysis of the semen may aid in identifying specific infectious causes. Serologic tests for *B. ovis* and *Helcococcus ovis* are available and are helpful in determining exposure to the organisms.[7]

Treatment and Prognosis Infectious causes of epididymitis are treated with systemic antibiotics selected by in vitro sensitivity. The ability of the antibiotic to gain access to the epididymides must be considered. Treatment should continue for 1 to 2 weeks after inflammatory cells disappear from the semen. In unilateral cases, removal of the testis, epididymis, and spermatic cord on the affected side may salvage some valuable animals for breeding. If unilateral castration is elected, sequential postcastration examinations are indicated to ensure that infection has not spread to remaining reproductive organs.

Treatment of ram epididymitis is usually not recommended but might be attempted in valuable animals with minimal clinical signs. Oxytetracycline 10 mg/kg and dihydrostreptomycin 25 mg/kg IM twice daily for 7 days resolved shedding of *B. ovis*.[8] Because ovine brucellosis is a reportable disease in many states and provinces, treatment of affected rams should be conducted with appropriate regulatory oversight.

In cases of moderate or severe bilateral epididymitis, the prognosis for recovery is poor. Obstructions and granulomas usually develop, resulting in sterility. Testicular atrophy is a common sequela to epididymitis.

Seminal Vesiculitis (Vesicular Adenitis)

Definition and Etiology Inflammation of the vesicular glands is uncommon in stallions but more likely in bulls.[1] Bacterial infections including *B. abortus* and *P. aeruginosa* are incriminated in stallions.[2-4] In bulls, a variety of microorganisms have been isolated from cases of vesicular adenitis, including *Actinobacillus actinoides*, *Aeromonas hydrophila*, *T. pyogenes*, *B. abortus*, *C. psittaci*, *C. renale*, *C. pseudotuberculosis*, *E. coli*, *H. somni*, *M. tuberculosis*, *Mycobacterium paratuberculosis*, *Mycoplasmas*, *P. mirabilis*, *Streptococcus*, *Staphylococcus*, *Ureaplasmas*, and *T. foetus*.[1,5-17] In bulls, the most frequent microorganism isolated is *T. pyogenes*.

Vesicular adenitis may affect bulls of all ages but is most common in young, growing bulls fed high-energy rations and housed together.[1] The prevalence may reach 20% to 30% in small groups of yearling bulls in close confinement.[18] The role of viral pathogens in outbreaks of the disease is not defined. Infections may arise by either ascending or descending routes from other areas of the urogenital tract, or hematogenously. Some bulls with vesicular adenitis submitted to necropsy presented anatomic defects at the level of the seminal colliculus, which could impair its normal opening and closing.[19] In addition, it has been suggested that spermatozoa or urine reflux into the vesicular glands could produce inflammation.[20] Frequent homosexual activity among young bulls, high nutrition, and fast growth rates may be involved in spread of the infection.[1]

Clinical Signs and Differentials The seminal vesicles of affected stallions may be of normal size or enlarged and

painful when palpated per rectum.[2,3] Stallions may refuse to cover or may be unable to ejaculate.[21] Semen contains numerous neutrophils and blood. Fertility of infected semen is reduced. Bacterial pathogens are readily recovered from semen of affected stallions, but special culturing methods may be needed (described below).

Bulls affected with vesicular adenitis may be asymptomatic or exhibit nonspecific clinical signs other than deterioration of semen quality. In severe cases, pelvic inflammation and peritonitis result in pain reflected by reluctance to move, stiff gait, tense abdomen, difficulty on defecation, and refusal to mate. In acute vesicular adenitis the palpation per rectum of the vesicular glands produces pain, and the examination is positive for an enlarged gland with loss of its lobulation and increased consistency. Other reproductive organs, particularly the ampullae, testes, and epididymides, may be inflamed.[1] Necropsy specimens of bulls with vesicular adenitis have shown concomitant inflammation of the prostate and bulbourethral glands (seminal vesicular syndrome)[1,22]; however, these changes cannot be detected by palpation per rectum. The vesicular glands may not be significantly increased in size during the acute phase. If inflammation becomes chronic, the glands usually enlarge, eventually losing their lobularity and becoming fibrotic. Abscesses are often caused by *T. pyogenes* and may rupture into the rectum or urinary bladder. Transrectal ultrasonography can be used to determine the degree and extension of the lesion in the vesicular glands.[23,24]

Purulent exudate is present in the ejaculate, sometimes as thick clots. Neutrophils may become less evident in semen as the condition becomes chronic. The ejaculate volume could be reduced. Presence of floccules or flakes in the ejaculate can be observed, and color can vary from normal to yellow-brown. Poor sperm motility, increased morphologic defects, and an elevated pH are characteristics of semen from bulls with vesicular adenitis.

Fertility of mildly affected bulls may remain satisfactory. More extensive involvement in which semen quality is markedly affected results in subfertility or infertility.[18] Semen from bulls with vesicular adenitis freezes poorly, and antibiotics used in extenders usually do not control the high numbers of bacteria present.[18,25,26]

Clinical Pathology

Bacterial pathogens can be recovered from the semen of affected stallions. However, without other evidence of infection of the accessory sex glands, recovery of pathogens from the semen should be interpreted with caution because the bacteria could originate from another location. Repeated samples for culture should be obtained from the sheath, penis, fossa glandis, preejaculatory fluid, urethra (before and after ejaculation), and seminal vesicle effluent manually expressed through a sterile urethral catheter positioned at the colliculus seminalis. Prostatic fluids can be collected through a catheter by massage per rectum. The first jet of a fractionated ejaculate includes the secretions of the ampullae. Alternatively, a suitable fiberoptic endoscope can be passed in the urethra to the level of the seminal colliculus and into the seminal vesicles. Purulent material may then be aspirated for culture.

Vesicular secretions from bulls can be collected either by using a sterile artificial vagina[9] or by extending and disinfecting the penis followed by irrigation of the distal urethra with sterile saline. A sterile catheter is then passed 30 cm into the urethra, and the accessory sex glands are massaged to stimulate their secretion. Fluid is collected in sterile containers. Recently, a new aseptic technique of semen collection as an alternative of both previous methods was developed. The procedure consists of clipping the preputial hairs, urination, antisepsis of the preputial area, flushing the preputial cavity with antiseptic solution, per rectum massage of accessory sexual glands, and semen collection by electroejaculation. Preliminary studies in healthy bulls using this method showed low contamination of semen samples.[27]

Treatment and Prognosis

Accessory sex gland infections are treated with antibiotics selected by culture and in vitro sensitivity. Antibiotics are administered for 2 to 4 weeks, but treatment failures may occur. Properties of antimicrobials suitable for parenteral treatment of accessory sex gland infections include high lipid solubility, a favorable pKa (higher than the pH of the target tissue or fluid), and low or limited protein binding. The antimicrobial should have a pH that is basic relative to the accessory gland fluid into which penetration is desired.[28] Vesicular and prostatic fluids have a pH of 7.3 to 7.5. Antimicrobials that may prove suitable for treatment include the newer macrolides, which are fat soluble and have a high pKa. Because of its antimicrobial spectrum and tissue diffusion characteristics, enrofloxacin has been found to be effective for systemic treatment of some cases of seminal vesiculitis in stallions. Treatment of stallions by lavage and instillation of antimicrobials directly into the seminal vesicles via a flexible videoendoscope can be accomplished by skilled operators. Removal of the affected gland has been performed in stallions and bulls.[2,25,29,30] A technique used with fair success in stallions with localized vesicular adenitis is repeated irrigation through a catheter guided into the vesicles by endoscopy. Antibiotics are instilled into the vesicular gland lumen after each irrigation. In bulls, some experts recommend antibiotic treatment, either oral or parenteral, for a minimum of 10 days.[31,32] In bulls, direct injection of different medications into the vesicular glands has been reported, but results are mixed.[32-35] In young bulls with vesicular adenitis, parenteral administration of antibiotics was no different than in the "no-treatment" group,[33] which is in agreement with previous reports describing spontaneous recovery.[18,35] Additional measures to treat inflammation include performing repetitive semen collections, not only for monitoring the ejaculate but to evacuate the inflammatory secretions from the seminal glands as well.[18] Massage of the seminal glands per rectum has also been proposed. The inclusion of nonsteroidal antiinflammatory drugs to reduce inflammation, pain, and fibrosis has also been suggested.[18]

Seminal vesiculectomy could be used as an alternative after lack of response to medical treatment. Different techniques have been applied with variable results and complications.[29,30,36] If the bull recovers from surgery, it can exhibit a decrease in seminal parameters such as motility, volume, sperm output, and seminal constituents, which could adversely affect the freezability of the semen.

The prognosis of vesicular adenitis is difficult to determine due to the multiple etiologic organisms. Therefore the prognosis for correction of vesicular adenitis is only fair to poor. Mild cases may recover spontaneously in 2 to 3 months. In chronic cases, glands that do not abscess become fibrotic and destroyed even though purulent material does not persist in the ejaculate. In stallions with vesicular adenitis, immediate filtration of the ejaculate in order to remove cellular debris and mixing of semen in an appropriate antibiotic-containing extender to control bacterial growth may maintain sperm motility and fertility.[21]

Blockage of the Efferent Ducts (Sperm Stasis)

Blockage of the efferent ducts between the testes and penile urethra sometimes occurs in stallions. If the condition is bilateral, azospermia results despite apparent ejaculation. The ampullae are frequently tense, and enlargement may be demonstrated by ultrasonography.[1] Massage of the ampullae per rectum followed by frequent intervals for semen collection may result in ejaculation of a semen sample with a high

VetBooks.ir

VetBooks.ir

concentration of spermatozoa, often present as "strings" or "plugs." Large numbers of detached sperm heads, often in clumps, are commonly observed. Collection of semen on a regular schedule may aid in preventing recurrence once the blockage is relieved. Some refractory cases have responded to administration of oxytocin or cloprostenol prior to attempt at breeding or semen collection. Empiric treatment by blockade of β-receptors and stimulation of α-receptors has been successful in some stallions that fail to ejaculate.[2]

Sperm granulomas caused by accumulation of spermatozoa in blind efferent ducts are a common cause of infertility in the buck and ram. Granulomas have also been identified in stallions.[3]

Critical Care and Fluid Therapy

K. GARY MAGDESIAN, *Consulting Editor*
MARIE-EVE FECTEAU, DARIEN FEARY, and C. LANGDON FIELDING

Equine Fluid Physiology

C. Langdon Fielding

Physiologic fluid compartments consist of total body water (TBW), extracellular fluid volume (ECFV), and intracellular fluid volume (ICFV). TBW is the most clearly defined compartment because it represents the total amount of water comprising an individual. Values for TBW in adult horses have been reported to range from 0.623 to 0.677 L/kg.[1-4] Values in foals are larger than in adult horses and have been reported as 0.74 L/kg.[5] Acute changes in TBW in clinical patients can be detected with serial body weight measurements, but this becomes less accurate over longer periods of time.

ECFV represents the component of TBW that is not contained within the cells. This includes plasma volume, interstitial volume, and transcellular compartments (gastrointestinal tract, joint fluid, cerebrospinal fluid [CSF], body cavities, etc.). The ECFV has been measured using a number of techniques in horses; reported values in adult horses range from 0.214 ± 0.01 to 0.253 ± 0.01 L/kg.[1,6] Estimations of ECFV in foals are significantly larger, including 0.38 to 0.40 L/kg in newborn foals and 0.290 L/kg in foals 24 weeks of age.[5,7] Plasma volume has been determined to be 0.050 L/kg in healthy adult horses and 0.090 in foals at 2 days of age.[5,7]

ICFV is the volume of fluid contained within cells. It has been estimated as the difference between TBW and ECFV. Bioimpedance technology has also been used to estimate the volume of intracellular space in horses, whereas standard indicator dilution techniques cannot be easily applied to the ICFV.[1,2] Reported values for ICFV in adult horses range between 0.356 ± 0.01 and 0.458 ± 0.06 L/kg.[1,2] The ICFV of newborn foals is estimated to be 0.38 L/kg.[5]

Rapid changes in fluid balance and compartment volumes can occur during disease states, especially critical illness. The next section discusses the physiologic relationships between these fluid volumes.

Plasma and Interstitial Balance

Although both the plasma volume and the interstitial volume are components of the ECFV, the plasma volume is separated from the interstitial space by blood vessel walls, with constant flow of fluid and proteins into the interstitial space. The plasma and interstitial volume therefore are in constant flux, and a single equation (the Starling hypothesis) describes the flow between these two spaces as net capillary filtration:

$$\text{Net capillary filtration} = K_f([P_{cap} - P_{if}] - \sigma[\pi_p - \pi_{if}])$$

where K_f is the capillary filtration coefficient, being dependent on capillary surface area and hydraulic conductivity. The other five terms in the equation represent the primary determinants of fluid balance between plasma and the interstitium:

1. π_p is the colloid osmotic pressure (COP) within the capillary (capillary oncotic pressure).

   The COP is determined by the concentration of plasma proteins, primarily albumin, and their ability to attract ions. Normal COP in adult horses is approximately 20 mm Hg (19 to 26 mm Hg) and in neonatal foals is 18.8 ± 1.9 (15 to 22.6) mm Hg.[8,9] Hypoproteinemia with resultant decreased oncotic pressure can occur during a variety of diseases in horses but is most often a result of loss or decreased production. Losses most commonly occur through the diseased gastrointestinal tract in large animal species (protein-losing enteropathies); losses may also occur as a result of glomerular diseases or large accumulations of protein-rich effusions within body cavities or the interstitial space. Decreased production of protein (specifically albumin) occurs in response to systemic inflammation because albumin is a negative acute phase protein.[10] Hypoproteinemia also occurs uncommonly because of liver disease.[11] Decreases in COP are also commonly observed during intravenous fluid therapy in horses undergoing general anesthesia.[12]
2. π_{if} is the COP within the interstitium.

   Interstitial COP is more difficult to measure than plasma COP, but estimates of this number include 12 to 15 mm Hg in other species under experimental conditions.[13] Changes in total plasma protein concentration are likely to also affect the interstitial protein concentration and therefore alter both oncotic pressure components in Starling's equation. This may explain why some horses with significant hypoproteinemia do not show clinical signs of interstitial fluid accumulation (i.e., edema). That is to say, the gradient between capillary and interstitial oncotic pressure is only minimally affected when both have decreased proportionally, especially with time. It has been speculated that acute changes in plasma total protein concentration, however, may lead to edema formation more often than chronic hypoproteinemia; this

VetBooks.ir

is because of a relatively larger decrease in plasma protein concentration as compared with that in the interstitium with acute disease. Conversely, administration of hyperoncotic intravenous fluids (fluids with a COP greater than 20 cm H_2O) can potentially shift the balance of oncotic pressure back to the vascular space by raising plasma COP. However, the colloid molecules from these fluids must remain within the vascular space to have this effect, which may be negated by significant alterations in capillary permeability.

3. P_{cap} is the hydrostatic pressure within the capillary.

   Vascular hydrostatic pressure represents the pressure of plasma within the vessels pushing out toward the interstitium. A number of factors influence this pressure, including blood volume, vascular tone, and central venous pressure (CVP). This outward pressure on the vessel walls serves as the driving pressure for the continuous flux of fluid and protein out of the vessels into the interstitium. Pathologic increases in hydrostatic pressure can be caused by right-sided heart failure or other obstructive processes, such as venous thromboses, which can lead to edema formation. Pulmonary capillary hydrostatic pressure increases with left-sided heart failure and significant pulmonary vasoconstriction. Administration of intravenous fluids can also increase capillary hydrostatic pressure. Fluid losses resulting from diuretic administration and acute blood loss are examples of changes that result in decreased capillary hydrostatic pressure.

4. P_{if} is the hydrostatic pressure within the interstitium.

   The hydrostatic pressure of the interstitium varies in different tissues but often is overlooked as a significant contributor to fluid balance between the vascular and interstitial spaces. The importance of the interstitial hydrostatic pressure as it pertains to fluid balance has been reviewed by Reed and Rubin.[13,14] Degeneration of the interstitial collagen network may cause a decrease in interstitial hydrostatic pressure, resulting in a shift of fluid into the interstitium. Inflammatory cytokines have been implicated as a cause for these changes in interstitial hydrostatic pressure. Severe burn injury can also result in marked negative pressures within the interstitium, causing a draw of fluid into the interstitial space and subsequent edema formation. In the future there may be practical therapeutic options to manipulate interstitial hydrostatic pressure and alter fluid balance.

5. σ is the capillary reflection coefficient for proteins.

   Changes in capillary permeability can dramatically increase the flux of fluid and protein from the intravascular space into the interstitium.[15] If this increase in flow cannot be balanced by a corresponding increase in lymphatic return, edema results. Increased vascular permeability has been regarded as a major mechanism of edema formation; however, it may be only one component of the significant fluid shift that results from a systemic inflammatory response syndrome (SIRS). Adult horses and neonatal foals may have significant differences in interstitial composition and vascular permeability. It has also been proposed that foals have an increased capillary filtration coefficient as compared with adults.[16] These hypotheses may explain the propensity of neonatal foals to form edema relatively easily in response to overzealous fluid administration. Because of this increased risk, careful monitoring and serial assessment of the balance between plasma volume and the interstitium are warranted when treating neonatal foals with fluid therapy.

Extracellular to Intracellular Fluid Volume Relationship

There are three main determinants of net movement of fluid between the ECFV and ICFV: tonicity of the ECFV, tonicity of the ICFV, and cellular membrane permeability.

TONICITY OF THE ECFV. The tonicity (or effective osmolality) of the ECFV is estimated by the following equation[17]:

$$\text{Effective extracellular fluid osmolality} = (2 \times \text{Na}) + \frac{\text{Glucose}}{18}$$

Under normal circumstances, sodium and chloride are the primary determinants of ECFV tonicity; the equation doubles the sodium concentration rather than including the concentration of specific anions, some of which may not be easily measured. It should be noted that blood urea nitrogen (BUN) is not included in the tonicity formula because BUN is an ineffective osmole. Other effective osmoles can be added to the ECFV, thereby increasing tonicity and inducing a shift of water from the ICFV to the ECFV. The tonicity of the ECFV is primarily regulated by vasopressin (antidiuretic hormone, or ADH). Administration of fluids with a tonicity greater or less than ECFV tonicity is a means to manipulate the balance of fluid between the ECFV and the ICFV. This explains why hypertonic saline causes a shift of water from the ICFV to the ECFV. Recent mathematic models have been used to predict the influence of tonicity on the absolute volumes of these fluid compartments.[18] Similarly fluid loss that has a tonicity different from the ECFV will also alter the ratio of fluid between the ECFV and the ICFV.

TONICITY OF THE ICFV. The tonicity of the ICFV is primarily determined by the intracellular concentration of potassium and its related anions. The tonicity of the ICFV and ECFV are the same at any given time, a homeostatic mechanism meant as a safeguard to prevent acute changes in cell volume. Any imbalance in tonicity between the two fluid spaces will result in a rapid shift of fluid in order to maintain osmolar equality. The tonicity of the ICFV can be altered over time by the cells in response to changes in ECFV tonicity; an example of such a response is the production of idiogenic osmoles during hypernatremia.[19] Significant changes to ICFV tonicity during disease (resulting from damaged cell membranes) can result in accumulation of intracellular potassium, calcium, or cellular debris.

CELLULAR MEMBRANE PERMEABILITY. Cell membranes are selectively permeable to water and ions. Changes in this permeability usually do not cause large alterations in global fluid balance during healthy states. However, cell membrane damage during disease states can result in significant fluid shifts. In fact, a shift of fluid from the ECFV to the ICFV is an indicator of cellular membrane damage.

Effects of Fluid Physiology on Clinical Fluid Therapy

Specific disease states dictate individualized fluid plans. However, with intravenous therapy the administered fluid enters the vascular space. From there, the characteristics of the administered fluid will determine its movement from the vascular space into the interstitium and from the ECFV to the ICFV. Hyperoncotic or hypertonic fluids result in the greatest relative expansion of plasma volume, with a corresponding reduction in ICFV. Hypotonic fluids result in the smallest increase in ECFV but add volume to the ICFV, resulting from a decrease in the tonicity of the ECFV. Estimates of the volumes of the different fluid spaces (whether based on clinical or laboratory values) before and during fluid therapy will allow for evaluation of the physiologic response in the clinical setting. The standard and universal administration of isotonic and hypo-oncotic fluids (such as lactated Ringer's solution [LRS] or physiologic saline) to all patients regardless of disease condition ignores the available research and clinical insight to suggest otherwise.

General Principles for Fluid Therapy in Critical Care

K. Gary Magdesian

Current guidelines for replacement fluid therapy in human critical care emphasize the "fluid challenge" method, believed to be more effective and safer than traditional estimates of percent dehydration.[1] The author's protocol of fluid administration in horses follows this same algorithm. Considerations for the fluid challenge technique incorporate four primary decision phases: (1) type of fluid, (2) rate and volume, (3) goals or end points of fluid therapy, and (4) safety limits to fluid therapy.

1. Types of fluids include crystalloids (isotonic, hypotonic, and hypertonic) and natural and synthetic colloids. There is much controversy and no consensus as to whether crystalloids or colloids are more effective or advantageous in human critical care.[1] The advantages of both fluid types are capitalized on by using them together in the treatment of some cases of hypovolemia that have concurrent hypoproteinemia. Otherwise, because of cost differences and lack of demonstrated benefit of colloids as compared with crystalloids in terms of mortality for fluid resuscitation in critically ill human patients, the use of colloids cannot be recommended over crystalloids.[2] Recent publications have suggested increased mortality and complication rates in humans receiving hetastarch as compared to crystalloids. See the Fluid Therapy for Diarrhea and Colitis in Horses section later in this chapter. Table 44.1 lists the composition of several commercially available crystalloids that are used in equine practice.
2. The rate of fluid therapy for replacement (i.e., treatment of hypovolemia) is based on the "fluid challenge" principles, whereby a 30- to 60-minute bolus of 10 to 20 mL of isotonic crystalloid per kilogram is administered with subsequent reassessment of perfusion parameters.[1] This rate would be faster for animals dying of hypovolemic shock, with pressure bags sometimes being used for rapid delivery. This fluid challenge method assumes that uncontrolled hemorrhage is not present because that would warrant hypotensive resuscitation instead, where the goal is a mean arterial pressure of 60 mm Hg and just enough perfusion pressure to perfuse organs. Perfusion parameters on the physical examination of horses and foals include mentation, heart rate, mucous membrane color, capillary refill time, jugular fill, extremity temperature (limbs, ears), and pulse quality. Blood or plasma lactate concentration, arterial blood pressure, urine output, and urine specific gravity are additional monitoring tools that aid in assessment for further fluid challenges. After the initial bolus, additional boluses—over 30 to 60 minutes depending on the degree of hypovolemia present—would be administered if perfusion parameters dictate a need for more fluid volume. These are repeated until signs of shock abate, a lack of improvement is noted with subsequent boluses, or fluid limits are reached (see later). Most animals require one to three of these boluses, and rarely are four required. Alternatively, or in addition to isotonic crystalloids, hypertonic saline (7% to 7.5%) can be administered at a rate of 4 mL/kg intravenously (IV) once. Plasma sodium concentration should be monitored, as hypernatremia can result. Because of their distribution that is limited to the central compartment, colloids are bolused at lower volumes than isotonic crystalloids, such as 3 to 5 mL/kg for hetastarch. Up to 10 mL of hetastarch per kilogram may be administered per day, being limited by development of dose-dependent coagulopathies, although concerns over a mortality rate increase and renal injury in human patients has markedly reduced the use of hetastarch in those patients.

   If after reassessment of the perfusion parameters additional resuscitative fluids are deemed necessary, another similar bolus is given, although each subsequent bolus is usually provided at a slightly slower rate unless the patient is markedly hypovolemic. This is repeated until signs of hypoperfusion resolve (end points are achieved) or safety limits are reached and there is no further positive clinical response to fluid bolus administration, at which point inotrope and/or vasopressor therapy is indicated if hypoperfusion persists.
3. The goals or end points of fluid therapy include both replacement and maintenance of fluid balance. *Replacement* refers to the replenishment of fluid deficits, primarily referring to those in the extracellular fluid compartment. *Maintenance fluid therapy* refers to the provision of maintenance fluid requirements to account for metabolism, insensible losses, growth, and ongoing losses. In general terms, *replacement* refers to replenishment of circulating volume and secondarily of interstitial fluid deficits; *maintenance* refers to provision of fluids after hypovolemia and dehydration have been corrected. Maintenance fluid therapy maintains both circulating volume and hydration status, including that of the intracellular compartment. In this section, replacement fluid

TABLE 44.1

Composition of Commercial Replacement and Maintenance Fluids

Crystalloid	Sodium (mEq/L)	Potassium	Chloride	Calcium	Magnesium	Osmolarity (mOsm/L)	Organic Salt
Replacement							
Lactated Ringer's solution	130	4	109	3	0	272-273	28 lactate
Saline (0.9%)	154	0	154	0	0	308	0
Ringer's solution	147-148	4	156	4.5	0	310	0
Plasma-Lyte 148 or Plasma-Lyte A	140	5	98	0	3	294	27 acetate 23 gluconate
Normosol-R	140	5	98	0	3	294	27 acetate 23 gluconate
Maintenance							
Plasma-Lyte 56	40	13	40	0	3	111	16 acetate
Normosol-M	40	13	40	0	3	110	16 acetate
45% NaCl + 2.5% dextrose	77	0	77	0	0	280	0
5% dextrose	0	0	0	0	0	252-253	0

VetBooks.ir

is emphasized; the goals of replacement fluid therapy include rapid correction of hypovolemia by reversal of the signs of shock, including improvement or correction of seven perfusion parameters: tachycardia (except in some neonatal foals, which may not demonstrate tachycardia as a manifestation of hypovolemia), pale mucous membranes, prolonged capillary refill time, cold extremities, poor pulse quality, depressed mentation, and, in horses, reduced jugular fill time. Urine production is another positive sign indicating correction of fluid deficits and subsequent perfusion of the kidneys. Dehydration, or the extravascular fluid deficit, is corrected more slowly than hypovolemia and is marked by reduced skin turgor (increased skin tent), dry mucous membranes, and dry corneal surface (reduced tear production). Additional goals of volume replacement include correction of hypotension, tachycardia, oliguria, and blood lactate concentration.[1] A decrease in urine specific gravity (in the absence of renal failure), an increase in arterial blood pressure and CVP, and improvement in venous oxygen saturation are specific end points. The goals of maintenance fluid therapy are different than those of replacement fluid therapy; they are to maintain a normal degree of hydration by providing for ongoing losses, including insensible losses (respiratory, cutaneous evaporative losses) and any abnormal ongoing losses such as diarrhea or reflux. Maintenance fluid rates for horses vary with ambient temperature, use, diet, and metabolic status. In general, a reasonable starting point for maintenance fluid requirements includes 2 to 3 mL/kg/h for adult horses (possibly slightly lower if off feed) and 4 to 6 mL/kg/h for neonatal foals.[3,4]

4. The safety limits to fluid therapy are indicators of intravascular volume overload, including supranormal CVP, a decrease in arterial oxygen saturation (PaO_2), and clinical indicators of volume overload and overhydration. Once maximal CVP is achieved (10 to 12 cm H_2O in neonatal foals and 15 cm H_2O in adult horses), replacement bolus fluid therapy must stop; if continued, edema may form as systemic and capillary hydrostatic pressures increase in response to further fluid boluses. A decrease in oxygen saturation in serial arterial blood samples, or in SpO_2 measured with pulse oximetry, in a horse receiving fluid boluses may be consistent with the possible development of pulmonary edema; this may precede development of tachypnea, increased respiratory effort, or frank edema in large airways or nostrils. Although no published reports address fluid overload in clinical equine patients, one experimental study evaluating hyperhydration before moderate-intensity exercise in horses suggested the development of arterial hypoxemia during exercise.[5] These animals were administered oral fluids equivalent to 6% of body weight (approximately 26 L of isotonic fluid by nasogastric tube). Hyperhydration resulted in arterial hypoxemia, suspected to be caused by pulmonary edema associated with hyperhydration, during moderate-intensity exercise.[5] Clinical indicators serving as limits to fluid therapy include visible subcutaneous edema and tachypnea; with optimal monitoring, fluid therapy will not be allowed to continue to this point. Another end point or limitation to fluid therapy is a lack of further improvement in perfusion parameters despite repeated fluid boluses. This would indicate that hypoperfusion is not solely due to hypovolemia and may require inotropes and/or pressor agents (e.g., dobutamine and norepinephrine, respectively). If safety limits are reached before the goals of fluid therapy are achieved, the next step is also to turn to inotrope and vasopressor therapy.

Prevention of fluid overload should be emphasized to the same degree as provision of fluid therapy. Fluid overload and tissue edema are very detrimental to tissue and organ health, as are dehydration and hypovolemia.

See the Fluid Therapy for Diarrhea and Colitis in Horses section later in this chapter.

Critical Care and Fluid Therapy Monitoring Techniques

K. Gary Magdesian

Monitoring tools provide for advanced critical care in the large animal intensive care unit. Several of these tools are pertinent to fluid therapy and provide guidance, end points, and safety limits. Many of these tools allow for direct monitoring of critical patient status during administration of therapy, whereas others provide indirect information through hemodynamic data. Both of these factors are important to overall case management of the critically ill equine patient.

Central Venous Pressure

Central venous pressure (CVP) is the pressure within the vena cava; the term most commonly refers to that within the cranial vena cava in most species. It is determined by blood volume, venous tone, and cardiac contractility. Increases in blood volume or venous tone increase CVP, as does suboptimal cardiac function. The use of CVP as a measure of adequacy of fluid resuscitation has been much debated, but less controversial is its utility as a limit on fluid administration. With serial measurements CVP can provide a limit to the administered volume of fluid. Normal CVP is approximately 2 to 12 cm H_2O (1.5 to 8.8 mm Hg) in foals and 5 to 15 cm H_2O (3.7 to 11 mm Hg) in adults.[1-4] Subnormal to negative CVP values indicate hypovolemia; however, normal values do not necessarily imply euvolemia. This is because CVP is affected by compensatory responses such as venoconstriction and by cardiac contractility and intrapleural pressures, among others.

CVP is easily measured in neonatal foals using 20- to 30-cm central venous catheters, including long-term single- to triple-lumen polyurethane intravenous catheters placed in the jugular vein. Placement can be easily confirmed through thoracic radiography, with the radiopaque catheters being visualized in the cranial vena cava just cranial to the cardiac silhouette. Measurements can be obtained in adult horses with the use of 55-cm commercial CVP catheters placed in the lower jugular vein. CVP can also be measured by passing a smaller gauge polyurethane catheter or polyethylene tubing through a 14-gauge, 5¼-inch standard intravenous catheter placed in the jugular vein. The actual measurement can be recorded with a disposable water manometer (for spot or intermittent readings of the CVP value) or using a pressure transducer for continuous waveforms. Interpretation of CVP waveforms requires knowledge of component waves and descents, including the "a," "c," and "v" waves, and the "x" and "y" descents. The "a" wave represents atrial contraction. The mean of the "a" wave is the appropriate point at which to measure CVP (during end-expiration in a spontaneously breathing patient). The "c" wave is associated with tricuspid valve closure and a bulging of the valve into the right atrium, and the "v" wave is caused by atrial filling from venous return. The "x" descent occurs after the "a" wave and represents the fall in pressure associated with atrial relaxation. The "y" descent occurs after the "v" wave, representing a drop in CVP caused by ventricular relaxation and reopening of the atrioventricular valves.

High CVP readings occur with fluid overload, as well as with pericardial tamponade, pleural effusion, or pneumothorax. False increases may result from catheter occlusion and air within the lines. For accurate and consistent serial results, a zero reference point should be selected and used for each measurement. The top of the sternal manubrium is a good reference point for the level of the pressure transducer or water manometer. The pressure transducer or water manometer

VetBooks.ir

can be taped to a fluid pole, providing a fixed zero point for repeated measurements in standing horses. Precision and reliability are limited by variable zero reference points, the effects of afterload and ventricular compliance, and alterations in intrathoracic pressure.[5]

It should be noted that adequacy of intravascular volume cannot be guided by any one CVP level. There is not a linear relationship between intravascular volume and filling pressures, and CVP should be regarded as only an indirect estimate of volume. Serial measurements and trends over time are more useful than single numbers. CVP can be used on a clinical level for monitoring fluid therapy as follows: If the patient responds to fluid boluses without increases or with only minor increases (2 to 3 cm H_2O) in CVP, it is appropriate to continue infusions until signs of hypoperfusion are reversed or improved, as long as other signs of fluid overload are not present.[5] Additional guidelines used in human patients are as follows: If the CVP increases to 3 to 7 cm H_2O (2 to 5 mm Hg), the infusion should be paused and perfusion reevaluated after a 10-minute wait. If the change in CVP was an increase of 7 cm H_2O or greater (≥5 mm Hg) after the fluid bolus, the infusion is stopped.[5] In this regard CVP is a better "upper limit" to fluid therapy rather than an actual goal to strive for, other than normalization of CVP in horses with subnormal values.

Arterial Blood Pressure

Arterial blood pressure measurements provide some insight into perfusion status, particularly when used in conjunction with clinical signs and lab work, such as blood lactate concentration. It can be measured either directly by using arterial catheters or indirectly with a blood pressure cuff on the tailhead. Arterial lines can be placed in the great metatarsal artery of recumbent foals and the transverse facial artery in standing adult horses for direct measurements. Indirect measurements are best performed with oscillometric blood pressure monitors that provide systolic, diastolic, and mean arterial pressure (MAP). Cuffs are provided by the manufacturer and vary in width and length with the size of the patient.

Arterial blood pressure in healthy neonatal foals is highly variable and depends on breed, gestational age, and size of foal. Reported mean arterial blood pressure (direct) in neonatal foals has been reported to be 84.4 ± 3.7 mm Hg at 1 day of age and up to 101.3 ± 4.4 mm Hg at 14 days of age.[2] Indirect blood pressure readings in Thoroughbred foals has been reported as 144 ± 15, 74 ± 9, and 95 ± 13 mm Hg for systolic, diastolic, and mean pressures, respectively.[6] Direct blood pressure has been reported for adult horses: 126 to 168 (systolic)/85 to 116 (diastolic) with a range for the mean arterial pressure of 110 to 133 mm Hg.[7-10] Indirect blood pressure in adult horses is reported as 111.8 ± 13.3 mm Hg for systolic pressure and 67.7 ± 13.8 mm Hg for diastolic pressure.[11]

Blood pressure values should not be regarded as the sole criteria for intervention. Rather, they should be used in conjunction with perfusion parameters, blood lactate concentration, and urine output in deciding whether there is need for further fluid administration or inotrope and vasopressor support. The exact blood pressure value that should trigger intervention in horses and foals is unknown and likely varies with the individual patient; however, end-organ perfusion requires a mean arterial pressure of 60 mm Hg, thereby making that a reasonable general minimal target.

Blood or Plasma Lactate Concentration

Blood or plasma lactate concentration is very useful in monitoring fluid support, as well as perfusion and metabolic status. Increased blood lactate concentration may be a result of hypoperfusion and reduced oxygen delivery (hypovolemia, hypotension, anemia, hypoxemia, heart failure). Other considerations for hyperlactatemia should include SIRS, sepsis, catecholamine surges, liver or renal failure, thiamine deficiency, alkalosis, hyperglycemia, exercise, seizure activity, and the action of drugs such as salicylates and theophylline.[12-15] Sepsis and SIRS may increase circulating lactate concentrations independent of perfusion status; inflammatory mediators and cytokines activate pyruvate dehydrogenase kinase, an inactivator of pyruvate dehydrogenase, resulting in reduced activity of the citric acid cycle. Normal lactate concentrations in horses are less than 2 mmol/L, with most horses having concentrations less than 1 mmol/L.[16-18] Neonatal foals have decremental values after birth, with reported concentrations of 4.9 ± 1.02, 2.25 ± 0.6, and 0.89 mmol/L at birth, 12 hours of age, and 24 hours of age, respectively.[18-20] In a study performed by the author, foals had values of 2.4 ± 1.0, 1.2 ± 0.3, and 1.1 ± 0.3 mmol/L at 0 to 2, 24, and 48 hours of age, respectively, compared with 0.6 ± 0.2 mmol/L in adult horses.[21]

Cardiac Output

Advanced monitoring in equine critical care includes cardiac output measurement. A number of methods of cardiac output monitoring have been described in horses, including the Fick principle, indicator dilution methods (such as lithium dilution), Doppler and volumetric echocardiography, pulse contour analysis, and partial carbon dioxide rebreathing. The most practical of these include lithium dilution and echocardiographic techniques.[22-26]

Lithium dilution precludes the need for placement of cardiac catheters. A small bolus of lithium chloride is injected into a peripheral vein or the cranial vena cava (via a central line). Arterial blood is sampled using an arterial catheter at a constant rate and passes through a lithium electrode to generate a lithium concentration-time curve. Cardiac output is calculated from the area under the curve for lithium over time. Advantages of lithium dilution include only moderate invasiveness, good accuracy, and requirements for only small volumes of injectate. Disadvantages include the need for continuous arterial blood and limitations on repetitive measurements owing to lithium accumulation.[25-27]

Noninvasive cardiac output measurements can be made using the Bullet method through volumetric echocardiography.[24] McConachie and colleagues[28] reported that the Bullet method provided an accurate estimate of cardiac output in anesthetized foals. The Bullet method, as well as the four-chamber area-length, Simpson, and right ventricular outflow Doppler methods, had reasonable agreement with lithium dilution in adult horses.[28] For the Bullet method, cardiac output is calculated using heart rate and stroke volume (CO = HR × SV), where stroke volume is estimated as follows:

$$SV = \left(\frac{5}{6} \times LVAd \times LVLd\right) - \left(\frac{5}{6} \times LVAs \times LVLs\right)$$

where *LVAd* is the left ventricular area in diastole (short-axis view), *LVLd* is the left ventricular length in diastole (long-axis view), *LVAs* is the left ventricular area in systole (short-axis view), and *LVLs* is the left ventricular length in systole (long-axis view).

Cardiac output in healthy adult horses (400 to 500 kg) is 32 to 40 L/min.[22] Normal cardiac index, which is cardiac output expressed per unit of body weight, is 72 to 88 mL/kg/min. In the neonatal foal, cardiac output has been reported to be 7.1 ± 0.4 L/min (cardiac index = 155.3 ± 8.1 mL/kg/min) in 2-hour-old foals.[2] At 24 hours of age, cardiac output was determined to be 9.0 ± 0.5 L/min (cardiac index = 197.3 ± 12.0 mL/kg/min). This increased further to 15.7 ± 1.5 L/min (cardiac index = 222.1 ± 21.6 mL/kg/min) at 14 days of age.[2] A general guideline for normal cardiac index is 100 to 300 mL/kg/min in neonatal foals.[24]

VetBooks.ir

Blood Glucose

Blood glucose concentration has been the focus of much study in human critical care in recent years. A number of initial studies demonstrated improved survival and reduced complications with tight glucose control using intensive insulin therapy in critically ill humans.[29,30] Maintenance of euglycemia (80 to 110 mg/dL) resulted in reduced mortality in surgical intensive care unit patients as compared with hyperglycemia (180 to 200 mg/dL). Hyperglycemia may be associated with detrimental effects in pediatric intensive care patients as well.[31] However, after these initial studies, additional studies, including meta-analyses, did not document similar benefits and revealed some adverse events with tight glycemic control, especially development of severe hypoglycemia.[32,33] Current guidelines therefore are more relaxed and recommend using a glucose concentration of 180 mg/dL or less as the target.[34] How these findings relate to critically ill horses is unknown, but prevention of hyperglycemia is likely warranted, and its effects in the equine intensive care unit require further study. In one study evaluating blood glucose in horses with acute abdominal disease, hyperglycemia in the first 48 hours of hospitalization was associated with a worse prognosis for survival to hospital discharge.[35] A study in hospitalized neonatal foals showed that foals with blood glucose concentrations less than 50 mg/dL or greater than 180 mg/dL at admission were less likely to survive.[36]

Monitoring Urine Analytes

Urine indices are useful for monitoring responses to fluid therapy. Successful production of urine output in response to fluid administration is a primary goal of fluid therapy, and measurement of urine production allows determination of "fluid balance" (input–output). Another important means of assessing the response to fluid loading is measurement of urine specific gravity and/or osmolarity. In the absence of renal failure, progressively dilute urine is a positive response to fluid administration. Horses on feed and water should be making 0.4 to 2.0 mL/kg/h urine, whereas those off feed and water will produce far less (0.13 to 0.5, up to 1 mL/kg/h depending on duration).[37,38] Horses on fluids should therefore be producing a minimum of 0.5 but optimally 1 to 2 mL/kg/h of urine.

Urinalysis should be performed, and fractional excretion of electrolytes, particularly of sodium, provides information regarding tubular function and can aid in differentiation of prerenal and renal azotemia. Normal fractional excretion is less than 1% in adult horses and 0.31% ± 0.18% in neonatal foals.[39-42]

Fluid Therapy for Specific Diseases and Disorders in Horses

Fluid Therapy for Liver Dysfunction and Hepatic Failure in Horses (Box 44.1)

K. Gary Magdesian

Acute liver disease may result in hypovolemia due to lack of water intake, third space losses into the gut and peritoneal cavity, and possibly pooling of blood in the portal circulation. Portal hypertension may result in gut edema with subsequent fluid loss. Considerations of fluid therapy in cases with hepatic dysfunction include reduced metabolic capacity as well as compromised synthetic ability of the liver. Because lactate clearance primarily occurs in the liver, fluids containing lactate optimally should be avoided in horses with significant liver failure when other options are available. Isotonic replacement fluids containing acetate rather than lactate as the alkalinizing anion, such as Normosol-R (Abbott Laboratories, North Chicago, Ill.) and Plasma-Lyte A or Plasma-Lyte 148 (Baxter Healthcare Corporation, Deerfield, Ill.), and acetated Ringer's solution are preferred over LRS. One millimole (mmol) of acetate yields 1 mmol of bicarbonate during metabolism and is therefore alkalinizing.[1] These balanced, polyionic fluids are optimal as compared with physiologic saline (0.9% sodium chloride) because of the propensity of the latter to produce a mild hyperchloremic metabolic acidosis (HCMA), and many horses with liver dysfunction have acidemia already.[2] Hyperchloremic acidosis has potentially adverse effects, including renal afferent arterial constriction, and has negative effects on organ function, including gastrointestinal, central nervous system, and coagulation.[3,4]

Provision of dextrose, even in the face of normoglycemia, should be considered unless enteral nutrition is adequate. The addition of dextrose to fluids will minimize gluconeogenesis demands on the liver as well as catabolism of endogenous tissues with subsequent increases in nitrogen turnover (and increased ammoniagenesis). With dextrose administration, the risk of hypoglycemia from liver dysfunction is also minimized, since patients may have insufficient liver and muscle glycogen reserves and impaired hepatic gluconeogenesis in order to maintain normal blood glucose concentrations. A common dextrose supplementation rate used by the author for adult horses is 1 mg/kg/min. This equates to 3% dextrose in fluids if 1 L/h of crystalloid is administered to a 500-kg horse. The author often begins with 0.3 to 0.5 mg/kg/min of dextrose and gradually advances the rate of administration as the horse tolerates the dextrose (aiming to keep the blood glucose concentration <160 to 180 mg/dL, or lower for horses that are prone to laminitis). The addition of B vitamins, diluted in the fluids, can be helpful for anorectic horses because they are required cofactors for oxidative metabolism. In addition, many of the B vitamins are stored in the liver. Injectable vitamin C is usually included by the author, at a rate of 20 mg/kg/day diluted in the fluids. Horses that remain anorectic for longer than 24 to 72 hours should be considered candidates for parenteral nutrition, with the addition of amino acid supplementation as the next step in nutritional support. If amino acids are administered, blood ammonia concentrations should be monitored in horses with liver dysfunction, as they may be intolerant of the additional nitrogen.

Horses with liver dysfunction should be monitored closely for hyperammonemia as a marker of hepatic encephalopathy. Fluids can be tailored to minimize the risks of hyperammonemia. Provision of potassium, even in the presence of normokalemia, enables an electrolyte draw of hydrogen atoms from intracellular stores, thereby lowering pH and promoting ionization of ammonia to its less diffusible form, ammonium ion, which is not able to cross the blood-brain barrier.[5] Hypokalemia also promotes metabolic alkalosis and may compound hepatoencephalopathy due to increased urinary losses of hydrogen ion (H^+) and increased tubular absorption of ammonia, and therefore should be avoided in liver failure cases. For similar reasons, sodium bicarbonate

BOX 44.1

Fluid Considerations for Liver Failure

1. A combination of balanced, polyionic crystalloids and colloids is optimal.
2. Acetated fluids, rather than lactated Ringer's solution, should be used whenever available.
3. Colloids, particularly plasma, can be beneficial if hypoalbuminemia is present and to minimize third space accumulation of fluids.
4. Potassium supplementation (20 to 80 mEq/L) may aid in reducing hyperammonemia (<0.5 mEq/kg/h total).
5. Dextrose supplementation (1 to 2 mg/kg/min) should be provided for energy support. Blood glucose should be monitored and hyperglycemia should be avoided.

VetBooks.ir

should be used judiciously and with caution in horses with a propensity for hepatic encephalopathy. Increases in the pH of plasma will result in conversion of ammonium ion to ammonia; unfortunately this facilitates the brain uptake of ammonia with subsequent intracerebral trapping of ammonium ion.

The rate of fluid administration for horses with liver dysfunction will vary with the volume and hydration status of the individual. In general, rates should exceed maintenance requirements to account for hypoperfusion and produce some degree of diuresis of ammonium and other toxins, such as conjugated (direct) bilirubin that would otherwise have been metabolized or eliminated by the liver. Volume of fluid administration should be monitored closely in horses with ascites or portal hypertension resulting from severe liver disease because of the propensity of these patients for third space fluid accumulation. Other considerations for horses with liver disease include hypoalbuminemia, hyponatremia, hypokalemia, coagulopathies, and hyperlactatemia. Monitoring CVP will aid in preventing rises in hydrostatic pressure that would contribute to transudates or ascites.

Fluid support, for "maintenance fluid therapy," can be modified in horses with preexisting ascites or edema to reduce the administered sodium load. These are hypotonic and should never be administered as a rapid bolus. Commercially available solutions with restricted sodium concentrations (maintenance crystalloids), such as Plasma-Lyte 56 or Normosol-M, can be used in foals. Because of their availability in only small volumes (1-L bags), combinations of isotonic crystalloids and sterile water or 5% dextrose in water (D_5W) can be used as maintenance fluids in larger patients (half isotonic fluid and half water or D_5W). If sterile water is selected, it should be allowed to mix with the isotonic fluid before entering the patient; administered alone, water could cause osmotic hemolysis. Another option in such horses is to restrict the volume of crystalloid administered through concurrent administration with colloids. Colloids expand the intravascular volume, limit the requirement for crystalloids, and may reduce the propensity of edema formation by raising oncotic pressure. However, consumptive coagulopathies would be contraindications to the administration of synthetic colloids.

Colloids are indicated in horses with significant hypoalbuminemia (<1.5 g/dL). Hetastarch previously has been recommended at doses up to 10 mL/kg/day unless coagulopathies are present, as these are a potential dose-dependent side effect of hetastarch. Liver failure may result in decreased production of clotting factors or antithrombin and can initiate disseminated intravascular coagulation (DIC). Because hetastarch can induce decreased activity of von Willebrand factor and factor VIII, as well as interfere with platelet function, it is contraindicated in horses with bleeding tendencies (after consumption of factors).[6] In addition, there has been much debate as to the safety of hetastarch and risks of acute kidney injury in humans, and some early evidence in dogs as related to number of days of hetastarch administration, which has markedly reduced the use of hetastarch in these patients.[7,8] Plasma is a colloid that has potential benefits for horses with hepatic failure, except perhaps for horses with virus-associated hepatitis (serum hepatitis). Coagulopathies associated with liver disease can be addressed through provision of exogenous antithrombin and clotting factors in plasma products. Plasma should probably not be administered to horses with serum hepatitis (Theiler's disease), since this disease is poorly understood and associated with prior administration of equine-origin biologics. Recently, viruses (e.g., flavivirus, parvovirus) have been associated with serum hepatitis.[9,10] Replacement of albumin is beneficial not only for oncotic pressure support but also for drug and toxin binding and as an endogenous buffer. If hypoalbuminemia is a result of hepatic dysfunction, and not urinary or gastrointestinal losses, colloids will have a longer retention time in the circulation.

BOX 44.2

Fluid Considerations for Horses With Diarrhea or Colitis

1. A combination of crystalloids and colloids has many benefits in horses with colitis.
2. Colloids are indicated when concurrent hypoproteinemia and hypovolemia are present.
3. Potassium, calcium, and magnesium should be supplemented as necessary.
4. Hypertonic saline has several potential benefits for horses with acute colitis, including volume expansion, immunomodulation, antiinflammatory effects, anti-edema effects, and positive inotropic effects.

Fluid Therapy for Diarrhea and Colitis in Horses (Box 44.2)

K. Gary Magdesian

Horses with acute colitis are often presented in a state of severe SIRS with endotoxemia, hypovolemia, and malperfusion of tissues. Fluid therapy is the cornerstone of hemodynamic support for these horses. Not only is low circulating volume an indication for fluid therapy in these cases, but acid-base and electrolyte derangements also warrant treatment with fluids. In addition to hypovolemia, horses with colitis often have both organic and inorganic acidoses as well as hyponatremia. Organic acidosis primarily results from hyperlactatemia, whereas inorganic acidosis is usually a result of relative hyperchloremia (or hyponatremia) from loss of sodium bicarbonate.

Because of the poor sensitivity of physical examination in detecting hypovolemia in horses, estimates of percent dehydration and water deficit are not very accurate.[1] A more structured means of providing fluids to sick horses is through the "fluid challenge" method described in the previous sections as adopted from human critical care.[1] In this protocol a bolus dose of 10 to 20 mL/kg of isotonic crystalloid is administered over approximately 30 to 60 minutes to horses with hypovolemia, with subsequent reassessment of perfusion parameters. Horses with marked fluid deficits may require the initial bolus to be administered as rapidly as possible, using a pressure bag. Perfusion parameters consist of mentation, peripheral pulse quality, heart rate, mucous membrane color, capillary refill time, and extremity temperature. Lactate, arterial blood pressure, and central venous oxygen saturation are monitoring tools that are used with the clinical examination in serial assessments to determine the best course of fluid therapy and serve as end points to replacement fluid therapy. Urine output is another clinical indicator of improvement in perfusion in response to fluid loading, and once urine production is present (as evidenced through ultrasonographic findings or urine collection) the rapid boluses can cease or slow in rate. Fluid challenge should continue as repeat boluses, albeit at progressively slower rates for each subsequent bolus, until perfusion parameters normalize or plateau in terms of improvement. No further improvement of perfusion parameters in response to boluses of fluids, with persistence of clinical indicators of hypoperfusion, suggests that inotrope or vasopressor support may be required and that further fluid therapy will not be of aid. Fluid overload is very detrimental to tissue oxygenation and cell function, and care should be taken to avoid it. A safety upper limit to fluid loading includes detection of a high normal CVP value, which should serve as a ceiling to fluid bolus administration.

Crystalloid fluid choices for horses with colitis include isotonic, balanced replacement fluids, such as Normosol-R, LRS, Hartmann's solution (compound sodium lactate solution),

VetBooks.ir

and Plasma-Lyte A or Plasma-Lyte 148. Normosol-R and Plasma-Lyte 148/A are slightly advantageous over LRS or Hartmann's solution from the standpoint of providing a wider strong ion difference (sodium-chloride difference). The sodium-chloride difference in these acetated fluids is 42. In contrast, LRS has a sodium-chloride difference of only 21 and Hartmann's solutions have a difference of 19 to 20. These lactated fluids have a chloride concentration greater than that of equine plasma (109 mEq/L in LRS, 111 to 112 mEq/L in Hartmann's solutions versus approximately 96 to 105 mEq/L in equine plasma), and this chloride excess can potentially compound an inorganic acidosis with large volume or duration of administration. Physiologic saline (0.9%) is even greater in its chloride concentration and produces a mild strong ion acidosis on administration of large volumes.[2] There is emerging evidence in human medicine that saline may be associated with adverse effects as compared to balanced electrolyte fluids such as LRS or Plasma-Lyte. A meta-analysis investigating the effect of different fluid therapies on mortality in septic patients suggested that balanced crystalloids were associated with an increased survival rate in septic patients compared to normal saline.[3]

In addition, Normosol-R and Plasma-Lyte 148 or Plasma-Lyte A contain acetate (and gluconate) rather than lactate as the alkalinizing salt. This may be an advantage in horses with hepatic dysfunction because the liver is the primary site of lactate metabolism, whereas acetate and gluconate are metabolized by many tissues.

Colloids may be adjunctive to crystalloid therapy, particularly for horses with hypoproteinemia such as those with acute colitis. In human critical care medicine there is no consensus as to whether crystalloids or colloids provide more successful fluid resuscitation.[1] A combination of both is likely optimal.[1] Colloids may be useful for horses with hypoproteinemia, such as those with colitis. Concurrent hypovolemia and hypoproteinemia warrant administration of colloids, because the use of crystalloids alone could result in dilutional hypoproteinemia.[4] Plasma may be considered the optimal colloid for use in horses with colitis at this time because of concerns over possible adverse effects of hetastarch on kidney function and mortality rates in humans and dogs, although the debate about possible negative versus positive effects of hetastarch is ongoing.[3]

Hypertonic saline (7% to 7.5%) is a rapid plasma volume expander that can be used in the early volume replacement period of volume resuscitation of the horse with colitis and acute diarrhea. Hypertonic saline increases plasma volume by three to four times the volume administered. In comparison, crystalloids increase plasma volume by only 0.25 to 0.33 mL for each milliliter administered. Hypertonic saline has additional advantages beyond volume expansion, particularly for the horse with endotoxemia. These include immunomodulatory, anti-inflammatory, anti-edema (particularly of the endothelium and erythrocytes), and inotropic effects.[5-7] Microvasculature effects enhance microcirculatory perfusion, which is often disturbed during sepsis and endotoxemia. Reduction of endothelial and erythrocyte edema, two processes that contribute to multiple organ dysfunction during sepsis, results in reduced vascular resistance and blood viscosity.[6,7] The hypertonicity created by hypertonic saline evokes vasodilation, which also contributes to microperfusion when coupled with an increase in cardiac output caused by contractility-enhancing effects of hypertonic saline. The antiinflammatory and immunomodulatory effects include anti-apoptosis, free-radical scavenging properties, inhibition of leukoactivation, and prevention of immunosuppression after sepsis.[5-7] In an experimental model of hemorrhagic shock in horses, hypertonic saline resulted in improved cardiac output, stroke volume, cardiac contractility, and blood pressure as compared with isotonic saline.[8] Hypertonic saline has demonstrated attenuation of cardiovascular derangements in equine endotoxemia models as compared with isotonic saline.[9]

The dose for hypertonic saline is 4 mL/kg once, and it should be followed with, or administered concurrent to, isotonic crystalloids to replace the "borrowed" water from the intracellular space. Hypertonic saline is generally safe but should be avoided in horses with uncontrolled hemorrhage when hypotensive resuscitation is indicated. In addition, horses with marked sodium derangements should not be administered hypertonic saline. It should also be used with caution in neonatal foals.

Fluid Therapy for Sepsis (Peritonitis, Pleuritis, Pneumonia, Metritis, etc.) in Horses (Box 44.3)

K. Gary Magdesian

The optimal fluid for resuscitation of patients with sepsis remains an area of investigation, although recent work supports the use of balanced electrolyte solutions over hetastarch or normal (0.9%) saline.[1-4] A rational approach to fluid therapy in patients with sepsis is to optimize hemodynamics (increase oxygen delivery, blood pressure, and urine output) while attempting to limit fluid overload and edema formation.[1,5,6] There is no evidence to support the use of synthetic colloids over balanced crystalloids.[1] Older meta-analyses of clinical studies comparing crystalloids and colloids in human patient populations showed no outcome difference, but more recent studies point to a mortality decrease in patients receiving balanced crystalloids over normal saline or synthetic colloids.[1-4,6-8]

Fluid therapy is a keystone in the management of severe sepsis and septic shock. This is because septic shock is associated with both absolute and relative hypovolemia. Relative hypovolemia is the result of vasodilation and peripheral blood pooling in the face of cytokinemia. Volume repletion allows for increases in cardiac output and subsequently in systemic oxygen delivery.[7]

The recommendations for fluid therapy in septic horses are extrapolated from those in human medicine and similar to those for horses with acute enterocolitis discussed earlier in this chapter; both conditions are examples of a SIRS. In fact, enterocolitis can be thought of as a form of sepsis. Sepsis incites a host of hemodynamic derangements that challenge fluid therapy. It causes a myriad of microperfusion and hemodynamic abnormalities; these include hypovolemia, myocardial depression, vascular permeability derangements, vasodilation, DIC, and cellular changes resulting in abnormal membrane potential and membrane pump or channel function.[8] These pathophysiologic processes must be considered when a fluid plan for horses with sepsis is designed.

Sepsis is a form of documented or suspected infection.[9,10] More recently, human medical organizations have redefined sepsis as a life-threatening organ dysfunction caused by a

BOX 44.3

Fluid Considerations for Horses With Sepsis

1. Crystalloids are the mainstay of fluid therapy in sepsis.
2. A combination of crystalloids and colloids may have advantages in patients with sepsis when hypoproteinemia is present.
3. Fluid challenge, consisting of 10- to 20-mL/kg boluses with reassessment of perfusion parameters and monitoring tools, is a safe and effective means of determining volume to be administered.
4. Monitoring of fluid therapy increases safety, especially in patients prone to edema. Monitoring should consist of measurement of central venous pressure, arterial blood pressure, and urine output.
5. Metabolic acidosis is very common among patients with sepsis.

VetBooks.ir

dysregulated host response to infection and septic shock as persistent hypotension after fluid therapy (vasopressor dependency) and an increased lactate concentration in the absence of hypovolemia.[11] Many equine cases, including horses with peritonitis, pneumonia, pleuritis, enterocolitis, meningitis, and metritis, fall into this category. Sepsis and SIRS are states of cytokine milieu in which cytokines and inflammatory mediators predominate. Aside from antimicrobials, the fundamental therapy is hemodynamic support, consisting of fluid and vasopressor therapy.

Initial fluid resuscitation centers on isotonic (or near isotonic) replacement-type fluids such as LRS, Hartmann's solution, or Plasma-Lyte 148 or Plasma-Lyte A, with some indications for colloids or hypertonic saline. These have been associated with improved outcomes in human patients versus normal saline or synthetic colloids.[1] Horses with sepsis often are presented with negative fluid balance resulting from both hypovolemia and dehydration. Fluid choices are the same as for horses with enterocolitis, and a combination of crystalloids and colloids, especially plasma, may have advantages in sepsis.[5] Such a combination would address both blood volume and interstitial deficits, with plasma expanding the vascular space, providing albumin, antibodies, endogenous anticoagulants and clotting factors, and crystalloids that address both fluid spaces. The use of synthetic colloids such as hetastarch has decreased in recent times due to the possible adverse effects noted with its use.[1] Hypertonic saline may have some advantages during sepsis, including immunomodulatory, antiinflammatory, anti-edema, vascular, and inotropic effects.[12-14] A dose of 2 to 4 mL/kg of hypertonic saline may be added to the combination of isotonic crystalloids and administered during or just before administration of isotonic crystalloids.

Care should be taken to avoid overexpansion of the extracellular fluid compartment with excessive fluid administration. Horses with sepsis have a predilection for edema because of the presence of concurrent hypoalbuminemia and increased vascular permeability. Therefore careful monitoring of fluid balance is warranted. *Fluid balance* refers to input and output of fluids, and it can be monitored with urinary collection systems. Under normal circumstances urine output should represent 50% or more of input, with the remaining output caused by fecal and evaporative losses (skin and pulmonary). CVP is also useful in monitoring for safety limits in this group of patients; maximal normal CVP (10 cm H_2O [8.8 mm Hg] in foals; 15 cm H_2O [11 mm Hg] in adults) should not be exceeded. Serial ultrasonography and arterial blood gas analysis can be used to detect pulmonary edema from relative or absolute fluid overload, before the development of gross signs (froth, crackles, and tachypnea) of edema.

Because of thrombotic risks associated with sepsis-induced coagulopathies, these patients should be instrumented with minimally thrombogenic catheters, such as long-term polyurethane catheters. Attention to asepsis and cleanliness is paramount.

In human critical care, "early goal-directed therapy" has been advocated by some clinical trials, although there is ongoing debate as to its universal effectiveness.[15] These studies have used goal-oriented therapeutic adjustments of preload, afterload, and contractility to achieve a balance between oxygen delivery and demand. End points have included normalization of central venous oxygen saturation (70%), blood lactate, CVP (8 to 12 mm Hg in humans), urine output (0.5 mL/kg/h or greater), and MAP (65 mm Hg or greater in humans).[16] The therapy consisted of crystalloids and colloids for correction of CVP, vasopressors and vasodilators for MAP, and dobutamine and red blood cell transfusions for central venous oxygen saturation. Patients receiving this early goal-directed therapy received a greater volume of fluids early (first 6 hours of treatment) and less later, as compared with patients in the conventional group. The treatment group had a lower mortality rate and less severe organ dysfunction, highlighting the importance of early identification of patients with insidious or occult malperfusion, consisting of patients with global hypoxia yet stable vital signs.[15] Whether this type of targeted fluid therapy will have a place in equine medicine remains to be studied.

Glucose should be monitored closely in horses with sepsis, as both hypo- and hyperglycemia may develop. See the previous section for glucose regulation in critically ill patients. The current goal in human patients is to maintain a blood glucose of 180 mg/dL or less.

Fluid Therapy for Renal Failure in Horses (Box 44.4)

C. Langdon Fielding • K. Gary Magdesian

Fluid therapy is the major component of treatment for renal failure in horses, regardless of cause. Renal replacement therapies have been reported in horses; however, they are not widely available, further highlighting the importance of fluid diuresis.[1-3] Peritoneal dialysis is an option to complement fluid therapy, particularly if unresponsive anuria is present.[2] Development of a fluid plan for horses with renal failure begins with classification of the disease into polyuric, anuric, or oliguric renal failure. Polyuria and anuria are self-explanatory; oliguric renal failure in this section refers to a normally hydrated animal with concurrent azotemia and urine production less than 0.5 mL/kg/h.

For both oliguric/anuric and polyuric renal failure, there are two primary considerations when beginning fluid therapy: fluid type and rate. The total amount of fluid administered is usually determined by the response to treatment and does not necessarily need to be identified at initiation of therapy.

POLYURIC RENAL FAILURE. The goal of fluid therapy in these patients is to induce diuresis, with removal of uremic

BOX 44.4

Fluid Considerations for Horses With Acute Renal Failure

1. Horses with acute renal failure can be polyuric, oliguric, or anuric.
2. Polyuric horses should be treated with isotonic crystalloids with the goal of diuresis. A rate of administration equal to two times a maintenance rate is a reasonable starting point, but fluid balance (input and output) should be monitored. This would equate to 4 to 6 mL/kg/h as an initial starting rate, which should be tailored (increased or decreased) to perfusion parameters, urine output, patient clinical status, and monitoring tools. Balanced, polyionic commercial electrolyte solutions, such as Normosol-R or lactated Ringer's solution, can be used in most cases.
3. Frequent reassessment of the patient's fluid status should be done to adjust rate accordingly.
4. Physiologic (0.9%) saline is mildly acidifying because of hyperchloremia and should be avoided in patients with renal failure because hyperchloremic metabolic acidosis may reduce renal blood flow.
5. Anuric or oliguric horses should be treated promptly. Adequacy of circulating volume and blood pressure must be ensured initially. If fluid loading with isotonic replacement crystalloids and correction of hypotension does not correct the lack of urine production, then furosemide, mannitol, and dopamine can be tried. Dialysis (hemodialysis or peritoneal) can be performed if there is potential for reversible renal injury.
6. Synthetic colloids (hetastarch, dextrans) should be avoided in horses with acute renal failure.

toxins and maintenance of fluid, acid-base, and electrolyte balance.[4,5] The degree of renal failure that is reversible is often unknown at the onset; this is evaluated over time, particularly with response to fluid therapy. It should be noted that azotemia may not improve for up to 72 hours after initiation of fluid therapy when acute renal failure is severe. A lack of initial improvement in plasma creatinine or BUN during the first day or two of therapy should not necessarily prompt a poor prognosis or discontinuation of therapy.

The rate of fluid administration should facilitate diuresis.[5] A rate of two times the maintenance fluid rate (4 to 6 mL/kg/h, where the maintenance rate is 2 to 3 mL/kg/h) is a reasonable starting point; however, there is a paucity of literature to recommend evidence-based rates of fluid administration for treatment of acute renal failure or other disorders. Similar fluid rates have been suggested in small animal patients with renal failure.[5] It is unknown whether increases in the fluid rate beyond this point are beneficial. Certainly, if urine output is greater than this rate, it should be matched with fluid input.

Fluid overload is a problem in renal failure and has been reported in human patients.[6,7] Excessive fluid administration may result in edema and associated morbidity and mortality. Measurement of CVP can be used to monitor excessive fluid administration and has become more practical in equine patients.[8-10] Reference ranges of less than 15 cm H_2O have been reported for adult horses; values exceeding 20 cm H_2O indicate a need to decrease the rate of fluid administration to avoid development of edema.[9] The value of CVP monitoring continues to be controversial, and CVP measurement should not be used as the sole means for monitoring fluid overload.[11]

A balanced isotonic crystalloid is suitable for diuresis while preventing significant electrolyte alterations.[5] Horses should be allowed free access to water whenever possible while intravenous fluids are administered. This allows for some degree of self-regulation of water balance and can provide free water for renal excretion of the large sodium load provided by isotonic crystalloids.

Hyperkalemia is a relatively common feature of acute renal failure.[12,13] This is often corrected when renal perfusion is optimized and diuresis is instituted. When hyperkalemia is present, anuria should be ruled out. Cardiac dysrhythmias can develop during hyperkalemia; potassium-free fluids (isotonic sodium bicarbonate; possibly normal saline, although this is controversial as noted below) should be administered to patients with dangerous hyperkalemia (>6 mmol/L), along with calcium, dextrose, and possibly insulin.

LRS has the benefit of containing a minor amount of free water (osmolarity 273 mOsm/L) and slightly less sodium than other fluids (130 mEq/L). A potential disadvantage, however, is that it contains more chloride (109 mEq/L) than equine plasma. Horses with renal insufficiency may be unable to excrete excess chloride provided by LRS diuresis. Mild hyperchloremia may result, causing a minor strong ion acidosis. LRS also contains potassium (4 mEq/L), which is a consideration in the hyperkalemic patient. However, studies in human renal transplant patients failed to demonstrate development of hyperkalemia as a result of LRS administration.[14]

Isotonic saline (0.9%) solution has an even higher chloride content (154 mEq/L) than LRS. In fact, neither the sodium nor the chloride concentration in this fluid is similar to those of equine plasma. Isotonic saline solution has been shown to cause hyperchloremia and a mild acidosis during prolonged administration.[15-17] This hyperchloremia may make isotonic saline a less ideal fluid for long-term management of acute renal failure. Saline does not contain potassium and therefore may be warranted in horses with hyperkalemia. However, creation of a metabolic acidosis because of hyperchloremia may also pose a risk for hyperkalemia by causing an extracellular shift of potassium; this shift occurs as a result of acute changes in blood hydrogen concentration, which occur in association with hyperchloremic metabolic acidosis.[14] The effects of saline on potassium balance in horses warrant further study. Metabolic alkalosis, caused by hypochloremia or relative hypernatremia, is an indication for saline administration.

Normosol-R and Plasma-Lyte 148 (or Plasma-Lyte A) have a sodium and chloride concentration most similar to equine plasma among the commercial isotonic or nearly isotonic fluids and are excellent fluids for diuresis of acute renal failure cases. It should be noted that these contain the highest potassium concentration (5 mEq/L) of all commercial fluids described; however, this potassium content is unlikely to contribute to clinically significant hyperkalemia in polyuric animals because of urinary excretion of excessive potassium (possible exceptions are uroperitoneum and anuria).

Isotonic sodium bicarbonate solution can be made by mixing sterile water and sodium bicarbonate to create a solution with a sodium concentration of approximately 150 mmol/L. Isotonic sodium bicarbonate does not contain potassium or chloride and can be modified to contain an increased amount of free water as needed by lowering the sodium concentration. It exerts an alkalinizing effect by increasing strong cation (Na^+) concentrations without a corresponding increase in strong anions (i.e., strong ion alkalosis).

Blending of fluids with different compositions is also an option in order to correct or maintain electrolyte and free water balance. Over time, horses often develop a plasma electrolyte profile similar to that of the administered fluid, especially when large volumes are administered for prolonged periods; therefore combining or changing fluids may be necessary if derangements develop. It is also clear that monitoring of electrolytes (one to four times per day) is particularly important in renal patients.

Synthetic colloids should be avoided in horses with acute kidney disease because renal injury is a known complication of administration of synthetic colloids in humans.

ANURIC OR OLIGURIC RENAL FAILURE. Anuria and oliguria should be considered emergency medical conditions; the longer the duration of little to no urine production, the lower the chances of correcting it. Urine output in healthy horses is approximately 1 mL/kg/h, but this may decrease by 80% (to 0.2 mL/kg/h) in horses deprived of water.[18,19] In humans without significant fluid deficits, a urine flow below 0.5 mL/kg/h is one criterion used to define acute renal *injury*, whereas acute renal *failure* is associated with a urine flow below 0.3 mL/kg/h.[20] Oliguric renal failure should be suspected in azotemic horses with urine production below 0.5 mL/kg/h despite the administration of intravenous fluids. Once anuria or oliguria is suspected, a methodic approach to fluid administration and monitoring should be instituted immediately because of the associated high mortality rate. A delay in instituting treatment makes reversal of anuria less likely.

Treatment of Anuria or Oliguria

1. Obtain baseline laboratory and hemodynamic parameters. These should include serum or plasma electrolyte levels, total plasma protein and blood lactate concentrations, packed cell volume (PCV), and clinical perfusion parameters. When possible, CVP, arterial blood pressure, and central venous oxygen tension should be measured as well. If possible, a body weight measurement should be obtained and recorded.
2. If CVP is not already significantly increased and there are no clinical signs of fluid overload (increased respiratory rate, peripheral edema, etc.), a fluid challenge should be initiated using 10 to 20 mL of an isotonic crystalloid per kilogram. CVP, clinical pathology, urine output, and physical examination status should be reevaluated for improvement after completion of the bolus.

3. If urine output has not increased significantly, additional fluid challenges should be given and the patient reevaluated until urine production begins or until CVP limitations are reached. A CVP value greater than 15 to 20 cm H_2O (>10 to 12 cm H_2O in foals) signifies an end point to fluid administration.
4. Arterial blood pressure should be monitored. If hypotension is present despite fluid loading, inotrope and vasopressor therapy should be considered. Dobutamine can be used as an inotrope (5 to 10 µg/kg/min). See the Fluid Therapy for Diarrhea and Colitis in Horses section earlier in this chapter.
5. Once urine flow has increased, fluids should be continued as described previously for polyuria; careful monitoring of CVP and fluid balance (measurement of serial body weight and urine output) should be done.
6. If urine flow does not begin over the next 30 to 60 minutes with fluid challenge, furosemide should be started with an initial bolus of 0.12 mg/kg IV followed by a constant rate infusion (CRI) of 0.12 mg/kg/h.[21] If CRIs are not possible, a bolus dose of 1 mg/kg IV, which can be repeated a second time 30 to 60 minutes later, can be administered instead. Furosemide may improve urine production, but there is no definitive evidence that it improves creatinine clearance or positively affects outcome in humans.[22]
7. If urine production does not begin within 30 to 60 minutes of instituting furosemide therapy, a dose of mannitol should be administered (0.25 to 0.5 g/kg bolus as a 20% solution). If still no urine is produced after an additional 30 minutes, another dose of mannitol can be administered; a total dose of 1 g/kg should not be exceeded in the anuric patient to prevent hypervolemia and edema formation. Alternatively, a CRI of mannitol (1 to 2 mg/kg/min) can be used, with a maximum cumulative dose of 1 g/kg. Plasma osmolarity should be monitored.
8. If urine output has not improved after furosemide and mannitol, the prognosis is grave without peritoneal dialysis or hemodialysis. Treatment with low-dose dopamine has been controversial in human medicine, and several large studies have failed to demonstrate a benefit.[23,24] In fact, furosemide, mannitol, and dopamine may increase urine flow but have not been shown to unequivocally improve outcome in humans with acute renal failure.[25] When dialysis is not an option for horses with anuric renal failure, dopamine can be tried in an attempt to produce urine flow (2 to 3 µg/kg/min); its proposed action is increasing renal perfusion with renal afferent arteriolar vasodilation.[26] Without urine flow, there is no opportunity to provide the patient with time to heal if the acute renal injury is reversible. If dopamine is successful at reversing anuria, this time can be provided.
9. Aminophylline can also be tried for reversal of anuria, at 0.5 mg/kg IV over 30 minutes. If improvement is noted, this can be repeated 2 to 3 times per day. It should be noted that aminophylline has a narrow therapeutic index, with toxicity occurring at plasma concentrations of 15 µg/mL or greater.

Hyperkalemia and metabolic acid-base disorders are common in horses with anuric or oliguric renal failure.[12] As noted earlier, hyperkalemia can be associated with life-threatening dysrhythmias. Rapid initiation of diuresis and administration of sodium bicarbonate, dextrose, and insulin are therapeutic interventions for hyperkalemia. If dysrhythmias are present, calcium should be administered to raise membrane threshold potential, thereby reducing the likelihood of abnormal rhythms.

As mentioned previously, hemodialysis has been reported infrequently in horses for clinical cases of renal failure.[1] Peritoneal dialysis has been described as a cost-effective and practical approach for horses with acute renal failure.[2] More recently, continuous venovenous hemodiafiltration was performed in experimental horses for short periods (6 hours). These therapeutic options may become more commonly used in horses that do not respond to conventional fluid therapy and medical treatments of anuria described earlier.

Fluid Therapy for Horses With Hypoproteinemia

K. Gary Magdesian

Horses with concurrent hypovolemia and significant hypoproteinemia (e.g., <4.5 g/dL) are at increased risk for edema formation with fluid therapy, making them among the most challenging to manage. The presence of concurrent hypovolemia and hypoproteinemia is a potential indication for colloids in addition to crystalloids. Administration of crystalloids alone may result in compounding of the hypoproteinemia through hemodilution.[1] With altered Starling's forces, crystalloids distribute to the extracellular fluid to a relatively greater extent than they would otherwise because of a lack of plasma oncotic force for retention. However, colloids can also extravasate due to increased vascular permeability, particularly if the endothelial glycocalyx is compromised, and therefore colloids should not be considered the definitive fluid in such cases because they too may exacerbate edema. Currently available colloids include hetastarch, dextrans, plasma, and concentrated human albumin.[2] Because of the increased potential for side effects associated with dextrans, there is no clear indication to use them over hetastarch. Side effects of dextrans reported in horses include muscle fasciculations, swaying of the hindquarters, tachycardia, and collapse in 8 of 64 horses.[3] Potential side effects of hetastarch products include coagulopathies. Other possible side effects in humans include allergic reactions and acute kidney injury, with some studies suggesting an increase in mortality rate as compared to crystalloids.[4] Therefore the use of hetastarches has decreased in human and veterinary critical care in recent years. The author rarely uses these products any longer and primarily relies on plasma for colloid support in horses and foals.

There are newer, lower-molecular-weight, and less substituted hetastarches that may be safer than traditional hetastarches.[5] The numbers after the name of the colloid (e.g., 130/0.4) refer to the average molecular weight and degree of substitution of starch molecules with a hydroxyethyl group, respectively. Standard hetastarch has an average molecular weight of 450 kDa and a degree of substitution of 0.7 (450/0.7); the newer hydroxyethyl starch (Voluven; 130/0.4) has been modified to have more complete renal elimination and less tissue storage than the standard product, with fewer side effects such as coagulopathies. These are referred to as tetrastarches. The U.S. Food and Drug Administration (FDA) has approved a veterinary tetrastarch colloid in normal saline for treatment of hypovolemia in dogs and cats with this molecular weight and substitution (VetStarch [Abbott Animal Health, Abbott Park, Ill.]). These tetrastarches may offer lower potential complications compared with hetastarch, including coagulopathy, allergic reactions, and renal injury. VetStarch has been studied in healthy neonatal foals, at a dose of 20 mL/kg, without any observable changes in coagulation parameters, and it increased colloid osmotic pressure for 3 hours after infusion.[5] It requires further study in sick foals and adult horses over a longer period of time before side effects and safety can be evaluated.

The risk-to-benefit ratio of the hetastarches may warrant use of low doses in conjunction with plasma in horses or foals with marked hypoproteinemia in the presence of hypovolemia. An example of a case where this may be warranted is *Lawsonia intracellularis* infection in foals. Doses of 10 mL/kg/day should not be exceeded in order to avoid side effects, and the hetastarch products should be used for as few days as possible, as duration of use may also play a role in side effects. Even lower doses

(e.g., 3 to 5 mL/kg) can be used in conjunction with plasma, if plasma alone is not enough.

Numerous commercial equine plasma products are currently available. Many include antibodies to salmonella, endotoxin, and clostridial organisms; these are unlabeled claims and are largely unstudied in terms of efficacy. Another advantage of plasma, especially for the hypoproteinemic horse, includes provision of albumin, antithrombin, and additional clotting factors. Because albumin has multiple functions, including as a carrier protein (drugs, toxins) and physiologic buffer, plasma cannot be entirely replaced with synthetic colloids. Concentrated albumin has been used in neonatal foals, but its use in adult horses may be limited by cost.[2] The potential side effects of human plasma products in horses are largely unknown and require further study. For horses with continual protein losses, such as with protein-losing enteropathies (e.g., acute enterocolitis), a continuous low rate infusion of plasma (e.g., 0.4 to 0.5 mL/kg/h) can be used.

In one study evaluating the response of hypoproteinemic horses with gastrointestinal disease to hetastarch, it was determined that the oncotic benefit lasted 24 hours; in contrast, hetastarch raised the oncotic pressure of healthy horses for up to 5 days.[1,6] Nevertheless, in some cases even a short-term benefit in oncotic pressure may be preferable to the further dilutional effects of crystalloids.

Fluid Therapy for Hemorrhagic Shock (Box 44.5)

K. Gary Magdesian

With the exception of prompt hemorrhage control, the key component to early trauma care is adequate fluid resuscitation. Traditionally, replacement with isotonic crystalloids of three times the volume of shed blood has been the approach in human trauma patients. Up to eight times the blood loss volume has been administered in severe shock states, because isotonic crystalloids distribute throughout the extracellular fluid compartment by volume, such that only 25% of the administered volume will remain within the circulating plasma volume.

Despite its importance, high-volume resuscitation is not innocuous; acute respiratory distress syndrome (ARDS) has been described in patients that received massive crystalloid resuscitation after trauma.[1] Severe trauma patients enter a phase of SIRS, with some patients developing multiple organ failure and others entering a compensatory antiinflammatory response syndrome (CARS). This latter syndrome causes immune suppression and increased susceptibility to infections. Commercial LRS brands used to contain a racemic mixture of L- and D-lactate. Those solutions, along with artificial colloids, namely dextrans and some hydroxyethyl starches, had proinflammatory effects.[2] Nonracemic LRS contains only the L-lactate form and does not share in the proinflammatory effect. It appears that the D-lactate (nonmammalian form) is largely responsible for the inflammatory reaction to racemic LRS because removing it from the solution eliminates this effect.[3] These fluids, both artificial crystalloids and colloids, can also cause neutrophil activation and upregulation of adhesion molecules.[4] Most currently available forms of LRS contain only the L-isomer form of lactate. Hypertonic saline, on the other hand, has been shown to be immunomodulatory and causes suppression of neutrophil oxidative burst activity and neutrophil-endothelial adhesions.[5-8] Hypertonic saline counteracts the inflammatory effects of dextrans when used in combination.[9] Therefore hypertonic saline has potential advantages for early fluid resuscitation of patients with significant blood loss, after the source of hemorrhage has been controlled. This should be followed with isotonic crystalloids, perhaps acetate-containing fluids, such as Normosol-R, or physiologic saline rather than racemic LRS. Hypertonic saline should not be used in cases of uncontrolled hemorrhage because it may raise blood volume and pressure too quickly. Plasma similarly does not result in inflammatory cell activation. If hetastarch is used in patients with acute blood loss, hemorrhage must be controlled before its administration because of rapid volume expansion as well as dose-dependent induction of coagulopathies.[10-15]

Aggressive fluid resuscitation in the face of uncontrolled hemorrhage cannot be justified. Such fluid protocols can exacerbate bleeding as a result of increases in blood pressure, disruption of clots, and hemodilution of clotting factors. Instead, a protocol of hypotensive resuscitation should be followed when bleeding cannot be stopped directly.[16] With hypotensive resuscitation, low volumes of crystalloids or whole blood should be administered to maintain organ vitality without normalizing pressures. A goal of maintaining a MAP of 60 mm Hg will still allow end-organ perfusion while allowing for hemostasis.

BOX 44.5

Fluid Considerations for Horses With Acute Hemorrhage

1. For horses with controlled hemorrhage, a combination of hypertonic saline and balanced isotonic crystalloids can be used.
2. Because of experimental evidence of proinflammatory effects of racemic lactated Ringer's solution (LRS) in severe trauma, use of this solution should be questioned in cases of severe trauma until further studies are available. Non-racemic LRS (with L-lactate) should be used when LRS is desired.
3. Hypertonic saline exhibits antiinflammatory effects and may have benefits for horses with severe trauma, especially when LRS or synthetic colloids are used for resuscitation, and after hemorrhage has been controlled.
4. For controlled hemorrhage, a volume three to four times the estimated blood loss should be administered in isotonic crystalloids.
5. For uncontrolled hemorrhage, hypotensive resuscitation should be used; small volumes of fluids are administered to maintain organ perfusion and a mean arterial pressure of 60 mm Hg until the hemorrhage can be controlled.

Fluid Therapy in Acute Neurologic Injury (Box 44.6)

Darien J. Feary

The approach to fluid therapy in horses and ruminants with acute brain or spinal cord injury is aimed at maintaining oxygen delivery, cerebral perfusion, and energy supply to meet the

BOX 44.6

Fluid Guidelines for Horses With Acute Neurologic Injury

1. The clinical outcome of large animal patients with brain and spinal cord injury may be improved by the prompt recognition and treatment of systemic and central nervous system hypoperfusion.
2. Isotonic crystalloid solutions appear to be the most appropriate fluids for resuscitation in acute neurologic injury, followed by careful administration of hyperosmolar therapy with mannitol or hypertonic saline if evidence of cerebral edema is present.
3. Diligent monitoring of clinical and laboratory measures of perfusion, osmolarity, and electrolyte concentrations is important for optimizing patient care and the likelihood of recovery in these patients.

metabolic demands of the neuronal tissue, and fluid therapy is a fundamental part of preventing or minimizing secondary neuronal injury, ischemia, and irreversible damage.

The primary goals of fluid therapy for both brain and spinal cord injury follow similar principles and include prevention or prompt recognition and treatment of hypovolemia and hypotension, intracranial hypertension (or cerebral edema), and glucose and electrolyte abnormalities. There is a large body of evidence in the human critical care literature that indicates hypoxemia (PaO_2 <60 mm Hg) and hypotension (systolic blood pressure <90 mm Hg) are independently associated with worse neurologic outcomes in traumatic brain injury (TBI).[1-7] Addressing hypoxia and hypotension should be a priority in large animal patients with neurologic injury, as soon as it is practical and safe to do so. Although both brain and spinal cord injuries are potentially life threatening in large animals, acute brain injury is likely to be the most influenced, either negatively or positively, by the fluid therapy plan that is instituted. This is mainly because the cranial vault is a closed space, composed of brain (approximately 80%), blood (approximately 10%), and CSF (approximately 10%). An increase in one component must result in a compensatory decrease in another. The presence of the blood-brain barrier, intact or not, is another important factor in the selection of the most appropriate fluid for management of acute brain injury.

The most important consideration in the management of cerebral injury is the maintenance of cerebral blood flow (CBF), which is often reduced post injury. The major determinant of CBF is cerebral perfusion pressure (CPP), which is the difference between MAP and intracranial pressure (ICP) as defined by the following equation: CPP = MAP – ICP. In the normal brain, cerebral autoregulation maintains a relatively constant CBF despite wide variations in perfusion pressure, within the range of 50 to 150 mm Hg (in humans). In the injured brain, autoregulation may be impaired, often with concurrent traumatic shock and hypotension, and CBF becomes directly dependent on CPP. Therefore it becomes critical to prevent hypotension by maintaining MAP above 80 mm Hg and to avoid increases in ICP that result from cerebral edema or hemorrhage. ICP is not routinely measured in large animal patients, limiting its use in guiding fluid therapy. However, neurologic signs suggestive of elevated ICP (e.g., obtunded mentation, mydriasis) indicate the need for specific treatment to reduce ICP, with frequent reassessment of neurologic status being important in determining response to treatment.

Fluid management in large animal patients with acute neurologic injury is essentially based on the principles and guidelines established in human medicine from extensive laboratory and clinical studies. The ideal fluid for these human patients remains controversial and is a topic of ongoing research. When presented with a large animal patient with central nervous system injury, the clinician should formulate a fluid therapy plan tailored to the individual animal, based on findings of thorough physical and neurologic examinations and assessment of laboratory data. The author suggests the following goal-directed approach:

- Goal 1: Treat hypovolemia and hypotension with adequate fluid replacement therapy to attain a normovolemic and normotensive state.
- Goal 2: Treat signs of cerebral edema or intracranial hypertension with hyperosmolar therapy.
- Goal 3: Use fluid additives to normalize glucose and electrolyte values, and provide thiamine supplementation.

REPLACEMENT FLUID THERAPY FOR NEUROLOGIC TRAUMA CASES. Although fluid restriction historically has been advocated for patients with TBI under the premise that intravenous fluids increase cerebral edema formation, this recommendation has been replaced by prompt restoration of adequate intravascular volume using the fluid challenge approach, with the goal of achieving and maintaining euvolemia, normal blood pressure, and tissue oxygenation.[8] This is best achieved and controlled through the intravenous route in injured horses. Overhydration should be avoided, particularly in neonates, which are more susceptible to volume overload than adult horses.

Balanced isotonic crystalloid fluids are traditionally used for volume resuscitation, although there may be a role for hypertonic saline during resuscitation, as well as for specific treatment of intracranial hypertension (see later).[8] Selection of the appropriate fluid for replacement therapy requires an understanding of the role of the blood-brain barrier. Because of its unique properties, the development of cerebral edema is fundamentally different from edema formation in other organs or tissues.[9] Briefly, the normal blood-brain barrier functions as a semipermeable membrane, separating the brain from the intravascular space. In the normal animal the blood-brain barrier is impermeable to large molecules (plasma proteins) but is only minimally permeable to most ions. It is freely permeable to water, however. The tonicity of the intravascular fluid, determined by its sodium concentration, influences the movement of free water across the blood-brain barrier by creating an osmotic pressure gradient between the brain interstitium and the intravascular space. In TBI the blood-brain barrier may be damaged, often producing heterogeneous regions of varying degrees of blood-brain barrier integrity and permeability. Unfortunately, demonstrating and predicting the extent of such injury in clinical patients is very difficult; the clinician often likely must assume the presence of normal brain and functional blood-brain barrier regions for certain principles of fluid management, such as osmotherapy, to be effective.[10]

Hypotonic crystalloids, such as 5% dextrose in water or 0.45% saline solutions, are contraindicated in patients with TBI. They lower plasma osmolarity and result in excess free water diffusion into the brain, with subsequent cerebral edema formation. Hypotonic fluids should be avoided for rapid volume replacement in patients with brain injury.

Isotonic crystalloids, such as LRS, Plasma-Lyte 148 or Plasma-Lyte A, and Normosol-R, create a minimal to no osmotic gradient across the blood-brain barrier, are readily available and inexpensive, and are therefore the current fluids of choice for replacement and maintenance therapy in patients with brain and spinal cord injury. Hypertonic crystalloids, such as 7.5% saline, create an osmotic gradient across the blood-brain barrier in favor of free water movement out of the brain, thereby reducing ICP. Hypertonic fluids have traditionally been recommended only after adequate provision of intravascular fluid volume in horses with signs of elevated ICP or deteriorating neurologic status. However, hypertonic saline has been increasingly advocated for initial fluid resuscitation in TBI in humans because of its ability to rapidly expand intravascular volume while simultaneously decreasing ICP.[11] The recent Brain Trauma Foundation's Guidelines for Prehospital Management of TBI recommend hypertonic resuscitation as a treatment option for patients with severe TBI (however, this is based on weak evidence).[12] It should be noted that in pediatric patients with TBI, the recommendation is to treat hypotension with isotonic fluids only.[12]

Colloids—such as plasma, human albumin, and the synthetic agents hetastarch, pentastarch, and dextran—exert variable oncotic pressures and are very effective for intravascular volume expansion and maintenance. The use of colloid solutions in neurologic injury is debatable, mainly because the major determinant of fluid flux across the blood-brain barrier is plasma osmolarity; because colloids contribute only a small number of particles in plasma, even large changes in plasma colloid oncotic pressure only minimally influence water movement across the normal blood-brain barrier. This is in contrast to the effectiveness of even small changes in plasma osmolarity.[13]

VetBooks.ir

In addition, the relatively higher cost of colloid solutions and the greater risk of development of hemostatic abnormalities and allergic reactions suggest little benefit of colloid solutions over crystalloids in cases of TBI. Furthermore, findings from the saline versus albumin fluid evaluation (SAFE) study showed an increased mortality in a subgroup analysis of human patients with TBI who were treated with albumin.[14]

HYPEROSMOLAR THERAPY IN BRAIN AND SPINAL CORD INJURY. Hyperosmolar therapy is the pharmacologic induction of supraphysiologic serum osmolality with either hypertonic saline or mannitol and is the mainstay of medical management of patients with intracranial hypertension (ICP >20 mm Hg) associated with TBI and intracranial hemorrhage.[13] If clinical evaluation of the equine patient with TBI suggests that the patient has or is at risk for developing intracranial hypertension, then osmotherapy may be indicated. Clinical signs such as obtunded mentation, progressive mydriasis, or any deterioration of neurologic status may indicate increased intracranial hypertension. Hyperosmolar solutions exert their effect of reducing ICP by creating an osmotic gradient across the blood-brain barrier of at least 10 mOsm/L. It is advisable to measure plasma osmolarity in large animal patients, at least before administration of hyperosmolar solutions, to avoid excessive increases in plasma osmotic pressure. Osmotherapy should be instituted only after restoration of adequate intravascular volume and blood pressure if CPP is to be optimized.

The two most commonly used and available hyperosmolar solutions for use in large animals are mannitol (20%) and hypertonic (3% to 23.4%) saline. Both agents have been shown to be effective in lowering ICP in human patients with TBI, although some studies suggest greater efficacy and fewer side effects with the use of hypertonic saline,[15,16] whereas other comparative studies have shown no benefit of hypertonic saline over mannitol in controlling ICP when multiple doses are administered over 5 days.[17] A proposed reason for this lack of benefit is an increased urinary loss of sodium with hypertonic saline and consequent inability to achieve higher serum sodium concentrations and osmolarity.

Although it is widely established that both mannitol and hypertonic saline are effective in acutely lowering ICP when it is increased, the recent Brain Trauma Foundation guidelines failed to find any evidence meeting current standards on which to base recommendations regarding osmotherapy.[12]

It is challenging to relate outcomes from research in human medicine to large animal patients because the etiology, type of brain injuries, and frequency of surgical intervention in human patients with TBI make them a very different patient population. Until ICP can be measured in the clinical setting, large animal veterinarians must use their frequent neurologic assessments, blood analysis (including osmolarity), judicious use of osmotherapy when indicated (neurologic evidence of increased ICP), and response to therapy.

Mannitol (20%) is a six-carbon sugar with an osmolarity of 1098 mOsm/L. The recommended dose is a 0.5 to 1 g/kg IV bolus administered over 20 to 30 minutes, every 6 to 8 hours. It is important to avoid rapid mannitol infusion (<5 minutes), since this can lead to transient hypotension. The ICP-reducing effects of hyperosmolar solutions are believed to be biphasic in nature. After bolus dose administration, an initial plasma-expanding effect reduces blood viscosity and hematocrit and improves rheologic properties of red blood cells, resulting in reduced ICP and improved CBF. After this immediate hemodynamic effect is a delayed osmotic diuretic effect resulting from the decreased reabsorption of sodium and water by the renal tubules, which also contributes to ICP reduction. Onset of effect of mannitol therapy is 15 to 30 minutes after bolus administration. Mannitol should not be administered as a continuous infusion for the purpose of treating cerebral edema, since it loses its plasma-expanding effects and increases the likelihood of development of side effects.[18]

The detrimental effects of mannitol are more likely to develop and become clinically significant with excessive or prolonged use (>2 to 3 days). Side effects include hypovolemia and hypotension caused by excessive diuresis, electrolyte disturbances (e.g., hyponatremia, hypochloremia, hypokalemia, hypocalcemia), acidosis, acute renal failure, and a rebound increase in ICP associated with reversal of the osmotic gradient, a phenomenon most likely explained by accumulation of the osmotic agent in brain tissue after movement across regions of a damaged blood-brain barrier.[18] A threshold level of serum osmolarity of 320 mOsm/L is often used as an indicator for decrease or withdrawal of mannitol therapy. However, serum osmolarity is not a sensitive indicator of mannitol-induced renal failure, and the osmolar gap (the difference between calculated and measured serum osmolarity) is more reflective of serum mannitol accumulation. Based on this, an osmolar gap threshold of 55 mOsm/kg has been suggested for monitoring mannitol therapy in TBI.[15] There is insufficient evidence to support the dogma that mannitol is contraindicated in the presence of intracranial hemorrhage.

Hypertonic (7.5%) saline has an osmolarity of 2400 mOsm/L and, similar to mannitol, effectively reduces ICP primarily through an immediate hemodynamic effect, followed by a delayed osmotic effect. Hypertonic saline (7.5%) can be administered as an intravenous bolus dose (4 mL/kg) or as a CRI. There are no clear guidelines as to the optimal concentration (3% to 23.4%) or dose of hypertonic saline in human patients with TBI. However, effective CRI dosing has been achieved in human patients using 3% hypertonic saline at 0.1 to 2.0 mL/kg/h, titrating to serum sodium concentrations of 145 to 155 mmol/L, and not exceeding serum osmolarity of 360 mOsm/L.[15] Hypertonic saline may have additional beneficial effects over mannitol in TBI because of rapid augmentation of cardiac output, contractility, and MAP with administration of smaller volumes. In addition, hypertonic saline is theoretically less likely to cross the blood-brain barrier than mannitol because the reflection coefficient of NaCl is 1 (not permeable), compared with 0.9 for mannitol (more permeable). Additional benefits of hypertonic saline on the injured brain include sodium-related stabilization of cell membrane electrochemical gradients and modulation of the inflammatory response.[19]

Laboratory studies investigating the effects of hypertonic saline in resuscitation after spinal cord injury have also shown promising results, with increased spinal cord blood flow, downregulation of the inflammatory response, and attenuation of spinal cord injury.[20] Further clinical studies are needed.

Complications of hypertonic saline are uncommon and include hypernatremia and theoretical development of central pontine myelinolysis.[15] Hypokalemia can occur because of kaliuresis in response to reabsorption of large amounts of sodium in the distal tubule, as well as hyperchloremic acidosis, emphasizing the importance of regular assessment of hemodynamic and plasma electrolyte and acid-base status. Coagulopathy and bleeding complications could occur as a result of dilutional effects but are of greater concern in the actively bleeding patient. Risks of hypovolemia and acute renal failure are not reported for hypertonic saline in TBI, although renal insufficiency is a relative contraindication to all hyperosmolar therapy. Rebound elevations in ICP can occur with withdrawal of therapy; therefore slow, gradual weaning of hypertonic saline infusions is recommended.[15]

Osmotherapy is likely to be most effective if initiated early following significant TBI in cases with clinical evidence of increased ICP, and with duration determined by response to therapy, limited to 24 to 48 hours, with close observation and monitoring of neurologic status, serum electrolytes, acid-base status, osmolarity, and renal function, to minimize development

of side effects. Because measurement of ICP is not practical to perform routinely in equine patients with TBI at this time (it has been measured in a research setting), the efficacy of and optimal recommendations for hyperosmolar therapy in equine patients with TBI remain unknown and are based on the human medical literature.

FLUID ADDITIVES IN NEUROLOGIC INJURY

Glucose. It has been widely recognized that hyperglycemia is a common occurrence in acute brain injury in humans.[21] Hyperglycemia is believed to worsen neuronal injury and is associated with increased mortality and neurologic outcomes after TBI.[21,22] Consequently, glucose supplementation during large-volume fluid replacement should be avoided unless the patient is hypoglycemic. As noted below, hypoglycemia should be avoided in patients with TBI.

Recommendations regarding glucose control in the critically ill patient have varied significantly in the last decade. Tight glycemic control (80 to 110 mg/dL) with the use of insulin was suggested for critically ill human patients, but these recommendations have been relaxed more recently because of associated incidences of hypoglycemia when centers resort to such tight glycemic control.[23] In addition, the human critical care literature suggests that hypoglycemia may be particularly detrimental to an acutely injured brain. The brain has limited ability to compensate for low glucose concentrations, and the addition of impaired cerebral autoregulation with fluctuations in cerebral blood flow after TBI may cause increased susceptibility to hypoglycemia.[24] Although there are no studies in horses with TBI to enable recommendations regarding the best management of blood glucose, recent human medical studies have shown that tight glycemic control after TBI is potentially detrimental due to increased regional glucose metabolism in the brain, leading to enhanced metabolic crisis, and increased markers of cellular distress (elevated lactate/pyruvate ratios and glutamate).[25] Therefore limiting the brain's glucose supply during a period of high metabolic demand after TBI may actually contribute to secondary injury. It is currently suggested that delivery of more glucose through mild hyperglycemia (120 to 150 mg/dL) may be necessary following TBI.[26]

These factors should be considered in the monitoring and fluid therapy plan for any large animal with neurologic injury, particularly neonates, since they are more susceptible to hypoglycemia.

Thiamine. Thiamine (vitamin B_1) is a water-soluble B vitamin synthesized only by plants and microorganisms. Most animals have a nutritional requirement for this vitamin, although adult ruminants and horses normally can obtain adequate quantities produced by bacteria in the rumen or cecum.

Thiamine, in its active form (thiamine pyrophosphate), plays a very important role in glucose metabolism and energy production, where it functions as a required cofactor for certain enzymes (pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, branched-chain ketoacid dehydrogenase, transketolase) involved in glycolysis, the citric acid cycle, and the pentose phosphate pathway. Thiamine is also important in nerve and muscle function, where it plays a role in neurotransmission and excitation.

Thiamine deficiency is known to be associated with neurologic disease in humans and in ruminants (polioencephalomalacia). Determination of thiamine status of an animal requires measurement of red blood cell transketolase activity; therefore measurement and documentation of thiamine deficiency in clinical cases is not routinely reported. Whether or not supplementation of thiamine in acute traumatic neurologic injury is indicated is not currently supported by published evidence. However, given the increased susceptibility of damaged neuronal tissue to inadequate energy production and supply, the practice of thiamine supplementation in neurologic injury in large animals appears justified. In addition, recent experimental investigation suggests a potential neuroprotective role of thiamine in reactive oxygen species–induced neuronal injury.[27] The author has used a dose of 5 to 10 mg/kg of thiamine diluted in crystalloid fluids. Thiamine should be protected from light.

Electrolytes. Sodium disturbances can have serious consequences in brain injury and should be corrected promptly if they are acute (<24 hours' duration). Isotonic fluid administration is appropriate in most cases. Glucose and mannitol cause translocation of water into the extracellular fluid, and excessive amounts can lead to a clinically significant reduction in sodium concentration, as can free water administration with hypotonic fluids. If hyponatremia (Na^+ <125 mEq/L) is believed to have been present for longer than 24 hours, slower correction (0.5 mEq/L/h or 10 mEq/day) is needed to avoid development of central pontine myelinolysis.

Calcium is essential in maintaining cell membrane potentials and promoting neurotransmitter release. Excessive intracellular calcium accumulation is also well recognized as one of the most important pathways of secondary neuronal damage. During conditions of cerebral or spinal cord ischemia, inadequate energy supply in the form of adenosine triphosphate (ATP) leads to widespread neuronal depolarization and alterations in ion channel permeability, ultimately resulting in excessive intracellular calcium concentrations and cell death.

Serum total and ionized calcium concentrations are measures of extracellular calcium, and so the goal of targeting intracellular calcium homeostasis is limited to maintaining normal extracellular fluid concentrations at this time. Because of the known toxic effects of excessive calcium in neuronal injury, a conservative approach to calcium supplementation may be justified in the acute fluid management of large animal patients. To prevent the detrimental effects of hypocalcemia, one approach may be to avoid the addition of calcium to the intravenous fluids over the initial 24 to 48 hours unless the ionized calcium concentration is ≤1.0 mmol/L or clinical signs of hypocalcemia are present.

Magnesium is an important cofactor in many enzymatic reactions and for the regulation of sodium and potassium transport across cell membranes through activation of the Na^+/K^+-ATPase pump. Magnesium is essential for central nervous system cellular energy metabolism, modulation of excitatory amino acid transmission, and calcium channel antagonism. After neurologic injury, disruptions in the blood-brain barrier may impair regulation of CSF magnesium concentrations, and hypomagnesemia is commonly recognized in human patients with brain injury.[28] Experimental and clinical evidence suggests that a depletion of CSF magnesium concentrations is associated with the risk of secondary neurologic injury.[29] Animal studies also suggest a neuroprotective effect of intravenous magnesium administration after traumatic brain injury.[30] However, studies in human patients with TBI have failed to show a consistent therapeutic effect of magnesium supplementation.[29] Although magnesium supplementation for the treatment of TBI in equine patients cannot be recommended at this time, it is important to monitor serum total and ionized magnesium concentrations to prevent and treat hypomagnesemia after neurologic injury. Selection of intravenous fluids containing magnesium, such as Normosol-R or Plasma-Lyte 148 or Plasma-Lyte A (Mg^{2+} = 3 mEq/L), may be beneficial.

Other electrolyte disturbances identified commonly in patients with neurologic injury include hypokalemia and hypophosphatemia. A combination of decreased dietary intake and increased renal loss as a result of diuretic therapy is a likely explanation. Because of the important role of potassium in establishing normal resting membrane potential and nerve conduction, among other functions, regular monitoring and intravenous fluid supplementation if serum potassium

concentration decreases to less than 3.0 to 3.2 mEq/L is indicated in large animal patients with neurologic injury.

Serum phosphate concentrations are not as routinely monitored as other electrolytes in large animal patients, and so deficiency is rarely reported. Clinical signs of hypophosphatemia usually do not manifest until serum concentrations fall below 1 mg/dL in humans and animals. It is important to recognize phosphate deficiency in patients with recent neurologic injury because it can cause or contribute to altered mental status, muscle weakness, seizures, respiratory insufficiency, and ventricular dysrhythmias. Because clinical manifestations of hypophosphatemia have not been reported in horses, it is difficult to make recommendations for supplementation. The author has used a dose of 0.01 mmol/kg/h of sodium phosphate when marked hypophosphatemia has been present in horses.

Fluid Therapy for Horses With Rhabdomyolysis (Box 44.7)

K. Gary Magdesian

Horses with severe rhabdomyolysis are at risk for renal failure from both myoglobinuria and hypovolemia. Myoglobin causes formation of tubular casts (with resultant tubular obstruction) by precipitation with secretory proteins from the tubular cells. It is also directly toxic through release of iron and formation of free radicals. Finally, myoglobin leads to release of platelet-activating factor and endothelins that lead to renal arteriolar vasoconstriction. In addition, horses and foals with severe rhabdomyolysis may develop marked electrolyte derangements from cell lysis, including hyponatremia, hypochloremia, hyperkalemia, and hyperphosphatemia.[1,2] In a study evaluating the electrolyte changes in horses with acute rhabdomyolysis, the most consistent abnormality was hypochloremia.[1] These changes have been reported in foals with rhabdomyolysis as a consequence of selenium deficiency, possibly combined with increased oxidant stress resulting from sepsis or hypoxia and reperfusion injury after parturition.[2] Three of four foals developed cardiac arrhythmias characterized by spiked T wave and decreased P wave amplitude on electrocardiographic analysis. Destruction of the major intracellular fluid compartment through extensive myonecrosis, combined with myoglobinuric renal insufficiency, produces major fluid shifts and electrolyte derangements. In that report, foals with hyperkalemia caused by rhabdomyolysis were effectively treated with mineralocorticoids, loop diuretics, and ion exchange resins to enhance elimination of potassium. Intravenous calcium, glucose, insulin, and sodium bicarbonate were also administered to help redistribute potassium back to the intracellular fluid.[2]

Metabolic acidosis is not common in horses with acute rhabdomyolysis, and alkalosis associated with hypochloremia may be more of a concern.[1] In fact, fluids with relatively higher chloride concentration as compared with horse plasma may be optimal when hypochloremia is present. These include LRS (chloride, 109 mEq/L) or Hartmann's solution (111 mEq/L). If LRS is used, attention should be paid to serum or plasma potassium concentrations because LRS contains potassium chloride in the amount of 4 mEq/L of potassium (see Table 44.1). LRS or Hartmann's solution might be preferable over acetate-containing fluids such as Normosol-R or Plasma-Lyte 148 or Plasma-Lyte A in acute rhabdomyolysis cases, because the liver is the primary organ of lactate metabolism, whereas the muscle tissue plays a larger role in metabolism of acetate. In addition, the chloride concentration of these acetated fluids is lower than that of LRS, which may be a slight disadvantage if horses have metabolic alkalosis resulting from hypochloremia. Lactate in LRS does not preclude its use in hyperlactatemic horses with muscle disorders, because hepatic metabolism of lactate occurs rapidly once plasma volume is expanded. In addition, lactate is not necessarily markedly increased in horses with rhabdomyolysis.[3]

LRS is preferred over normal saline for treatment of humans with rhabdomyolysis.[4] In a randomized blinded study of humans with rhabdomyolysis, urine and plasma pH was higher in the LRS group, whereas serum sodium and chloride concentrations were higher in the saline group.[4] Unlike the saline group, the LRS group needed little supplemental sodium bicarbonate and did not develop metabolic acidosis. Acidic urine favors formation of myoglobin-induced tubular casts and tubular obstruction. Therefore LRS is considered by many to be the fluid of choice to maintain adequate urine flow in patients with rhabdomyolysis. One potential disadvantage of LRS in treatment of rhabdomyolysis is the presence of a low concentration (3 mEq/L) of calcium. Calcium influx plays a role in cell lysis after lipoperoxidation of muscle cells. How these data apply to adult horses, which generally have alkaline urine at baseline, requires further study. Because 0.9% saline is mildly acidifying in horses as well, it likely is not the optimal fluid choice for horses with rhabdomyolysis either. Because foals often have acidic urine, LRS may be a good fluid choice for foals with rhabdomyolysis as well.

In addition to crystalloid support, sodium bicarbonate is recommended for human rhabdomyolysis only if necessary to correct a systemic metabolic acidosis.[5] Mannitol is administered to maintain urine output (300 mL/h or greater urine output in adult humans).[5]

Hereditary causes of rhabdomyolysis in horses include polysaccharide storage myopathy, glycogen branching enzyme deficiency, and recurrent exertional rhabdomyolysis (RER).[6-8] Because an alteration in muscle cell calcium regulation is a primary feature in the pathophysiology of RER, calcium supplementation of fluids administered to affected horses should be avoided.[9] Serum potassium concentrations should be monitored frequently in horses with rhabdomyolysis because of risks associated with hyperkalemia.

Because horses with acute rhabdomyolysis are at risk for renal failure, rates of fluid administration should exceed maintenance requirements to provide diuresis and dilution of urine myoglobin concentration. In adult human patients with rhabdomyolysis, the goal of urine production is greater than 300 mL/h.[5] Myoglobin is nephrotoxic directly to renal tubular epithelium; as well, it indirectly causes renal arteriolar vasoconstriction and secondary hypoperfusion. Rates of fluid administration vary with individual fluid balance and renal function, but 1.5 to 2 times maintenance requirement is a reasonable starting point. The rate can be adjusted based on the rate of creatine kinase (CK) decline and resolution of myoglobinuria.

BOX 44.7

Fluid Considerations for Horses With Rhabdomyolysis

1. Horses with acute myopathies often exhibit hypochloremia and may have concurrent hyponatremia, hyperkalemia, and hyperphosphatemia, especially when the rhabdomyolysis is severe.
2. Lactated Ringer's solution is a fluid with a physiologic basis for use with rhabdomyolysis.
3. Horses with acute myopathies should be administered fluids at a rate greater than maintenance requirements in order to provide for dilution and diuresis of myoglobin.

Fluid Therapy for Hyperkalemic Periodic Paralysis (Box 44.8)

K. Gary Magdesian

Hyperkalemic periodic paralysis (HYPP) is caused by a genetic defect in the sodium channel on the sarcolemma, resulting in

VetBooks.ir

BOX 44.8

Fluid Guidelines for an Acute Hyperkalemic Periodic Paralysis Episode

1. 4 to 20 mL of 0.9% saline per kilogram, depending on severity and duration.
2. 2% to 5% dextrose (2% to 2.5% if ≥5 L are administered; 5% if 2 L are administered to a 500-kg horse)
3. 0.2 to 0.5 mEq/kg of calcium (0.2 to 0.5 mL/kg of 23% calcium gluconate total, diluted in fluids); calcium should be administered early (along with dextrose), since it is protective against arrhythmias. Dilution of 23% calcium gluconate should be to a final ratio of no more than 50 mL of calcium gluconate/L of fluid.
4. 0.5 to 1 mEq/kg of bicarbonate in second bag of normal saline, along with dextrose. Note that sodium bicarbonate and calcium should not be mixed in the same bag.
5. For refractory cases, insulin can be added to dextrose supplementation (regular insulin, 0.005 to 0.1 unit/kg/h).

intermittent signs of sweating, muscle fasciculations, stridor, and weakness.[1] Stressors such as anorexia, anesthesia, concurrent illness, trailering, and cold environmental temperatures can precipitate hyperkalemia and onset of clinical signs. Fluid therapy for horses with hyperkalemia should be low or free of potassium. Physiologic (0.9%) saline and isotonic sodium bicarbonate (1.3%) are both potassium-free options that have been used. Note that these two fluid types have potential effects on acid-base physiology, with saline producing a mild strong ion acidosis and sodium bicarbonate a metabolic alkalosis. There is some evidence in human medicine that the strong ion acidosis induced by the chloride excess in saline can actually increase potassium concentrations by causing shifts from the intracellular space. There are small studies to suggest that the use of balanced crystalloids in the presence of mild hyperkalemia is safe. However, larger studies are needed before balanced crystalloids can be recommended.

Horses experiencing stressors such as forced withholding of feed before surgery or being off feed because of concurrent illness should be administered fluids with dextrose and/or calcium supplementation prophylactically at a maintenance rate. Supplementing with dextrose (2.5% to 3% dextrose at 1 L/h for an average-size horse, or 0.8 to 1 mg/kg/min of dextrose) may minimize the development of hyperkalemia and subsequent HYPP episodes. Calcium does not decrease serum potassium concentrations significantly but rather protects the heart from its adverse effects by raising threshold potential for the action potential on the sarcolemma.

Horses experiencing an active episode of hyperkalemia or showing clinical signs of HYPP should be administered 0.9% saline as the fluid choice, with the additives of calcium (0.2 to 0.5 mEq/kg of 23% calcium gluconate total, diluted as ≤50 mL 23% calcium gluconate/L of fluid) and dextrose (5% if 2 L of fluids are administered, or up to 2% to 2.5% if 5 L are administered). If signs persist, a second bag with sodium bicarbonate (0.5 to 1 mEq/kg of bicarbonate empirically) and dextrose should be added. Calcium and sodium bicarbonate should not be administered concurrently in the same fluid administration set because of a potential for precipitation. LRS also contains calcium, and therefore sodium bicarbonate should not be added directly to it.

Administration of two 5-L bags of saline to a 500-kg horse, with 2% to 2.5% dextrose, with the first bag containing calcium (0.5 mL/kg of 23% calcium gluconate total) and the second containing sodium bicarbonate (0.5 to 1 mEq/kg of bicarbonate) is a reasonable approach to treating an acute and severe episode. Each of these bags would be given sequentially. Some horses may not require this volume of crystalloid and can be treated with less; if less volume is desired, 4 to 6 mL/kg of normal saline can be administered. In this case, dextrose, calcium, and sodium bicarbonate can be added to 1-L bags; the sodium bicarbonate and calcium must be kept separate from one another. In this case, 5% dextrose and 0.2 mL/kg of 23% calcium gluconate would be administered in the first 1-L bag, and 5% dextrose and 0.5 mEq/kg of bicarbonate can be used in the second 1-L bag.[1]

Long-term management of horses with HYPP consists of a low-potassium diet, regular exercise, attempts to minimize stressors, and medications such as acetazolamide and phenytoin.[2] Horses undergoing chronic acetazolamide therapy could theoretically develop hyperchloremia and a tendency toward metabolic acidosis because of the effects of long-term inhibition of carbonic anhydrase. Administration of large volumes of 0.9% saline can compound hyperchloremia[3]; to minimize acidemia, it can be coadministered with isotonic sodium bicarbonate or other alkalinizing crystalloid when such horses require large-volume or long-term fluid therapy devoid of or low in potassium. Phenytoin can mask the clinical signs of HYPP, even when hyperkalemia is present; it must be emphasized that phenytoin should not be the sole prophylactic medication in these horses, because hyperkalemia may be left unchecked.[2]

Fluid Therapy for Competitive Endurance Horses

C. Langdon Fielding

Approximately 4% to 9% of endurance horses are eliminated from competition for metabolic reasons that include colic, rhabdomyolysis, synchronous diaphragmatic flutter, and exhaustion.[1,2] Veterinarians are responsible for the emergency treatment of horses with metabolic derangements, and fluid therapy is an essential component of the therapeutic management of critically ill endurance horses.

GENERAL APPROACH TO FLUID MANAGEMENT OF ENDURANCE HORSES. Endurance horses experience significant fluid losses during competition; even horses that successfully complete rides lose approximately 5% of body weight in water.[3,4] Horses presented for treatment of metabolic problems often exhibit clinical signs of hypoperfusion. In evaluating sick endurance horses, the following seven clinical perfusion parameters should be evaluated:

1. Mentation
2. Heart rate
3. Pulse quality
4. Mucous membrane color
5. Capillary refill time
6. Extremity temperature
7. Jugular fill

Urine production, when apparent, can be used as an additional perfusion parameter. In the absence of polyuric renal failure, urine output signifies renal perfusion, which is one means of assessing organ perfusion. Horses with altered mentation, persistent tachycardia (>60 bpm), poor peripheral pulse quality, pale mucous membranes, capillary refill time greater than 2 seconds, cool extremities, or lack of urine production should be considered candidates for fluid therapy. Laboratory parameters consistent with dehydration, such as increased PCV, increased total protein, and increased serum creatinine, have been identified in endurance horses at risk for metabolic failure.[5]

The rapid administration of large volumes of crystalloids is the basis of treatment at many ride events. Volume loading increases preload, thereby enhancing stroke volume, cardiac output, and subsequent oxygen delivery. One suggested protocol for fluid resuscitation of hypovolemic endurance horses is the fluid challenge method described earlier; this consists of a bolus dose of 20 mL/kg of isotonic crystalloid (10 L for an

VetBooks.ir

average, 500-kg horse) followed by reassessment of the seven perfusion parameters. If the parameters have not improved in response to the initial bolus, another 20 mL/kg bolus should be administered and followed by clinical reassessment. Approximately 1 hour is required to administer a 10-L bolus through a 14-gauge intravenous catheter and standard administration set; multiple catheters or those with large bores (10 gauge) can be used for more rapid administration. Most endurance horses requiring emergency intravenous fluid administration during competition typically require 20 to 30 L of fluids.[6,7] However, more severely affected horses may require up to 40 to 60 L of crystalloids to address hypovolemia.

Several types of intravenous crystalloids are available for administration to endurance horses. LRS and Normosol-R are balanced polyionic crystalloids commonly administered to treat hypovolemia in these horses. Specific electrolyte abnormalities may dictate the use of isotonic saline (when hypochloremic alkalosis is present) or fluid additives (potassium chloride or calcium gluconate when hypokalemia or hypocalcemia is identified, respectively). However, in one study, 0.9% sodium chloride resulted in hyperchloremia when administered to eliminated endurance horses.[6] The electrolyte and serum biochemistry profiles of endurance horses that fail to finish a race are not necessarily markedly abnormal and allow the use of commercial fluids such as LRS and Normosol R.[4] A range of electrolyte abnormalities has been identified in competing endurance horses and includes hypokalemia and an increased strong ion difference (SID).[8,9] Calcium supplementation is common during fluid therapy of eliminated endurance horses. However, results of studies examining the concentration of total and ionized serum calcium in horses during endurance rides have been equivocal as to calcium status.[3,4,10] If calcium is used, it can be added to fluids through calcium gluconate (1 mL/kg of 23% calcium gluconate at a rate of ≤50 mL/L of crystalloid). Calcium supplementation is required in horses with synchronous diaphragmatic flutter and should be administered until clinical signs resolve.[11] Excessive use of calcium in endurance horses may not be warranted, since it plays a role in cell death and apoptosis, particularly with reperfusion injury; supplementation of calcium in humans with rhabdomyolysis is controversial.[12]

Endurance horses with prolonged ileus or anorexia may benefit from dextrose supplementation of fluids. A dose of 0.5 to 1 mg/kg/min of dextrose is well tolerated by most adult horses and is equivalent to 1.5% to 3% dextrose in fluids administered at a rate of 1 L/h for a 500-kg horse. Ideally, blood glucose concentrations should be monitored in horses administered dextrose to avoid hyperglycemia.

Medications commonly used in the treatment of endurance horses with metabolic derangements may affect fluid balance and should be considered in horses receiving fluid therapy. Sedatives and tranquilizers such as α_2-adrenergic agonists (xylazine, detomidine, romifidine) and phenothiazines (acepromazine) have deleterious effects on cardiac output and/or blood pressure.[13,14] Drugs such as dimethyl sulfoxide (DMSO) and α_2-adrenergic agonist sedatives also affect urine output and can therefore alter fluid balance.[15,16]

The following metabolic conditions are common metabolic disorders of endurance horses.

EXERTIONAL MYOPATHY. Intravenous fluid therapy is the most important feature of treatment for rhabdomyolysis. See the Fluid Therapy for Horses with Rhabdomyolysis section earlier in this chapter. Fluids should be administered in 10-L (20 mL/kg) boluses until urine output is achieved and the urine is grossly clear. Low doses of flunixin meglumine (0.5 mg/kg IV) are indicated for inflammation once hypovolemia is resolved and diuresis (i.e., urination) is achieved. Adequate fluid resuscitation is indicated before release of affected horses, because exertional rhabdomyolysis has been associated with severe renal failure in both humans and horses.[17,18] Horses with myopathies should be monitored closely and reevaluated within 48 hours for azotemia and progress of increased muscle enzymes.

FAILURE TO RECOVERY. Horses that are eliminated from ride events because of persistent tachycardia warrant close monitoring. Such horses often require treatment at a later time. The seven clinical perfusion parameters should be evaluated thoroughly, and any animal with equivocal circulatory or hydration status should be reevaluated frequently to make sure that it is improving through voluntary eating and drinking, rather than deteriorating further. Those with clear hypovolemia or failure to improve with rest should be administered intravenous fluids as described earlier.

SYNCHRONOUS DIAPHRAGMATIC FLUTTER (THUMPS). Synchronous diaphragmatic flutter is typically associated with hypocalcemia, and concurrent metabolic alkalosis, hypochloremia, and hypokalemia are often also present and have been implicated in its development.[19] Many affected horses are otherwise stable hemodynamically and meet all the criteria for adequacy of perfusion. Despite these findings, horses with thumps often require treatment with intravenous fluids supplemented with calcium for resolution of hypocalcemia and clinical signs. Calcium gluconate can be added to 5-L bags of crystalloid (0.5 mL/kg of 23% calcium gluconate per 5-L bag for a 500-kg horse), and fluids with dilute calcium can be administered as a bolus. Adverse effects of rapid calcium administration include bradycardia, and therefore calcium warrants slow administration. Many mildly affected horses would likely resolve synchronous diaphragmatic flutter with oral electrolytes and/or the consumption of feed (particularly alfalfa).

COLIC. Colic is a common problem identified in eliminated endurance horses and can result in significant mortality.[20] All horses exhibiting signs of colic should have a nasogastric tube passed, as nasogastric reflux (likely resulting from ileus) is a common finding in these horses.[20] Intravenous fluids should be administered as outlined previously until the horse is no longer producing gastric reflux and it is passing manure regularly. Flunixin meglumine (0.5 to 1 mg/kg) can be administered intravenously once hydration is restored. Calcium gluconate can be added to 5-L bags of crystalloid (0.5 mL/kg of 23% calcium gluconate per 5-L bag for a 500-kg horse), and fluids with dilute calcium can be administered as a bolus. Managing endurance horses with colic can be challenging because many show significant levels of pain. It is important to remember that endurance horses with colic rarely have a surgical lesion and typically respond to aggressive medical therapy.[9,20]

Fluid Therapy for Burn (Thermal) Injury in Horses (Box 44.9)

K. Gary Magdesian

Horses with severe burn injuries develop hypovolemic shock and require large volumes of balanced electrolyte replacement fluids.[1] Hypertonic saline and colloids (primarily plasma) may also be used but should be followed with isotonic crystalloids. In humans with burn injuries, the guidelines for rate of administration of isotonic fluids is 2 to 4 mL/kg for each percentage of surface area burned (Parkland formula).[2] A retrospective study found that significantly larger volumes of fluid (i.e., 5.58 mL/kg per percent total body surface area affected) were administered to patients during the first 24 hours of hospitalization than was predicted by the Parkland formula.[3]

If significant smoke inhalation has occurred, the affected horse is at risk for pulmonary edema. In this case, fluid deficits should be corrected carefully so as not to overhydrate the

VetBooks.ir

BOX 44.9

Fluid Guidelines for Burn Injury Patients

1. Hypertonic saline can be used in the resuscitative phase of burn patients but should be followed with isotonic crystalloids.
2. Isotonic crystalloids are often necessary because of tremendous sodium losses through burn wounds.
3. Plasma is an important component of fluid therapy in the severely burned patient because of the potential for protein loss.
4. Administration of excessive volumes of fluids should be avoided because edema is a common complication of burn injuries.

BOX 44.10

Fluid Guidelines for Acute Respiratory Distress Syndrome

1. The ideal initial resuscitative fluid choice for acute respiratory distress syndrome (ARDS) patients is unknown, but crystalloids rather than colloids should probably be used because of the risk for compounding pulmonary edema as colloids leak into lungs. The exception would be the hypoproteinemic patient, in which plasma should be used to correct albumin deficits.
2. Hypovolemia and dehydration should be corrected, but excessive fluid volume should be avoided to minimize worsening of edema. A conservative long-term fluid plan is warranted.
3. Fluid balance in patients with ARDS should be assessed frequently; central venous pressure is a useful means of monitoring fluid balance to prevent large increases in capillary hydrostatic pressure.

animal and compound the edema. Administration of excess crystalloids or high rates of fluids after resolution of hypovolemic shock can result in exacerbation of tissue and pulmonary edema, which is detrimental to the healing of burned tissues and smoke-injured lungs, respectively. Once hydration is adequate, fluid therapy should be discontinued (if drinking) or administered at a rate necessary only to maintain hydration status. If maintenance rates of fluids are required, patients with severe burns may require more sodium than provided for by commercial hypotonic maintenance fluids owing to the tremendous sodium losses through wounds.[4] In these cases, isotonic crystalloids may be required, and therefore monitoring of serum sodium concentrations is important in burn patients.[5] Excess free water should be avoided in these patients, since it can promote intracellular tissue edema.[5]

An important component of fluid therapy of the patient with thermal injury is the administration of plasma. Significant amounts of plasma proteins are lost through cutaneous burns.[4] In addition, burn patients are at risk for coagulopathies, although this has been reported to be rare.[6] Plasma transfusions are an effective source of albumin, as well as antithrombin for coagulopathies. Horses with significant burns can require large volumes of plasma in the first 2 to 3 days. A CRI of plasma can be provided when ongoing losses are present.

Fluid Therapy for Acute Respiratory Distress Syndrome in Horses (Box 44.10)

K. Gary Magdesian

ARDS presents a therapeutic challenge; because of altered Starling's forces (increased vascular permeability) in the pulmonary capillaries, affected horses and foals often have significant pulmonary edema, with protein-rich fluid.[1] Pulmonary capillary hydrostatic pressure becomes the main determinant of edema in these patients due to the increased permeability of pulmonary capillaries.[2] Despite this propensity toward edema formation, horses and foals with ARDS should not be allowed to develop dehydration. Maintenance of normal blood volume and hydration status is critical to tissue oxygenation, including the diseased pulmonary tissue. The goal in therapy of ARDS patients is to reduce extravascular lung water while still maintaining hemodynamic stability and perfusion. In a human clinical trial, conservative fluid management in patients with acute lung injury (ALI) improved lung function and shortened duration of mechanical ventilation and intensive care as compared with patients managed with a liberal fluid strategy, although there was no difference in mortality.[3] The conservative management did not increase nonpulmonary organ failures.[3] It should be noted that the patients in this study were volume replete and relatively stable hemodynamically. Conservative fluid therapy therefore applies to the postresuscitation phase of these patients, when administration in excess of physiologic needs can be detrimental.

Large swings in pulmonary vascular pressures should be avoided to minimize increases in pulmonary hydrostatic pressure. To avoid these wide fluctuations, intravenous fluids should be provided as a continuous infusion rather than as intermittent boluses in horses with respiratory distress.[4] The ideal type of fluid for volume replacement at the time of initial therapy of ARDS patients is unknown; however, colloids should be used judiciously due to the theoretical risk of potentiating pulmonary edema through extravasation of colloids across the leaky pulmonary vasculature. This concern warrants further study; one study demonstrated no increase in transmicrovascular flux of radiolabeled colloids when COP was raised with albumin administration in human patients with pulmonary edema.[5] Isotonic crystalloids, administered at a modest rate and only to effect in normoproteinemic patients, and replacement of plasma proteins in hypoproteinemic patients with the use of plasma are probably the safest fluid guidelines for these patients with the current level of understanding.

Patients with ALI or ARDS should therefore be monitored closely for hypoproteinemia. Correction of hypoproteinemia in human patients with ALI benefits from concurrent administration of albumin.[6] Hypoproteinemic patients receiving both furosemide (as a CRI) and albumin had improved oxygenation, increased net fluid loss, and better maintenance of hemodynamic stability compared with those receiving only furosemide.[6] In addition, 50% of patients in the treatment group achieved resolution of the ALI or ARDS, compared with only 11% of controls. Consideration should be given to correction of hypoproteinemia in foals and horses with ARDS or ALI. An additional benefit of albumin is its antioxidant properties. Albumin can also reduce microvascular permeability and endothelial cell apoptosis.[7-9]

Monitoring of fluid therapy in these patients is especially important in order to avoid marked increases in pulmonary hydrostatic pressure. This can be accomplished through measurement of pulmonary capillary wedge pressure; however, this requires placement of an intracardiac catheter. Alternatively, CVP can be measured. This is easily performed through central lines—those placed in the cranial vena cava. In a study comparing the use of pulmonary artery catheters with that of central venous catheters in guiding treatment of ALI in humans, it was found that pulmonary catheter–guided therapy did not improve survival or organ function and was associated with more complications than central venous catheter–guided therapy.[10] The predominant catheter-related complication was development of arrhythmia. It was concluded that pulmonary catheters should not be routinely used for the management of ALI.[10]

VetBooks.ir

BOX 44.11

Fluid Guidelines for Metabolic Acidosis

1. The two primary forms of metabolic acidosis in horses are organic acidosis, most often resulting from hyperlactatemia, and inorganic acidosis, often resulting from relative or absolute hyperchloremia.
2. Treatment of hyperlactatemia consists of addressing the underlying cause. In many cases, lactic acidosis is caused by hypovolemia.
3. Commercial acetated fluids, such as Normosol-R or Plasma-Lyte 148, and lactated Ringer's solution are good fluid choices for hypovolemia, although volume rather than type of fluid is the most important component of treatment.
4. The use of sodium bicarbonate is controversial in lactic acidosis and may be contraindicated.
5. Sodium bicarbonate is the treatment of choice for inorganic acidosis (hyperchloremia).
6. Sodium bicarbonate can be administered as a fluid in the form of an isotonic solution.

Fluid Therapy for Horses With Metabolic Acidosis (Box 44.11)

K. Gary Magdesian

Both organic and inorganic acidoses are found in horses with critical illness. A common cause of organic acidosis in horses is lactate (lactic acidosis). Hyperlactatemia occurs with hypovolemia, sepsis, and SIRSs such as endotoxemia, marked hypoxemia, heart failure, cytopathic hypoxia, and liver failure.[1-4] Volume resuscitation can be performed with a combination of crystalloids and colloids, and possibly hypertonic saline. Acetated crystalloids (such as Normosol-R or Plasma-Lyte 148/Plasma-Lyte A) do not contain lactate; however, even LRS (which contains sodium lactate) will correct hyperlactatemia when it is caused by hypoperfusion. Providing for hepatic perfusion will allow for clearance of the lactate previously accumulated. The exception is in liver failure, where fluids devoid of lactate should be administered because metabolism will be reduced. Other less common causes of organic (high anion gap) acidosis include ethylene glycol, salicylate toxicity, and uremic acidosis. The treatment of lactic acidosis is correction of the underlying pathogenesis. If the cause is hypoperfusion, reversal of that state should be the goal of therapy; this is accomplished through restoring blood volume, cardiac output, and finally systemic vascular resistance through the administration of fluids, dobutamine, and vasopressors, respectively. Sodium bicarbonate is therefore not a part of the routine treatment of lactic acidosis; its use in lactic acidosis is in fact controversial.[5,6] In a canine model of lactic acidosis, the administration of sodium bicarbonate actually caused a decrease in pH and bicarbonate concentration and an increase in lactate.[7] Similarly, in a model of endotoxemia in ponies, administration of sodium bicarbonate resulted in an increased blood lactate concentration.[8] Despite these controversies with sodium bicarbonate and lactic acidosis, when the pH of the patient's blood is below 7.2, administration of sodium bicarbonate until the pH reaches 7.2 is justified in order to prevent the detrimental effects of severe acidemia, even when the acidosis is a result of lactate. Severe acidosis can lead to life-threatening cardiovascular complications such as impaired contractility, sensitization to ventricular arrhythmias, and impaired responses to pressors.[9] Small doses of sodium bicarbonate should be administered slowly to increase the pH to 7.2, at which point increasing perfusion should be the goal and sodium bicarbonate can be discontinued.

Inorganic acidoses occur because of strong ion acidosis associated with electrolyte derangements. In horses these commonly result from hyperchloremia or hyponatremia, both of which decrease the strong ion difference. Common diseases associated with these metabolic abnormalities include enteritis, colitis, renal failure, and renal tubular acidosis (RTA). In these cases the acidosis is often caused by renal or gastrointestinal dysfunction of electrolyte homeostasis, whereas perfusion may be normal (i.e., normal plasma lactate). Chronic administration of carbonic anhydrase inhibitors, such as acetazolamide, is another cause of hyperchloremia. The fluid of choice for patients with hyperchloremic metabolic acidosis is one containing only strong cations without strong ions. Because sodium bicarbonate contains only strong cations (sodium), it is an ideal choice for patients with normal anion gap (hyperchloremic) acidosis. Sodium bicarbonate should be administered slowly to allow time for distribution and evaluation of its effects. As a fluid choice, rather than as a supplement, isotonic (1.3%) sodium bicarbonate can be used; this formulation contains 150 mEq each of sodium and bicarbonate ion per liter. Potential side effects of rapid or large-volume sodium bicarbonate therapy include hypernatremia, hypokalemia, ionized hypocalcemia, vasodilation, metabolic alkalosis (if in excess), and an increased affinity of hemoglobin for oxygen (left shift of the oxygen dissociation curve).[8]

Fluid Therapy for Heart Failure (Box 44.12)

K. Gary Magdesian

The cardiac patient represents a unique challenge to fluid therapy. Volume expansion poses significant risk to the horse with heart failure by raising venous pressures (edema risk) and potentiating sodium retention. Administration of sodium-containing fluids can lead to or compound edema and body cavity effusions. Despite these risks, patients with heart failure sometimes require fluid therapy, such as when they develop anorexia, renal failure, or diarrhea. Monitoring of CVP should be performed in these patients at a referral center in order to aid in prevention of edema. Initial fluid therapy should consist of conservative rates, with frequent reassessment of the effects of fluids on the patient. Continuous, slow administration of fluids, rather than boluses, should be used to avoid rapid swings in CVP. Any rise in CVP should be avoided in horses with heart failure.

The choice of fluid depends largely on concerns over sodium retention in the patient with heart failure. Fluids with lower sodium content may be preferable for maintenance fluid therapy, such as maintenance fluids (0.45% NaCl/2.5% dextrose, Plasma-Lyte 56, or combinations of isotonic replacement fluids mixed with sterile water in a 1 : 1 ratio).[1] As soon as the patient is able to drink water, the intravenous fluids should be discontinued.

Because of sodium retention in heart failure, these horses are often treated with diuretics such as furosemide, which aid in minimizing edema formation.[1] A fine balance between fluid therapy and diuretics is required.

BOX 44.12

Fluid Guidelines for Heart Failure

1. Horses with heart failure are intolerant of significant changes in central venous pressure.
2. Fluid boluses should be avoided, and fluids should be administered at a slow, continuous rate.
3. Consideration of the amount of sodium administered should be a priority.
4. Conservative fluid rates are warranted.
5. Concurrent and careful use of diuretics may be indicated.
6. Central venous pressure should be monitored.

Fluid Therapy in Ruminants

Marie-Eve Fecteau

General Principles

In addition to its obvious use for correction of dehydration, fluid therapy in ruminants can be instrumental in the treatment of a variety of disorders, including sepsis, electrolyte and acid-base disturbances, gastrointestinal disease, liver disease, and renal disease. Although enteral fluid therapy is commonly used in adult cattle, parenteral fluid therapy is often regarded as impossible in field situations because of practical and/or economic reasons. In many cases of severely debilitated ruminants, targeted fluid therapy is the key treatment aiding in the recovery from a disease process. This section addresses some key principles of fluid therapy in ruminants, for both field situations and hospital setting, focusing on a variety of commonly encountered disease processes.

In adult ruminants, estimation of dehydration can be based on several factors, including eyeball recession, upper eyelid skin tent, heart rate, and mucous membrane moistness (Table 44.2). Once the degree of dehydration is determined, maintenance fluid requirements (2 to 3 mL/kg/h for adults and 4 to 6 mL/kg/h for neonates), as well as ongoing losses, also need to be considered. The amount of water an adult dairy cow needs just to make up for lactation is often underestimated. The daily water requirement of a 600-kg cow eating a corn silage–based diet in a thermoneutral environment, and milking 45 kg of milk per day, is at least 140 L of water per day.[1] Although laboratory measurements are necessary to confirm and quantify electrolyte and acid-base derangements, those derangements can be predicted on the basis of the suspected disease process. For example, cattle with abomasal volvulus typically suffer from a hypochloremic, hypokalemic, metabolic alkalosis, whereas ruminants with acute grain overload are typically acidotic and often hypocalcemic.[2] Patient-side biochemistry analyzers can be very useful during the initial evaluation of the patient and for monitoring fluid therapy in field situations. An attempt should be made to match fluid composition (either oral or parenteral) to the (suspected or confirmed) electrolyte and acid-base deficits of the animal. However, one should remember that restoration of kidney function alone (by providing fluid volume) may represent the most effective step in addressing the metabolic derangements of the patient.

Oral fluids are practical and economical and can be useful in correcting mild to moderate dehydration and metabolic disturbances in ruminants. In the adult ruminant, the rumen should be viewed as a large reservoir capable of absorbing large volumes of water and electrolytes.[3] The main force for water movement across the rumen wall is the gradient of osmolality between ruminal fluid (normally isoosmotic) and blood perfusing the ruminal epithelium.[4] Studies in adult cattle have shown that net flow of water from rumen to plasma occurs whenever plasma osmolality exceeds rumen osmolality by at least 20 mOsm/kg,[5] which means that to optimize free-water absorption, rumen osmolality should be hypoosmotic. The opposite situation is best represented during an episode of acute grain overload when the rumen quickly becomes hyperosmotic and water is drawn to the rumen from the extravascular space, leading to severe dehydration in those animals.[6] Therefore the practitioner should take advantage of the ruminal capacity for water and electrolyte absorption by administrating hypoosmotic oral electrolyte solutions to mildly and moderately dehydrated ruminants that do not suffer from preexisting abdominal distention or ileus. Enteral fluids should contain Na^+, K^+, and Ca^{2+}. Because most dehydrated adult ruminants are alkalotic, nonalkalinizing fluid formulations are preferred.[2]

Intravenous fluids are preferred in patients that are severely dehydrated (≥8%) and/or that suffer from severe metabolic disturbances or sepsis. An intravenous catheter is typically placed in a jugular vein, although the use of an auricular vein has also proved useful in calves and adult cattle.[7] The animal should be restrained in a tie stall or box stall and given enough length of fluid administration set to allow him or her to lie down. Large-bore coiled intravenous fluid administration sets are useful for this purpose because they have a lesser tendency to become entangled when the animal moves around the stall.

Commercially available crystalloid solutions such as LRS, Normosol-R, Plasma-Lyte 148/Plasma-Lyte A, or 0.9% NaCl may be used, although homemade solutions can also be prepared cheaply on the farm or in a hospital setting. For example, a 0.9% NaCl solution can be prepared by adding 180 g of table salt to 20 L of filtered water using large plastic carboys. Additional recipes for homemade electrolyte solutions for cattle are included in Table 44.3. If tap (unfiltered) water is used in

TABLE 44.2

Guide to Estimation of Dehydration in Adult Ruminants

Percentage of Dehydration	Eyeball Recession	Upper Eyelid Skin Tent	Mucous Membranes
Mild (6%-7%)	Slight	Slightly prolonged (2-3 seconds)	Moist
Moderate (8%-9%)	Obviously sunken	Obviously prolonged (3-6 seconds)	Tacky
Severe (10%-12%)	Severely sunken into orbits	Remains tented indefinitely	Dry

the mixing of the fluids, the author recommends that the animal not be kept on those fluids for extended periods (<48 hours) and that parenteral antimicrobials be used concurrently to minimize the risks of bacteremia and sepsis in the patient.

Response to fluid therapy should be closely monitored and adjusted as needed. Correction of electrolyte and acid-base imbalances should be based on laboratory results when available. For additional fluid therapy monitoring techniques, see the Critical Care and Fluid Therapy Monitoring Techniques section earlier in this chapter.

Fluid Therapy for Specific Ruminant Diseases and Disorders

Fluid Therapy for Abomasal Disorders and Upper Gastrointestinal Obstructions

Ruminants with simple abomasal displacements that are managed promptly usually do not require aggressive fluid therapy. Because simple displacements (left or right) of the abomasum do not constitute a complete gastrointestinal obstruction, they rarely cause severe electrolyte and acid-base derangements in the adult cow. In cows that appear mildly dehydrated, enteral fluids (10 to 20 L) consisting of water and electrolytes usually suffice. Older, high-producing dairy cows often have some degree of subclinical hypocalcemia, especially in the early postpartum period, and should therefore be supplemented with calcium. If present, ketosis should be treated with intravenous infusion of dextrose or oral administration of propylene glycol.

Ruminants with abomasal volvulus, abomasal impaction, or other forms of upper gastrointestinal obstructions such as intestinal volvulus or intussusception typically have more severe metabolic derangements as a result of the trapping of fluid and electrolytes within the gastrointestinal compartments proximal to the obstruction. Those animals are typically moderately to severely dehydrated and require a more aggressive approach to fluid and electrolyte therapy, usually intravenously. The acid-base and electrolyte abnormalities of ruminants with upper gastrointestinal obstructions typically include hypokalemia, hypochloremia, metabolic alkalosis (although reduced perfusion of peripheral tissues may lead to metabolic acidosis terminally), hypocalcemia, and prerenal azotemia.[8-9] To replenish fluid losses and improve the circulating blood volume, an initial fluid bolus of 15 to 20 L (20 to 25 mL/kg) of isotonic crystalloid solution should be administered prior to or during surgery. It is the author's opinion that the best crystalloid fluid choice for cattle with hypochloremic metabolic alkalosis is 0.9% NaCl because of the relative chloride excess in normal saline, although other balanced crystalloid solutions such as LRS, Hartmann's solution, Normosol-R, and Plasma-Lyte may also be appropriate. Following the initial bolus, fluid therapy should be continued with an additional 30 to 40 L (3 to 5 mL/kg/h) of 0.9% NaCl or another balanced crystalloid solution, supplemented with at least 20 to 40 mEq/L of potassium chloride. In metabolic alkalosis, hypokalemia may result from redistribution of potassium from the extracellular to the intracellular compartment.[10] Ruminants with severe hypokalemia may also have to be supplemented orally (10 g KCl per 100 kg body weight [BW], twice daily [bid])[11] through stomach tube or in gelatin caps, especially if the intravenous fluids are supplemented with dextrose, which may cause a shift of potassium intracellularly.[12] When potassium chloride is supplemented, 1.0 g yields approximately 14 mEq. Care must be taken to never exceed 0.5 mEq/kg/h of potassium in order to avoid cardiotoxicity.[11] Multiparous cows in the postpartum period may also benefit from calcium supplementation at a rate of 25 mL/L of 23% calcium borogluconate.

Hypertonic solutions (7.2% to 7.5% NaCl), at a rate of 2 to 4 mL/kg, can also be used to rapidly expand the intravascular volume in severely dehydrated cattle.[11] Ideally, the infusion of hypertonic solution should be followed by intravenous infusion of an isosmotic crystalloid solution, as stated previously. Cattle should also have access to a supply of fresh water and electrolytes or be administered oral fluids through stomach tube if intravenous fluid administration is not possible. Oral fluid administration should be used only following surgical correction of the abomasal volvulus because a large volume of orally administered fluids may worsen abdominal distention before surgery.

Fluid Therapy for Metabolic Acidosis (Acute Rumen Acidosis and Diarrhea)

In ruminants, severe metabolic acidosis may be encountered in a variety of cases including acute grain overload (rumen acidosis) and severe enteritis with profuse diarrhea. Severe ketosis, pregnancy toxemia, and sepsis can also lead to the development of a metabolic acidosis in the affected ruminants. Fluid therapy for ruminants with severe ketosis and sepsis is discussed later in this chapter.

Animals with acute rumen acidosis are typically severely debilitated and need aggressive medical and surgical therapy. Acute ruminal acidosis is discussed in detail in Chapter 32. The rapid accumulation of lactic acid in the rumen osmotically draws water into the rumen, resulting in marked dehydration.[6] In addition, the chemical damage to the rumen mucosa allows bacterial transposition into the peritoneal cavity and portal circulation, resulting in the development of endotoxemia.[13-14] Moreover, the fermentation of larger amounts of carbohydrates induces an increased concentration of organic acids that leads to a decrease in intraluminal pH. This decrease in pH favors the overgrowth of bacteria that are able to produce high quantities of D- and L-lactate, also contributing to the acidosis. Finally, third spacing of proteins in the rumen as well as in the abdominal cavity can result in profound hypoproteinemia in the affected animals, which further compounds their precarious hemodynamic state by its negative impact on the animal's oncotic pressure. Moderate to severe hypocalcemia is also common in these cases.

Fluid therapy in calves with diarrhea is discussed at length in Chapter 20. Adult ruminants with severe enteritis and diarrhea, such as those with salmonellosis, often require intravenous fluid therapy if they are completely anorectic, depressed, and significantly dehydrated. Oral fluids and electrolytes may be helpful in ruminants that are mildly to moderately dehydrated, but the effectiveness of those fluids may be compromised by malabsorption and ileus resulting from the enteritis. Similar to ruminants with acute rumen acidosis, cattle with acute diarrhea will suffer from varying degrees of metabolic acidosis, which is a result of the loss of bicarbonates in the diarrhea and from the enteric bacterial production of D-lactate. The poor perfusion of peripheral tissues that is sometimes seen in severe cases of hypovolemia may lead to the development of a lactic acidosis, which may also contribute to the overall acidosis in these patients. Also, similar to ruminants with acute grain overload, ruminants with severe enteritis and diarrhea can develop hypoproteinemia from gastrointestinal losses and third spacing within the abdominal cavity. Finally, although a lesser concern in adult ruminants, sepsis caused by severe enteritis may pose an additional problem that should be addressed by the use of intravenous fluids. Intravenous fluid therapy for sepsis is discussed further later in this chapter.

The goals of fluid therapy in ruminants with severe acute rumen acidosis or acute enteritis with profuse diarrhea should be (1) volume repletion, (2) correction of acid-base and electrolyte disturbances, (3) addressing the endotoxemia or sepsis, and (4) providing colloid support. Fluids should be provided in the intravenous form, especially in the case of rumen acidosis, to avoid exacerbating the abdominal distention

VetBooks.ir

and because most animals suffer from severe ileus. The choice of crystalloid solution should be based on the documented or suspected metabolic disturbances. Therefore nonacidifying solutions such as LRS and Plasma-Lyte should be preferred over 0.9% NaCl solutions. In cases of severe acidemia (blood pH <7.20), a sodium bicarbonate solution (1.3% to 5%) may be preferred until the blood pH is closer to normal range. The amount of sodium bicarbonate required to correct metabolic acidosis can be calculated by the following formula: $NaHCO_3$ (mmol) = BW (kg) × base deficit × 0.3. If laboratory data are not available, a clinician may choose to alternate between fluid solutions (e.g., between LRS and bicarbonate solution) in order to avoid overcorrection of the metabolic acidosis. An initial bolus of 25 to 50 mL/kg of crystalloids (without additives) should be followed by a CRI of crystalloid fluids containing potassium (20 to 40 mEq/L) and calcium (25 mL/L of 23% calcium gluconate solution). Fluids containing potassium and/or calcium should not be bolused in order to avoid cardiotoxicity. Care should also be taken not to fluid-overload the patient, especially small ruminants and young cattle, as excessive fluid administration may result in edema, including pulmonary edema. Animals known to have hypoalbuminemia (<2.0 g/dL) before the start of intravenous fluid therapy should be monitored carefully for development of edema. To address the hypoproteinemia and the poor oncotic pressure, colloids (whole blood, plasma, or hetastarch) should be considered if finances allow. Colloids are substances with a high molecular weight that are too large to pass through a semipermeable membrane and are therefore restricted to the plasma compartment and provide sustained plasma volume expansion.[11] Details for collecting, harvesting, storing, and administrating whole blood and plasma are available elsewhere.[15] Hetastarch, a high-molecular-weight glucose synthetic polymer, is supplied as a 6% concentration in 0.9% NaCl and can be administered at a rate of 5 to 20 mL/kg/d.[11] This may be more feasible in small ruminants or young cattle, because the use of colloids may be cost prohibitive in a full-size cow.

Fluid Therapy for Sepsis (Toxic Mastitis, Metritis, Peritonitis)

Endotoxemic shock, which often accompanies disease processes like coliform mastitis, toxic metritis, and septic peritonitis, can lead to marked hypovolemia necessitating aggressive fluid therapy in affected animals. For the septic patient, expanding the effective circulatory blood volume in order to improve tissue perfusion and counteract the decreased cardiac output and hypotension is crucial. Fluid therapy in ruminants with sepsis is similar to that recommended for ruminants with severe enteritis or acute rumen acidosis (see previous section).

Oral fluids can be useful in ruminants that are mildly dehydrated; however, in animals that are moderately to severely dehydrated and that have signs of endotoxemia, intravenous fluids are preferred. If intravenous fluid therapy cannot be achieved because of practicality or costs, the combination of intravenous hypertonic saline (7.2% to 7.5%) and oral water and electrolytes should be considered. Following administration of hypertonic saline, the increase in plasma osmolality results in movement of water from the extravascular space to the intravascular space.[11] In adult ruminants, the rumen represents the major reservoir from which the animal can draw water. For this reason, the administration of intravenous hypertonic solution alone, without following with oral or isotonic intravenous fluids, is insufficient and inadequate at addressing the hypovolemia. For a typical adult cow, 1 to 2 L of hypertonic saline (2 to 4 mL/kg)[11] intravenously is followed by the administration of approximately 20 L (5 gallons) of water orally. If intravenous fluid administration is an option, isotonic fluids should be continued at a rate of 4 to 5 mL/kg/h for a total of at least 40 to 60 L (for a typical adult cow) during the first 24 hours. Care should also be taken not to overload the patient with fluids, especially small ruminants and young cattle, as excessive fluid administration may result in edema, including pulmonary edema. As discussed earlier in the Fluid Therapy for Metabolic Acidosis section, a combination of crystalloids and colloids may also have advantages in treating patients with sepsis, because colloids may attenuate capillary leak associated with sepsis.[16] In addition, some animals with severe sepsis may suffer from coagulation disorders such as DIC and may benefit from plasma or hetastarch administration.[17]

Whether fluid resuscitation is performed orally or intravenously, calcium supplementation (25 mL/L of a 23% solution) should also be considered, because hypocalcemia is often encountered in toxic cattle.[18,19] The reason for the decrease in calcium concentrations in endotoxemic cattle is not fully understood.[18,19] Ruminants that are anorectic should also be supplemented with potassium chloride (20 to 40 mEq/L). Although septic adult ruminants rarely become hypoglycemic (as opposed to neonates), dextrose supplementation (2.5% to 5%) may be beneficial in anorectic patients with concomitant ketosis and/or hepatic lipidosis. The animal's blood glucose concentration should be monitored and kept between 80 to 110 mg/dL to avoid a hyperglycemic state.

Fluid Therapy for Negative Energy Balance Disorders (Hepatic Lipidosis, Ketosis, Pregnancy Toxemia)

The vast majority of cattle and small ruminants with type 1 (primary) ketosis respond quickly to simple treatments that usually involve the administration of glucose precursors (such as propylene glycol) and/or a single administration of intravenous dextrose. However, cattle and small ruminants with severe ketosis, hepatic lipidosis, or advanced pregnancy toxemia may need more aggressive treatment, which usually involves the use of a CRI of intravenous fluids containing dextrose. Ruminants with liver dysfunction or failure have a decreased ability to perform normal metabolic functions such as gluconeogenesis, to synthetize proteins, and to clear a variety of metabolites, including lactate.

The main goal of treatment of hepatic lipidosis, severe ketosis, and pregnancy toxemia is to limit the mobilization of fat by increasing the availability of glucose or glucose precursors and promoting uptake of glucose by the cells. It is important to note that providing dextrose is critical in such cases, even in the face of normoglycemia, because it will minimize gluconeogenesis demands on the liver and prevent further production of ketone bodies. A CRI of isotonic fluids such as Normosol-R or Plasma-Lyte, containing 2.5% to 5% dextrose, is preferred over the use of D_5W because the latter contains too much free water. Because lactate clearance primarily occurs in the liver, and may be impaired in those animals, LRS should be avoided. In ruminants with suspected or confirmed metabolic acidosis, saline solutions (0.9% NaCl) should also be avoided, since they will compound the acidemia through hyperchloremia. Small ruminants with severe pregnancy toxemia may require an initial bolus of fluids containing 10% to 50% dextrose to break the cycle of negative energy balance. The rate of glucose administration should be approximately 1 to 2 mg/kg/min, which for a typical adult cow equates to approximately 1 L/h of a fluid solution containing 3% to 6% dextrose. The animal's blood glucose ideally should be monitored and kept between 80 to 110 mg/dL to avoid hyperglycemia. Insulin (e.g., zinc protamine) can be used subcutaneously every 24 to 36 hours to promote glucose uptake by the peripheral tissues and inhibit lipolysis. The addition of B vitamins to the fluids may also be useful in anorectic ruminants.

Fluids should also contain potassium chloride (20 to 40 mEq/L), since most ruminants with severe liver disease are partially or completely anorectic and may also experience a

VetBooks.ir

shift of potassium intracellularly in response to dextrose administration.[12] Special caution should be taken to monitor plasma potassium concentrations closely in cows receiving mixed glucocorticoid-mineralocorticoid drugs to aid in the treatment of hepatic lipidosis, since their chronic use has been associated with the development of severe hypokalemia.[20] As discussed earlier, cows with marked hypokalemia should receive oral and intravenous supplementation with potassium chloride. Calcium supplementation (25 mL/L of a 23% solution) is also important, since most cows with hepatic lipidosis are in the peripartum period and may also suffer from subclinical hypocalcemia; in addition, clinical signs of pregnancy toxemia may resemble those of preeclampsia in small ruminants. Plasma or serum phosphorus concentrations should also be monitored in ruminants receiving repeated infusions of intravenous dextrose because this can cause significant decreases in plasma phosphorus concentrations.[21,22]

Fluid Therapy for Obstructive Urolithiasis

Most ruminants with obstructive urolithiasis are presented with azotemia, which is usually postrenal in origin, although prerenal azotemia from dehydration and renal azotemia from renal injury are also possible. Metabolic disturbances typically include metabolic alkalosis, hyperkalemia, hyponatremia, and hypochloremia.[23] Hypophosphatemia is another common biochemical finding in goats presenting with acute urolithiasis.[23] If a rupture in the urinary tract is present on admission, the degree of hyperkalemia may be severe. Ruminants with urinary tract obstruction, particularly those with severe electrolyte disturbances, often need to be stabilized before surgery.

Although it may not be advised to administer large volumes of intravenous fluids prior to relieving the obstruction, most patients' hemodynamic state will benefit from a fluid bolus prior to surgery. In very unstable patients with severe electrolyte disturbances (K^+ >6 mmol/L), draining the bladder (or the uroabdomen) prior to surgery by performing a cystocentesis or by placing a self-retaining suprapubic cystic catheter (Bonnano catheter [BD, Franklin Lakes, N.J.]) can be beneficial. The suprapubic catheters can stay in place for up to 24 hours in most small ruminants and allow for urine egress from the bladder while the patient is receiving intravenous fluid therapy. It should be emphasized that the ultimate goals of preoperative fluid therapy are to improve the patient's hemodynamic state and to address its most severe electrolyte abnormalities (usually hyperkalemia) so that the patient can more safely undergo general anesthesia. It should be noted, however, that surgery should not be delayed until the animal's azotemia is completely resolved, as azotemia may persist for several days following surgery in some animals.

Much has been written about the best fluid composition to use in hyperkalemic animals. The most common recommendation is to administer fluids that do not contain potassium, such as physiologic saline, D_5W, or isotonic sodium bicarbonate solution. However, others may argue that balanced electrolyte solutions such as LRS also represent a valid option, even in the face of hyperkalemia.[24] Insulin may also be used to help correct the hyperkalemia, especially preoperatively. If insulin is used, blood glucose concentrations should be monitored closely, especially in young ruminants, since they are at greatest risk of becoming hypoglycemic. Potassium plasma concentrations should also be monitored closely following the combination of insulin and diuresis, since many ruminants will become hypokalemic postoperatively, especially if they remain anorexic for some time.

The fluid rate should be tailored to the patient's hydration needs, level of azotemia, and urine production. Although overhydration is rarely a concern in adult cattle with normal kidney function, small ruminants with acute renal failure should be monitored closely to avoid pulmonary edema. An initial rate of administration of 1.5 to 2 times maintenance is usually used until the azotemia is resolved.

Rational Antimicrobial Therapy

BARBARA A. BYRNE, *Consulting Editor*
LISA A. TELL, KRYSTA MARTIN, and MICHAEL PAYNE

Antimicrobial Stewardship

The dearth of antimicrobial drug development with the advent of increasingly resistant bacteria necessitates that we use these drugs in a judicious manner that prolongs their effectiveness. Not only does inappropriate use of antimicrobial drugs result in the emergence of resistance to these drugs, appropriate or inappropriate use also can have such an impact on the normal microbiota that severe and sometimes fatal gastrointestinal disease can develop. Furthermore, there is the potential for transmission of resistant zoonotic pathogens to humans. Hence veterinarians have an obligation to use antimicrobial drugs in a responsible manner.

Antimicrobial stewardship is defined as "an activity that includes appropriate selection, dosing, route, and duration of antimicrobial therapy" so that a positive clinical outcome can be achieved with a minimum of unintentional consequences.[1,2] The American Veterinary Medical Association (AVMA) defines antimicrobial stewardship for the veterinarian as follows: "Antimicrobial stewardship refers to the actions veterinarians take individually and as a profession to preserve the effectiveness and availability of antimicrobial drugs through conscientious oversight and responsible medical decision-making while safeguarding animal, public, and environmental health."[3] Although a number of other definitions exist, the central concept of antimicrobial stewardship is to use antimicrobial drugs in a rational and responsible manner to have a positive clinical outcome while minimizing the emergence of resistance and adverse reactions.[4-7] The details regarding implementation of an antimicrobial stewardship program will vary according to an individual practice or hospital needs; however, certain elements should be incorporated.

Many antimicrobial stewardship guidelines describe the use of the "3 Rs" for antimicrobial stewardship. These are (1) reduction of the use of antimicrobial drugs whenever possible, (2) refinement of the use of an antimicrobial agent that considers dosing and antimicrobial choice based on pathogen, pharmacokinetics and pharmacodynamics, and host factors so that the emergence of resistance is minimized while clinical efficacy is maximized, and (3) replacement of antimicrobial agents with evidence-based alternatives. Page and Prescott advocated for the use of the "5 Rs" approach to antimicrobial stewardship that incorporates the aforementioned reduction, refinement, and replacement and adds the responsibility of the veterinarian to commit to antimicrobial stewardship and review of stewardship programs with the aim of continuous improvement, including compliance with policies and incorporation of new evidence-based best practices.[8]

The AVMA has established core principles for antimicrobial stewardship and judicious use of antimicrobials that incorporates many of the ideas found in the 5 Rs.[3,9] Judicious use principles can include attention to disease prevention strategies and biosecurity to prevent introduction or spread of pathogens, veterinary oversight of antimicrobial use, use of antimicrobials only after careful review including evidence provided by culture and susceptibility results, use of narrow-spectrum drugs when possible, and use of regimens of antimicrobial treatment based on evidence and scientific principles including pharmacokinetic data. Other veterinary associations and government agencies have advocated or provided guidelines for antimicrobial stewardship or prudent use of antimicrobials, including the American Association of Bovine Practitioners, American Association of Equine Practitioners, American Association of Swine Veterinarians, and the Center for Veterinary Medicine (CVM) of the U.S. Food and Drug Administration (FDA).[3,9-12]

Antimicrobial therapy is the cornerstone for treatment of infectious diseases. Therapy depends on appropriate identification of the infectious agent, determination of antimicrobial susceptibility of the causative organism, and application of pharmacokinetic and pharmacodynamic principles to achieve therapeutic levels of drug at the site of infection. Often this is referred to as the five rights: right drug, right dose, right route, right time, and right duration.[6] Additional factors such as adverse effects, cost, compliance with administration, penetration of the drug of interest to the site of infection, host factors, and development of resistance must be considered when choosing an antimicrobial drug regimen (Box 45.1). Avoiding the development of resistant pathogens or commensal flora is also desirable. This chapter focuses on the use of antimicrobial drugs directed toward bacterial pathogens; however, similar principles apply when choosing antifungal, antiparasitic, or antiviral therapies. The ultimate goals of antimicrobial therapy are to provide effective treatment, with the fewest adverse events and at the lowest cost, and to prevent development of resistance. Indiscriminate or inappropriate use of antimicrobial agents leads to development of resistance in the targeted pathogen as well as in the host microbiota. The consequences of resistance are manyfold, including the inability to treat certain infections, superinfections, and transfer of resistant organisms to humans.[13] As veterinarians, we have an ethical obligation to protect both animal and human health and well-being through judicious use of antimicrobial drugs. Consensus statements published by the American College of Veterinary Internal Medicine provide guidance for use of antimicrobial

Host factors
Penetration of antimicrobial drug to the site of infection
Route of administration
Severity of the infection
Withdrawal time

drugs and raise important considerations for the veterinarian regarding their use.[13,14]

One recommendation is that veterinarians develop standardized antimicrobial drug use guidelines for different types of cases (e.g., wounds, respiratory infections) that are appropriate for their hospital or clinical practice.[13-15] Often this requires some knowledge of likely pathogens and their antimicrobial susceptibility. Development of a hospital or regional antibiogram consisting of antimicrobial susceptibility data on the most common pathogens over a period of a year or two can be very helpful in devising empirical antimicrobial use strategies.

Antimicrobial therapeutics may also be categorized into tiers for use: primary, secondary, and tertiary drugs and those that are either restricted or have been elected to not be used by the practice. Primary drugs are those that are reached for most commonly, often either before or while awaiting culture and susceptibility testing results. Often these are older antimicrobials that may have a narrower spectrum of activity for pathogens (e.g., penicillin, older tetracyclines, sulfonamides). Secondary drugs generally are reserved for more serious infections or for when susceptibility data indicate resistance to primary drugs. Frequently these second-line drugs are also important in human medicine, thus avoidance of resistance development is important. Examples of these drugs include fluoroquinolones and third-generation cephalosporins. Tertiary drugs are those that are often effective against resistant bacteria and are also important drugs used for human patients, such as carbapenems. These tertiary drugs should be reserved for serious infections with confirmed resistance to all primary and secondary drugs. Thus use of higher-level drugs should always be directed by antimicrobial susceptibility testing. Finally, an example of a drug that may be used only after approval by an institutional committee (i.e., restricted) or prohibited is vancomycin.

In addition to establishing tiers of drugs for antimicrobial use, it is important to follow a logical approach when deciding on the type of antimicrobial drug to use. The goal is to use an antimicrobial drug to which the organism is susceptible and that will reach adequate concentrations at the site of infection, has little to no host toxicity, and is economically suitable for the owner and/or producer. This starts with establishing whether an infection is present, identifying the organism(s), determining antimicrobial susceptibilities, and considering host factors. Once therapy has been initiated, assessment of the patient is essential to decisions regarding length of treatment and whether antimicrobial therapy should be altered. In addition, adjunctive therapies such as surgical interventions should be considered.

Is There an Infection?

This is a frequently overlooked step when determining what type of antimicrobial therapy should be instituted. Too often, antibacterial drugs are used "just in case" there is an infection, without proper examination for the signs of infection. A number of clinical signs and clinical laboratory findings can be evaluated that may point to the presence of an etiologic agent. The old saying that redness, swelling, and heat are cardinal signs of infection and inflammation still holds true. Certainly, one frequently encountered finding is elevation of body temperature. However, inflammation for reasons other than the presence of an infectious agent may result in fever. Swelling and redness are frequent indicators of a localized infection. Development and appearance of purulent material is further evidence of infection.

Clinicopathologic findings are also important supportive evidence for an infectious disease. Elevated or depressed peripheral white blood cell counts frequently accompany significant infections. In large animal species, fibrinogen elevations are observed in bacterial infections. Serum biochemistry values may also inform the decision to use antimicrobial therapy. For example, elevations in globulin may indicate production of excess immunoglobulin as seen in subacute to chronic infectious, primarily bacterial, processes. Decreases in serum albumin may develop as a negative acute phase protein in response to inflammation accompanying an invasive pathogen.[16] If possible, cytologic examination of material from the site of suspected infection should be performed. The presence of neutrophils, particularly with features of degeneration, is indicative of a septic process. Observation of infectious agents, ideally intracellularly, helps to confirm the presence of an infection.

What Organism Is Present?

Once the presence of an infection is determined, the next step is to decide what organism might be present. Ideally, samples should be collected prior to initiating therapy so that an etiologic diagnosis can be made and susceptibility testing can be performed. In the case of a serious or life-threatening infection, therapy must be initiated prior to receipt of culture and susceptibility results. Empirical therapy often relies on clinical judgment and knowledge regarding the likely organisms present, depending on the body system affected and its likely susceptibility patterns. Additional findings such as results from cytologic examination help to inform the antimicrobial choice.

Sample Selection and Transport to the Laboratory

Appropriate collection and transport of samples to the microbiological laboratory are essential to detection of the causative agent. The site of the infection should be sampled. This may seem obvious; however, a surprisingly large number of inappropriate samples are submitted to the microbiology laboratory. In general, sterile sites are the best regions to sample. For example, sampling of nasal discharge is almost never the appropriate choice when faced with purulent nasal discharge. Identification of the large number of normal bacteria and interpretation of the findings are difficult when normally colonized sites are sampled. The actual source of the discharge, such as the sinus, guttural pouch, or lung, should be determined and sampled directly. An exception to this rule is in the case of equine *Streptococcus equi* subsp. *equi* infections. Lesions such as a draining tract are problematic. Frequently they have superficial contamination of the opening of the tract that is inadvertently sampled. When possible, underlying soft tissue or bone should be collected rather than inserting a swab into the tract. Drains or urinary catheter tips are also inappropriate for samples. Too often they carry a biofilm of contaminating bacteria that may or may not be indicative of the disease process.

If anaerobic culture is deemed necessary, it is important that adequate volume of tissue or fluid be collected to preserve

VetBooks.ir

the anaerobic environment. If possible, at least a milliliter of fluid or a square centimeter of tissue should be collected. Swabs are inappropriate for anaerobic culture because air can be trapped between the fibers, leading to death of nonaerotolerant obligate anaerobes. If the sample is smaller and not taken immediately to the laboratory, it should be placed in some sort of anaerobic transport medium that will maintain an anaerobic environment. These anaerobic systems will maintain the presence of aerobic and facultative anaerobes as well.

Samples for microbiological culture should be transported to the laboratory as soon after collection as possible. The sample should be refrigerated if it cannot be delivered quickly, and it should be kept cool or cold but not frozen for transport to the laboratory. An exception to this rule is when anaerobic transport medium (e.g., Anaerobe Systems, Morgan Hill, Calif.) is used. These vials should be maintained at room temperature. It is possible that samples that are not kept adequately chilled can have overgrowth of contaminating bacteria, which can obscure detection of the "true" pathogen.

It is best if samples are collected prior to initiation of therapy. However, if antimicrobial treatment has already been instituted, the clinician should consider withdrawing therapy for a short period before sampling. Waiting between 24 and 36 hours after the last administration of drugs is advisable, and 99% of the drug should be eliminated after 7 half-lives. In seriously ill animals such as the septic foal, delaying antibiotic therapy for any amount of time to collect samples may be detrimental. In such cases, samples should be collected just prior to the next administration of drug. Some blood culture systems contain resins that bind or inactivate antimicrobial drugs and have proven to increase the ability to detect bacteria within the sample.[17]

Microscopic Examination of Sample

Initial examination of a sample provides important clues to the type of organism present. A Wright-Giemsa–type stain is frequently used to examine cytologic preparations made from samples. This staining technique can provide much information on the bacterial or fungal organism present. Identification of coccoid or rod-shaped bacteria along with the site of infection will often result in a differential diagnosis list of organisms to consider. An examiner with a practiced eye may be able to make an educated guess about the genus of the organism observed. A Gram stain provides additional information. Although many veterinarians do not use this stain in their clinical practice, the technique is rapid and, with a little practice, easy to perform and interpret. Identification of an organism as gram-negative or gram-positive further informs the practitioner of the likely organisms present and helps to guide empirical antimicrobial choice (Box 45.2).

What Is the Severity of the Infection?

One of the first decisions to be made when considering antimicrobial therapy is the severity of the infection. The clinician needs to decide if therapy must be initiated immediately or whether the patient can wait for results of culture and susceptibility testing before initiating therapy. Obviously, life-threatening infections require immediate and aggressive antimicrobial therapy. Infections of sites such as joints or other orthopedic structures may necessitate empirical therapy while awaiting the results of microbiological testing. In these cases, samples should be taken for identification and susceptibility testing before initiating therapy. In cases of serious infection, empirical therapy may include use of a bactericidal drug or a combination of antimicrobial agents (see section on Combination Therapy). On the other hand, an animal with a chronic, mild, or moderate infection may wait to receive antimicrobial drugs until testing has been completed.

BOX 45.2

Gram-Stain Reaction and Morphology of Commonly Encountered Large Gram Stain of Animal Bacterial Pathogens

Gram-Positive Cocci

Enterococcus spp.
Staphylococcus spp.
Streptococcus spp.
Peptostreptococcus anaerobius (anaerobe)

Gram-Positive Rod or Filamentous

Trueperella pyogenes (formerly *Arcanobacterium pyogenes*)
Clostridium spp. (obligate anaerobe)

Gram-Negative Rods

Actinobacillus spp.
Brucella spp.
Bordetella spp.
Escherichia spp.
Haemophilus spp.
Histophilus spp.
Klebsiella spp.
Mannheimia spp.
Pasteurella spp.
Pseudomonas spp.
Bacteroides spp. (obligate anaerobe)
Fusobacterium spp. (obligate anaerobe)

What Is the Likely or Confirmed Antimicrobial Susceptibility of the Organism?

In a perfect world, the clinician should have laboratory-generated antimicrobial susceptibility results to guide therapy. However, frequently therapy must be initiated prior to receipt of culture and susceptibility results. Empirical therapy should be based on knowledge of the inherent resistance of suspected agents and the antimicrobial susceptibility patterns observed in the practice region. Susceptibility data should be compiled regularly by the regional microbiology laboratory and used by the practitioner in the hospital setting.

The microbiology laboratory should be proficient in antimicrobial susceptibility testing and follow guidelines established by the Clinical and Laboratory Standards Institute (CLSI) or similar institution.[18] Quality assessment testing should be performed regularly. A number of methodologies are used to examine susceptibility to different antimicrobials. Two frequently used methods for antimicrobial susceptibility testing are disk diffusion, also known as Kirby-Bauer test, and broth dilution or broth microdilution, which uses a 96-well plate.

Disk diffusion is a relatively straightforward testing methodology that can be performed with little specialized equipment. It involves creating a lawn of bacteria using a standardized concentration, placing disks containing a set amount of antimicrobial drug on top of the bacterial lawn, incubating, and measuring the zone of inhibition around the disk. This zone diameter determines whether the bacterium should be considered susceptible, intermediately susceptible, or resistant to a particular drug. The advantages of this method are that it is rapid and easy to perform provided strict protocols are followed. The disadvantages are that it cannot be used for slow-growing bacteria and it provides only an interpretation rather than information about the specific concentrations of

VetBooks.ir

drug that inhibit growth. Consequently, knowledge about the pharmacokinetics of a particular drug cannot be fully used to develop a treatment regimen to deliver optimal dose of the drug to the site of infection.

The broth dilution or microdilution method involves inoculation of a standard amount of bacteria into tubes or wells containing an antimicrobial drug. Most clinical laboratories use twofold dilutions of drug centered on the concentration of drug found systemically using typical dosing strategies. The inocula are subsequently incubated, and then the wells are examined for visible growth. The lowest concentration of drug that inhibits visible growth is called the minimum inhibitory concentration (MIC). Sometimes the wells are subcultured to a nonselective agar and then incubated, and this agar is examined for growth. The lowest concentration of drug that results in no growth is the minimum bactericidal concentration (MBC). For cost reasons, most clinical laboratories do not determine the MBC for each organism.

The MIC is unique for each bacterium-drug combination. The resulting MIC guides interpretation of the bacterium as susceptible, intermediately susceptible, or resistant to a particular drug. The concentration of drug at which the interpretation of testing changes from susceptible to intermediate or resistant is called the *breakpoint*. For example, *Enterobacteriaceae* isolated from adult horses are considered susceptible to amikacin if the MIC is 4 μg/mL or less; they are deemed resistant if the MIC is 16 μg/mL or greater. If the MIC is 8 μg/mL, the isolate is considered intermediately susceptible.[18] Generally, the clinician needs to use the interpretation only when deciding which drug to choose for therapy. However, the MIC can be used to refine therapy, by altering the dose of drug or frequency, to optimize treatment.

Interpretation breakpoints for susceptibility testing of a bacterium as susceptible or resistant are set by the CLSI. This body bases interpretation on three major factors: the epidemiologic breakpoint of a population of bacteria, pharmacokinetic data, and (when available) clinical outcome from treatment of animal or human patients.[19] A graph showing MICs of a population of a single species of bacterium frequently has a bimodal distribution. The trough between the two peaks is the epidemiologic breakpoint; those bacteria with higher MICs have acquired some sort of resistance determinant. The pharmacokinetic information used to assist with determination of the breakpoint includes the peak concentration of drug, the area under the pharmacokinetic curve, and time the drug is above a particular MIC. A simplified way to think about how these data are used is to look at a bacterium with a high MIC. It would be considered resistant because the amount of drug that would have to be administered to exceed the MIC would be considered toxic to the animal host. Generally, the highest concentration of drug tested is near or a bit above the highest concentration of drug that can be achieved with recommended dosages.

Antimicrobial therapy should be directed to achieve levels that are above the MIC for a particular isolate. Ideally, the "best" antimicrobial drug to use depends on many factors other than the susceptibility result. Obviously, the organism should be susceptible to the drug chosen, but other considerations should be included, such as route of administration, penetration to the site of infection, toxicity, cost, and convenience. All of these factors being equal, the optimal drug is one for which the organism's MIC is several dilutions below the breakpoint. However, further refinement is possible when one understands the pharmacodynamic properties of the drug and bacterium.

Bactericidal and Bacteriostatic Antimicrobial Drugs

The terms *bactericidal* and *bacteriostatic* refer to the in vitro observation that a drug kills or merely inhibits growth of a particular bacterium, respectively. If one examines the relationship between the MIC and MBC, these two values are close or nearly identical for bactericidal drugs. In contrast, the MBC is several twofold concentrations above the MIC for bacteriostatic drugs. To be clear, it takes a higher drug concentration to kill bacteria with a static drug. The in vivo consequence of this relationship means that more drug must be delivered to the site of infection to kill the bacteria with a bacteriostatic drug. Often this is not achievable given the toxicity and pharmacokinetics of the drug. In the case of bacteriostatic drugs, the clinician must rely on the host immune responses to clear the inhibited organisms. Accordingly, bactericidal drugs should be used in an immunocompromised patient. Some drugs are concentrated in areas of infection. For example, drugs undergoing renal clearance are found in high concentrations in urine. Thus drugs that show in vitro bacteriostatic activity may achieve concentrations high enough to kill bacteria in the bladder. The converse is also true; use of a bactericidal drug at inadequate dosages or that has poor penetration to the site of infection may not achieve high enough concentrations to kill the offending organism. Thus some drugs can be considered either bactericidal or bacteriostatic. In practical terms, in an immunocompetent host without an overwhelming bacterial burden, the differing impact of a bacteriostatic versus bactericidal drug is minor provided that adequate concentration of the drug reaches the site of infection.

Concentration and Time-Dependent Antimicrobial Drugs

Pharmacokinetic (PK) and pharmacodynamic (PD) principles can also be used to guide antimicrobial therapy. Pharmacokinetics refers to drug absorption, distribution, metabolism, and elimination. Pharmacodynamics examines the effect of the drug concentration on the microorganism at the site of infection over time. The relationship between PK and PD principles describes the relationship between the drug concentration and the effect on the pathogen and clinical response.[20] Parameters that explore relationships between PK and PD principles, such as the peak concentration relative to the MIC, are reflected in the PK/PD index.[21] The relationship between the MIC and PK parameters may determine the outcome of therapy.

There are two categories of antimicrobial drugs: concentration-dependent drugs and time-dependent drugs. This categorization is primarily based on in vitro work but is supported by clinical data in animals and humans.[22] Concentration-dependent drugs are those whose antimicrobial activity is best predicted by the relationship between peak drug concentration and the MIC of the organism. Drug classes that are considered concentration-dependent drugs include aminoglycosides and fluoroquinolones. The ratio between the peak drug concentration and the MIC should equal at least 8 to 10.[23] Using the example of amikacin given earlier, if the bacterium had an MIC of 2 μg/mL, the drug should be dosed to reach a peak concentration of 20 μg/mL. The time that the drug concentration is above the MIC appears to be less important for concentration-dependent drugs. Accordingly, many concentration-dependent drugs can be administered infrequently (e.g., once daily). This dosing strategy can be advantageous with certain drugs with toxicity. For example, nephrotoxicity of the aminoglycosides is best determined by trough concentrations of drug. These antimicrobials may be administered at high dosages once daily to achieve the high peak concentration, well above the MIC, while having prolonged low trough levels. Many concentration-dependent drugs have prolonged postantibiotic effect, meaning that the effect of the drug to inhibit growth of the organism is apparent for some time after the drug is removed.

Fluoroquinolone efficacy is best predicted by the area under the concentration curve (AUC) in relation to the bacterial

MIC. The AUC/MIC ratio should be 125 or greater for gram-negative organisms.[22-25] This ratio should be 60 or greater for gram-positive bacteria.[22] Some studies indicate that ratios that approach 250 or greater be used to avoid development of resistance.[22]

Time-dependent drugs are those whose antimicrobial activity is best predicted by the time the drug concentrations are above the MIC. Many drug classes are considered time dependent, including the β-lactam drugs and tetracyclines. These drugs should remain above the MIC for at least 50% of the time. These antimicrobial drugs generally are dosed more frequently or via continuous rate infusion for those with short half-lives.

Knowledge of the PK and PD principles can guide the practitioner in appropriate dosages and frequencies for an individual drug. Monitoring of drug levels can further aid development of the therapeutic plan. Table 45.1 summarizes the PK and PD parameters and activities of some antimicrobial drugs.[26,27]

Where Is the Infection?

Too often the question of where the infection is located is not considered when choosing an antimicrobial drug. Penetration of the drug to the site of infection is essential for successful therapy. Remember that the MIC and interpretation of the MIC are focused on systemic (plasma) levels of drugs and rarely include information on drug penetration to various anatomic locations; CLSI is increasingly providing site-specific interpretations of MICs.[18] Some anatomic locations are particularly difficult to enter, such as the central nervous system, ocular fluid, and bone. Abscesses are another structure that is difficult for antimicrobial drugs to penetrate; they are surrounded by a thick capsule with poor blood supply and lack of oxygen, which can limit penetration into the abscess and offer poor entry into the bacteria. The pH is generally low, which may inactivate some agents, and there is abundant protein present to bind antimicrobial drugs. A further complication is the presence of purulent debris that can provide metabolic precursors for bacteria to bypass inhibitors of metabolism, such as trimethoprim-sulfonamide combination drugs. In general, lipophilic drugs will be better able to penetrate these difficult-to-reach anatomic locations. Highly polar or charged molecules have difficulty reaching these sites.

If the causative organism is found intracellularly, as seen with rhodococcal pneumonia or *Corynebacterium pseudotuberculosis* infections, the host cell membranes are additional impediments to drug penetration. Fortunately, some drugs penetrate cells well, such as macrolides, rifampin, chloramphenicol, fluoroquinolones, and trimethoprim-sulfonamide combinations.

Empirical Versus Definitive Therapy

Empirical therapy is used for severe infections prior to obtaining culture and susceptibility results. The choice of antimicrobial drug depends on the clinician's knowledge of the likely agents present at the site of infection and their predicted susceptibilities. Knowledge of the Gram stain results can further guide therapy. Generally, empirical therapy is broad spectrum to cover multiple possible etiologies. Eventually, once the etiologic agent and its susceptibility have been identified, definitive therapy, using a drug or drugs with narrower spectrums, can be initiated. Definitive therapy should be directed to best result in a cure, using the narrowest spectrum of drug therapy, and have limited toxicity for the patient. The goal is to de-escalate the spectrum of activity of the drug as much as possible with definitive therapy in order to minimize the impact on commensal bacteria and development of resistance.

Combination Therapy

Many infections can be treated effectively with a single antimicrobial drug; however, in some instances, combination therapy may be chosen. Some drug combinations have been demonstrated to be synergistic based on both in vivo and in vitro studies. Synergy occurs when the ability of the combination to kill bacterial growth is greater than the mere additive effect of each drug. Drug combinations can also be indifferent, where each drug's effects are merely additive. Finally, a drug combination may be antagonistic, where the drug combination's effectiveness is less than the sum of the independent effects. Synergistic antimicrobial drug combinations are best used to treat resistant organisms. A common synergistic pair of antimicrobial drugs is the combination of trimethoprim

TABLE 45.1

Antimicrobial Drugs, Classifications, Activities, Postantibiotic Effect, and Pharmacodynamic Index

Drug	Activity	Bacterial Effect	Postantibiotic Effect[a]	PK/PD Index[b]
Aminoglycosides	Bactericidal	Concentration-dependent	Yes	AUC_{24}/MIC, Cmax/MIC
β-Lactams	Bactericidal	Time-dependent	No, gram negative; yes, gram positive	T > MIC
Fluoroquinolones	Bactericidal	Concentration-dependent	Yes	AUC_{24}/MIC, Cmax/MIC
Glycopeptides (Vancomycin)	Bactericidal	Time-dependent	Yes	AUC_{24}/MIC
Macrolides	Bacteriostatic	Time-dependent	No	T > MIC
Sulfonamides	Bacteriostatic	Time-dependent	No	
Tetracyclines	Bacteriostatic	Time-dependent	Yes	AUC_{24}/MIC
Trimethoprim	Bacteriostatic (unless combined with sulfonamide)	Time-dependent	No	

[a] *Yes*, Prolonged effect longer than 6 hours; *no*, less than 1 hour.

[b] AUC_{24}/*MIC*, Area under the concentration curve over 24 hours/minimum inhibitory concentration; *Cmax/MIC*, maximum concentration/minimum inhibitory concentration; *T >MIC*, time drug concentration is greater than the MIC.Adapted from Martinez M, Toutain PL, Walker RD: The pharmacokinetic-pharmacodynamic (PK/PD) relationship of antimicrobial agents. In Giguere S, Prescott JF, Baggot JD, et al., editors: *Antimicrobial Therapy in Veterinary Medicine*, ed 4, Ames, IA, 2006, Blackwell Publishing, pp 81-106; and Martinez M, Toutain PL, Turnidge J: The pharmacodynamics of antimicrobial agents. VetBooks.ir

VetBooks.ir

and a sulfonamide. Either agent alone would be considered bacteriostatic, but since each of these drugs inhibits sequential steps in folic acid metabolism, they are considered bactericidal.

A combination of antimicrobial drugs might be chosen for empirical therapy before the agents and their susceptibilities are known in order to provide broad-spectrum therapy. The combination of a β-lactam drug with an aminoglycoside is frequently chosen as empirical therapy in serious infections in equine patients. This combination is synergistic as well as broad spectrum. It is important to remember that in these cases, therapy should be reduced to a single agent or a less broad spectrum of activity as soon as testing results become available.

The presence of a polymicrobial infection is another reason why combination therapy may be used when a single agent will not be able to treat all bacteria present. For example, intraperitoneal infections are frequently caused by more than one agent. It is difficult to find a single antimicrobial drug to treat all possible bacteria present, such as *Enterobacteriaceae*, gram-positive bacteria, and anaerobes. Individual drugs that are sufficiently broad spectrum are available for use in humans; however, many of these would be cost prohibitive in large animal patients. The clinician should be cautious, however, of isolation of multiple agents from a single site such as a wound. Superficial samples taken from these sites may have contaminating bacteria, often with highly resistant antimicrobial patterns, that are not truly part of the infectious process.

Combined antimicrobial drug therapy can be used to prevent emergence of resistant bacteria. Certainly, for serious or difficult-to-treat infections such as those caused by *Pseudomonas* spp., avoiding development of resistance is important not only to the patient receiving treatment but also to others who come in contact with the bacteria. The best illustration of this principle is in the treatment of human patients for *Mycobacterium tuberculosis*, in which combination therapy is always used to prevent development of resistance.[28] Resistance to certain antimicrobial drugs, such as rifampin, can emerge quickly when they are used alone; thus these drugs are best used in combination.

There are some drawbacks to using combination therapy. One is the possibility of antagonism between antimicrobial drugs. Most instances of antagonism have been demonstrated in vitro, although in vivo reports have appeared.[28,29] Interestingly, combination therapy of penicillin with chlortetracycline was found to be inferior to penicillin alone in survival rates in human pneumococcal meningitis.[29] Antagonism was also seen with the combination of chloramphenicol with gentamicin used to treat immunocompromised mice with a *Proteus mirabilis* infection and in a rabbit model. Interestingly, this antagonism was not evident in immunocompetent mice, suggesting that the effect of antagonism was evident only with a diminished immune response.[28,30] Use of antimicrobial drug combinations also represents an increased cost to the client. Finally, there is an increased possibility of adverse effects of and/or hypersensitivity reactions to the drugs when used together. Antimicrobial drug combinations that may be detrimental include penicillin with tetracyclines and chloramphenicol with erythromycin. Combination therapy should not be chosen merely to provide comfort to the clinician, but rather clinicians should have specific reasons for their choice.

Drug Incompatibility

Drug incompatibility or antagonism can be the result of direct incompatibility, meaning that the drugs should not be mixed together for administration or that they should not be used together therapeutically. For example, certain penicillin or cephalosporin drugs should not be mixed with an aminoglycoside in the same vial because of inactivation of the aminoglycoside and formation of precipitates. Examples of therapeutic antagonism in vivo are harder to find. The few that have been well documented have been described in humans or animal models of disease rather than in spontaneously occurring veterinary patients. Still, these antagonistic effects are worth noting, as they may someday be demonstrated to be important in veterinary patients.

Host Factors That Influence Antimicrobial Choice or Dosage

Age

The age of the animal may influence many aspects of antimicrobial therapy. Bioavailability of certain drugs varies with age where some drugs can be used orally in neonatal or young animals but are poorly absorbed in mature animals.[31] The drug distribution may also vary with age because young animals generally have a larger volume of distribution than adults due to their larger percentage of total body water.[32] Drug biotransformation in neonates may vary from that in adults as well.[32] Therefore drug dosages and/or frequencies may have to be adjusted in young animals to provide adequate levels of drug at the site of infection and to minimize toxicity.

Fluoroquinolone use in young and adult animals should be considered carefully. This class of antimicrobial drug has been documented to cause cartilage damage in several species of young animals, and ciprofloxacin has been associated with tendinopathies in humans.[33-35] Of interest is the observation that fluoroquinolones are capable of having chondrotoxic effects on equine and canine chondrocytes in vitro,[36,37] whereas a lamb model failed to demonstrate chondrotoxicity.[38] Unfortunately, specific guidelines for the safe use of fluoroquinolones in young animals are lacking. If fluoroquinolone use is necessary in young animals, it is important to limit the duration of therapy in order to minimize the chance of damage to developing cartilage. Along the same line, tetracyclines should also be avoided in young patients to avoid discoloration of enamel of developing permanent teeth.

Reproductive Status

Antimicrobial drugs may have deleterious effects on reproduction and the developing fetus. Depending on the drug, type of placentation, and stage of gestation, some drugs are able to reach the fetus. For example, use of potentiated sulfonamides in pregnant mares has been associated with anemia, fever, and abortion.[39] Administration of pyrimethamine and trimethoprim-sulfamethoxazole to stallions has been associated with weakness and abnormal copulatory form and function.[40]

The lactating large animal must also be considered. Many antimicrobial drugs can be found in milk and may be transferred to the lactating animal or human who consumes the milk. Some drugs reach the milk in high concentrations, whereas others are found in low amounts relative to plasma. Regardless, almost all antimicrobial drugs may be found in milk. Such adulteration may make the milk unsuitable for human consumption, and appropriate withdrawal times should be adhered to before milk enters the human food chain.

Treatment of bacterial mastitis presents several challenges and is covered in more detail elsewhere in this book. Treatment should be initiated early and be based on susceptibility of the causative agent. If individual milk culture and susceptibility testing are not feasible, treatment should be based on historical information from the affected herd. Penetration into milk is also an important consideration when using systemic drugs to treat mastitis. Many drugs, such as the β-lactams and sulfonamides, are found in much lower concentrations in milk. Others, such as the macrolides, can be concentrated into milk. Because of the low concentrations found in milk for many of the drugs used systemically in food production animals, intramammary administration is preferred, although systemic administration can also be used and is probably indicated in the systemically

VetBooks.ir

ill animal or when intramammary abscesses preclude delivery of the drug via the intramammary route. As for systemic administration, withdrawal times should be closely followed with intramammary infusions.

Renal and Hepatic Function

As for all drugs, metabolism of antimicrobial drugs takes place in the liver and/or kidney, and excretion follows these routes. Therefore compromised renal or hepatic function should be considered when choosing an antimicrobial drug. Aminoglycosides are well known for their nephrotoxicity and should be avoided in cases with elevations in serum blood urea nitrogen or creatinine. If their use is still warranted despite renal dysfunction, the frequency of administration or, in some cases, the dose should be altered. Therapeutic monitoring of aminoglycoside levels should be performed to guide therapy. Macrolides and rifampin are metabolized and excreted via the hepatic route, and liver enzymes should be monitored for elevation during use. Knowledge of the route of excretion of active drug can be used to concentrate drugs at the site of infection. In the case of bacterial pyelonephritis or cystitis, renal excretion of many antimicrobial drugs can be used to the clinician's advantage during treatment.

Immune Status

The effectiveness of the immune response is important for successful antimicrobial therapy. Many drugs only reach bacteriostatic levels at the site of infection, therefore only inhibiting growth of the offending agent. In these cases, the immune response is essential for clearing the infection. Bactericidal concentrations of drugs at the site of infection should be used in cases of immunocompromise. Immunodeficiency, whether primary or secondary, may be an indication for use of combination therapy.

Duration of Therapy

Unfortunately, there are few guidelines in veterinary medicine that direct duration of therapy. Certainly, serious or deep-seated infections such as endocarditis, pyelonephritis, and osteomyelitis warrant prolonged antimicrobial administration. However, a meta-analysis of human infection outcomes in critically ill patients demonstrated that shorter duration of therapy for infections such as urinary tract infections, ventilator-associated pneumonia, or community-acquired pneumonia had no impact on mortality.[41] In addition, prolonged antimicrobial use can be associated with adverse effects and emergence of resistant secondary infections. In veterinary medicine we must frequently rely on response to therapy. Resolution of pyrexia, decreases in white blood cell count or fibrinogen, or resolution of abnormal radiographic and ultrasonographic findings are important parameters to monitor when deciding to cease therapy. In some cases, sampling and culture of the previously infected site may be warranted to demonstrate microbiological cure. For simple infections, treatment for a few days past resolution of clinical abnormalities and clinicopathologic findings may be adequate. For complicated infectious processes or chronic infections, treatment may be needed for weeks or longer after apparent cure.

Route of Administration

The route of administration varies depending on the patient species, age, severity of the infection, bioavailability of orally administered drugs, and site of the infection. Intravenous delivery of antimicrobials is indicated for serious life-threatening infections in which high levels of drug at the site of infection are indicated. Many drugs with good oral bioavailability in small animals, such as β-lactams, cannot be administered orally in large animal patients, necessitating parenteral administration. Oral administration of antimicrobials should be used cautiously in large animal species to minimize disruption of ruminal or colonic microflora in ruminants and horses, respectively. The route of administration may also be influenced by client or patient compliance and the drug label. Intramuscular administration may be difficult for some clients and patients, resulting in inadequate duration of therapy and possible development of resistance by microorganisms. Guidelines for therapeutic use of antimicrobial drugs in feed are provided later in this chapter.

Monitoring of Therapy

The response to treatment should always be monitored throughout antimicrobial drug administration. It helps to guide decision making regarding duration of therapy and effectiveness of the chosen antimicrobial regimen. As mentioned, clinical and clinicopathologic findings are useful guides to judge therapeutic success. Failure to respond to therapy could indicate that the organisms present in the infection are resistant to the chosen drug, particularly if the drug was chosen empirically. It may also indicate development of resistance during therapy or that there is poor penetration of drug to the site of the infection. Monitoring drug levels may be indicated to determine whether dosage and/or frequency is adequate in cases of treatment failure. A positive response to therapy may be an indication that antimicrobial treatment can be de-escalated in the case of broad-spectrum administration or that the patient can be switched from parenteral to oral administration.

Prophylactic and Metaphylactic Use of Antimicrobial Drugs

Antimicrobial drugs for prophylactic or metaphylactic use should be used only for cases or situations that are deemed high risk for infection and in which clinical data have demonstrated that this use is effective for preventing infection or decreasing morbidity or mortality.[13] Prophylactic use of antimicrobial drugs is therapy directed toward preventing infection in which the risks or consequences of development of an infection are great and outweigh the risks of adverse outcome from the drug used. Its most frequent application is in the surgical setting to prevent surgical site infections. The decision to use prophylactic antimicrobials depends on the type of surgery and the possibility of entering nonsterile sites such as the gastrointestinal or genitourinary tract, the length of the surgical procedure, the use of surgical implants, and the degree of tissue damage. It is important that the antimicrobial drug be present at therapeutic levels at the time of contamination to be effective in preventing surgical site infections.[42] The therapy should be directed toward the pathogens likely to cause the infection. In the case of surgical site infections of large animals, these include *Enterobacteriaceae*, *Staphylococcus*, and *Streptococcus*.[43-45] Generally, the drug should be administered 30 to 60 minutes before the surgery begins.[46,47] If the surgery is prolonged, repeated administration of the antimicrobial drug should be performed. However, the timing of surgical antimicrobial prophylaxis should be tailored to the drug used to ensure adequate concentrations at the surgical site at the time when contamination might occur.[48] Perioperative administration is what is important to prevent surgical site infections, and continued use after completion of surgery is unnecessary as determined in human patients.[48,49] Therapy beyond this point will not appreciably reduce the incidence of surgical site infections and may predispose to development of resistance or superinfections and increase the likelihood of adverse reactions.[42]

Prophylactic antimicrobials should be drugs other than those used therapeutically so that treatment options remain available should an infection develop. It has been recommended that

VetBooks.ir

older drugs be used so that newer drugs may be used therapeutically.[50] Prophylaxis should never be used in the place of good aseptic technique and is not indicated for use to prevent infection of intravenous catheters or other similar indwelling devices. Antimicrobial use in these instances only increases the likelihood that if infection develops, it will more likely be resistant.

Metaphylaxis is use of antimicrobial drugs after exposure to an infectious agent but before development of clinical signs. Examination of parenteral treatment of calves at high risk for infection in the bovine respiratory disease complex prior to or upon entry to the feedlot has shown decreased morbidity and mortality.[51,52] However, more recent studies have demonstrated either no benefit or mixed results.[53,54] Furthermore, multidrug-resistant *Mannheimia haemolytica* has been isolated from calves receiving prophylactic or metaphylactic antimicrobials.[55] It is important to note that metaphylactic use of antimicrobial drugs will not eliminate all infections and may have a greater impact on the severity or duration of the illness. Metaphylactic administration may not always be practical for large groups of animals, and labeling may preclude antimicrobial use in this manner.

Biosecurity and Infection Control

A cornerstone of effective antimicrobial stewardship is to prevent infections in the first place through biosecurity and infection control measures on the farm and in the veterinary hospital or clinic. Segregating animals coming onto a farm, eliminating predisposing factors for bacterial disease, and vaccinating for viral diseases can limit infections and the need for antimicrobial drugs. The single most important step to control spread of disease in the clinic or hospital or from farm to farm is frequent hand washing and attention to personnel hygiene. Isolation or segregation of animals with contagious or highly resistant organisms and control of movement of animals can go a long way toward decreasing infection rates. Infection control and hygiene plans are important for any premises where animals are managed, not just for veterinary hospitals or clinics.[13,14]

Microbial Factors Affecting Therapy

Resistance

A number of microbial factors may influence the success of therapy. Resistance of the agent to the chosen therapeutic is a common occurrence in therapeutic failure. Resistance can result from the inherent properties of the microbe. For example, mycoplasmas lack a cell wall and are impervious to the effects of cell wall–targeting drugs like the β-lactams. Other drugs may not be able to penetrate the bacteria, as is seen in the inability of anaerobes to take up aminoglycosides in the anaerobic environment. A major contribution to resistance is acquisition of resistance determinants. Resistance may result from alteration of the antimicrobial target, gain of genes capable of degrading the drug (e.g., β-lactamases), or acquisition of genes encoding efflux pumps (e.g., tetracyclines, aminoglycosides, fluoroquinolones) that pump antimicrobials out of the bacterial cell. Bacteria can develop resistance through mutation of the gene encoding the protein target of the drug (e.g., fluoroquinolones and DNA gyrase). These events are not frequent, occurring once every 10^{10} to 10^{14} cell divisions. However, the rapid multiplication rate of a large number of bacteria makes this a real possibility. These events are often random, and their appearance is generally not influenced by the presence of a particular antimicrobial drug. However, if a drug is present, bacteria with the mutation will have a selective advantage and will rapidly outcompete nonresistant bacteria.

Alternatively, bacteria can acquire genes encoding a resistance determinant. Bacteria can obtain resistance genes through several mechanisms. Movement of plasmids, a type of extrachromosomal DNA, through conjugation between bacteria of the same or different species is a major means by which resistance develops. Other mobile DNA elements can move resistance genes between bacteria. Resistance genes are frequently associated with transposons, DNA capable of excision from host genomic DNA to plasmids and subsequent transport to other bacteria. Bacteriophages (bacterial viruses) may also move resistance genes between bacteria through a process called *transduction*. Finally, resistance genes can be taken up as naked DNA in the bacterial environment through a process known as *transformation*.

The simple act of using antimicrobial drugs will result in selection of bacteria that are resistant. Survey of gastrointestinal microbes, such as *Escherichia coli*, after initiation of antibiotic therapy has shown that resistance will develop in normal flora.[56-59] The most effective way to avoid resistance is to minimize the use and duration of antimicrobial drugs and, when they are used, to be sure that they are delivered to the site of infection at adequate levels to kill the bacteria.

Biofilms

Bacteria can move from existing as individual cells, also known as planktonic growth, to develop into a population that functions more as a multicellular organism known as a biofilm. The definition of a *biofilm* is "aggregated microbial cells surrounded by a polymeric self-produced matrix, which may contain host components."[60] Biofilms are notoriously difficult to treat with simple antimicrobial therapy and are known to form on a variety of surfaces, including catheters, orthopedic implants, and bone. Biofilm bacteria are different from planktonic organisms in several ways. First, they are less susceptible to antimicrobial agents. Second, they persist in the animal despite a vigorous immune response. Unfortunately, effective treatment of the biofilm-associated infection necessitates removal of the infected implant or bone.

Adverse Reactions

Adverse reactions to antimicrobial drugs certainly occur, although hundreds or thousands of doses may have to be given before they are observed. A report from Switzerland indicated that 20% of adverse reactions to drugs were to antimicrobial agents.[61] Adverse events associated with antimicrobial use can range from a hypersensitivity reaction to direct toxicity to disruption of normal microbiota. Fortunately, antimicrobial agents are directed toward the prokaryotic structures of bacteria that generally differ to some degree from the eukaryotic equivalent of the host. Consequently, they are less likely to result in direct toxicity in the patient. Some drug toxicities are predictable based on their mechanism of action or accumulation in certain cells of the host. Hypersensitivity reactions are the result of immunologic stimulation by the drug or carriers in the drug formulation. One frequently observed adverse event associated with antimicrobial use is the development of severe gastrointestinal disturbances. These may be the result of changes in the gut microbiota and/or proliferation of pathogenic bacteria such as *Clostridioides difficile* or *Salmonella*. Adverse reactions to antimicrobial drugs should be reported to the manufacturer and to the Food and Drug Administration Center for Veterinary Medicine.

Adjunctive Therapy

In some cases, antimicrobial drugs alone are unable to clear the infection. In these cases, adjunctive therapy should not be overlooked. Surgical débridement of necrotic material and reestablishment of an adequate blood supply help to remove bacteria and allow better antimicrobial penetration. Sometimes simple drainage of an abscess is all that is necessary to treat certain infections, obviating the use of antimicrobial drugs.

VetBooks.ir

Topical treatment may be possible in some instances. Superficial skin infections may be treated with either topical antimicrobial drugs or antiseptics. Deep or severe infections may need both systemic and topical treatment. Most ocular infections are successfully treated topically where high drug concentrations can be delivered.

Local treatment of severe internal infections can also be used as an adjunct to systemic therapy. Intraarticular administration of antimicrobials and/or regional perfusion are frequently used to treat joint and bone infections in large animals. These routes deliver high levels directly to the site of the infection. Although efficacious, adjunctive therapy, including débridement and lavage, are important to remove the bacterial burden and inflammatory substances that may be detrimental to joint structures. In these instances, systemic administration is indicated.

Medicating animals that are used to produce food for human consumption is a worldwide phenomenon. Medications can be used to increase production, treat illnesses, produce healthier animals, or prophylactically and/or metaphylactically prevent or reduce morbidity and/or mortality caused by diseases. In recent years the potential impacts of drug residues have become of increasing concern for consumers, regulators, and legislators. To maintain public safety, it is important for veterinarians to educate themselves and work closely with their clients to help minimize drug residues in the human food chain.

Definition of Food-Producing Animal Species

For the purposes of this chapter, a food animal is any animal whose tissues or products have the potential to enter the human food chain. In the United States, food animals are further categorized as major or minor food animal species. The Food, Drug, and Cosmetic Act defines the major food-producing species of animals to include cattle, swine, chickens, and turkeys. The CVM, a branch of the FDA, has a list of definitions for bovine, swine, and poultry species and classes, which can be found in Table 45.2.[1] Furthermore, in addition to these definitions, the Code of Federal Regulations (CFR) has defined dairy cattle to include all female cattle of a recognized dairy breed over 20 months of age.[2] Both dry and lactating dairy cattle are in this category. "Minor" food animal species are defined by exclusion, meaning that the "major" animal species have been identified and all others are considered "minor." Examples of "minor" food animal species are goats, sheep, and cervids.

On-Label Drug Use

In food animal medicine, medications can be administered to an individual animal or a herd or flock depending on numbers of animals needing treatment, disease, and/or overall management practices. Practitioners treating food-producing animals in the United States can use FDA-approved veterinary products according to the label. Using medications according to the label directions is called *on-label drug use*, where all of the drug label specifications (animal species and class, administration route, dose, dosing frequency or interval, indication, limitations, and withdrawal time) are fulfilled and the FDA-approved withdrawal time (WDT) is observed. The FDA-approved WDT is the amount of time that must be observed after the last dose is administered and before the food product intended for human consumption can enter the human food chain. There are multiple databases where label information for FDA-approved veterinary medications is accessible and can be consulted. Table 45.3 lists a few resources.

Extralabel Drug Use and the Animal Medicinal Drug Use Clarification Act of 1994

Prior to the enactment of the Animal Medicinal Drug Use Clarification Act (AMDUCA) in 1994, veterinarians could legally treat food animals with on-label medications only. Passage of AMDUCA legalized most instances of extralabel drug use (ELDU) in food animals by or on the order of veterinarians.[3] Extralabel drug uses include prescribing or administering a human or veterinary drug at a higher or lower dose, frequency, or duration; by a different route of administration; in a different species or production class; or for a different indication than described on the product's label. For food animal practitioners, with this privilege comes the weighty responsibility of protecting the health of consumers of animal products. Veterinarians must meet very specific conditions before they may legally use or prescribe drugs in an extralabel fashion. Under AMDUCA, ELDU is limited to cases in which the health of the animal is threatened or suffering or death may result from a lack of treatment. ELDU may not be used to enhance production or for nontherapeutic reproductive cycle

TABLE 45.2

U.S. Food and Drug Administration's Definitions of Species and Classes of Major Food Animals[1]

Species	Class			Definition
Cattle	Beef Cattle (cattle intended for meat production)	Suckling Calves		Immature, preruminant cattle (including *dairy breeds* intended for meat production), maintained with and dependent on their dam for nourishment. Veal calves are not considered suckling calves.
		Pasture Cattle (stocker, feeder, slaughter, and sometimes replacement beef heifers)		Weaned cattle (including dairy breeds) maintained on pasture and receiving most of their diet from grazing. The term *pasture cattle* is intended to refer to cattle considered to be stockers, feeders, and/or slaughter cattle. Therefore parenthetical reference to *stocker*, *feeder*, or *slaughter cattle* is typically included in labeling. *Stockers* refers to weaned calves grazing pasture to enhance growth prior to finishing and slaughter; they are usually younger, weigh less, and are of lower condition (finish) than "feeders." *Feeders* refers to weaned calves grazing pasture and of sufficient weight and maturity to be placed on high-energy rations for finishing; they are generally older, weigh more, and carry more condition (finish) than stockers. *Slaughter* refers to cattle grazing pasture and suitable for slaughter. Sex differentiation (e.g., heifers, steers, and/or bulls) should be indicated on product labeling. *Replacement beef heifers* may be added to the Pasture Cattle class if the drug has been shown to have no negative impact on reproduction in female cattle during the period from weaning until first calving and the female cattle are intended for reproduction to produce calves intended for meat production.
		Cattle Fed in Confinement for Slaughter		Cattle (including dairy breeds) confined in group pens and fed a high-energy diet ad libitum until slaughter. Sex differentiation (heifers, steers, and/or bulls intended for slaughter) should be indicated on product labeling.
		Growing Cattle on Pasture or in Dry Lot (stocker and feeder)		Weaned cattle (including dairy breeds) maintained on pasture or in a dry lot and receiving most of their diet from forage.
		Lactating Beef Cows		Lactating beef breed female cattle nursing calves intended for meat production; their milk is not intended for human consumption.
		Non-Lactating Beef Cows		Female beef breed cattle that previously nursed calves intended for meat production but are not currently producing milk.
		Replacement Beef Bulls		Intact male beef breed cattle intended for reproductive purposes.
	Veal Calves			Immature cattle (including dairy breeds) lacking a functional rumen and intended for meat production. They are recognized as a separate class from suckling calves because of their handling, housing, and proximity to slaughter.
	Dairy Cattle (cattle intended for production of milk for human food)	Lactating Dairy Cows		Female dairy breed cattle that are producing milk.
		Dry Dairy Cows		Female dairy breed cattle that previously lactated but are not currently producing milk (cows between two lactations).
		Non-Lactating Dairy Cattle	Replacement Dairy Heifers	Female dairy breed cattle from weaning until first calving.
			Replacement Dairy Bulls	Intact male dairy breed cattle intended for reproductive purposes.
			Dairy Calves	Female or male dairy breed cattle being fed a ration that includes milk or liquid milk replacer and that are not intended for veal production.

TABLE 45.2

U.S. Food and Drug Administration's Definitions of Species and Classes of Major Food Animals—cont'd

Species	Class	Definition
Swine	Boars	Intact, sexually mature, male pigs intended for breeding purposes; generally not intended for slaughter in the United States.
	Barrows	Castrated male pigs intended for slaughter.
	Gilts	Female pigs intended for slaughter or breeding purposes; have not yet farrowed a litter.
	Replacement Gilts	Breeding female pigs that have not yet farrowed a litter; usually weigh 220 to 300 lb (100 to 135 kg).
	Sows	Female pigs that have had at least one litter.
	Nursing Pigs	Pigs from birth until weaning and still nursing.
	Starter or Nursery Pigs	Boars, barrows, and gilts from approximately 2 to 4 weeks of age and approximately 50 to 60 lb (23 to 27 kg).
	Growing Pigs	Barrows and gilts from approximately 50 to 60 lb (23 to 27 kg) to 120 to 150 lb (55 to 68 kg).
	Finishing Pigs	Barrows and gilts from approximately 120 to 150 lb (55 to 68 kg) to market weight for slaughter.
Chickens	Egg	From in ovo until hatching.
	Laying Hens (or layers)	Hens that produce eggs for human consumption.
	Chicks	Chickens from day of hatch until they are able to survive in ambient temperature (no longer brooded).
	Broiler Chickens (or fryers or frying chickens)	Meat-type chickens normally grown to a market age of 35 to 49 days and market weights between approximately 4 and 7 lb (1.80 and 3.2 kg).
	Roasters (or roasting chickens)	Meat-type chickens grown to market weights between approximately 6 and 9 lb (2.7 and 4.1 kg).
	Replacement Chickens	Chickens intended to become laying hens or breeding chickens.
	Breeding Chickens	Sexually mature male and female chickens of any type intended for the production of fertile eggs; the eggs are not intended for human consumption.
Turkeys	Egg	From in ovo until hatching.
	Laying Hens (or layers)	Hens that produce eggs for human consumption.
	Poults	Turkeys from day of hatch until they are able to survive in ambient temperature (no longer brooded).
	Growing Turkeys	Turkeys grown for meat purposes to a market age of approximately 17 (female) or 22 (male) weeks; may be further divided into heavy or light turkey strains.
	Finishing Turkeys	Turkeys intended for meat production during the last 2 to 4 weeks of growth.
	Replacement Turkeys	Turkeys intended to become laying hens or breeding turkeys.
	Breeding Turkeys	Sexually mature male or female turkeys intended to produce fertile eggs; their eggs are not intended for human food use.

Modified from U.S. Food and Drug Administration: Animal & Veterinary. 2009. Appendix III, Species and Classes of Major Food Animals. In CVM's Guidance for Industry (GFI) #191: Changes to Approved NADAs–New NADAs vs. Category II Supplemental NADAs. [WWW page]. https://www.fda.gov/downloads/AnimalVeterinary/GuidanceComplianceEnforcement/GuidanceforIndustry/UCM052460.pdf. (Accessed 20 July 2018).

manipulation in healthy animals and can occur only on the order of a veterinarian within the context of a veterinarian-client-patient relationship (VCPR), as described in Box 45.3. ELDU may be considered in food-producing animals only when no approved drug is available that contains the same active ingredient in the required dose, form, and concentration or when the veterinarian finds that there is no approved drug that is clinically effective for the intended use. ELDU in or on animal feed is also expressly prohibited.

AMDUCA stipulates that ELDU applies only to FDA-approved human and veterinary medications. It does not legalize the extralabel use of Environmental Protection Agency (EPA)–regulated pesticides or U.S. Department of Agriculture (USDA)–regulated biologics. New animal drug application (NADA) or abbreviated new animal drug application (ANADA) numbers are a good indication of whether a drug is FDA approved. The presence of a NADA or ANADA number on the product label is an indication that the veterinary drug has FDA approval. Similarly, for human drugs, every approval has a unique new drug application (NDA) number for pioneer drugs or abbreviated new drug application (ANDA) number for generic drugs. Approval status of both animal and human drugs can be found on the FDA-CVM (http://www.fda.gov/AnimalVeterinary/) and FDA (http://www.fda.gov) websites, respectively.

When veterinary products are used in an extralabel manner, a withdrawal "interval" must be estimated based on scientific evidence and extended beyond the FDA-approved WDT regardless of the dose, route, or indication. This ensures that there are no illegal residues, another stipulation in AMDUCA. A residue is considered either the parent compound or a metabolite of that parent compound that may accumulate, deposit, or otherwise be stored within the cells, tissues, organs, or edible products (e.g., milk, eggs) of an animal after its use to prevent, control, or treat animal disease or to enhance production.[4] As stipulated by AMDUCA, veterinarians' obligations regarding ELDU are listed in Box 45.3.

Veterinarians who violate state or federal laws regulating the transport, sale, or use of drugs may face a variety of sanctions, including warning letters, fines, temporary or permanent revocation of license, and incarceration.

Veterinary Feed Directive

To help combat antimicrobial resistance and protect human safety, the FDA took action by eliminating claims for production use of medically important antimicrobials (MIAs) and by increasing veterinary oversight by transitioning MIAs from over the counter (OTC) to Veterinary Feed Directive (VFD) or Prescription (Rx). MIAs for use in or on feeds that were

VetBooks.ir

BOX 45.3

Conditions Necessary for Extralabel Drug Use

1. Extralabel drug use (ELDU) is permitted only by or on the order of a veterinarian.
2. The veterinarian judges on-label treatments to be unavailable or ineffective.
3. ELDU uses only U.S. Food and Drug Administration (FDA)–approved animal and human drugs, not drugs imported from foreign countries or compounded from bulk sources. When treating food animals, approved food animal drugs should be used before approved animal drugs, which should be used before approved human drugs.
4. A valid veterinarian-client-patient relationship (VCPR) exists in which the veterinarian:
   - Oversees medical treatment decisions on the farm
   - Is familiar with animal care through appropriate and timely visits
   - Has sufficient knowledge to initiate a diagnosis
   - Is available for follow-up care as needed
5. ELDU is for therapeutic or humane purposes only, not to increase production or manipulate reproductive cycles in normal animals.
6. ELDU applies only to administration to individual animals and in water, not in feed.
7. Animal identification and treatment records are sufficient to identify treated animals and their treatment history and are maintained for 2 years.
8. The veterinarian establishes an extended drug withdrawal period protective of human health supported by scientific evidence. ELDU resulting in violative or dangerous food residues is not permitted.
9. Drug labels list the name and address of the prescribing veterinarian, animals to be treated, and the drug name, disease indication, dose, frequency, duration, cautions, and withdrawal periods associated with treatment.
10. Certain extralabel uses specifically prohibited by the FDA are not used (see Box 45.4).

previously OTC now require a VFD, while MIAs as a water additive became prescription only. A list of MIAs is provided in Appendix A of the FDA's Guidance for Industry #152 (https://www.fda.gov/downloads/AnimalVeterinary/GuidanceComplianceEnforcement/GuidanceforIndustry/UCM052519.pdf). Drug classes not affected by these changes include ionophores, bacitracins, and coccidiostats. These changes became effective on January 1, 2017.

A VFD is a written statement issued by a veterinarian with a valid VCPR for the use of a VFD drug or VFD combination drug in or on animal feed. A list of sponsor applications being affected by the FDA rulings can be found at https://www.fda.gov/AnimalVeterinary/SafetyHealth/AntimicrobialResistance/JudiciousUseofAntimicrobials/ucm390429.htm. A list of drugs and approved VFD drug combinations can be found on the FARAD website (http://www.farad.org/vfd-drug-combinations.html). For a veterinarian to write a VFD, the veterinarian must be licensed to practice in the state the animals reside in, have a valid VCPR, and issue the VFD in compliance with the drug's approved labeling and conditions. Extralabel use of VFD drugs is prohibited.

California Senate Bill 27

In the state of California, Senate Bill 27 (SB 27) became effective on January 1, 2018. SB 27 was created to address antimicrobial resistance. It is similar to the federal regulations on judicious use of MIAs, but it extends veterinary oversite of MIAs further. For animals being treated in California, all forms of MIAs, including oral, injectable, topical, and intramammary, now require a prescription from a veterinarian. This means that MIA formulations that are designated as OTC at the federal level will be designated as prescription in the state of California. The prescription status for medications affected by this ruling can be found on VetGRAM on the FARAD website. In addition to increasing veterinary oversite of MIAs, SB 27 requires the California Department of Food and Agriculture to collect data on MIA drug sales and usage, antimicrobial resistant bacteria, and livestock management practice.

Extralabel Drug Use of Medicated Feeds in Minor Species

Even though AMDUCA prohibits the extralabel use of medications in feed, a Compliance Policy Guide (CPG) 615.115 for extralabel use of medicated feeds for minor animal species does exist.[5] The AMDUCA prohibition of extralabel use of medications in feed was generated because of concerns of antibiotic resistance. AMDUCA's Section 530.11 specifically prohibits the "extralabel use of an approved new animal drug or human drug in or on an animal feed." As a matter of enforcement discretion, the CVM generally has not objected to mixing a drug with an individual animal's feed, but extralabel mass medication in feed is prohibited "without limitation or exception." Veterinarians may, however, be called on to treat minor food animal species such as farmed exotic ruminants, fish, or game birds. The CVM has found that for many of these species, very few approved drugs exist. In addition, the CVM recognizes that some minor food animal species (such as fish and game birds) cannot be practically medicated in any way other than through the use of medicated feeds. In such situations, a veterinarian may determine that extralabel use of medicated feeds (approved for use in other species) can prevent suffering and death in these minor species.

Although AMDUCA prohibits ELDU in feed, in the previously described circumstances the CVM "ordinarily will not consider regulatory action" against the veterinarian or animal producer provided that certain criteria listed in Box 45.4 are met.[5] The CVM policy being implemented in these cases is akin to that of ELDU by veterinarians before the 1994 passing of AMDUCA. The drug use is still illegal, but the CVM will apply regulatory discretion relative to taking enforcement action. A critical aspect of the CVM's regulatory discretion in this practice is that labeled treatment alternatives are not available. The best resource to aid practitioners in determining what treatments are approved for minor food animal species is the Minor Use Animal Drug Program website (http://www.nrsp-7.org).

Prohibited Drugs and Drug Classes Prohibited From Extralabel Drug Use in Food Animals

Certain drugs may not be prescribed or used even under the auspices of AMDUCA.[6] Under statutory authority provided in AMDUCA, the FDA-CVM has prohibited approximately a dozen drugs or drug classes, making their extralabel use in food animals illegal. Other compounds not specifically listed in AMDUCA are prohibited because no approved animal or human products are commercially available. Last, extralabel use of treatments is also regulated by the Pasteurized Milk Ordinance (PMO). The extralabel use in food animals of the compounds listed in Box 45.5 represents one of the FDA's highest priorities for regulatory attention. It is advised that the FDA-prohibited drug list be checked on a regular basis for updates, as it is subject to change. FARAD and AVMA websites both list prohibited drugs.[7,8] Alternatively,

VetBooks.ir

BOX 45.4

Conditions Necessary for Extralabel Use of Medicated Feed in Minor Species

1. Extralabel use of medicated feed is only for treatment of minor species, defined by exclusion as animals other than cattle, horses, swine, chickens, turkeys, dogs, and cats.
2. Extralabel use of medicated feed is limited to farmed or confined minor species but not unconfined wildlife.
3. Extralabel use of medicated feed is limited to situations in which the health of an animal is threatened and suffering or death may result from failure to treat.
4. There is no alternative therapeutic dosage form (besides feed) that can be practically used under legal extralabel use.
5. Only feeds formulated and labeled for use in a major species animal are used.
6. Extralabel use of medicated feed in aquaculture is limited to medicated feed products approved for use in aquatic species.
7. The medicated feed is used within 3 months of a veterinarian's written recommendation. Recommendations, feed labels, and invoices are kept for at least 1 year. Adverse reactions are reported to the U.S. Food and Drug Administration within 10 days.
8. All other Animal Medicinal Drug Use Clarification Act requirements are complied with, including a valid veterinarian-client-patient relationship, lack of label alternatives, treatment records, animal identification, and extended withdrawal times (see Box 45.3).
9. The medicated feed is used in accordance with federal, state, and local environmental regulations and approval. This is particularly important for aquaculture uses.
10. The producer has followed worker safety provisions in the approved product labeling.

BOX 45.5

Drugs or Drug Classes Prohibited From Extralabel Drug Use[a]

Diethylstilbestrol (DES)
Chloramphenicol
Nitroimidazoles (including dimetridazole, metronidazole, and ipronidazole)
Sulfonamide (other than sulfadimethoxine) in adult dairy cattle[b]
Clenbuterol
Fluoroquinolones (e.g., enrofloxacin, danofloxacin)
Glycopeptides (e.g., vancomycin)
Nitrofurans (including nitrofurazone, furazolidone; topical use prohibited as well)
Phenylbutazone in adult dairy cattle[b]
Adamantane and neuraminidase inhibitors in poultry
Cephalosporins (not including cephapirin) in cattle, swine, chickens, or turkeys:
(i) For disease prevention purposes
(ii) At unapproved doses, frequencies, durations, or routes of administration
(iii) If the drug is not approved for that species and production class

[a]Extralabel use of some drugs or drug classes (not specifically addressed in the Animal Medicinal Drug Use Clarification Act) are prohibited because these drugs are not available as approved animal or human products, by U.S. Food and Drug Administration (FDA) policy or in the Pasteurized Milk Ordinance (see chapter text).

[b]Defined by the FDA as dairy cattle (lactating or dry) older than 20 months of age.

21CFR530, the section of the CFR pertaining to ELDU, may be accessed directly.[9]

If any of these prohibited drugs are mistakenly used in a food-producing animal, that animal and its by-products should never be allowed to enter the human food chain and ideally that animal should be isolated from other food animals.

Drugs Prohibited From Use in Food Animals

1. Diethylstilbestrol: From the 1940s to the 1970s, U.S. physicians prescribed diethylstilbestrol (DES, a potent nonsteroidal synthetic estrogen) to pregnant women to prevent miscarriage and other reproductive diseases. In 1971 a link between in utero exposure to DES and a rare vaginal cancer (clear cell adenocarcinoma) was established. In the same year the FDA published an alert advising doctors against the use of DES during pregnancy. The USDA banned the use of DES in food animals in 1979.
2. Chloramphenicol: An estimated 1 in 10,000 to 50,000 people exposed to chloramphenicol will develop a non-dose-related aplastic anemia. Because of concerns that this idiosyncratic and frequently fatal complication could be triggered by residues, chloramphenicol use in food animals was prohibited in 1984. The prohibition extends to all formulations of chloramphenicol, including ophthalmic ointments. Florfenicol, a synthetic member of the chloramphenicol family, lacks the p-NO_2 group thought to be responsible for inducing the aplastic anemia. Florfenicol may be used extralabel in food-producing species. However, veterinarians should be aware that extralabel use of florfenicol in dairy cattle older than 20 months of age requires extended withdrawals to allow depletion of drug residues in the liver to a level below detection by the Food Safety and Inspection Service (FSIS).
3. Nitroimidazoles: Historically, dimetridazole and ipronidazole have been approved for the treatment of histomoniasis (infectious enterohepatitis, blackhead) in turkeys. Ipronidazole and the human drug metronidazole have been used off-label to eliminate the carrier state of trichomoniasis in bulls. Laboratory studies of members of this drug class demonstrated mutagenicity and carcinogenicity, leading to the prohibition of their use in food animals. Because there are no approved veterinary nitroimidazole labels, the use of any member of this drug class in food animals is illegal.
4. Nitrofurans: In the past, nitrofurazone and furazolidone were approved for a variety of protozoal and bacterial infections in poultry and swine. Topical formulations (sprays and "puffer" products) have also historically been marketed for wounds and ocular infections in livestock ("pinkeye"). Based on laboratory evidence of carcinogenicity and the absence of a reliable detection method, the FDA withdrew approval for systemic animal nitrofuran products in 1991 and prohibited all extralabel treatment (including topical use) in 2002. Because nitrofurans have no approved food animal uses, the use of any member of this drug class in food animals is illegal.
5. Clenbuterol: Marketed in the United States as an equine bronchodilator, this synthetic sympathomimetic has been used illicitly to increase weight gain and lean body mass in food animals, particularly show animals. Because muscle depletion and fat redeposition commences after drug withdrawal, producers may be tempted to market animals with little or no withdrawal interval. Cooking temperature only minimally denatures the compound, and toxicity from residues has resulted in hundreds of emergency hospitalizations in consumers of tainted beef in Spain and Italy.[10,11]
6. Glycopeptides: Vancomycin, the only glycopeptide antibiotic available in the United States, is often the therapy of last resort for methicillin-resistant *Staphylococcus aureus* (MRSA) infections in humans. Demonstration of

VetBooks.ir

vancomycin-resistant *Enterococcus* in the feces of poultry and swine fed the glycopeptide avoparcin led the CVM to prohibit extralabel use of glycopeptides in food animals in 1997.

7. Phenylbutazone in adult dairy cattle: The use of phenylbutazone, a nonsteroidal antiinflammatory drug, in humans has been associated with various adverse drug reactions, including fatal blood dyscrasias. After USDA reports of a high incidence of phenylbutazone tissue residues in cull dairy cows, the CVM prohibited its use in female dairy cattle older than 20 months of age. Anti-inflammatory therapy for lactating dairy cattle is available as flunixin meglumine. Flunixin should be used only on-label (intravenously) because intramuscular or subcutaneous administration can greatly extend withdrawal times.[12]
8. Antiviral drugs in poultry: Concern exists that use of antiviral drugs in poultry could promote drug resistance in zoonotic pathogens, particularly avian influenza H5N1 ("bird flu"). These concerns led the CVM to prohibit extralabel use of two drug classes used in treating human influenza in 2006. Adamantanes and neuraminidase inhibitors may not be used in chickens, turkeys, and ducks. Aside from compounds specifically prohibited through AMDUCA, there are several compounds that the CVM has reminded veterinarians cannot be legally obtained as finished animal or human products and therefore have no legal extralabel uses.
9. Dipyrone: At one time approved for humans and animals, dipyrone was withdrawn from the market because of concerns of adverse events in humans associated with its use, including teratogenicity, prolonged bleeding times, and agranulocytosis.
10. Estradiol cypionate: Before 2003, estradiol cypionate (ECP; a synthetic estrogen) was commercially marketed as reproductive therapy in food animals. ECP had not undergone a formal approval process, however, and discretionary marketing was discontinued for lack of food safety and efficacy data. Use in or compounding of ECP for food animals remains illegal.
11. Gentian violet: Gentian violet was originally used as an additive to poultry feed as a mold inhibitor. However, the FDA has never approved the use of this product as a feed additive or as an animal drug, and the impact of any residues on human health is unknown. Therefore any use in feeds constitutes extralabel use of a medicated feed and unapproved animal drug. In addition to medicated feeds, topical formulations containing gentian violet are currently being marketed. However, in 2007, the FDA issued a warning advising veterinarians of the illegal nature of using topical products containing gentian violet in food-producing animals.
12. Hormone implants in veal calves: Although growth-promoting hormone implants have been marketed for ruminating cattle, these products never underwent regulatory approval for nonruminating veal calves. Concern existed in the CVM that nonruminating calves may eliminate the hormone contained in the implants differently than ruminants. In 2005 a new warning statement was added to the label of all growth-promoting hormone implants, reminding producers and veterinarians that their use in veal calves is illegal.
13. Dimethyl sulfoxide and colloidal silver: Besides AMDUCA, the Grade A PMO also directs how drugs will be used and stored on dairy farms. Dimethyl sulfoxide (DMSO) and colloidal silver may not be used in or on dairy animals and, if found during a dairy inspection, can result in "debits."

Drug Classes Prohibited From Extralabel Drug Use in Food Animal Species

In addition to the aforementioned specific drugs that the FDA has prohibited, there are drug classes for which some drugs may have FDA approval for use in food-producing animals, but these drug classes are prohibited from any ELDU. Drug classes with an ELDU prohibition include the following:

1. Cephalosporin-class antibiotics: On April 5, 2012, in hopes of preserving their effectiveness for human populations and decreasing the likelihood of the emergence of cephalosporin-resistant strains of foodborne bacterial pathogens, the extralabel use of cephalosporins in cattle, swine, chickens, and turkeys was prohibited. This prohibition does not include (1) the extralabel use of cephapirin in food-producing animals; (2) use of a cephalosporin to treat an extralabel indication, provided that all other label directions are followed, including species, dose, route, duration, and frequency; and (3) extralabel use in minor food-producing animal species (i.e., species that do not include cattle, swine, chickens, or turkeys).
2. Sulfonamides in adult dairy cattle: The observed carcinogenicity of sulfonamides in laboratory animals, coupled with the frequent finding of sulfonamide residues in milk, led to the prohibition of extralabel use of these compounds in adult dairy cattle. The FDA defines a lactating cow as any dairy cow (milking or dry) older than 20 months of age. The use of any sulfonamide in adult dairy cattle other than approved uses of sulfadimethoxine (SDM), sulfabromethazine, and sulfamethoxypyridazine is illegal. This would include using a higher dose of SDM or slow-release formulation SDM boluses.
3. Fluoroquinolones: Uncertainty exists related to the magnitude and significance of human pathogen resistance resulting from antibiotic use in animals. Fluoroquinolones are mainstay treatments of antibiotic-resistant *Salmonella* and anthrax infections in humans. Concern that fluoroquinolone use in food animals was promoting human pathogen resistance prompted the CVM to prohibit extralabel use of these compounds in 1997. Any deviation from a fluoroquinolone product label (altering species use, dosage, route of administration, or disease indication) is illegal. In the case of the approved beef cattle formulation of danofloxacin, this prohibition extends to use in all non-beef-production animals, including lactating and nonlactating dairy cows, heifer replacements, bulls, and veal calves. The same applies to enrofloxacin, with the exception of nonlactating dairy cattle, defined by the FDA as dairy cows younger than 20 months of age, for which there is a label indication.

Considerations for Treatment of Companion Food Animal or Pack Animal Species With Prohibited Substances

The previously detailed FDA-prohibited drug and drug class lists pertain to food-producing animals only and not to companion species such as dogs and cats. Veterinarians treat companion animals belonging to a food-producing species, but the FDA does not make a distinction between food-producing and companion status. Even if the food-producing species with companion status are not to be slaughtered, consideration for why the prohibition exists should be carefully examined and prudent pharmacovigilance should be used. Practitioners who have used a prohibited substance in a companion or pack animal that subsequently enters the food supply are subject to enforcement actions under the Food, Drug, and Cosmetic Act. In choosing to use a prohibited drug in a companion or pack animal, the practitioner is accepting a certain amount of liability because the fate of such treated animals is often beyond their control. Practitioners may choose to have owners sign an agreement (entered into the medical record) not to introduce the animal into the human food chain.

VetBooks.ir

BOX 45.6

Requirements for Compounding in Veterinary Practice

1. No approved animal or human drug can be used in its available dosage form and concentration.
2. Only approved animal or human drugs are used in the compounding, specifically not foreign or bulk drugs.
3. Compounding is performed by a licensed pharmacist or veterinarian in compliance with state pharmacy laws.
4. Adequate procedures are in place to ensure the safety and effectiveness of the product.
5. Withdrawal intervals are set by the veterinarian, not by the pharmacist.
6. The scale of the compounding operation is commensurate with the established practice needs.
7. All other Animal Medicinal Drug Use Clarification Act requirements are met (see Box 45.3).

Compounding of Medications for Food Animals

Compounding is defined as a manipulation to produce a dosage form of a drug other than that provided for in the labeling, such as reconstitution. The CVM recognizes the need for compounding within certain areas of veterinary practice, such as mixing or dilution. Because of the absence of safety, efficacy, and food safety data for compounded drugs, the potential exists for adverse reactions in treated animals or consumers of their products. In addition, if there are not sufficient scientific data to estimate a withdrawal for a compounded medication, it is the responsibility of the veterinarian to ensure that the animal and any food products that result from that animal do not enter the human food chain. Under AMDUCA, it is legal for veterinarians (or pharmacists on the order of a veterinarian) to compound from U.S.-approved animal and human drugs if the conditions listed in Box 45.6 are met.[3]

Overall, when treating a food-producing animal, the use of compounded medications should be only a last resort because safety of the food chain should be the veterinarian's priority.

Antidotes Compounded From Bulk Drug

Despite the prohibition, several chemicals commonly recommended as food animal antidotes are available only through compounding from bulk drug. As described in the previous section, compounding veterinary medications from bulk drugs is illegal. However, analogous to its policy concerning ELDU in feed for minor species, the CVM will not normally consider regulatory action against veterinarians compounding certain antidotes from bulk sources if certain conditions are met, essentially those listed in Boxes 45.3 and 45.6. The FDA is currently developing a new guidance document on compounding animal drugs from bulk drug substances (https://www.gpo.gov/fdsys/pkg/FR-2015-05-19/pdf/2015-11982.pdf). Inquiries can be directed to the FDA-CVM, Division of Compliance, at 240-402-7002 or via email at AskCVM@fda.hhs.gov. It is critical that veterinarians recognize that in toxicity cases, withdrawal periods will need to be established not only for the antidotes but also the toxicants. Some antidotes require substantially extended withdrawals, which may affect the decision to treat.[13] As a practical matter, toxicity cases are frequently resolved based on testing in state or federal laboratories. Because of these complexities, practitioners are advised to consult the diagnostic laboratories and/or FARAD when dealing with such cases in food animals.

FARAD: The Food Animal Residue Avoidance and Depletion Program

One of the regulatory requirements for legal ELDU is that the attending veterinarian recommend a scientifically based withdrawal interval before the producer can market the milk, meat, eggs, or other edible products. Commonly, the most efficient way for a food animal practitioner to meet these requirements is to consult FARAD. Veterinarians, producers, students, or regulatory personnel may obtain free consultation with specialists by contacting 1-888-US-FARAD or accessing the FARAD website at http://www.farad.org and submitting a request. Recommendations are made on a case-by-case basis depending on the individual variables of each exposure, changing tolerances or FDA withdrawal times, and new information in the literature. FARAD also advises on pesticide exposure and accidental contaminations (biotoxins, heavy metals, radionuclides, unintended feeding of medicated feed).

FARAD maintains a database of all food animal products approved in the United States, with thousands of pharmacokinetic citations describing depletion for numerous chemicals in various species. The FARAD website now has a portal for searching what citations are included in the FARAD bibliographic database. FARAD collects, analyzes, and evaluates scientific data to provide withdrawal intervals when drugs are used in an extralabel manner. The FARAD website contains a database of approved food animal drugs searchable by drug, trade name, and species, known as VetGRAM (http://www.farad.org/vetgram/). A mobile version of VetGRAM is also available on the FARAD website. Veterinarians may also find downloadable copies of published summary recommendations as well as a quick review of past recommendations there.

Published techniques for estimating a withdrawal interval (WDI) after ELDU in food animals are available.[14-16] Information that FARAD considers when estimating a WDI includes the following:

1. General factors affecting pharmacokinetic parameters and drug residues, such as conditions affecting drug absorption and elimination as well as dose, duration of treatment, and administration route.
2. Existence of an FDA-established withdrawal time. AMDUCA stipulates that a substantially extended withdrawal should be applied for any ELDU. Therefore doses that are less than the labeled dose will still require a withdrawal that is longer than the labeled WDT.
3. Physiologic factors and compromised health conditions affecting pharmacokinetic parameters and drug elimination (e.g., dehydration, renal dysfunction, gastrointestinal disease).
4. Published pharmacokinetic parameters (i.e., time versus concentration data, including drug residue serum, tissue, or milk data).
5. The existence of an established tolerance or maximum residue limit (MRL).
6. Analytical testing method and limits of detection.
7. Foreign drug approval data.

Testing for Drug Residues

If a practitioner or producer/owner wants to confirm that edible products (i.e., meat or milk) are at or below the tolerance, they can consider testing for drug residues. A number of commercial rapid tests exist for drug residue testing using a milk, serum, or urine matrix. Examples of manufacturers of these tests include IDEXX Laboratories, Inc.; Charm Sciences; DSM Food Specialties; Neogen Corporation; and Silver Lake Research Corporation. Care should be taken to ensure that the test used detects residues to a level at or below the FDA-established tolerance to be certain that the food product is safe to enter the human food chain. Alternatively, samples or

VetBooks.ir

carcasses can be submitted to a commercial laboratory or state veterinary diagnostic laboratory for residue testing. Processing plants may be willing to test milk. FDA-established tolerances can be found on the FDA animal drugs website or FARAD's VetGRAM website.

Regulatory Monitoring of Drug Residues in Animal Products

Once products begin the process of entering the human food chain, they may undergo residue testing as part of the National Residue Program (NRP). The FSIS, EPA, and FDA cooperate to regulate animal drug residues, pesticides, environmental contaminants, and any other chemical hazards in meat or egg products. Every year, the sampling plan, known as the "Blue book," is released, which includes such details as the number of tissue or egg samples that will be tested and which chemical or drug residue will be tested for. Results of the testing are also made publicly available on an annual basis in the "Red book."

After remaining unchanged for many years, in July 2012, FSIS announced that scheduling of the NRP sampling plan will be changing.[17] Sample numbers per production class will be reduced because of the adoption of new analytical methods. Analysis for more chemical residues per sample will be possible, requiring fewer overall samples than in the past.

Biosecurity and Infection Control

PAUL S. MORLEY and J. SCOTT WEESE, *Consulting Editors*

Infection control, biosecurity, biocontainment, and biosafety are essential functions at all health care operations, including veterinary practices.* All veterinarians at some level recognize and act to prevent adverse outcomes in patients. However, as major outbreaks of health care–associated infections (HAIs) at veterinary hospitals have become increasingly publicized,[1-15] it has become obvious that coordinated infection control practices are a critical component of delivering high-quality care at veterinary facilities, especially those with large caseloads and those that specialize in intensive care of patients. This threat is relevant to all veterinarians and all hospitals. Two surveys of veterinary referral hospitals at American Veterinary Medical Association (AVMA)–accredited institutions reported that a majority had experienced outbreaks of HAIs in the preceding 5 years (81% and 65%, respectively, for the two surveys),[16,17] and at least 45% recognized more than one outbreak.[16] The two agents most commonly associated with outbreaks reported in both surveys were *Salmonella enterica* and methicillin-resistant *Staphylococcus aureus* (MRSA), but 12 other agents were also implicated. More than half of the participating hospitals had to restrict admissions to protect patients and allow mitigation, and a large number of the equine hospitals were temporarily closed. Even with very limited surveillance, more than half of these same hospitals recognized significant illness in veterinary personnel during the study periods. The agent most commonly implicated in human illnesses was *Cryptosporidium parvum*.[16,17]

The standard of veterinary care is changing such that sporadic occurrence and outbreaks of HAIs may no longer be interpreted as unavoidable accidents when coordinated measures are not routinely used to minimize their likelihood. Our understanding of infection control issues in veterinary medicine has also advanced significantly during the previous two decades. As such, what may have passed as sufficient for infection control in veterinary practices 10 or 20 years ago may often not be sufficient today. It is also important to realize the important part that infection control and biosecurity must play in ambulatory practices and on our clients' premises. Inherently, healthy animals with lower contagious disease risks represent a smaller proportion of hospital populations than they do among populations in their home environments. However, veterinarians are obviously called on to contact those animals most likely to be shedding contagious pathogens regardless of whether this is in hospitals or in the field. In addition, there are several examples in which patients discharged from hospitals were the likely source of viral and bacterial infections for animals in their home environments.[6,9] The magnitude of this potential hazard is perhaps best illustrated by the equine herpesvirus 1 (EHV-1) outbreak, which occurred in association with the National Cutting Horse Association Western National Championship in Ogden, Utah, in May 2011.[18,19] It is likely that exposure to a single horse that was shedding EHV-1 at this event resulted in more than 165 horses developing clinical disease that was known or suspected to be caused by EHV-1; at least 13 of these horses were euthanized. The outbreak spanned at least 10 western U.S. states and 2 Canadian provinces. Clearly the need to apply sound biosecurity and infection control practices extends well beyond the walls of veterinary hospitals.

It is also clear that dramatic outbreaks are not the only circumstances in which HAIs affect patients. Lessons learned in human health care settings show that endemic HAIs typically create a much greater overall burden in exacerbated morbidity and mortality than do epidemics. Unfortunately, information from veterinary care settings regarding rates of endemic HAIs is limited, but there is no reason to believe that the situation would be different. Based on limited numbers of systematic studies conducted in veterinary hospitals, the burden of disease associated with sporadic or endemic HAIs is substantial in veterinary patients. A recent multicenter study performed in five academic referral hospitals reported that nosocomial events monitored as seven different clinical syndromes were recognized during hospitalization in 19.7% (95% confidence interval [CI] = 14.5% to 26.7%) of equine patients admitted for gastrointestinal (GI) disease at a rate of 3.9 events per 100 days of hospitalization (95% CI = 2.9 to 4.3 events per 100 hospitalization days).[20] Other studies reported in equine patients have principally focused on HAIs related to surgical site infections.[21,22] These rates are not dissimilar from rates reported for HAIs among humans in critical care settings. Thus these notable outbreaks of HAIs and the emerging awareness of the importance of endemic occurrences should create an acute awareness that dramatically sharpens our focus on preventing all types of HAIs, including those that seem sporadic. Although the discussions in this chapter are mostly framed in the context of hospital settings, the concepts and issues apply much more broadly to ambulatory practices and animals' home premises.

*Throughout this chapter, the terms *infection control* and *biosecurity* are used interchangeably to encompass all practices related to the prevention of introduction and spread of infectious diseases in populations of animals or their human caregivers.

VetBooks.ir

How Much Is Enough? How Much Is Too Little?

Exposures to contagious disease threats, HAIs in patients, and zoonotic infections in care providers are undeniable risks in every veterinary practice. Because veterinarians have ethical and legal obligations to take reasonable protective actions to prevent their patients and employees from foreseeable harm associated with their actions (and inactions), it is clearly possible to not pay sufficient attention to infection control efforts. The consensus opinion of veterinary infection control experts is that there is a recognizable standard of practice for infection control in veterinary medicine and appropriate effort must be given to the control and prevention of infectious disease transmission in all animal populations.[23] The implication that should be recognized is that it is possible to commit malpractice by not paying enough attention to infection control while caring for patients. There are key areas that must be addressed in all comprehensive infection control programs, including patient contact, hygiene, surveillance, communication, and education (Box 46.1).[24] However, we cannot determine whether we are meeting an acceptable standard of care for infection control by listing the specific prevention strategies that are used. Rather we must evaluate the occurrence of HAIs in a veterinary practice along with how we respond to the identification of these HAIs. Few prevention practices for HAIs are universally considered applicable and efficacious for preventing HAIs in all settings. Rigorous attention to hand hygiene would meet these criteria, but many other common control methods such as the use of disinfectant footbaths or protective clothing (e.g., coveralls, barrier nursing gowns) do not. Thus it is not possible to judge whether a control program is sufficiently rigorous solely by cataloging procedures, protocols, and policies. Recognition of the risks for legal liability undoubtedly gives reason for pause, but a better motivation for emphasizing infection control practices should be to provide the best care possible within the scope of a practice's specialization. The implications of suboptimal infection control may not always be apparent, but both sporadic/endemic infections and outbreaks can have a significant effect on patient morbidity, patient mortality, hospital economics, personnel health, personnel morale, and facility reputation.

BOX 46.1

Principal Goals and Major Action Areas for Infection Control Programs in Veterinary Medicine

- Four principal goals for infection control programs:
  - Decreasing the likelihood of exposure to infectious agents among patients and personnel
  - Decreasing the intrinsic risks for health care–associated infections (HAIs)
  - Maximizing participation of personnel in infection control activities
  - Optimizing the efficiency of infection control procedures and policies
- These goals are achieved through five major actions:
  - Decreasing direct and indirect patient contact
  - Optimizing hygiene
  - Using proven directed actions that decrease risks or are protective against HAIs, as well as actions that have a reasonable likelihood of efficacy based on biology, principles of pathogen transmission, and data from other species
  - Identifying high-risk patients and HAIs through efficient surveillance strategies
  - Optimizing communication and education among all personnel

Although HAIs are an undeniable hazard associated with caring for patients, and although it is possible to reduce the risk of infections through a variety of prevention strategies, it is important to note that not all HAIs are preventable using practical and cost-effective control programs. Even impractical and cost-prohibitive programs would not eliminate HAIs, since an undefined but undeniably significant "nonpreventable" fraction of infections will occur despite any infection control practices. To be most successful, it is important that over time administrators and personnel responsible for infection control programs strive to better understand and target prevention efforts at the preventable fraction of all HAIs.

Principles of Infection Control

In general, all comprehensive infection control programs center on the four principal goals and five major actions listed in Box 46.1, but each operation must tailor programs to optimally fit their specific practice. When initiating an infection control plan, it is important to make a global assessment of the contagious disease hazards in a practice, the level of risk aversion, and the resources that can be expended on infection control efforts. If a veterinary practice predominantly works in preventive health care under extensive field conditions, the contagious disease hazards may be less common and less severe than those encountered by a practice that concentrates on intensive care of patients in a hospital. Further, an ambulatory practice will need to integrate their infection control efforts with on-farm biosecurity practices to provide maximum benefit to owners. The specific disease hazards will also vary with the types of patients being managed (e.g., sick neonates versus patients with acute GI disorders versus reproduction cases, equine versus bovine versus camelid). Risk aversion relates to how much a person or business is unwilling to accept or allow a negative event to occur. The inverse of risk aversion can be thought of as risk tolerance. The more risk averse a person is, the more it may be reasonable for him or her to initiate and maintain a rigorous infection control program. In contrast, a more risk-tolerant veterinarian may recognize the potential for contagious disease hazards in his or her practice but may not believe it is necessary to engage in preventive strategies that are considered extreme. However, the risk tolerance of an individual or facility cannot be the sole deciding factor; a baseline level of risk aversion must be present as an ethical imperative. As our understanding of risks for HAIs advance, the bar for expectations in all practices is being raised, resulting in professional and legal risks should veterinarians fail to ensure that they are adequately pursuing infection control in their daily practices. The third component of this internal inventory is to assess the resources that will be available for infection control activities. The term *resources* in this context is intended to broadly encompass monetary resources, personnel time, and effort.

While considering this assessment of mindset and resources, the next step in developing an infection control program is to elaborate the specific goals for the program. Managers can then tailor their infection control program to meet their specific practice needs using a systematic process for evaluation of disease hazards and design of control systems. This systematic approach allows design of control systems that triage efforts to optimize efficiency. One systematic approach that the authors have used successfully is hazard analysis and critical control points (HACCP) methodology.[25] After identifying which specific hazards (contagious disease) are most likely to occur, as well as when and where in the systems these events might occur or be prevented, the next step is to define specific control measures. As mentioned, most of these prevention efforts are effective because they decrease the likelihood of exposing patients to infectious agents (i.e., by optimizing hygiene in the

VetBooks.ir

environment, personnel, or patients or by decreasing direct and indirect contact among patients). A few other prevention practices are effective because they reduce the inherent susceptibility to infection. To identify control measures of greatest importance, it is critical to consider the life cycle and methods of transmission for the specific agents of concern. Among the questions that should be asked: Is the agent most transmitted through direct contact, or are respiratory aerosols or contaminated surfaces and fomites also important sources of exposure? Is there a subclinical carrier state associated with agent shedding, or is shedding mostly restricted to clinically affected patients? Does the agent persist well in the environment, and can common disinfection procedures readily inactivate organisms?

Each infectious disease may be considered individually in this evaluation process, but it is useful to remember that control measures that are effective against one agent are usually effective against others, particularly if they share common routes of transmission or have common risk factors in patients. Design of infection control programs should focus on practical actions for known problems, but it is important not to ignore the potential for newly recognized and re-emerging diseases.[26-28] The general strategy used in infection control protocols should be sufficiently rigorous to protect against most emerging issues, at least at a basic level. However, infection control programs should also be adequately fluid so that they can be modified to address new issues.

Another critical aspect in the practice of infection control is effective targeting of efforts. Taken to hypothetical extreme, the most rigorous infection control methods would prescribe that *every* patient be handled in complete isolation using barrier precautions verging on those used by "hazmat" personnel. Clearly this is not practical or needed in most situations, yet in a few rare circumstances this level of precaution is warranted. In many more situations, some lesser level of precaution is warranted beyond that used in casual encounters with animals in their home environments. By their very nature, these extra control measures will inevitably inconvenience caregivers and clients in addition to increasing costs associated with care. These measures could also affect the quality of patient care and result in a corresponding *increase* in morbidity when taken to the extreme. The challenge is to target prevention efforts to just those patients that warrant increased concern and to use the most appropriate, albeit inconvenient, methods for controlling risks to personnel and other patients.

Another side effect of the inconvenience created by infection control efforts is that people by their very nature gravitate to the most convenient methods for daily activities. As such, the more personnel are inconvenienced through infection control efforts, the less likely they are to follow prescribed policies unless they understand and believe that procedures are needed and have value. Thus a critical component of any effective infection control program is maximizing awareness of personnel and educating them on potential hazards and the value of established control measures. Establishing interactive communication regarding risks and concerns coupled with logical, objective, evidence-based presentations is clearly an important approach for convincing personnel of the need to fully participate in infection control efforts. Feedback from surveillance efforts will also provide important objective information regarding the significance of specific disease risks in a practice.

Informed Consent and Implications for Infection Control

The principle of informed consent, as it applies to veterinarians caring for animals, implies that owners have the right to receive adequate information prior to treatment to allow them to appropriately weigh risks and benefits when making decisions for their animals and themselves.[29,30] As professionals with specialized training, veterinarians can be assumed to have knowledge about the health and care of animals that goes beyond that of people without this training. An agreed-upon component of the informed consent process is the disclosure to owners of potential risks that may be associated with a veterinarian's management of animals, particularly in situations in which there is greater than average risk for a particular adverse consequence.[31] As such, it is reasonable and prudent for veterinarians to routinely disclose the potential for HAIs as part of the informed consent process for all patients. This is especially true for patients with an enhanced risk of acquiring HAIs (e.g., because of required invasive procedures or because patients are compromised), but can also be applied to risks for all patients. For example, if there is a known or suspected increased risk of nosocomial infections for patients at a facility, there is likely an ethical and legal obligation to disclose *prior* to admission how this risk pertains to new patients. It is extremely prudent to document the informed consent process in writing with clients. Sometimes there is reluctance to do so based on concerns that it may deter clients from using a facility, but this process can also provide an opportunity to educate clientele (and thereby increase their overall understanding) and highlight measures that are being used to mitigate risks.

Paying for Infection Control Activities

As mentioned previously, procedures used to decrease risks of HAIs inherently increase labor and material costs related to patient care. Infection control activities are an essential part of delivering veterinary care, and it is reasonable to pass on these costs to clients. It should not be expected that these costs reduce profits or be paid by veterinarians or hospitals. Remembering that only a portion of HAIs are preventable, if veterinarians have met an expected standard of care for infection control, it is reasonable to assume that costs incurred for treating complications associated with HAIs are paid by the client. Knowing that HAIs are an expected risk, veterinarians and hospitals should develop financial plans to address these risks. Consider how expenses for infection control efforts will be assessed and tracked, as well as how a practice might recover these costs from clients. The costs could be passed on to clients by directly accounting for each item, which is most reasonable when specific charges can be attributed to a specific patient (e.g., increased nursing or materials costs associated with care of a specific patient in isolation). However, this is less applicable when costs relate to care and protection of more than one patient (e.g., costs related to cleaning and disinfecting the hospital environment). In these situations, it may make more sense to compensate for costs by aggregating expenses into a general fee category related to infection control (such as a daily surcharge) or to include these costs in overhead that is compensated by general admission or hospitalization fees. It is also wise to have a contingency fund that will allow veterinarians to address special circumstances, such as when it is necessary to investigate or mitigate against suspected outbreaks of infections.

Environmental Hygiene

Much attention is paid to the possible role of the inanimate environment in HAIs of large animals. Contamination of the hospital environment by microorganisms is inevitable and entirely expected, and detection of microorganisms in a hospital environment does not, by itself, indicate anything of clinical relevance. A variety of factors are likely involved in the potential clinical relevance of contaminants, including the organism, numbers present, likelihood of contact with susceptible hosts, degree of susceptibility of potential hosts, environmental effects (temperature, ultraviolet exposure, humidity), and routine infection control protocols. Many microorganisms grow well on environmental surfaces, provided there is adequate moisture

VetBooks.ir

and organic debris, and may survive for very long periods. Even with relatively inhospitable conditions, many organisms persist for extended periods. If environmental pathogens can contact the appropriate body site of a susceptible individual in adequate numbers, disease could result. Environments where patients are housed or veterinary care is delivered can be expected to have greater numbers of environmental microorganisms than corresponding areas with less animal and human traffic.[32]

The relevance of environmental contamination is often difficult to determine. Even recovery of genetically indistinguishable organisms from the environment and from a patient does not confirm that exposure to an environmental reservoir was the source of infection, since it can be difficult to distinguish cause versus effect. However, environmental contamination is of concern for both direct (e.g., oral inoculation from a reservoir of microorganisms in a stall) and indirect (e.g., transmission of an organism from an environmental reservoir to the hands of a care provider and then to an animal) transmission. Measures should be used in all veterinary care environments to reduce the environmental pathogen load. This involves cleaning and disinfecting environmental sites.

Cleaning

Cleaning is defined as the removal of all visible debris[33] and is arguably the most important step in decontaminating animal environments. Even the best disinfectants will be minimally effective when used in the presence of moderate volumes of dirt and organic debris such as feces and bedding material. Dirt and debris hamper disinfection by inactivating many chemicals, acting as a physical barrier between disinfectants and microorganisms, and providing a nutritional source for microorganisms. Not only does cleaning enhance the efficacy of the disinfection process by providing optimal conditions for desired biochemical reactions, but it can actually remove a majority of microorganisms so that fewer need to be killed by disinfectants. Therefore removal of as much organic debris as possible is required for optimal disinfection. This involves manual labor, consisting of removal of all bedding and feces and scrubbing surfaces to remove adherent debris and biofilms. Detergents should be used to loosen organic debris, emulsify oils and fats, and remove biofilm. The disinfectant to be used must be considered when choosing a detergent because there can be interaction between chemicals in detergents and disinfectants.

Because of the effort required to clean and scrub stalls and other large areas, less labor-intensive methods are often sought. For example, high-pressure (>120 psi) washers are frequently used in barns and hospitals. There are theoretical advantages that seemingly justify use of high-pressure washers, especially when they are designed to dispense high-temperature water and steam. Although power washing can be quite helpful in removing organic debris, this process can also exacerbate infection control problems by aerosolizing and widely dispersing infectious agents. Further, when used indiscriminately, they can damage surfaces, which then impairs subsequent cleaning and facilitates survival of pathogens. The true risk related to the use of high-pressure washers is unclear. However, the convenience of using high-pressure systems must obviously be balanced with more intensive manual cleaning methods in order to minimize unwanted consequences. Using high-pressure systems on surfaces with large amounts of gross contamination should be avoided.[34] In areas likely to be contaminated with important contagious pathogens (e.g., isolation facilities), it is logical to use high-pressure systems minimally or at least only as a secondary cleaning process on surfaces that have already been manually cleaned and disinfected.

Disinfection

Disinfection is the process of substantially reducing the burden of microbial contaminants on inanimate objects in order to reduce the likelihood of transmission of infectious agents. This should be contrasted with sterilization, which is the inactivation of all microbial agents on an object, typically performed only on materials used in invasive procedures. Disinfectants are biocidal chemicals that must be used at appropriate concentrations, allowing for adequate contact time to achieve the intended effect. Even with proper cleaning and selection of an appropriate disinfectant, disinfection errors can occur. It is also important to remember that microbial responses to disinfectant exposures are not uniform. There is tremendous variation in the ability of microorganisms to tolerate cleaning and disinfection. Most enveloped viruses are easy to eliminate, whereas protozoal oocysts, nonenveloped viruses, and bacterial spores may be difficult or impossible to kill with surface disinfectants.[35]

For disinfection to be effective, a few key factors must be considered: the presence of organic debris, disinfectant concentration, temperature, and contact time. Organic debris inactivates disinfectants to varying degrees, emphasizing the need for careful cleaning. Most disinfectants are available as concentrates and must be diluted prior to use. Excessively dilute disinfectant solutions may have little or no effect, whereas excessively concentrated solutions can be dangerous to use in addition to being wasteful of resources. Dilution of disinfectants is an important process and must be performed by measurement, not estimation. One method to easily ensure that disinfectants are appropriately diluted is to use metered dispensing units that can be either wall mounted or attached to the end of a hose. For some disinfectants, different concentrations may be recommended for different situations. Test strips that can commonly be purchased from a variety of vendors can also be used to verify appropriate dilution and activity disinfectant solutions. This is especially important when stock solutions are prepared for use over time. Cleaning personnel must be informed of the importance of disinfectant dilution and trained in proper methods. Contact time is critical, particularly for certain disinfectants and difficult-to-kill microorganisms. If disinfectants are applied and immediately rinsed away, there is little chance that they can be effective. Most disinfectants require 10 to 30 minutes of contact time to provide maximal microbial reduction. Chemical reactions that produce disinfection are slowed in cold temperatures, which should be considered when determining the amount of contact time required. Disinfectants should never be combined because of the potential for inactivation and production of noxious or toxic gases.

Disinfectants

It is critical to be aware that all disinfectants do not have the same effectiveness. As with antimicrobial drugs, disinfectants have a spectrum of activity that can be highly variable between disinfectant classes (Table 46.1). Choosing the most appropriate disinfectant can be complex, involving a variety of factors including spectrum of activity, relative efficacy in the presence of organic debris, toxicity to animals and humans, potential damaging effects on certain surfaces, cost, and potential environmental effects. There is no standard disinfectant that can be used in all situations in large animal facilities, although oxidizing agents such as accelerated hydrogen peroxide and potassium peroxymonosulfate are increasing in popularity because of their broad spectrum of activity, acceptable performance in moderate amounts of organic material, relatively rapid action at room temperature, relative safety for personnel, and environmental friendliness. Other options may be appropriate in certain situations. When disinfectants with a narrower spectrum of activity are used as the primary disinfectant, protocols should be in place to use alternative products should situations that require a higher level of activity be encountered. There is no evidence that rotation of disinfectants is useful.

VetBooks.ir

TABLE 46.1

Disinfectants Commonly Used in Veterinary Medicine[a]

Disinfectant	Activity in Organic Debris	Spectrum	Comments
Bleach (sodium hypochlorite)	Rapidly inactivated	Broad, including nonenveloped viruses and bacterial spores. No activity against *Cryptosporidium*.	• Used to disinfect clean environmental surfaces. • Sporicidal activity is particularly useful. • Efficacy decreases with increasing pH, with decreasing temperature, and in the presence of ammonia and nitrogen. • Varying concentrations can be used; 1:64 dilution of standard commercial (4% hypochlorite) bleach is most common. Higher concentrations, up to 1:10, can be used but should be reserved for infrequent use in special situations. • Inactivated by cationic soaps/detergents and sunlight. • Chlorine gas can be produced when mixed with other chemicals. • Bleaches fabrics and is corrosive to concrete.
Quaternary ammonium	Moderate	Variable. In general, effective against gram-negative bacteria and enveloped viruses, variably effective against gram-positive bacteria, limited activity against enveloped viruses, and no activity against bacterial spores or *Cryptosporidium*.	• There are differences among types of quaternary ammonium compounds. • Commonly used primary environmental disinfectant, although the spectrum is not necessarily optimal. • In general, low toxicity. • Inactivated by anionic detergents. • Some residual activity after drying. • Less effective in cold temperatures and low pH. • Stable in storage.
Phenols	Very good	Relatively broad spectrum, with limited activity against nonenveloped viruses and no activity against bacterial spores or *Cryptosporidium*.	• Main advantage is better activity in organic debris. • Can be irritating to skin and mucous membrane surfaces. • Reportedly toxic to cats and pigs. • Some residual activity after drying. • Noncorrosive.
Peroxygen/ accelerated hydrogen peroxide	Very good	Broad spectrum, including bacterial spores and nonenveloped viruses. Some activity against *Cryptosporidium*.	• Excellent choice for routine environmental disinfection, footbaths, and environmental fogging. • Rapid action makes it a good choice for footbaths. • Low toxicity except at high concentrations. • Environmentally friendly. • Peryoxygen products can be corrosive to plain steel, iron, copper, brass, bronze, vinyl, rubber, and concrete. • More expensive than most other disinfectant options.
Alcohols	Rapidly inactivated	Moderate to no activity against nonenveloped viruses, bacterial spores, and *Cryptosporidium*.	• Not appropriate for environmental disinfection. Can be used to disinfect certain medical and patient care items, but better options are available. • Flammable. • Minimally toxic. • Fast acting.
Chlorhexidine	Rapidly inactivated	Moderate. Limited activity against enveloped viruses. No activity against nonenveloped viruses, bacterial spores, and *Cryptosporidium*.	• Not appropriate for environmental disinfection. • Appropriately diluted solutions are suitable for use on tissues or on materials that contact skin or mucous membranes. • Minimally toxic. • Bactericidal activity on skin is more rapid than many other compounds, including iodophors. Residual effect on skin diminishes regrowth.
Povidone iodine	Rapidly inactivated	Moderate. Limited activity against enveloped viruses. No activity against nonenveloped viruses, bacterial spores, and *Cryptosporidium*.	• Not appropriate for environmental disinfection. • Appropriately diluted solutions are suitable for use on tissues or on materials that contact skin or mucous membranes. • Minimally toxic but some people can become sensitized to skin contact. • Appropriate dilution is important to maximize activity.

[a]It is critical to handle disinfectants and other chemicals using appropriate safety precautions. Refer to the Material Safety Data Sheet (MSDS) for each product to obtain recommendations on appropriate handling and recommended personal protective equipment.

VetBooks.ir

Effect of Surface Material on Cleaning and Disinfection

The material to be cleaned and disinfected can also have a tremendous impact on efficacy. Many surfaces found in large animal clinics and farms are not amenable to thorough cleaning and disinfection. These include unsealed wood surfaces, unsealed block, dirt flooring, and areas that are difficult to clean. For stalls, solid walls with a sealed surface are optimal for disinfection. This may be difficult to achieve; however, certain procedures can be performed to facilitate disinfection.[34] Cement block walls can be reasonably well sealed with at least two coats of good-quality enamel. Wood walls can be sealed using two or more coats of marine epoxy. Regular maintenance of stalls is required to seal defects that result from kicks or chewing.

The optimal floor surface, in terms of cleaning and disinfection, is a smooth, solid, completely sealed surface. However, surfaces meeting these criteria are not all amenable to animal housing, so a compromise may be required. Finding the right balance of floor cushion, traction, durability, ease of cleaning, and cost is difficult. Regardless, certain key factors should be considered. The floor should be completely sealed so that water (and pathogens) cannot seep underneath, since this creates an obvious environmental reservoir and prevents adequate contact with disinfectants. Damaged stall matting has been cited as the likely environmental reservoir associated with serious outbreaks of HAIs.[1] If obtaining a seamless, water-impervious floor surface is not possible, floor coverings should be completely removable (i.e., rubber mats over sealed concrete floor) and must be removed regularly for disinfection. Dirt, sand, and other organic materials cannot be disinfected and are therefore unsuitable for permanent flooring in hospital stalls or other veterinary care facilities. If sand is required for care of orthopedic patients, this material should be completely removed and discarded between every patient.

Animal Contact Items

For items that are used in patient care, disinfection processes are sometimes divided into three categories: high, intermediate, and low level. High-level disinfection involves eliminating all viruses and vegetative bacteria but is not expected to inactivate bacterial spores, fungal spores, or protozoal oocysts. High-level disinfection is difficult to attain and uncommonly used. Intermediate-level disinfection involves eliminating all vegetative bacteria but not necessarily all viruses (especially nonenveloped viruses), spores, or oocysts. Low-level disinfection results in elimination of most but not all potentially pathogenic bacteria and enveloped viruses. Items requiring disinfection should be classified according to the level of disinfection required; Table 46.2 shows examples of these.

After use, all items in a patient's stall should be considered to be potentially contaminated with pathogens that the animal might be shedding. Thus for patients suspected or known to have contagious diseases, every item in the stall should be treated as a source of infectious material and must be appropriately decontaminated or discarded. Many stall items may be difficult to disinfect, or it may not be possible to be confident in the ability to fully decontaminate them. If it is cost effective, disposal of these items is ideal. Otherwise, standard principles of cleaning and disinfection apply. It must be recognized that rough, damaged, and permeable surfaces may be very difficult to adequately disinfect. Particular attention should be paid to disinfecting surfaces that patients contact orally, such as feeders and water bowls, as well as surfaces likely to be contacted by hands of personnel. Appropriate decontamination of water bowls can be problematic. Ideally, the water supply should be turned off, and the bowl should be drained, cleaned, and applied with disinfectant for an appropriate time before it is rinsed and the water is turned on again. Nets used to hold hay have a high likelihood of contamination and are difficult to disinfect without use of gas or plasma sterilization techniques. As such, their use should be avoided if possible.

TABLE 46.2

Examples of Items Requiring Different Levels of Disinfection

Level of Disinfection	Example Items
High level	Endotracheal tubes
	Tonometer tips
	Urinary catheters
Intermediate level	Dental equipment
	Endoscopes
	Thermometers used on multiple patients
	Vaginal specula
Low level	Thermometers used on individual patients
	Feeding instruments
	Muzzles
	Nasogastric tubes
	Oral specula
	Stethoscopes
	Twitches

Certain items may be at particular risk for contamination. For example, thermometers used on animals with salmonellosis are almost assuredly contaminated, and complete disinfection of digital thermometers is very difficult. It is reasonable to dedicate thermometers to individual patients and discard them when they are no longer required. An alternative is the use of disposable temperature strips, which are sometimes used in human medicine. These have not been specifically validated but are routinely used in some large animal hospitals.[36]

Twitches and muzzles have a high potential for contamination with pathogens such as *Streptococcus equi* and MRSA. Rope used for twitches is extremely difficult to disinfect, apart from removing the rope for autoclaving. Chain twitches are easier to disinfect, but many find them less desirable to use. The ideal twitch material is easy to disinfect, is atraumatic, and provides good grip on the nose. It is debatable whether the ideal material is available at this time. Twitches should be routinely disinfected, to the best of the ability considering the material. Consideration should be given to regularly changing or autoclaving rope used for twitches and routinely decontaminating twitches with the understanding that complete disinfection may not be possible. Twitches used on animals that are known to harbor or are likely harboring nasal or upper respiratory tract pathogens should be considered contaminated and the material discarded or disinfected.

Few areas show a greater difference in approach to infection control between human and veterinary medicine than the handling of hypodermic needles after use. In human medicine, recapping needles is strictly forbidden because of the potential for needlestick injuries and subsequent exposure to life-threatening bloodborne pathogens. In veterinary medicine, recapping needles is very common, and needlestick injuries are often not perceived to be a significant health threat to veterinary personnel. Currently, there are minimal risks to veterinary personnel in almost all situations regarding bloodborne transmission of infectious agents from large animals. However, infectious disease hazards clearly continue to emerge, and it is prudent to develop safe practices that minimize the potential for exposure to bloodborne pathogens that might be transmitted from domestic large animals. In addition, physical trauma from the needle and accidental inoculation of some vaccines (e.g., RB51 modified-live *Brucella abortus* vaccine),

VetBooks.ir

BOX 46.2

Indications for Hand Hygiene in Medical Practice

- When hands are visibly dirty or contaminated with proteinaceous material, blood, or other body fluids.
- Before direct contact with patients.
- Before donning sterile gloves for invasive procedures (e.g., suturing wounds).
- Before inserting an indwelling urinary catheter, peripheral vascular catheter, or other invasive device that does not require a surgical procedure.
- After contact with a patient's intact skin.
- After contact with body fluids or excretions, mucous membranes, nonintact skin, and wound dressings.
- After contact with an inanimate object in the immediate vicinity of a patient.
- After removing gloves.
- Before eating and after using a restroom.

Adapted from Centers for Disease Control and Prevention: Guideline for hand hygiene in health-care settings: recommendations of the Healthcare Infection Control Practices Advisory Committee and the HICPAC/SHEA/APIC/IDSA Hand Hygiene Task Force. *MMWR* 51(No. RR-16), 2002. http://www.cdc.gov/mmwr/PDF/rr/rr5116.pdf. (Accessed August 14, 2018.)

BOX 46.3

A Recommended Technique for Handwashing

- Wet hands first with water and then apply an appropriate amount of disinfectant soap (as recommended by the manufacturer).
- Vigorously rub hands together for *at least* 15 seconds, covering all surfaces of the hands and fingers. Make sure to scrub fingertips and clean under fingernails.
- Rinse hands with water and dry thoroughly with a disposable paper towel. Multiple-use towels of any type are not recommended.
- Use towel to turn off the faucet (and open doors when exiting a restroom).
- Avoid using hot water because repeated exposure to hot water may increase the risk of dermatitis.

Adapted from Centers for Disease Control and Prevention: Guideline for hand hygiene in health-care settings: recommendations of the Healthcare Infection Control Practices Advisory Committee and the HICPAC/SHEA/APIC/IDSA Hand Hygiene Task Force. *MMWR* 51(No. RR-16), 2002. http://www.cdc.gov/mmwr/PDF/rr/rr5116.pdf. (Accessed August 14, 2018.)

medications (e.g., hormones, cancer chemotherapeutic drugs), or the person's own skin microbiota can lead to serious outcomes.

Hand Hygiene

Rigorous use of hand-hygiene procedures is one of the oldest recognized infection control measures, and it is perhaps the single most important infection control practice. Unfortunately, extremely poor compliance with best practices in human and veterinary hospitals as well as in the community negates much of the potential benefit. Centers for Disease Control and Prevention (CDC) guidelines suggest that health care workers in human hospitals should wash their hands or use hand-sanitizing products before and after every contact with patients, as well as prior to eating and after using the restroom. It is hard to argue that less stringent procedures are warranted in veterinary hospitals.

Numerous indications for hand-hygiene procedures in health care settings have been identified as part of guidelines for human medicine. As shown in Box 46.2, hand hygiene is needed frequently in a clinical situation, something that may be problematic in typical settings where veterinary care is provided to large animals. Maintaining optimal hand hygiene can be especially important for ambulatory clinicians, yet can also be particularly difficult to achieve because of logistical difficulties. A variety of options exist for decontaminating hands.[37,38] The most common practices are handwashing and use of waterless hand-sanitizing solutions. Both are acceptable methods in most situations, and each has individual benefits and drawbacks. There are a variety of commercially available products that have documented efficacy for use as topical antiseptics and hand sanitizers; the most common ingredients of these products include ethanol, isopropanol, povidone-iodine, benzalkonium chloride, benzethonium chloride, and chloroxylenol.[37,38] Recently, products containing triclosan and a variety of other active compounds used in hand washes and rubs have been deemed to be unsafe for repeated human exposure by the U.S. Food and Drug Administration, and health care workers should be aware that additional investigations have been called for to support the general expectations of safety and efficacy of other active ingredients.[38]

Handwashing

Washing with antibacterial soap has been a standard method of decontaminating the hands of health care workers for more than a century. However, the potential benefits of this practice generally are not realized because of failure to use appropriate methods or failure to wash hands at all.[39,40] Common errors include inadequate duration of handwashing, inadequate thoroughness, failure to use soap, use of contaminated items to dry hands, and contamination of hands immediately following handwashing (e.g., through contact with contaminated faucets or door handles). An appropriate technique for handwashing is outlined in Box 46.3.

The importance of the type of soap used in handwashing is also often overlooked. Plain soaps, those without antibacterial agents, have minimal direct antibacterial activity. The main benefit of these is assistance with removal of dirt and organic debris, although efficacy data are conflicting. The use of plain soap can slightly decrease bacterial numbers on hands, but studies in human medicine have failed to demonstrate effective removal of significant pathogens from the hands of hospital personnel.[41] Also, the routine use of plain soap can at times be associated with *increases* in numbers of bacteria carried on hands if use of these products results in skin damage and irritation through drying.[42] Plain soaps are preferable to not washing hands in the absence of suitable alternatives (such as in field settings) but should be avoided whenever possible in health care situations.

Most soaps used in hospital settings contain biocides such as chlorhexidine, which produce greater decreases in skin contamination compared with plain soap.[40] Iodine and iodophors have been used as skin antiseptics and have a broader antibacterial spectrum. However, both (particularly iodine) can be irritating to skin and are less commonly used for routine handwashing and skin disinfection in medical personnel. In addition, some people become sensitized to skin contact with these products.

Compliance with handwashing protocols is often poor for a variety of reasons. The time required is a major factor, particularly in situations in which contact with many patients is likely. Although handwashing requires less than a minute to complete, if it is indicated 100 times in a day, this represents a significant amount of time cumulatively committed to this activity. Lack of convenient access to proper handwashing facilities is also frequently a problem. If access to sinks with running water, soap, and disposable towels is not convenient (i.e., not adjacent to where animal contacts occur), it is less likely that handwashing protocols will be rigorously followed. Regardless of the type of soap used, frequent handwashing leads to skin irritation and damage, which compounds compliance

problems by making people reluctant to wash their hands; as well, skin damage associated with handwashing increases the potential for colonization or transient carriage of potential pathogens.[42-45]

Nail care and jewelry can also be significant impediments to achieving optimal levels of hand hygiene.[46] Colonization with higher bacterial numbers, colonization with bacterial pathogens, and outbreaks of infectious disease have been reported in human hospitals in association with effects related to long fingernails and artificial nails.[47] Studies have shown that these hamper effective hand disinfection, and many health care facilities, particularly intensive care units, prohibit their staff from having long (¼ inch or longer) or artificial nails. The role of these factors in risks to patients in veterinary settings is unclear, but some veterinary facilities have developed similar protocols and restrictions.

Waterless Hand Sanitizers

Waterless hand sanitizers have proliferated in health care facilities and in the community because of their low cost, ease of use, and efficacy. The CDC has concluded that hand sanitizers are the preferred method for cleaning hands that are not visibly dirty in comparison to handwashing.[39] Most waterless hand sanitizers use varying concentrations of alcohol (isopropanol, ethanol, n-Propanol, or a combination), although a few products contain alcohol plus biocides or biocides (e.g., benzalkonium chloride) alone. Alcohol products are most commonly available, with concentrations ranging from 60% to 95%, although lower concentration products can sometimes be encountered and should be avoided. Concentrations greater than 95% should also be avoided because the presence of water is important for the bactericidal activity. They may be in liquid, gel, or foam preparations.

Alcohols have excellent effect against gram-positive and gram-negative bacteria but not bacterial spores or protozoal oocysts.[39,40] Antiviral effects are variable, with less reliable effects against nonenveloped viruses. Alcohol-based products have been shown to have good effect on reduction of hand contamination of health care workers and have been shown to be more effective than standard handwashing.[48] Frequent contact with alcohol can lead to significant drying of skin, so most commercial products contain emollients, humectants, or similar skin-conditioning agents. Alcohol-impregnated towelettes are also commercially available but contain a small volume of alcohol and are no more effective for hand decontamination than washing with plain soap.[49]

In human health care, hand-hygiene efforts are focused on increased use of waterless hand sanitizers. One concern that is sometimes expressed in large animal practice about waterless hand sanitizers is their activity in the presence of organic debris. However, a study of the efficacy of hand sanitizers on hand disinfection after performing physical examinations in horses reported that both alcohol and alcohol/chlorhexidine hand sanitizers were more effective for decreasing bacterial contamination than washing hands for 15 seconds with antibacterial soap.[50] This level of disinfection was noted even though the culture fluid collected off the hands was visibly dirty, indicating that there was a reasonable amount of gross contamination. Thus waterless hand sanitizers are likely to be effective under normal large animal practice situations. However, when contamination of the skin is readily apparent, handwashing is probably required for optimal effect. It is important to remember that alcohol-containing products are flammable. Although very rare, fires have been associated with exposure to open flame. Common sense and ensuring that hands are rubbed together until all alcohol has evaporated should greatly minimize any risks.

While most available products contain only alcohol as a sanitizing agent (in addition to humectants or emollients), some commercial products contain alcohol plus other biocides such as chlorhexidine. These are sometimes present because of a purported residual effect; however, evidence of residual activity of chlorhexidine has been challenged.[51]

One of the main advantages of waterless hand sanitizers is their portability. Although it is difficult to make the water source needed for handwashing portable or always accessible, these products can be easily placed in ambulatory vehicles, carried by individual staff, and easily placed throughout hospitals. As such, there is a greater likelihood of obtaining compliance by facilitating access. Unfortunately, regardless of the types of products used, compliance with hand hygiene is often a major problem.[52,53] Infection control programs need to address hand-hygiene compliance through a variety of means to increase use of this critical infection control tool.

Surgical Hand Antisepsis

Scrubbing the hands and forearms with disinfectant solutions has been a standard practice prior to surgery, but there is increasing movement to the use of waterless products. Recommended techniques for presurgical scrubbing vary somewhat but typically involve a systematic 2- or 3-minute scrub of all hand and forearm surfaces.[54] One concern with repeated surgical scrubbing is the potential for skin irritation and subsequent increases in bacterial contamination. This has led to increasing use of brushless techniques, especially with the use of waterless hand sanitizers containing 1% chlorhexidine gluconate and 61% ethanol, which has been shown to be equal or superior to brush application of 4% chlorhexidine soap.[55] These can be directly applied to the hands and arms as the sole preoperative skin antisepsis method, or if there is concern about the degree of gross contamination, hands can be washed and dried, followed by application of the waterless product.

Barrier Protocols and Protective Attire

Barrier nursing techniques are an important infection control tool. The basic premise for their use is that placing some type of barrier between caregivers and patients prevents skin or clothing from being contaminated, whereas the contaminated outer barrier item can be discarded or left in the contaminated environment. Prevention of contamination of personnel's skin, regular clothing, personal items, and medical instruments can substantially reduce the risk of transmission of pathogens between animals, contamination of the general environment, and zoonotic transmission.

Use of Barrier Precautions

Basic barrier techniques should be used in all veterinary hospitals. Standardized, clean, protective outwear should be worn over hospital-dedicated attire for any patient contact, regardless of the anticipated nature of contact or the assumed infectious disease status of the patient. The need for other barrier items varies with circumstances and is often dictated by the type of disease syndrome being managed (e.g., diarrhea or GI disease, respiratory disease, wound infection, fever of unknown origin) as opposed to documentation of specific infections or diseases. Other factors that might indicate a need for additional barriers include farm of origin (e.g., farms with endemic *S. equi* or rotavirus infections) or a patient that is considered to have an increased risk of infection (e.g., compromised neonates). Gloves, gowns, and overboots are the most commonly used items for additional barrier protection, but masks, caps, and eye protection may also be required at times. In some facilities, overboots are not used in all areas, but personnel are required to wear footwear that can be readily disinfected. Disinfection of this footwear is required after exiting potentially contaminated areas.

VetBooks.ir

Limitations to Barrier Precautions

The greatest limiting factors associated with use of barrier precautions in infection control are poor compliance and improper use. Written protocols that document practical use of barrier precautions should be developed. They should specifically state when additional barriers are required; it is not possible to achieve consistent results if protocols are ambiguous or suggest too much discretionary interpretation. In addition, it is critical to educate personnel on the need for barrier nursing precautions and on proper application. Many human hospitals require physicians and nursing staff to undergo practical training in the proper use of barrier precautions to avoid inadvertent spread of contaminants, and this type of active training may help to ensure uniform understanding and application of protocols. It is also important to regularly monitor compliance with protocols.

Protective Outerwear

Standard protective outerwear for large animal veterinary personnel should include clean coveralls, lab coats, scrubs, or other dedicated clothing (hospital uniforms), in addition to easily cleanable footwear. Protective outerwear should be worn for every animal contact and should be changed regularly. This includes any time outerwear becomes visibly soiled or otherwise contaminated with body fluids perceived or known to be contaminated with potential pathogens (e.g., feces, blood, nasal exudates, urine, or uterine fluid). In addition, outerwear should be changed frequently (at least daily) because gross contamination does not need to be present for pathogen contamination to have occurred. Hospital personnel should change their hospital outerwear before leaving the building to decrease the risk of transfer of infectious agents from the hospital to the community. To facilitate this control measure, it is optimal from an infection control perspective for veterinary practices to provide laundry services or laundry facilities. Clothing that is potentially contaminated with biohazardous material should be handled appropriately so that personnel handling laundry are aware of the hazards and how to reduce risks for exposure.

Gloves

Gloves are an important component of barrier precautions if used properly. The CDC recommends glove use by health care workers to reduce the risk of transmission of infections from patients to personnel, to prevent health care workers' skin flora from being transmitted to patients, and to reduce transient contamination of the skin on the hands of personnel by microorganisms that can be transmitted from one patient to another.[56] The same concepts apply to veterinary medicine. In certain situations, glove use has been shown to be an effective means of reducing pathogen transmission in human medicine.[57] However, incorrect use can negate these effects or even be harmful. Common errors with glove use include failing to wear gloves when needed, not changing gloves after contact with infectious items, touching items (e.g., cell phones, computers, pens, medical supplies) while wearing contaminated gloves, contamination of hands or clothing while removing gloves, and failing to wash hands after glove removal.[58] Although gloves are used to prevent contamination of hands, the potential for inadvertent contamination through microbreaks in the glove surface or contamination during glove removal necessitates use of handwashing or application of hand-sanitizing solutions in conjunction with glove use.[56]

There are no widely accepted standards in veterinary medicine for when gloves must be used, apart from the use of sterile gloves during surgical procedures. Examination gloves that are clean but not sterile are often used when handling wounds or infected body sites and for contact with animals known or suspected to be shedding contagious pathogens. Despite relatively widespread use of examination gloves in a variety of circumstances in veterinary medicine, it is quite unusual for practices to have formal protocols regarding how and when they should be used.

Gowns

Although protective gowns have traditionally been used during surgery, their use as a barrier garment when contacting high-risk patients is increasing in both human and veterinary medicine. The CDC has produced guidelines for human medicine stating that "gowns should be worn by personnel during the care of patients infected with epidemiologically important microorganisms to reduce the opportunity for transmission of pathogens from patients or items in their environment to other patients or environments."[56] In general, gowns should be worn whenever direct or indirect contact with patients or their environment may result in contamination of caregivers' clothing or skin that facilitates transmission of pathogens.

The ideal barrier gown would cover all areas of the body that might become contaminated, prevent penetration of liquids, be of adequate strength to resist tearing and puncture under normal activities, be comfortable to wear for long periods, be available in appropriate sizes for all personnel, be easy to put on and remove without contamination of regular attire, be nonabrasive to skin, be unlikely to startle patients, and be of acceptable cost. Unfortunately, a product with all of these characteristics does not currently exist, and facilities must prioritize the relative importance of different gown properties. This is often difficult because neither the overall effectiveness of gowning nor the effectiveness of different gowns in veterinary situations has been adequately evaluated. The problem most likely to be encountered with barrier gowns in veterinary practice is poor resistance to liquids, especially under direct contact or pressure. In large animal practice, there is a greater likelihood of contact with relatively large volumes of fluids (e.g., with diarrheic animals) or direct contact with patient surfaces that have moist secretions or excretions (e.g., animals with nasal discharge or large infected wounds). The types of anticipated activities may also have an impact on the required size of gown. Gowns that do not completely cover the legs and feet may be useful in some circumstances but ineffective in situations with prolonged direct contact, such as assisted neonatal nursing.

In human medicine, there are conflicting data regarding the efficacy of gowning for prevention of HAIs.[57,58] Gowns may be more effective for reducing infection of personnel. It is possible that the most significant advantage in some situations is not the protective effect of gowns or other protective outerwear, but rather the raised awareness of the potentially infectious nature of the patient, which may in turn encourage concurrent application of other important infection control practices.

Footwear, Footbaths, and Footmats

Contaminated footwear has been shown to be an important factor in transmission of contagious pathogens in intensive agriculture settings,[59-62] but the role of footwear contamination in spread of contagious diseases in veterinary hospitals or human health care facilities is less clear.[63] A few investigations have noted the dissemination of *Salmonella* on floors in veterinary hospitals, indicating a potential for transmission via this route, but these have not directly linked disease transmission to environmental contamination.[1-4,64] Regardless, use of disposable shoe covers or footwear that is dedicated for use in isolation areas is a commonly implemented control strategy in veterinary hospitals, as is the use of footbaths or footmats containing disinfectants. Use of disinfectant footbaths or footmats does not affect total numbers of bacteria found on floor surfaces,[32,65] nor do these products completely sterilize footwear. It must

VetBooks.ir

be remembered that disinfection is a chemical process affected by time, temperature, and the presence of organic debris, whereas footbaths are frequently used with an unreasonable expectation of immediate sterilization. However, broad-spectrum, rapidly acting disinfectants such as peroxygens and accelerated hydrogen peroxide products have been shown to decrease bacterial counts on footwear surfaces if adequate time is allowed for action and if surface contamination such as manure is routinely removed from footwear.[66-71] Implementation of requirements for change of footwear or use of footbaths or footmats should not be undertaken lightly, as enforcing uniform compliance with these policies can be difficult and the cost for implementing can be significant. Further, a substantial effort is required to ensure that reusable footwear is kept clean and that disinfectant solutions are frequently changed (at least daily, but typically more frequent changes are warranted when solutions become dirty, as this significantly decreases the activity of disinfectant solutions). Still, it is our impression that rigorous use of disposable or dedicated footwear in isolation areas, in addition to the best-practice use of disinfectant footbaths or footmats, provides a useful adjunct in the control of diarrheal agents such as *Salmonella*. It is less clear that they provide substantive benefit in control of highly resistant agents such as rotavirus, respiratory agents, or contact-transmitted agents such as MRSA. Regardless, easily cleanable, closed-toe footwear should be mandatory for working in large animal health care environments.

Eye and Face Protection

The use of protective eyewear, including goggles and face shields, is common in human medicine during procedures that generate aerosols or airborne droplets of blood, body fluids, and secretions[72] but often overlooked in veterinary medicine.[73] Face shields have the advantage that they decrease the potential for facial mucous membrane exposures in addition to ocular exposures. Inexpensive disposable face shields are commonly available and are generally quite comfortable for people with varying face shapes and sizes, and thus would seem to have great potential for use in all large animal practices. Despite the current low prevalence of bloodborne zoonotic pathogens in large animal species, it would be prudent to consider the use of some type of eye protection whenever generation of small particulates or aerosols of liquids or secretions is likely to occur, including when motorized equipment is being used for dental procedures, foot trimming, or orthopedic surgery. Situations in which eye protection should be seriously considered include examination of animals with suspected viral encephalitides or draining abscesses and working with a struggling animal with a respiratory or skin/soft tissue infection where infectious agents might be aerosolized during movement. Although not studied, face protection may also help protect against zoonotic disease involving fecal-oral transmission, such as *C. parvum*, which has an extremely small infectious dose, most likely through prevention of inadvertent hand-mouth contact.

Respiratory Protection

Masks and respirators are often used to reduce the risk of respiratory and oral exposures to infectious agents, to reduce the risk of contamination of patient sites with organisms from personnel, and in some situations to prevent contamination of hands with nasal or oral microflora. Standard surgical masks may be effective against the spread of large-particle droplets that are transmitted by close contact and travel only short distances (up to 3 feet) from infected patients.[74] However, the overall effectiveness of surgical masks in hospital situations has recently been questioned.[75]

Airborne transmission of zoonotic pathogens is of minimal concern in most veterinary settings, and mask use is uncommon in veterinary hospitals apart from during surgical procedures. One exception that has been frequently overlooked is the risk of zoonotic *Coxiella burnetii* transmission when handling periparturient ruminants, especially during obstetrical procedures in small ruminants.[28] The actual reduction in zoonotic disease risk that might be associated with the use of surgical masks during routine patient contact is unclear. However, increased awareness of risks of specific zoonotic diseases and infections in immunocompromised personnel and others with special disease risks has prompted reconsideration of recommendations regarding personal protective equipment in some circumstances. For example, although clinical Q fever is considered relatively rare, it has become abundantly clear that people working with small ruminants are very commonly infected with *C. burnetii*, and the significant health consequences of these rare clinical infections may warrant mandatory use of respiratory protection when handling high-risk patients, especially if people have a higher risk for serious infection sequellae (e.g., pregnant women). In addition, although airborne transmission is not considered an important route of exposure for MRSA, the hospital personnel primarily become colonized in the nasal passages, and hand-to-nose contact is frequent. Thus mask use may prevent direct contact of hand and nose, thereby decreasing hand contamination or decreasing the risk of inoculation of the nose following contamination of the hands during animal contact. Mask use may be particularly important for prevention of MRSA exposure when working in barns containing many MRSA-positive animals and high dust burdens. This is most relevant for swine veterinarians but could include clinicians entering veal calf units in some regions. Masks capable of filtering non-oily particulate aerosols with 95% capability (N95 masks) are recommended in human medicine for dealing with airborne contagions such as the severe acute respiratory syndrome (SARS) coronavirus. Although there is currently little indication for routine use of these masks, except in regard to periparturient small ruminants,[28] it is reasonable to expect facilities to at least have a plan in place to implement N95 masks if required. A critical aspect of the use of N95 masks is fit testing and training in their use, since improperly fitted or used masks may confer little or no benefit over surgical masks. Use of powered air-purifying respirators (PAPRs) has become increasingly common in large veterinary teaching hospitals in situations where risks for small-particle transmission of zoonotic agents are recognized.[28,36] PAPRs require a larger initial investment, but they do not require fit testing, and minimal training is required for effective use in controlling airborne hazards.

Animal Movement and Housing

Housing and movement can have a profound effect on the likelihood of exposure of patients to pathogens. Ideal facilities have no contact between inpatients and outpatients, allow for grouping and segregation of animals with different risks for contagious diseases, prevent direct contact with adjacent animals, reduce the potential for indirect exposures through contact with contaminated environments, and have adequate space so that there is time to properly disinfect all housing and handling environments between use with different animals. This, of course, is completely dependent on early recognition and effective management of patients with higher risks of transmitting contagious diseases.

One major problem frequently encountered in large animal facilities, particularly older facilities, is that construction and design factors often hinder infection control activities. Infection control issues were often not given high priority when designing many older facilities, so a variety of problems are often encountered. These include patient traffic flow problems, requisite mixing of inpatients and outpatients, inability to segregate different cohorts in the population, heavy traffic

VetBooks.ir

around important areas (e.g., surgery, isolation), inadequate stall numbers, inadequate isolation facilities, poor ventilation, improper drainage, use of materials that are difficult to clean and disinfect, and design issues that hinder adequate cleaning and disinfection. A variety of challenges come with designing an optimal facility. Many measures used to enhance infection control are inherently inconvenient, and designs that optimize infection control often have a significant impact on building costs and efficient use of the facility. It can be difficult to reconcile ease of operation with the level of infectious disease risk that is desired. However, development and rigorous use of sound infection control protocols can overcome most deficits in design and construction to achieve an acceptable practice standard for minimizing HAIs.

Outpatient Areas

In general, outpatients tend to have a lower contagious disease risk, in terms of both likelihood of shedding infectious agents and their susceptibility to infectious disease. However, "lower" risk does not mean "no" risk, and it is important to design holding areas that minimize contact with other animals while clinicians obtain histories and initial examinations to more clearly categorize patients relative to their contagious disease risk. Ideally, outpatients should have little or no contact with inpatient animals and minimal contact with areas visited by inpatients. However, this is often not entirely possible. For example, it is often impractical to build separate areas for diagnostic imaging of inpatients and outpatients. However, the general principle of separation of inpatients from outpatients should be adhered to as much as possible.

Holding stalls in admission and outpatient examination areas may need to house many animals every day. As such, it is important that a sufficient number of stalls is available to allow appropriate cleaning between use, that there are established mechanisms to allow admitting clinicians to identify high-risk cases, and that this information is promptly conveyed to relevant personnel so that extra precautions can be taken with that patient and the environment with which it has been in contact. Environmental precautions may range from routine cleaning and disinfection to restricting use pending high-level cleaning and disinfection, stall cultures, or patient cultures.

Inpatient Areas

Inpatients pose greater challenges than outpatients because they often have significant risk factors for infectious disease acquisition such as comorbidity, dietary changes, antimicrobial treatment, disruption of natural defense mechanisms, surgery, and placement of invasive devices. Compromised inpatients, particularly certain patient groups (e.g., those with GI disease), may be more likely to shed infectious agents such as *S. enterica*. Thus infection control protocols should emphasize the need to reduce the risk of transmission of infectious agents from inpatients to other hospitalized animals and hospital personnel and to minimize risks related to contamination of the hospital environment. A variety of methods can be used to manage this risk, which needs to be balanced with levels of risk aversion and available resources to support infection control efforts.

One method of reducing the risk of disease transmission between individuals and groups (i.e., between animals in different wards or those assigned to different services) is to assign animals to different cohorts and then create physical and procedural separation among the different groups. It is important to group animals based on known or suspected infectious disease status or infectious disease susceptibility, as well as to group and separate animals with different disease syndromes (e.g., respiratory disease or GI disease). It is also logical to group and segregate animals that are managed by different clinical services in order to decrease the probability of transmitting infectious agents through indirect contact and to increase the ability to contain a cluster of infections related to one clinical service. Examples include segregating patients managed by surgery and medicine services to help reduce risks for transmission of different contagious agents and managing cattle separately from other large animal patients (especially horses) to reduce risks for *Salmonella* transmission. In general, managing inpatients as smaller cohorts helps to contain transmission risk, thereby decreasing the likelihood of a widespread outbreak in the entire patient population. Creating smaller cohorts of patients with different risks for contagious disease also facilitates the use of varying levels of infection control precautions for different groups.

The design of some facilities does not allow for the separation of different cohorts in different buildings or wards. When physical separation of inpatient groups (excluding isolation cases) is impossible or impractical, animals with different disease risks can still be managed differently in a common ward system. One approach is to designate areas within large wards for different cohorts. Another is to identify animals in different risk categories, applying different levels of infection control precautions, but to allow interspersing of animals from different risk categories in the same area. This is similar to the approach for patient isolation used in most human hospitals, but it is only effective for diseases that are not transmitted by aerosols (i.e., it is not generally effective for contagious respiratory diseases such as influenza or EHV) and where there is a reasonable ability to prevent direct (e.g., nose-to-nose contact over stall walls) or indirect (e.g., cross-contamination from stall cleaning supplies) transmission. Physical separation within a ward can be enhanced by the use of chain or rope barricades to identify and minimize access to patients with elevated contagious disease risk status. A key for successful infection control using this type of system is the absolute need for prominent identification of different groups, having defined protocols for each group, and maintaining effective communication about the disease status of these patients. One system that has been used is color labels to indicate infection control status. For example, colored adhesive dots can be placed on stalls or stall cards of all patients; red dots might indicate animals with a known highly contagious disease, yellow dots might indicate that animals are suspected of having an infectious disease or may have increased risk of acquiring infectious disease, and green dots might indicate that animals are considered to have an average or low risk of carrying or acquiring contagious disease agents. This type of system is easy to apply and easy to understand. In addition, more prominent signs can be used to more clearly indicate certain concerns (e.g., *Salmonella*, MRSA, rabies suspect) to all personnel. One consideration with these more specific labels, however, is whether visitors could obtain confidential and sometimes prejudicial information from visible notices.

Isolation of Highest Risk Patients

The most rigorous control of contagious disease hazards requires that transmission potential be absolutely minimized for patients suspected or known to be infected with highly contagious pathogens or pathogens associated with highly consequential diseases. In general, this means that these patients should have no direct or indirect contact with other animals or areas used in the routine care of patients via personnel, fomites, aerosols, or other materials. It also means that human access to these patients and their care environment should be tightly controlled. In general, to achieve this level of isolation, these patients will require housing in a separate, specially designed unit.

Most isolation protocols in large animal medicine focus on a limited number of pathogens. Protocols for large animal facilities tend to focus heavily on animals clinically affected by *S. enterica*, viral respiratory pathogens, and *S. equi*, and more recently on horses with neurologic disease because of the risks related to EHV-1. Whether these protocols are adequate or

VetBooks.ir

excessive for control of other pathogens is debatable, and a broader scope is likely required in many facilities. That said, protocols that reduce the risk of transmission of one agent generally reduce the transmission potential of other agents, particularly if there are similarities regarding transmission routes or risk factors for exposure and infection.

Large animal isolation protocols need to consider a variety of issues, including indicators for isolation, cleaning and disinfection, personnel movement and barrier precautions, patient contact and movement, manure disposal, and supply stocking. Defining methods for identifying animals that need to be isolated and establishing specific criteria for handling these animals are critical steps, and these methods must be properly communicated to all individuals associated with patient or facility care. Developing protocols for rapid identification of patients that represent a contagious disease hazard is critical to the success of any infection control program. The best isolation units are not effective if unoccupied. Specific disease and syndrome criteria for isolation should be developed to facilitate prompt isolation of appropriate individuals, typically in advance of confirmation of the presence of an infectious agent. Isolated animals should be kept physically separate from the rest of the hospital population at all times if possible. This means that isolation units should be designed so that animals will rarely if ever need to leave the unit, except for an emergency procedure such as surgery. Stocks, examination areas, and scales should be available. A major deficiency of many large animal isolation facilities is the inability to use mechanical hoists and slings to safely manage recumbent, profoundly ataxic patients, which is important because of concerns regarding herpesvirus myeloencephalitis resulting from EHV-1 infections. Ideally, there should be minimal contact of personnel with isolated animals and their stall environment. The ability to monitor patients in isolation using viewing windows or by remote electronic means (e.g., web cameras, closed-circuit video) facilitates the ability to deliver excellent patient care while minimizing risks associated with direct contact.

These units must be strictly managed with specific predetermined protocols in order to reliably manage the risk of transmission. Isolation protocols should be comprehensive and clearly documented in writing. Proper training of all staff, particularly lay staff that may have no background in infectious diseases and infection control, is critical. Standardized protocols for management of isolation units in human health care settings have been published by the CDC.[74] However, similar standardized guidelines have not been established for veterinary medicine, and protocols used at veterinary facilities are highly variable because they are tailored to specific operations and different facility and logistic resources. It is logical for veterinary facilities to consider guidelines that have been developed at other veterinary facilities and in human health care settings when developing their own isolation protocols.

In some situations, housing of potentially infectious animals in an isolation unit is not possible because of patient care issues or limitations in isolation space. As a result, consideration needs to be given to management of higher risk patients within the general hospital environment. This can be done in a few different ways, including grouping those with general risk and applying intermediate isolation techniques to cases that are considered at higher risk of being infectious but not deemed candidates for housing in an isolation unit. In-hospital isolation protocols allow for an increased level of protection but are not a replacement for a proper isolation unit and should not be used solely for clinician convenience. Protocols should be developed regarding the handling of animals, the stall, and the area around the stall. Animals that are isolated in the hospital should not leave stalls unless they are being moved for required procedures. If movement is necessary, feet should be cleaned and disinfected using appropriately diluted chlorhexidine solutions. The potential for environmental contamination can be reduced by having a person follow the animal with a bucket to collect any feces that may be passed during transit. Traffic areas should be promptly cleaned and disinfected. Protective barrier clothing such as full waterproof coveralls or full-length waterproof gown, gloves, and dedicated footwear or boot covers should be worn for any contact with the patient or its environment. The area around the stall entrance should be considered potentially contaminated and disinfected routinely (at least three to four times per day). Disinfectant footbaths or footmats used at stall doors can reduce bacterial contamination of footwear.[66-68] Attention should be paid to the pattern of water drainage from the stall and in the area. If water runs from the stall to the breezeway or runs down the breezeway past the stall, then housing potentially or known infectious animals in the stall may be inappropriate. Animals should not be allowed contact with neighboring animals. Barriers may be required if solid walls are not present on all sides. Specific protocols should be developed for cleaning in-hospital isolation stalls. These stalls should be cleaned last, personnel cleaning the stalls must wear protective gear, and items used to clean the stalls must be disinfected immediately after use.

Isolation guidelines for human medicine target the prevention of five different types of transmission: contact transmission, droplet transmission, airborne transmission, common vehicle (fomite) transmission, and vector-borne transmission.[56-58,72-74]

- Contact transmission is typically the most important mode of transmission and involves transmission of infectious agents to patients by caregivers or directly between patients. In large animal medicine, this could include situations such as transfer of MRSA from a colonized person to an animal under his or her care, transmission of *S. equi* between horses by personnel, or direct transmission of viral respiratory pathogens between horses in adjacent stalls that can have nose-to-nose contact.
- Droplet transmission involves transmission of infectious agents in relatively large fluid droplets generated by coughing, snorting, or vocalizing. These large droplets do not remain suspended in the air for long periods, nor are they transmitted long distances; therefore special air handling is not required. An example of this is transmission of bacterial agents from a coughing horse to another horse stabled in relative proximity. An extrapolation to veterinary context might also include transmission of surface contaminants during environmental cleaning processes with water under high pressure.
- Airborne transmission involves agents that can be transmitted effectively in small particles (5 μm or smaller) that can remain suspended in air and travel greater distances. Special air handling is required to control this route of transmission. Equine influenza can be spread through a barn via the airborne route over extended distances.
- Common vehicle or fomite transmission involves infection caused by contact with contaminated items such as feed bins, muzzles, twitches, thermometers, and other medical equipment.
- Vector-borne transmission involves vectors such as mosquitoes, flies, and rodents. This may be of particular concern in some areas with reportable vector-borne diseases such as equine infectious anemia.

Surveillance

HAIs occur in all veterinary facilities; if HAIs are never recognized, it is because surveillance has been ineffective at detecting them. All comprehensive infection control programs should have a surveillance component because the information collected serves as sensory input to guide ongoing efforts so that they are focused and efficient. Without surveillance information,

VetBooks.ir

infection control programs will be guided more by emotions and opinions than by data and evidence. Infection control programs will have much greater acceptance and utility if, in the long term, decisions are based on objective information about infection and disease occurrence at a specific hospital. Useful surveillance goals for infection control programs include developing a system to allow prompt identification of contagious disease threats, evaluating the effectiveness of infection control practices, measuring personnel compliance with infection control procedures, providing a basis for logical infection control decisions, and stimulating efficient and economical use of resources.

Surveillance Options and Strategies

Theoretically, an optimal surveillance system would allow real-time detection of all HAIs. However, pursuing this goal would be unrealistic for reasons of practicality and would be an inefficient use of resources. Although all HAIs are important relative to patient well-being, some are more common and more important than others. This is because the impact on patient health is much more significant for some diseases, as well as because highly contagious diseases are more likely to affect a larger number of patients. Further, regardless of whether there is a contagious etiology, HAIs that affect a large number of patients can have a tremendous impact on the cost of care and the overall burden of morbidity for patients. Focusing surveillance on these high-impact HAIs is logical, as a greater proportion of these occurrences are also likely to be preventable in comparison to more sporadic problems. Further, experiences with infection control in human health care settings have shown that it is possible to be more cost and effort efficient if high-risk, high-frequency, and high-cost problems are targeted.

Determining which specific HAIs were likely preventable is a difficult and potentially contentious task. Rather than focusing on individual infections, infection control efforts in human hospitals have benefited by focusing on comparing rates of infection and estimating the proportion that might be preventable by referencing some accepted standard. During the past 30 years, human hospitals have made great efforts to characterize rates of HAIs that can be expected even under the best of circumstances. By estimating rates for these "nonpreventable" infections, it has then been possible to identify hospitals with higher-than-average rates for HAIs. Because of the tremendous differences among hospitals and patient populations, it has become standard to focus on more restricted, high-risk patient groups for which there is better comparability (e.g., neonatal or cardiac intensive care patients). It is also far more feasible to perform surveillance for HAIs in these high-risk patient subgroups than it is in the general population, which has much lower risks of HAIs. Performing surveillance with standardized case definitions[20] over time allows identification of specific risk factors, which could then be used to prospectively refine management of patients (i.e., a high-risk patient could be identified and subjected to more aggressive control measures as a preventive strategy). Unfortunately, there is very limited information available on rates of disease related to HAIs at individual hospitals let alone estimation of rates in multiple hospitals; this information would be required in order to obtain interhospital comparisons that would be useful in identifying latent problems at specific facilities. Although making standardized comparisons between hospitals would require tremendous cooperative effort, individual facilities could make significant progress in identifying important changes in rates for HAIs if efforts were made to benchmark their infection rates over time.

When designing a formal surveillance effort to aid infection control programs, it is important to tailor efforts to a specific facility or practice. A wide variety of design possibilities are available for hospital surveillance systems, and the specific focus and methods should be carefully matched to the needs and resources of each establishment. Diseases that are the highest priority for surveillance must be specified along with standardized case definitions that will be used to identify these cases. Efforts may target disease caused by HAIs that are related to specific procedures or organ systems, or just as commonly they may target specific infectious agents of interest. For example, systems might be established to look for surgical or intravenous catheter site infections, methods may target surveillance for respiratory tract infections, or efforts may specifically target detection of infections with specific etiologic agents such as *Salmonella* or MRSA. It must also be determined whether clinical disease will be the outcome of interest or whether it is important to look for animals with subclinical infections. This will generally vary by disease and likely will be determined by the natural history or pathophysiology of the disease (i.e., Does shedding occur in the absence of clinical signs? Is there a chronic carrier state? What risk factors are related to the likelihood of shedding?). Further, if clinical disease is the outcome of interest, it is important to consider whether the case definition will include some type of etiologic confirmation, or whether diagnoses will be syndromic in nature and based on clinical signs (i.e., surgical site infections could be defined based on recovery of a bacterial agent in the presence of clinical disease, or it could be defined solely on the presence of a predetermined combination of clinical signs such as erythema and drainage). As discussed, another consideration is whether surveillance will target specific subgroups of the population or include all patients. The major benefit of targeted surveillance is that it decreases the cost and effort of data collection, but the trade-off is the inability to detect potential problems in the patients that are not being monitored. However, increasing awareness of infection control methods for common or more important diseases generally has the effect of increasing awareness and compliance with control measures that relate to other potential HAIs. It also must be determined whether surveillance will be active (i.e., patients with HAIs will be actively sought out) or whether passive surveillance (i.e., reporting is voluntary) is acceptable and appropriate. In general, active surveillance will be used only in targeted subpopulations and only to look for more common and more important diseases, and syndromic surveillance should be more heavily relied on when the targeted population is larger or as a supplement to culture or etiologically based surveillance efforts.

Another important consideration is how data will be gathered for this effort. Significant personnel compliance is needed for active culture-based surveillance of large numbers of patients. Similarly, any type of chart review system for benchmarking expected rates of HAIs requires a significant time commitment. Surveillance efforts are greatly aided by computer-based search mechanisms, and it is strongly recommended that practices consider using electronic medical record systems to maximize the ability to perform surveillance and that medical record systems be designed to facilitate collection and recovery of infection control–related data. For example, something as simple as being able to monitor the number of febrile or leukopenic patients daily could be extremely powerful as an aid to infection control efforts. Even financial databases can be useful in surveillance efforts. For example, they may be very useful for benchmarking antimicrobial prescriptions or specific procedures, such as intravenous catheterization, surgeries, or submission of samples for diagnostic tests.

Generalized, nontargeted surveillance to look for potentially pathogenic bacteria that can be found in health care environments is widely considered of no real benefit to infection control efforts. This includes sampling surfaces in surgical theatres to catalog the different bacteria that can be found. However, there is utility in targeted environmental cultures where there

VetBooks.ir

is biological plausibility as to their relevance and a plan to act on the results (and where the action differs if results are positive or negative). For example, monitoring for contamination of veterinary hospitals with *Salmonella* has been a useful adjunct to patient surveillance in comprehensive infection control programs at veterinary hospitals.[36,64,76,77] In addition, in some situations, such as when attempting to control ongoing outbreaks, there is no substitute for culturing the hospital environment to detect important environmental reservoirs.[1,3,4] Use of electrostatic household wipes has been extremely useful for sampling to detect *Salmonella* in routine surveillance as well as in the face of outbreaks.

The use of rapid and sensitive diagnostic tests is particularly important for the management of highly contagious diseases. As such, polymerase chain reaction (PCR) and antigen detection tests, which can be much more rapid than traditional culture systems for bacteria and viruses, have become more widely used for both patient and environmental surveillance efforts. However, these tests cannot fully replace culture-based assays because analysis of microbes is essential to fully understand the epidemiologic implications for each recovery. For example, if on a single day three patients were found to be shedding *Salmonella* after use of PCR testing, it would not be possible to know whether these were unrelated events. In contrast, if shedding were detected using culture and the *Salmonella* isolates were then shown to be from different serogroups, this would make it unlikely that shedding was related to exposures from a single source. In some situations, it may be logical to use both a rapid and a culture-based assay to maximize both speed and ability to perform epidemiologic investigations. Availability of qualified laboratories, rapidity of testing, and costs all have to be considered and balanced.

Monitoring Personnel Compliance

Success of an infection control program depends on universal participation within a hospital or other animal care facility that is born from a well-developed sense of responsibility among individuals. Actively engaging all personnel in infection control programs becomes increasingly difficult as organizations become larger and more complex. Unfortunately, the most cautious actions of a majority of personnel can be for naught if even one individual neglects to take appropriate precautions under just the right (wrong) circumstances. Although it is very important for administrators to engage in surveillance to detect systematic noncompliance with policies, it is just as important to empower and expect all personnel to monitor for individual acts of noncompliance. Remembering that most noncompliance is born from a natural tendency for people to revert to the most convenient practices, which are not necessarily the most "safe" practices from the infection control perspective, it is important to couple surveillance efforts with education so that all personnel fully understand why they are being inconvenienced. In addition, providing useful feedback and communication about issues that arise in the hospital will help to reinforce the need for compliance. For example, monitoring and reporting bacterial shedding or environmental contamination detected as a part of surveillance programs can help to keep hospital personnel aware of the potential hazards of reduced infection control efforts.

Measurements Related to Health and Disease

Although outcomes for individual animals may be the most important bottom line for many clinicians, it is important to remember that infection control by its very nature often has a larger population-based perspective. Thus although diagnostic test results for an individual animal obviously have great relevance for that animal, for the population a positive test result may not have great meaning unless it is interpreted contextually. It is therefore critical to remember that in addition to tracking numerators (e.g., numbers of infections or animals with disease caused by HAIs), some type of denominator information is needed to provide relevance over time or among different subpopulations. Examples of relevant denominators are patient admission totals for a given period, patient-days of hospitalization, numbers of procedure events such as surgeries or catheter placements, and numbers of samples submitted for culture.

Developing a Comprehensive Surveillance Strategy

As mentioned, it is unrealistic to expect to detect all occurrences of HAIs or all animals shedding agents of interest through any hospital surveillance system. Rather, veterinarians should work toward developing strategic surveillance programs that will allow reliable estimation of rates for important events if they occur with any significant frequency, as well as rapid detection of unexpected important events. It is likely that a mix of strategies described previously will be used for the various agents and disease problems. For example, if *S. enterica* shedding occurs at some low-level yet regular frequency in a hospital (e.g., 3% of all hospitalized equine patients) and is considered an important potential hazard for other patients, it is reasonable to develop an active surveillance program that allows detection of clinical and subclinical shedding of *Salmonella* as a patient management tool and detection of important trends over time so that outbreaks of HAIs can be rapidly identified and stopped. In contrast, *Clostridium difficile* or EHV-1 may not have been detected with any regularity in patients at a particular hospital or may be more difficult to actively monitor because of available testing methodologies, yet they may still be considered important because of their significance as pathogens and their potential for contagious spread. For these pathogens, it may be more reasonable to use a reliable passive surveillance strategy to call attention to patients when clinical signs or diagnostic testing indicates that these agents may be present. In addition, maintaining some level of surveillance for compliance with infection control procedures and policies is necessary to ensure that an infection control program is functioning properly.

Education and Awareness

Education of all personnel regarding infectious disease hazards to themselves, patients, and veterinary practices is essential to the long-term success of any infection control program. Successful programs are critically dependent on all personnel knowing and following procedures and policies used for control of contagious disease transmission in a practice. Although this type of information can be acquired over time through personal experience, this is an inefficient and unreliable method for disseminating critical information.

Written Protocols

The first step to ensuring that necessary information is disseminated to all personnel is to document policies and protocols in writing. This effort is valuable for all veterinary practices but is especially critical in larger and more complex veterinary hospitals. This relatively simple step has many benefits. First, documenting procedures requires a thorough review, which by itself is beneficial. Second, documenting policies and protocols in writing imbues the infection control program with a sense of purpose and commitment. Third, documenting procedures helps to ensure consistency in application across all personnel as well as over time. As discussed, all infection control procedures are inherently inconvenient, and the natural tendency is for personnel to drift toward more convenient ways of performing activities that may not provide an adequate degree of protection against HAIs. Fourth, documenting policies

VetBooks.ir

demonstrates a degree of due diligence, which is useful from a legal liability standpoint relative to the occurrence of HAIs or zoonotic infections.

Once these protocols have been documented, it is important to require their use as a reference and to make a specific effort to educate personnel about the policies and procedures. A written document serves no purpose if it is not used. Veterinarians and other personnel are busy people, and the immediacy of caring for patients and clients can easily overwhelm seemingly mundane tasks such as studying written protocols. A valuable aid in this process is to have some type of training program. This does not necessarily mean formal presentations; it is valuable to organize a meeting of all personnel for the sole purpose of discussing infection control issues. Although this seems logical, training in infection control practices is not a universal occurrence even in teaching hospitals. In a survey of teaching hospitals at AVMA-accredited institutions, only 42% (16 of 38) of responding institutions reported that they required personnel (students, technical staff, veterinarians) to participate in some type of formal training program regarding infection control and biosecurity, and only 7 of these institutions provided more than a single training exposure.[16]

Training Programs

It is also important to consider the differences in training and experience among personnel. By their nature, infection control programs are dependent on adherence to important protocols by all personnel regardless of their position description. Nonveterinarians are invaluable members of most veterinary practice teams, and even personnel who may never touch patients but instead serve as receptionists or have the single specific task of cleaning are absolutely critical for the success of infection control programs and may be exposed to infectious agents on periodic or routine bases. Veterinarians sometimes underappreciate how their specialized training has provided them with a broad appreciation for basic principles of contagious disease transmission and control. Without the experiences of a veterinary education, many personnel simply do not have the same understanding of contagious diseases. Telling people to follow certain rules without them understanding why the rules are necessary leads to inevitable compliance problems. Without a thorough understanding of why inconvenient infection control practices are needed, these practices will be discarded over time as seeming illogical. To help ensure uniformity of education among all personnel, some hospitals have developed training documents and require that new employees pass a written evaluation before they are permitted to begin work. Regardless of the type of training program, documentation of that training (and ideally an outcome measure such as a quiz) is important from a due diligence standpoint. Simply telling people to read a manual does not likely constitute adequate training.

Another important aspect of education and awareness is to instill a need to lead by example and to empower all personnel to hold anyone else in the practice accountable for their actions. The hierarchy in authority that is often used in the delivery of patient care (e.g., veterinarians at the top of the hierarchy, personnel without formal training at the bottom) can interfere with optimal infection control. A common non sequitur related to infection control is that those with the most training can be the persons least likely to adhere to important policies. This is true in both human and veterinary medicine, as has been repeatedly shown relative to hand hygiene.[39,40] In numerous studies conducted in a variety of settings, physicians and residents have been shown to be significantly less likely than nurses to adhere to appropriate hand-hygiene protocols. Observations in the veterinary setting suggest that the same trends are true for hand hygiene as for appropriate use of barrier nursing precautions. All people pick up cues for behavioral expectations from their surroundings. If personnel who clearly understand the importance of preventive measures (physicians and veterinarians) such as handwashing fail to routinely follow best infection control practices, there is little hope that trainees and laypersons will routinely trouble themselves to habitually use an important albeit inconvenient practice. Further, it seems that the more respected position a person holds in a practice, the more likely it is that acts of noncompliance by that individual will be influential on the actions of others. Students in teaching hospitals can watch classmates correctly follow infection control policies throughout the day yet be more influenced to be noncompliant by observing the single time a senior clinician ignores a practice guideline.

One way to improve compliance and counter the influences noted previously is to use disseminated enforcement by actively encouraging all personnel to call attention to noncompliance. Once it has been determined which procedures are required for a particular situation and this has been documented, there is no reason why nontechnical staff should be any less capable than a veterinarian in determining whether a procedure has been followed correctly. It is important that this community enforcement be empowered by all in a spirit of friendly camaraderie and team building. Some hospitals have noted significant improvements in compliance using this method of enforcement and have even used competitions among "teams" with the incentive of agreeing that the loser must pay a reward to the other team (e.g., pizza lunch).

Zoonosis Awareness

Every patient, healthy or sick, carries multiple potentially zoonotic pathogens in their commensal microbiota. Some patients pose higher risks because of additional pathogens, shedding of higher levels of common opportunists, or disease or behavior factors that increase the risk of transfer of pathogens.

One of the most important objectives for an infection control program is to protect personnel and clients from illness associated with zoonotic pathogens. This is another area in which veterinarians sometimes forget that not all personnel understand hazards or how to take appropriate actions to protect themselves. Without this knowledge, personnel may take inappropriate risks or may overreact to perceived hazards in a low-risk situation. Most of the zoonotic disease prevention program focuses on routine practices that should be used on all patients because of the potential for shedding of pathogens by any patient, the potential for shedding of certain pathogens prior to the onset of clinical signs, and the fact that routine practices form the core preventive measures. Understanding and complying with those practices, and knowing when and how to use enhanced practices, are the main areas of emphasis for zoonotic disease prevention. Table 46.3 provides a summary of some zoonotic pathogens that may be transmitted from domestic large animals through occupational activities of veterinary personnel.

Personnel With Increased Risk of Infection

All personnel are at some risk of zoonotic infection, through being at increased risk of either disease following exposure to a pathogen or serious disease compared to lower risk individuals. Some individuals may be at increased risk because of concurrent disease (e.g., immunosuppressive disorders, skin diseases or lesions), treatments (e.g., immunosuppressive therapy, antimicrobial therapy), age, or pregnancy. Being "immunocompromised" or "high risk" is not a single state, and there can be marked differences in the degree of increased susceptibility as well as the risk posed by particular pathogens. Quantifying the degree of risk is difficult, and specific information about risks posed by certain conditions and the effect of preventive measures is generally lacking. In general, preventive measures are the same for high-risk individuals, as strict compliance with core infection control practices is likely the most important factor.

TABLE 46.3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible Through Occupational Exposures to Veterinary Personnel[a]

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Bacillus anthracis (Anthrax) • Gram-positive, spore-forming, anaerobic bacterium	All species	There are three clinical forms of anthrax in humans: cutaneous, pulmonary, and gastrointestinal. Cutaneous infections manifest as skin papules and vesicles with associated cellulitis that evolve into a characteristic black eschar (scab). Pulmonary anthrax initially resembles upper respiratory infection and can evolve into severe respiratory compromise and death. The gastrointestinal form results in gastroenteritis with vomiting and dysentery.	Cutaneous transmission occurs through direct contact. Respiratory transmission occurs through inhalation of bacteria or spores. Gastrointestinal transmission results from eating undercooked contaminated meat.	Enhanced barrier precautions, including eye protection and respiratory protection using a minimum of an N95 mask, should be used when handling affected animals or working in their environments. Blood and secretions from anthrax suspects should not be allowed to contact skin. Necropsy should not be performed on animals that have died from anthrax.
Bordetella bronchiseptica • Gram-negative bacterium	Pigs, dogs, cats, rabbits, horses	Disease is rare in humans and occurs predominantly in immunocompromised individuals, resulting in pneumonia and upper respiratory tract infections.	Respiratory infection through contact and droplet routes.	Immunocompromised individuals should avoid contact with mucous membranes and nasal discharges of susceptible animal species. Barrier precautions and adherence to good hand-hygiene protocols reduce the risk of exposure.
Brucella melitensis, *Brucella abortus*, *Brucella suis*, *Brucella canis* (Brucellosis) • Gram-negative bacterium	Cattle, sheep, goats, camelids, pigs, horses, dogs, other species	Flu-like illness, gastrointestinal signs occur frequently in adults but less often in children; irritability, insomnia, mental depression, and emotional instability sometimes develop. Recurrent fevers are the hallmark of chronic infections in addition to fatigue, arthritis, and cardiac and other complications.	Contact, droplet, or aerosol exposure to infected fetuses, placenta and placental fluids, or infected tissues; contact with contaminated fomites. Ingestion of unpasteurized milk or milk products.	Avoid contact with fluid or tissues from abortions. Use of barrier precautions. including gloves, protective eyewear, and a minimum of N95 respiratory protection. is recommended when performing obstetric procedures or performing necropsies on high-risk animals.
Burkholderia mallei (Glanders and Farcy) • Gram-negative bacterium	Horses and other equid species	Flu-like symptoms, photophobia, lacrimation, diarrhea, septicemia, pneumonia, ulcerative and suppurative cellulitis, lymphadenopathy, splenic and hepatic abscesses.	Direct contact or droplet exposures to skin or mucous membranes; prolonged contact with infected animals is generally required for infection.	Enhanced barrier precautions, gloves, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols are warranted when working with infected animals.

TABLE 46.3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible Through Occupational Exposures to Veterinary Personnel—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Campylobacter jejuni and *Campylobacter coli* • Spirochete bacterium	Cattle, sheep, goats, camelids, pigs, poultry, dogs, cats, other species	Disease varies from mild gastrointestinal distress that resolves within 24 hours to fulminating or relapsing colitis. Signs may include watery diarrhea, fever, nausea, vomiting, abdominal pain, headache, and muscle pain. Feces may contain frank blood. The acute symptoms usually diminish in 2-3 days and resolve in 7-10 days. Complications are rare but include Guillain-Barré syndrome, a disorder of the nervous system.	Fecal-oral transmission after contact with infected animals or their environments is a suspected but not well-documented risk factor. Ingestion of contaminated water and food, including undercooked poultry or meat, raw milk.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.
Clostridium difficile • Gram-positive, spore-forming, anaerobic bacterium	Pigs, horses, cattle, dogs, cats, other species	Colitis leading to fever, abdominal cramps, diarrhea or dysentery, dehydration, and electrolyte imbalances. Rarely, severe colitis can lead to life-threatening complications such as toxic megacolon, peritonitis, and colonic perforation.	Oral-fecal exposure through contact or droplet exposure to infected animals or their environments.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments; personnel should use respiratory protection when cleaning practices may produce droplet exposure. Avoid eating or drinking near animals or their environments.
Clostridium perfringens • Gram-positive, spore-forming, anaerobic bacterium	All species	Wound infections can result in gas gangrene with accompanying fever, swelling, and erythema of affected area, systemic signs as disease progresses. Oral exposure is associated with abdominal cramps, diarrhea, and in rare cases necrotic enteritis and septicemia.	Wound contamination through contact or droplet exposure, ingestion of food contaminated with large numbers of bacteria, potentially oral-fecal exposure through contact or droplet exposure to infected animals or their environment.	Routine use of protective outer garments or dedicated attire when working with animals or their environments. Strict adherence to good hand-hygiene protocols and appropriate cleaning and management of wounds.

TABLE 46.3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible Through Occupational Exposures to Veterinary Personnel—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Coxiella burnetii (Q fever) • Gram-negative, spore-forming, intracellular bacterium	Primarily sheep, goats, cattle, but also camelids, horses, dogs, cats, other species	Symptoms of Q fever include fever, chills, headache, fatigue, and chest pains. Pneumonia and hepatitis can occur in serious cases. In pregnant women, infections can cause premature delivery, abortion, and infection of the placenta. In people with preexisting heart valve disease, endocarditis may occur.	Contact, droplet, or aerosol exposure to urine, feces, milk, and especially fetuses and placental tissues from infected animals. Respiratory exposure to contaminated dust, occasionally ingestion of unpasteurized milk or milk products.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Caution is warranted when handling tissues or fluids of infected animals or aborted fetuses. Consider use of respiratory protection when performing obstetric procedures on high-risk animals. Enhanced barrier precautions, gloves, a minimum of N95 or powered air-purifying respiratory protection and strict adherence to good hand-hygiene protocols are warranted when working with periparturient small ruminants.
Cryptosporidium parvum (Crypto) • Apicomplexan protozoan parasite	Ruminants, pigs, horses, poultry, dogs, cats, other species	Gastrointestinal disease, including signs of abdominal pain, nausea, anorexia, and profuse watery diarrhea. Severe infections can require hospitalization for fluid therapy and electrolyte imbalances. The disease is usually self-limiting but may be chronic and debilitating in immunocompromised individuals.	Oral-fecal transmission primarily through contact with infected animals or their environments, but also through droplet exposures during cleaning.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments; personnel should use respiratory protection when cleaning practices may produce droplet exposure. Avoid eating or drinking near animals or their environments.
Dermatophilus congolensis • Gram-negative, actinomycete bacterium	Cattle, sheep, goats, camelids, horses, rarely pigs, dogs, cats, other species	Pustular desquamative dermatitis.	Direct contact with lesions on affected animals.	Use gloves when handling affected animals; strict adherence to good hand-hygiene protocols.
Erysipelothrix rhusiopathiae (Erysipelas in pigs, erysipeloid in humans) • Gram-negative, facultative anaerobic bacterium	Pigs, other species	Characteristic cellulitis with raised red lesions, edema, and intense pruritus. Skin infections can progress to involve other cutaneous sites and also rarely to systemic infections with flu-like illness, septicemia, and arthritis.	Primarily via direct contact with infected animals, contamination of skin wounds. There are rare reports of transmission through ingestion of undercooked pork.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Gloves should be used when working with clinically affected animals. Avoid eating or drinking near animals or their environments.

TABLE 46.3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible Through Occupational Exposures to Veterinary Personnel—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Shiga toxin–producing *Escherichia coli* (STEC, including O157:H7 and other serogroups) • Gram-negative bacterium	Cattle	Fever, enteritis, diarrhea, or dysentery. In children under 5 years and the elderly, infections can cause hemolytic uremic syndrome (hemolysis and kidney failure).	Oral-fecal transmission via contact or droplet exposure through exposure to cattle or their environment or through ingestion of contaminated water and food.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.
Francisella tularensis (Tularemia) • Gram-negative bacterium	Sheep, rabbits, cats, other species	Flu-like illness, rashes, nausea, splenomegaly, papular or ulcerative lesions at site of cutaneous exposure, lymphadenopathy and ulcerative lymphadenitis, pleuropneumonia from inhalation or hematogenous spread; ingestion is associated with enteritis, stupor, and delirium.	Contact, droplet, or aerosol exposure to tissues or secretions of infected animals, ingestion of tissues from infected animals.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments are warranted when handling tissues or fluids of infected animals or aborted fetuses. Gloves, eye protection, and a minimum of N95 respiratory protection should be used when performing obstetric procedures on high-risk animals.
Foot-and-mouth disease virus • Nonenveloped, single-stranded RNA virus	Cattle, sheep, goats, camelids, pigs, other species	Infection in humans is very rare; headache, fever, vesicular lesions on the hands or feet or in the mouth.	Contact, droplet, or aerosol exposure to infected animals.	When working with infected animals, enhanced barrier precautions, gloves, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols.
Giardia duodenalis • Flagellated protozoal parasite	Ruminants, pigs, poultry, dogs, cats, other species	Gastrointestinal disease, including signs of diarrhea, intestinal gas, stomach cramps, and nausea. A significant proportion of patients develop lactose intolerance while infected. The illness usually lasts 1 to 2 weeks, but chronic infections can last months to years.	Oral-fecal transmission through contact with infected animals or their environments or through ingestion of contaminated water or food.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.
Hendra virus • Enveloped, single-stranded RNA virus	Horses, other species	Fever, lethargy, respiratory distress, neurologic signs including headache and disorientation.	Occupational contact with infected horses or their tissues.	Classified as a Biosafety Level 4 agent; contact with infected animals or their tissues should be avoided unless personnel are specifically trained to work with this agent.

TABLE 46.3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible Through Occupational Exposures to Veterinary Personnel—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Influenza virus • Enveloped, single-stranded RNA virus	Pigs, aquatic fowl; influenza viruses are generally host restricted.	Cross-species infection with influenza strains is unusual under normal circumstances but has been rarely documented with swine and avian influenza viruses resulting in fever, malaise, upper respiratory illness, and pneumonia.	Close contact with infected pigs leading to respiratory exposure through contact, droplet, and aerosol routes.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. When working with infected animals, use enhanced barrier precautions, gloves, eye protection, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols.
Leptospira spp. (Lepto) • Spirochete bacterium	All mammals appear to be susceptible to at least one species of *Leptospira*.	Severity of illness varies greatly; signs include flu-like illness with fever, chills, headache, and severe myalgia. Aseptic meningitis can occur, and 5% to 10% of cases may be associated with multiple organ failure.	Skin or mucous membrane contact with urine or less commonly with blood and tissues of infected animals, ingestion in contaminated water or food.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. A minimum of N95 respiratory protection may be appropriate if droplet exposure to urine is likely. Avoid eating or drinking near animals or their environments.
Listeria monocytogenes • Gram-positive bacterium	All species	Contact can result in papular lesions on hands and arms. Most commonly, flu-like illness and gastroenteritis. Less commonly, infections can result in a mononucleosis-like syndrome (glandular listeriosis) or in fetal infection, abortion, stillbirth, neonatal septicemia, or meningoencephalitis. Meningoencephalitis is also noted in the elderly and immunocompromised.	Immunosuppression greatly increases the risk of infection. Direct contact of skin or mucous membranes with infectious material, feces, or contaminated soil. Respiratory exposure to secretions from infected animals via droplet or aerosol routes. Oral-fecal exposures through contact, droplet, aerosols, or ingestion of contaminated foods.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments, especially among immunocompromised people. Avoid eating or drinking near animals or their environments. Enhanced barrier precautions, gloves, eye protection, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols are warranted when performing obstetric procedures on high-risk animals or when handling aborted fetuses or tissues and fluids of infected animals.

TABLE 46.3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible Through Occupational Exposures to Veterinary Personnel—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Mycobacterium tuberculosis, *Mycobacterium bovis*, *Mycobacterium avium* complex, non-tuberculous mycobacteria • Acid-fast bacterium	All species	Signs depend on the organ system involvement. General signs of infections include anorexia, weight loss, fatigue, fever, and chills. Signs of pulmonary infection include coughing and hemoptysis. Skin lesions are characterized by ulcers, papular lesions, and suppurative lesions. Signs of other organ involvement relate to the specific system.	Inhalation and oral exposure through respiratory droplet and aerosol transmission from infected animals, oral or cutaneous exposure through contact with infected tissues or contaminated surfaces, ingestion of raw or unpasteurized milk and milk products.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. A minimum of N95 respiratory protection may be appropriate if working with infected animals with clinical pulmonary disease or if performing necropsy.
Nipah virus • Enveloped, single-stranded RNA virus	Pigs, other species	Fever, neurologic signs including drowsiness, headache, disorientation and confusion, shortness of breath, and coughing.	Occupational contact with infected pigs.	Classified as a Biosafety Level 4 agent, contact with infected animals or their tissues should be avoided unless personnel are specifically trained to work with this agent.
Parapox viruses (Orf virus and bovine papular stomatitis virus [BPSV]) • Enveloped, double-stranded DNA virus	Sheep and goats (Orf virus), cattle (BPSV)	Papular lesions at areas of contact (usually hands or arms). Lesions can be 1 cm in diameter, and surrounding tissues often become swollen and painful.	Contact with lesions on animals, scabs, or contaminated objects.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Gloves should be worn when examining mouths of animals suspected of being infected.
Rabies virus • Enveloped, single-stranded RNA virus	All mammals	Encephalitis with accompanying behavioral and physical signs.	Bite injuries from infected animals, contact with infected animals, and contact with bats or their habitats are the most common methods of human exposure. Contact, droplet, and aerosol exposure to saliva and respiratory secretions of infected livestock is also thought to be a possible method of infection but is not well documented.	Complete isolation of animals suspected of infection, minimizing contact with personnel. When necessary to examine or manage suspect animals, use enhanced barrier precautions, gloves, a minimum of N95 respiratory protection, eye protection, and strict adherence to good hand-hygiene protocols. Personnel that may be exposed to rabies should be vaccinated in accordance with CDC recommendations.[60]

TABLE 46.3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible Through Occupational Exposures to Veterinary Personnel—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Rift Valley fever virus • Enveloped, single-stranded RNA virus	Cattle, sheep, goats, camelids, other species	Flu-like illness, photophobia, neck stiffness, and vomiting, which may progress in severe cases to one of three characteristic syndromes: eye disease, meningoencephalitis, or hemorrhagic fever. Retinal lesions are the prominent sign associated with eye disease.	Contact with blood, other body fluids, or tissues of infected animals. Accidental inoculation through sharps injuries or by inhalation of droplets or aerosols. People may also become infected by mosquitoes or possibly from ingestion of raw milk.	Extreme caution should be taken when working with animals during epidemics. An inactivated vaccine has been used experimentally to protect veterinary and laboratory personnel at high risk of exposure. Enhanced barrier precautions, gloves, eye protection, and a minimum of N95 respiratory protection are strongly recommended when working with high-risk animals or their tissues. Universal precautions should be taken when obtaining and processing specimens from patients. Samples should be handled only in laboratories by trained staff and processed in suitably equipped laboratories. Control of the mosquito vectors and use of personal protection are important.
Rhodococcus equi • Gram-positive facultative intracellular bacterium	Horses, also found in feces of sheep and cattle	A problem with growing recognition, infections in immunocompromised people commonly lead to life-threatening chronic, progressive, granulomatous pneumonia. In contrast, infections are very rare in immunocompetent people and are typically less severe.	Regular contact with horses is a documented risk factor for infection, presumably through oral-fecal exposure via direct contact or droplets, although there is often no documented direct exposure to horses.	Immunocompromised people working with horses should adhere to good hand-hygiene protocols and routinely use protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.
Ringworm (*Microsporum* and *Trichophyton* spp.) • Fungi	Cattle, horses, dogs, cats	Characteristic circular, well-circumscribed, red lesions that are pruritic. In immunocompetent people, infection is limited to the keratinized layers of the skin and hairs. In immunocompromised people, infections may extend to deep tissues or become systemic.	Direct contact with lesions on affected animals or objects that have contacted affected areas.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Gloves should be worn whenever working with animals known to have dermatophytosis.

TABLE 46.3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible Through Occupational Exposures to Veterinary Personnel—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Salmonella enterica • Gram-negative bacterium	All species	Flu-like illness, gastroenteric disease, diarrhea or dysentery, septicemia.	Oral-fecal transmission through contact with infected animals, their environments, contaminated items or through ingestion of contaminated water or food.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Enhanced barrier nursing precautions are needed when working with clinically affected animals. Avoid eating or drinking near animals or their environments.
Staphylococcus aureus (methicillin resistant, MRSA) • Gram-positive bacterium	Horses, pigs, dogs, cats, other species	*S. aureus* commonly colonizes the anterior nares and other sites without causing clinical signs. Infections most commonly involve skin and soft tissues, either as a primary infection or by infecting cuts or other skin injuries, including sites of intravenous injection or catheterization. Infections of the respiratory tract and urinary tract are also noted. The risk of infection may be increased in immunocompromised people. Skin infections most commonly result in swollen, painful, erythematous lesions that can often be purulent.	Direct contact with colonized or affected animals; droplet or aerosol exposure to discharge from infected sites.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with horses or pigs. Enhanced barrier nursing precautions and gloves should be required when working with animals known to be colonized or infected. Cuts and abrasions should be kept bandaged and disinfected regularly.
Streptococcus suis	Pigs	Meningitis, septicemia, hearing loss, endocarditis, and arthritis.	Contact with pigs or their environments; infection risk is likely enhanced via skin wounds, mucous membrane exposure to blood or secretions from infected pigs, eating raw or undercooked pork products.	Protective clothing and gloves should be used when handling live pigs or carcasses. Strict hygiene should be observed when butchering pigs. Skin wounds should be kept clean, covered, and protected when working with pigs or carcasses. Avoid eating undercooked pork, especially in regions where *S. suis* zoonoses are common.
Vesicular stomatitis virus • Enveloped, single-stranded RNA virus	Cattle, sheep, goats, camelids, pigs, horses, other species	Infections in humans are very rare and typically result in flu-like symptoms. Less commonly, oral vesicles and cervical lymphadenopathy can be noted.	Mucosol exposure via direct, droplet, or aerosol exposures with clinically infected animals.	Enhanced barrier nursing precautions and gloves can be used when working with animals known to be colonized or infected. Eye protection and N95 respiratory protection may also be warranted when examining or treating lesions.

[a]This is not a complete list of all zoonotic diseases; less common diseases and those with vector-borne or solely foodborne routes of transmission are not included.

VetBooks.ir

In some situations, use of enhanced barriers, avoiding certain procedures, or avoiding specific patients might be indicated, but these are uncommon.

One potential weak link in the management of higher risk personnel is identification. Some individuals do not realize their increased risk, highlighting the importance of general infection control training to ensure that individuals can self-identify as higher risk. Higher risk individuals also need to be able to take precautions while reducing any concerns about stigma, privacy, and job security. Involvement of the person's physician (or an Occupational Health or Infectious Disease physician) may be indicated.

Intervention and Investigation of Outbreaks of Health Care-Associated Infections

An outbreak is defined as an increased occurrence of infection or disease above the expected baseline (endemic) level. Outbreaks are an ever-present risk in all health care facilities, veterinary or otherwise, and outbreaks will occur despite rigorous infection control protocols. As stated regarding surveillance, if HAIs are not being identified in health care settings, then methods are not sufficient to detect their occurrence. It follows that you cannot manage what you have not detected. The general principles of outbreak management are to contain the outbreak and reduce the overall impact on individual animals and the facility. It is critical to note that despite the stigma often attached to outbreaks, an outbreak of disease does not necessarily indicate poor management or malpractice. Making no attempt to identify HAIs, neglecting signs of a developing outbreak, or responding inappropriately to the spread of HAIs could all be construed as poor management and even malpractice. Thus there are many reasons why plans for a logical, aggressive, organized, and cooperative response should be developed before outbreaks have ever been identified. Consultation with internal and external experts in epidemiology, infectious diseases, microbiology, and infection control can be useful. It is unlikely that the person involved in coordinating the outbreak response will be an expert in all areas. Consulting others does not indicate a lack of ability on the part of the response team; rather, it indicates a logical approach to typically complex problems. It makes sense to consult with those who, through interactions at multiple facilities, have gained experience that usually cannot be obtained while concentrating on primary responsibilities as a clinician at a single institution. Ideally, these individuals are consulted early in the outbreak, and it may be prudent to develop contingency plans and contact consultants in anticipation of potential problems. The use of external consultants can be particularly useful because they can examine a situation and facility without the same degree of inherent bias that develops through experience and habit of regular daily practice in a facility.

One of the most important factors in outbreak intervention is early recognition of "clusters" of cases that may be related. Ideally, laboratory testing, clinical disease reporting, or syndromic surveillance will be used to aid in systematic efforts for early identification of suspicious clusters of cases. First-generation transmission—that is, transmission from the index case (directly or indirectly) to other animals—can be difficult to detect, particularly in situations where the index case is infectious prior to developing clinical disease. The most important control aspect related to the first generation of cases is prompt identification so that an outbreak can be recognized early enough to implement measures to reduce the risk of further transmission to a second generation of cases. Often outbreaks are not identified or addressed until multiple generations of transmission have occurred, thereby increasing the overall morbidity and mortality and complicating the response.

General principles of outbreak response include identification of the infectious agent, identification of infectious animals, identification of animals that have likely been exposed, determination of the mode of transmission, and prevention of further transmission by means such as isolation, implementation of barrier precautions, active surveillance, environmental surveillance, increased environmental disinfection, restriction of animal and personnel movement, and under extreme conditions minimizing new exposures through restricting admission of new patients.

While useful, initial intervention measures do not require definitive identification of the etiologic agent. In the absence of a confirmed etiology (i.e., recognizing a cluster of patients with diarrhea of unknown cause), outbreak intervention can still be performed using general infection control practices combined with knowledge of appropriate response regarding the most likely causes. General principles such as isolation of infected or affected animals and their direct contacts, use of barrier precautions, close attention to personal hygiene, restriction of animal and human movement, regular examination of animals and careful attention to cleaning and disinfection are important measures that are useful for most types of infectious disease outbreaks. Indeed, these measures alone will often constitute the full response even after an etiologic agent is identified.

Identification of animals likely to be shedding the agent responsible for the outbreak is critical. Definitive confirmation is not required, and a syndromic response is often better. For example, amid a *Salmonella* outbreak, it is wise to consider all animals with diarrhea, depression, or fever as likely to be infected and shedding bacteria even if culture results have been negative for some. The same is true for horses that develop fevers when others suspected of having herpesvirus myeloencephalitis or influenza are hospitalized in the same facility. This will result in some misclassification, but erring on the side of being overly sensitive in identifying infectious animals is more appropriate when trying to halt the spread of disease. The main problem with this type of response is imposing excessive strain on available resources (e.g., isolation stalls, personnel time) because of excessive misclassification.

Identification of potentially exposed animals is also critical. Depending on the pathophysiology of disease, these animals may or may not require segregation or isolation. For some pathogens, clinical disease precedes development of the infectious state, so exposed animals can be monitored and isolated if required. For example, horses exposed to *S. equi* consistently develop fever prior to shedding the organism;[78] as such, regular monitoring of body temperatures of exposed animals and prompt isolation of animals developing fever may be sufficient to prevent propagation of an outbreak. For many pathogens, screening of all potentially exposed animals can be useful. In particular, the use of rapid screening techniques that can provide a turnaround time of a few hours (e.g., antigen detection test for equine influenza, *S. equi* PCR) can be very useful. However, testing strategies should also include some use of culture so that whole organisms will be available to aid epidemiologic investigations. Sampling should be based on the pathophysiology of infection and disease (i.e., sampling when shedding is most likely to occur). Widespread screening of hospitalized animals will often be required to determine the extent of the outbreak and facilitate removal of infectious animals from the population. Therefore if imposed as a response to suspected spread of HAIs, it is essential that screening not be an elective procedure. As such, it is prudent for facilities to have previously considered how costs for diagnostic testing will be distributed in the event of suspected HAIs. Surveillance for shedding of specific contagious agents at the time of admission can facilitate prevention of outbreaks as well as intervention responses. In situations in which recently exposed animals do not necessarily develop consistent overt clinical signs or rapid diagnostic testing is not

VetBooks.ir

available, it may be necessary to segregate all potentially exposed animals, either in an isolation unit or in the main hospital.

Determination of the likely mode(s) of transmission is also required for initiation of an effective response. This is usually relatively clear based on the identity of the known or suspected pathogen. Regardless, all agents of concern for HAIs can generally be spread through contact and common vehicle (fomite) transmission, and thus controlling all methods of contact exposure to patients will be critical in response to suspected outbreaks. Although droplet transmission might be most important for respiratory agents, practicalities of cleaning hospital environments for large animals usually necessitates use of large volumes of water, which can also create hazards related to droplet transmission for other agents such those with oral-fecal transmission. As such, the potential for droplet transmission should also be tightly controlled in response to suspected outbreaks. Generally, only highly contagious viral respiratory agents such as influenza virus pose a true hazard for airborne transmission. However, in situations in which routes of transmission are not clear, it is prudent to assume the worst and manage the outbreak as if the pathogen is highly transmissible by multiple routes until proven otherwise.

Prevention of further transmission is obviously one of the most important goals of outbreak response. A variety of factors need to be considered to achieve this. In addition to identification of infectious animals, measures need to be established to prevent direct and indirect contact of these animals with other animals and the general hospital environment. Isolation and the use of barrier precautions can achieve this. The response to implemented infection control measures should be monitored closely to determine their adequacy, with an understanding that there is an inherent lag time from implementation of measures to control of the outbreak that is proportional to the incubation period for infectious diseases.

At times, partial or complete closure of the facility may be useful or necessary to protect patients that would be admitted in the future. Restricting new admissions decreases the number of newly susceptible individuals that might promote propagation of an outbreak. Further, if new infections appear to be occurring despite implementation of best control efforts, it is important to consider whether it is prudent or ethical to continue admitting new patients. It is also critical to consider the tremendous burden that can be necessitated by the need to deal with infection control measures and the possible effects on patient care. During outbreaks, stall space, particularly isolation space, may become limited, and decreasing the number of admissions facilitates depopulation of the facility for proper cleaning and disinfection. Clinical personnel are often overworked during outbreaks because of the number of ill animals, and excessive workload can contribute to breaches in disease prevention protocols. Although there may be reluctance among some people to restrict hospital admissions because of potential negative impacts related to public relations and finances, early, short-term closure of a facility to stem a small but developing outbreak is much better than a subsequent longer closure in response to a larger outbreak with more affected animals. A key component of facility closure is proper communication to staff and the public, emphasizing the proactive approach that is being taken to protect patients and clients and to prevent a major problem from developing. Regardless of whether it is deemed necessary to restrict admission of new patients, as described previously, whenever outbreaks of HAIs are suspected, it is critical to consider whether standard informed consent procedures suitably convey the risks associated with hospitalization to clients.

If environmental contamination is suspected of being widespread, complete depopulation of a ward or even the entire hospital may be necessary to allow for thorough cleaning and disinfection. The availability of multiple wards can facilitate this process, as individual problem wards can be closed and disinfected while allowing the hospital to remain functioning. Assuming that sensitive culture or other antigen detection methods are available, postdisinfection environmental screening may be indicated for certain pathogens (e.g., *S. enterica*) prior to reopening.

Although vaccination is often perceived as a cornerstone of infection control, the indications and limitations of vaccination must be considered. No vaccine confers protection to all vaccinated animals, and vaccination should never be used as a replacement for good infection control practices. A more appropriate perspective is that vaccination is principally useful when methods used to prevent exposures to infectious diseases have failed. Requiring vaccination prior to hospital admission is an area that has received limited consideration in large animal practices. Although vaccination requirements are difficult to enforce in animals admitted for emergency procedures, it may be reasonable for facilities to consider encouraging or requiring vaccination against relevant pathogens prior to admission for elective procedures. For example, requiring vaccination for influenza in horses or bovine viral diarrhea (BVD) in pregnant cattle prior to admission could decrease the risk of infection and transmission in hospitals. Problems that might be encountered with such an approach include the lack of relevant efficacy data for many vaccines, potential concerns regarding adverse effects with some vaccines, difficulty ensuring compliance, and competitive issues if all competing practices do not have the same standards.

Vaccination may be a useful intervention measure during some outbreaks, but the time lag between vaccination and protective immunity limits the potential role of most vaccines. Further, the efficacy of vaccines typically have not been evaluated in the face of outbreaks. It is important to remember that three possible outcomes are associated with any intervention, including vaccination: it may help, it may have no effect, or it may be harmful. For vaccination during an outbreak to be helpful in control efforts, the vaccine must be given to susceptible animals prior to exposure, must initiate a protective response before natural exposure, and must not be harmful when administered to animals that are incubating disease. These criteria are often difficult or impossible to meet during an outbreak. The greatest potential use for vaccination during an outbreak is likely intranasal influenza vaccination, since this type of vaccine can provide a rapid and effective immune response and is not contraindicated in exposed animals.

Infection Control Issues Related to Specific Pathogens

Although all contagious diseases have the potential to be important hazards for the health of individual patients, there is more empirical evidence on the importance of some diseases. Further, while safeguarding the health of veterinary personnel must be a priority for all veterinary practices, some zoonotic diseases have been shown to be of greater concern. Information follows on control of diseases of particular importance as hazards for HAIs and zoonotic disease.

Salmonella

S. enterica is the agent most commonly reported in association with outbreaks of HAIs and closure of large animal hospitals. In two different surveys of teaching hospitals at AVMA-accredited institutions, 20 of 38 (65%) and 6 of 20 (30%) participating institutions reported identifying epidemics of *Salmonella*-associated HAIs during the previous 5 years.[16,17] Many of these institutions had to restrict admissions or even close completely to facilitate management of the outbreaks. *S. enterica* is recognized as a pathogen around the world, and HAIs have been identified in many countries. However, the average risk among large animal patients varies tremendously

VetBooks.ir

among species, production practices, and even geographically within a country. In North America, the general risk of shedding is very low among animals raised in the northernmost regions and can be very high in warmer latitudes. All species are susceptible to infection, but large, intensively managed populations generally often have the highest prevalence of shedding, and the likelihood of shedding in patients while hospitalized is greatly influenced by the prevalence of infection in animals at home premises. Cattle and swine from large populations often have a higher likelihood of shedding compared with horses, camelids, and small ruminants. Given these factors that affected variability in infection rates, it is prudent for large animal hospitals to objectively assess the risk of shedding among their specific patient populations in order to appropriately adjust the rigor of surveillance and control efforts.

A notable number of patients shed *Salmonella* without evidence of associated illness, but infected patients are significantly more likely to shed if they show signs of GI illness or are systemically ill. Numbers of organisms shed per gram of feces are generally much greater in clinically affected animals. Animals known or suspected to be infected with *Salmonella* generally should be managed in isolation with strict barrier precautions and hand-hygiene protocols. Shedding tends to be more commonly detected in the summer and fall and may also be more common in warmer climates. Whereas outbreaks of HAIs are usually detected because of clusters of clinical disease, subclinical infections can be more common than clinical infections during outbreaks. Zoonotic infections in veterinary personnel have been commonly detected in association with outbreaks of HAIs. There is apparent variability among strains in virulence, infectivity, and ability to persist in the environment, and this strain variability may be a very important determining factor regarding outbreaks of HAIs. Environmental contamination near infected patients is the rule rather than the exception,[64] and active surveillance has shown that contamination can become disseminated to quite distant areas of the hospital from only a single infected patient. In one study, 12% of 452 environmental samples collected over 10 weeks in a nonepidemic period using electrostatic household wipes were positive for *Salmonella*.[76] Experience has shown that environmental contamination is even greater during outbreaks. In nonepidemic situations, there tends to be great variability in phenotypic markers (serogroup, serotype, and antimicrobial susceptibility) among isolates recovered from patients over time, which often makes it possible to differentiate isolates in epidemiologic investigations. In other situations, especially when certain strains are circulating actively in the region of a hospital, genetic analysis may be necessary in order to differentiate strains of *Salmonella* for purposes of epidemiologic investigations. Methods used in diagnostic laboratories for culture and molecular diagnostics are highly variable, which can significantly affect the reliability of assays. As such, veterinarians should seek out laboratories that are known to have optimized laboratory methods for use in diagnostic situations. PCR assays for *Salmonella* are available commercially at a number of laboratories. However, because of the importance of phenotypic and genotypic comparisons of isolates for epidemiologic investigations conducted as part of prevention and control efforts, PCR assays are not recommended for sole use in surveillance programs without parallel analysis using culture. Active surveillance programs are commonly used in large hospitals as a management tool to detect clinical and subclinical infections in large animal patients. In addition, environmental surveillance is sometimes used as an adjunct to detect environmental contamination. All common disinfectants are effective against *Salmonella* organisms under optimal conditions. However, the common association of *Salmonella* with fecal material, other organic matter, and dirt requires careful adherence to good cleaning (physical disruption of surface matter using detergents) and disinfection procedures in order to minimize the likelihood of environmental persistence. Mitigation in response to outbreaks of HAIs requires thorough decontamination of all environmental surfaces, which may be possible only after closure to new admissions, although disinfectant misting may be a useful alternative in some situations.[79,80]

Clostridium difficile

Although less commonly implicated in hospital outbreaks of diarrheic disease than *S. enterica*, *C. difficile* can be an important pathogen in horses and is often associated with outbreaks of neonatal diarrhea on breeding farms. *C. difficile* should be considered a differential diagnosis in horses with diarrhea and duodenitis-proximal jejunitis. Standard infection control methods used for salmonellosis should be adequate to control transmission of *C. difficile*, with the exception of disinfection. Because *C. difficile* is a spore-forming bacterium, sporicidal disinfectants (e.g., accelerated hydrogen peroxide, bleach) should be used after thorough cleaning. An additional albeit unsubstantiated concern is the potential for zoonotic transmission of *C. difficile* from horses or cattle to humans. The strains of *C. difficile* isolated from animals are often indistinguishable from those that cause disease in humans. Therefore animals infected with *C. difficile* should be considered potential sources of zoonotic infections in humans.

Cryptosporidium parvum

Cryptosporidiosis may be the most common zoonotic disease affecting large animal veterinary personnel. Although it usually causes self-limiting diarrhea in healthy individuals, cryptosporidiosis can be severe (including life-threatening) in certain immunocompromised populations.

Animals of all ages in a variety of host species have been shown to shed *C. parvum* oocysts, but the shedding prevalence is much greater in young animals, and the primary infection control hazard involves shedding by diarrheic neonates, especially calves. This is because of the extraordinary numbers of oocysts shed by affected young animals, the small infectious dose, and the hardiness of organisms. Affected calves can shed more than 10^7 oocysts per gram of feces during peak shedding, whereas humans and other animals can be clinically infected with fewer than 100 oocysts, although there does appear to be some difference among individuals as well as among strains. While there has been less study, *Cryptosporidium* also infects foals, and foal-human transmission has been documented in a veterinary hospital.[81] To further complicate control, oocysts are profoundly resistant to all disinfectants that can be regularly used in hospitals.

Because of the high prevalence of *Cryptosporidium* in calves, all calves should be considered a source of exposure, with additional concern about diarrheic calves because of the likely greater level of shedding. While less is known about foals, some degree of risk should be considered. It is very prudent to house diarrheic neonates in isolation and handle them with strict barrier precautions and hand-hygiene protocols. Personnel cleaning these housing areas should avoid using high-pressure water to minimize the risk of aerosol and droplet exposure. This is complicated by the inherent resistance of coccidian parasites to all disinfectants, which necessitates reliance on vigorous scrubbing with soap and rinsing with copious amounts of water in decontamination efforts. The likelihood of inadvertent oral exposures while cleaning can be reduced by using face shields or disposable masks along with gloves and fastidious attention to hand hygiene. Strict adherence to basic practices to prevent inadvertent oral exposure (e.g., good hand hygiene; preventing contamination of items such as clothing, pens, and cell phones) is critical.

Equine Rotavirus

Although outbreaks of rotavirus are fairly common on breeding farms, outbreaks in veterinary clinics are rare. Equine rotavirus

VetBooks.ir

is of most concern in facilities with a large neonatal caseload. Rotavirus may be shed in the feces of affected foals, clinically normal foals, and adult horses. Thus prevention of exposure is difficult. However, it is likely that clinically affected foals are the most common source of infection, through direct contact or common vehicle exposure. As a result, isolation of affected animals and the use of barrier precautions are the most important infection control measures. With the exception of disinfectants, protocols directed at control of *S. enterica* should be adequate for rotavirus control. Little specific information is available regarding the relative effectiveness of different disinfectants on equine rotavirus. However, as a nonenveloped virus, equine rotavirus should be expected to be resistant to environmental degradation and many disinfectants commonly used in veterinary medicine. While phenolics have been recommended in the past because of their better activity in the presence of organic debris, use of oxidizing agents such as accelerated hydrogen peroxide is probably better because of similar to superior effectiveness and a much lower potential for toxicity.

Bovine Viral Diarrhea Virus and Border Disease Virus

The closely related members of the genus *Pestivirus* are not commonly considered disease hazards caused by HAIs, but this may be more because of a lack of detection than a lack of occurrence. The main infection control hazard is related to exposure of susceptible pregnant cattle, sheep, goats, or camelids to persistently infected animals, which continuously shed large amounts of virus. The long period between infection of pregnant females and the birth of affected offspring complicates the ability to make relevant observations about the origin and frequency of HAIs. As such, it may be important to encourage or require vaccination of valuable pregnant cattle or alpacas prior to admission. In addition, animals known or suspected to be persistently infected should be managed in isolation with barrier precautions to minimize transmission. This includes neonates showing signs of congenital infection. Increased infection control precautions should also be used with animals from herds with a recent history of disease related to these viruses. Direct contact with persistently infected animals is an efficient method of transmission, but limited research shows that calves can be infected through contact with contaminated stalls and through droplet or aerosol exposure over a distance of at least 1.5 m.[82] Appropriate use of cleaning and disinfection methods should readily decontaminate the environment, and all common disinfectants are effective against these viruses under optimal conditions.

Strangles (*Streptococcus equi* subsp. *equi*)

An important aspect of *S. equi* control is identification and management of subclinically infected animals.[78] Syndromic guidelines for isolation upon admission (i.e., isolation when patients are admitted from farms with a recent history of clinical *S. equi* infections, or isolation of horses with fever of unknown origin or unexplained nasal discharge) can help in managing potentially infectious horses so that they can be isolated pending the results of screening. However, the ubiquitous nature of *S. equi* and the possibility that essentially any hospitalized horse could be a subclinical carrier mean that there is an ever-present likelihood of *S. equi* introduction into the hospital environment, and clinicians should be alert to history and clinical signs that may be indicative of previous infection in hospitalized horses. Screening and isolation of horses from farms with endemic *S. equi* is a reasonable control strategy. Nasal rinsing or guttural pouch lavage performed for diagnostic testing should be conducted only in facilities where drainage and aerosolized fluids can be contained, and thorough environmental cleaning and disinfection should be conducted before use with other patients. Standard infection control measures, including preventing direct contact of hospitalized animals, optimizing hand hygiene, using appropriate cleaning, and disinfection, should be useful for reducing the risk of *S. equi* transmission should a colonized horse be admitted. Prompt examination and isolation of horses developing fever of unknown origin during hospitalization can indicate which horses should be removed from the general population before the onset of bacterial shedding. Vaccination during an outbreak with vaccines that are currently available is not recommended because of a lack of proven efficacy and concerns regarding development of purpura hemorrhagica. There is also no evidence of a need to require vaccination of elective cases prior to hospital admission. *S. equi* is susceptible to all common disinfectants when used properly.

Equine Influenza

Influenza is one of the most contagious diseases affecting horses. Immunity is transient, and horses can be repeatedly affected during their lifetime. There is no carrier state, and maintenance in a population depends on transmission from one acutely infected horse to another. In horse populations aggregated at racetracks, shows, or other venues, attack rates can reach 15% to 30%.[83] The incubation period from exposure to onset of clinical signs is typically about 2 to 4 days, which commonly coincides with the onset of virus shedding, although viral shedding can sometimes start before the onset of clinical signs. Horses are often febrile and obtunded at the onset of disease. Paroxysmal coughing is a classical sign of influenza infection that develops in some horses as disease progresses. Because of its contagious nature, identification of multiple acutely febrile horses can be an early indication that influenza virus is spreading in the population. Rapid identification and confirmation of animals shedding virus allows initiation of efforts to minimize contagious spread. Antigen detection assays are commercially available and very useful for rapid confirmatory testing (e.g., Directigen EZ Flu A+B [BD Diagnostic Systems, Franklin Lakes, NJ]). However, this assay has limited sensitivity; virus shedding was detected in only approximately 30% of clinically affected horses during outbreaks using this assay, so tests should be performed on multiple clinically affected horses and interpreted in the aggregate for the population.[84,85] Negative test results for individual samples should be interpreted with caution because of the consequences associated with not using appropriate control measures during an outbreak of a highly contagious disease. Reverse transcription PCR (RT-PCR) tests are available and are likely more sensitive than antigen detection assays,[85] but there is limited published validation of the highly variable RT-PCR assays used in diagnostic laboratories. Influenza virus can be transmitted through aerosol, droplet, and contact transmission and can easily be transmitted over several feet in respiratory aerosols generated by coughing horses. As such, horses confirmed to be infected should be managed in complete isolation with full barrier precautions, paying strict attention to hand-hygiene protocols. Influenza virus can survive on surfaces at most for a few days in a cool, moist environment. As an enveloped virus, influenza is susceptible to damage from extreme environmental conditions and is readily inactivated by all common disinfectants if they are properly applied. Whereas clinically affected animals are the most likely to shed large amounts of virus, in nonaffected horses sampled during large outbreaks, seroconversion and virus shedding can be found in about 30% and 5% of the exposed populations, respectively.[83,84] As such, it is prudent to increase infection control precautions for all exposed but apparently unaffected horses in order to minimize risks of transmission. Early vaccination of all horses with intranasal vaccine may be of value in abbreviating the course of an epidemic. If new admissions are allowed when there is an elevated risk of influenza virus infection, horses should

VetBooks.ir

be required to be recently vaccinated with vaccines having proven efficacy prior to admission (preferably a minimum of 2 weeks prior to admission). Regardless of vaccination history, it is unwise to admit very young or immunocompromised horses when there is an increased risk of infection with influenza virus. Influenza virus is susceptible to all common disinfectants when used properly. Zoonotic risks of currently circulating H3N8 equine influenza viruses seem to be very low, but there is always some potential for infection.

Equine Herpesviruses

Equine herpesvirus types 1 to 5 are ubiquitous in horse populations and are highly contagious. EHV-1 and EHV-4 are the most widely recognized as important causes of outbreaks of disease in horses, and HAIs have been noted for both agents. EHV-4 infections are associated with contagious respiratory disease that principally affects horses under 3 years of age. EHV-1 is of greatest concern regarding HAIs. Infections are associated with respiratory disease, neurologic disease, peracute pulmonary vasculitis, abortion, and neonatal mortality in congenitally infected foals. The potential for contagious spread of herpesvirus myeloencephalitis was dramatically highlighted in 2011 when infections among horses at a horse show in Ogden, Utah, resulted in subsequent spread to documented clinical infections in 180 horses (29% with neurologic disease) on 63 premises located in 14 states and Canadian provinces, and subsequent euthanasia or death of 14 horses.[18,19] Documented spread of infections within hospitals as well as at the home premises of previously hospitalized horses further highlights the risk for HAIs with EHV-1.[8-10] Immunity is relatively short lived, and infections likely occur throughout the lives of horses. Many if not most of these infections are undetected or occur with only mild clinical signs. The most common clinical sequela of infection is mild respiratory disease during the first 2 years of life. More infrequently, EHV-1 infections can result in more severe complications such as abortions in pregnant mares or paralysis. All EHV-1 and EHV-4 infections originate in the respiratory tract, but epidemiologic evidence suggests that contact and droplet transmission among horses in relative proximity is much more common than aerosol transmission over greater distances. Fever is commonly the initial clinical sign exhibited by infected horses, and identification of multiple acutely febrile patients can be an early indication of nosocomial spread of equine herpesvirus in the population. Most horses can be shown to be latently infected with EHV-1 and EHV-4 by the time they reach adulthood, and subsequently any hospitalized horse might serve as a source of infection for other patients by recrudescing virus in response to stresses of disease, hospitalization, and transport. However, clinical experience suggests that EHV-associated HAIs most commonly originate from clinically affected horses. As such, rapid identification of animals suspected of being infected, isolation of affected horses with complete segregation of materials used in their care, and use of barrier precautions with appropriate hand-hygiene protocols are generally effective for minimizing risks for HAIs. All horses exhibiting ascending weakness, paresis, or paralysis should be suspected of EHV-1 infection and managed in isolation until the animal can be proven to have stopped shedding or another diagnosis is confirmed. Herpesvirus infection should also be promptly ruled out in horses with upper respiratory disease or fever of unknown origin. Use of PCR testing as an adjunct to thorough clinical investigation is often extremely useful for this purpose. Herpesviruses are enveloped viruses, and routine cleaning and disinfection procedures should be adequate for decontamination of surfaces, assuming that appropriate protocols are followed. PCR testing of nasal secretions is the most useful assay for rapid confirmatory testing. Serial testing of horses is useful for establishing that shedding has stopped because field data and study involving experimental infection have shown that shedding can be intermittent and negative results for individual tests must be interpreted with caution.[10] Although many laboratories offering PCR testing now provide information about the ORF30 genotype (D versus N, or sometimes labeled as "neurotropic" and "non-neurotropic" genotypes), both genotypes can cause neurologic disease, both genotypes of virus are contagious, and both genotypes can cause epidemics of disease. As such, this information should not affect the level of caution taken with infected or exposed horses.[86] Without adjunctive testing, infected horses should be quarantined for a minimum of 28 days after cessation of disease.[9,10] Using serial testing as a confirmatory adjunct, this quarantine period might be shortened to 14 days after cessation of disease.[10,86] Field data from one outbreak suggest that about 60% of horses can be shedding virus at the onset of clinical disease irrespective of the severity of clinical signs, and shedding can persist for 10 to 14 days after disease onset.[10]

EHV-3 is less commonly considered a problem regarding HAIs, but it has been noted to spread through contact with contaminated materials during reproductive procedures as well as between horses during coitus. As such, it is a notable hazard for practices that specialize in reproductive services. EHV-3 causes coital exanthema, a pustular disease affecting the vulva and vagina of mares and the penis and prepuce of stallions. Appropriate cleaning and disinfection of materials used in reproductive examinations, avoiding the use of examination sleeves and gloves with multiple horses, and rigorous adherence to sound infection control precautions for breeding populations should control the spread of EHV-3. The prevalence of latent EHV-3 infections is not well documented.

EHV-5 has been associated with equine multinodular pulmonary fibrosis (EMPF); however, the epidemiology of this disease has been poorly described. The risk posed by horses with EMPF is unclear, and healthy horses may also shed this virus, so optimal hospital preventive approaches are unclear.

Enveloped viruses, including all herpesviruses, are susceptible to all common disinfectants when used properly.

Methicillin-Resistant *Staphylococcus aureus*

MRSA is emerging as an important veterinary and zoonotic pathogen. In large animals, MRSA infections have been most commonly identified in horses, veal calves, and pigs. Transmission of MRSA between these species and attending personnel can occur, and MRSA colonization and infection appear to be an emerging occupational risk associated with large animal veterinary practice, particularly in northern Europe where livestock-associated clones (e.g., sequence type 398) are more common and nonzoonotic MRSA infections are rare. Transmission of MRSA is thought to mainly occur through direct or indirect contact between infected or colonized people or horses and hospitalized horses. Aerosol transmission from MRSA-contaminated dust is a concern in intensive indoor housing situations, particularly swine barns. The potential for droplet and airborne transmission in less intensive situations is unknown and may be limited. The largest problem related to HAIs with MRSA in large animals has been the infection and colonization of equine patients. Infections are principally noted at surgical sites and wounds, whereas colonization predominantly occurs in the nasal passages, although GI colonization has also been noted. If not identified by active surveillance, colonized horses can be silent yet prolific reservoirs for infection of humans and horses. Prevention of MRSA transmission requires careful attention to practices that prevent contact and common vehicle transmission, including use of good hand-hygiene practices, restriction of horse contacts and isolation of infected or colonized animals, and use of specific measures aimed at identifying carriers. All colonized or infected horses should be treated as infectious, housed in isolation, and handled with strict

VetBooks.ir

attention to contact barrier precautions. Screening by culture of nasal swabs collected at the time of admission can help control MRSA in areas where it is endemic in the community or the horse population; however, the need for routine screening varies depending on the facility, the MRSA prevalence in the patient population, and other factors. Although colonized personnel can be a source of infection of patients, staff screening is fraught with complex issues (e.g., privacy, occupational health) and is difficult to justify in the absence of an ongoing outbreak that is uncontrolled with improvement in routine infection control practices. Various studies have demonstrated high rates of MRSA carriage among equine veterinary personnel, so it is reasonable to assume that all equine facilities regularly have one or more colonized staff. For this reason, good attention to standard hygiene and infection control practices is critical. *S. aureus* is susceptible to most disinfectants if used properly.

Coxiella burnetii

C. burnetii is the causative agent associated with Q fever in people and coxiellosis in animals. Although most infections in humans are subclinical, personnel who contact livestock have a greater risk of infection and disease that can be severe and even fatal in a small portion of cases. It is also highly infectious, has a low infective dose, and can be transmitted through contact as well as by droplet and airborne routes. *C. burnetii* can be found in a variety of animal species, but zoonotic transmission is most commonly associated with periparturient ruminants (especially small ruminants) and aborted fetuses. Serum antibody tests, antigen detection assays, and PCR can be used to identify infected animals, but the sensitivity of these assays has been questioned. Because of the potential significance of clinical infections in humans, all attending personnel should be appropriately aware of the zoonotic potential and risks associated with Q fever.[28] The risk of serious clinical consequences should be noted by pregnant women, people with valvular heart disease, and those who are immunosuppressed. Medical histories for individuals and flocks should be considered to determine if there is an indication that *C. burnetii* may be a greater than average risk. Infection control measures that can be used to minimize hazards to people with a high risk of clinical infection include isolating periparturient small ruminants, paying strict attention to hand-hygiene protocols, using respiratory protection and barrier nursing precautions when handling potentially infected animals, and even excluding periparturient small ruminants from care. Particular care should be taken during parturition and when handling aborted fetuses and newborn small ruminants. For animals known to be infected, care should be used when cleaning and disinfecting stalls or other housing environments, and contaminated bedding and other materials should be handled cautiously. *C. burnetii* is susceptible to most disinfectants if used properly.

Antimicrobial Resistance and Antimicrobial Stewardship

Although antimicrobials are undoubtedly required for proper management of a significant percentage of hospitalized large animals, any use of antimicrobials creates some degree of selection pressure for antimicrobial resistance. This can be relevant on multiple levels, including resistant infections in individual patients, outbreaks of infections caused by resistant pathogens, and increasing the pool of resistant organisms and resistance genes in the horse population.[87,88] Of additional concern is the potential transmission of resistant pathogens to people or the less well understood potential for transmission of resistance genes from animal-associated pathogens or commensals to human pathogens.

Antimicrobial use is a required part of management of many veterinary patients. The need for access to a range of antimicrobials is critical for maintenance of the health and welfare of animals, economic production of food, food safety, and food security. However, the potential consequences of antimicrobial resistance on human and animal populations cannot be ignored in this era of antimicrobial resistance. There has been (and will continue to be) increasing scrutiny of antimicrobial use in animals, particularly livestock. All of these factors highlight the need for "antimicrobial stewardship," which is a coordinated approach to optimizing the use of antimicrobials and maximizing patient care while also minimizing the risk of resistance, toxicity, or other adverse events. It involves a multifaceted approach to determine *when* to prescribe antimicrobials; *what* drug, dose, and duration is appropriate, *how* antimicrobials are administered, and *whether* other approaches (e.g., surgery, wound care, management of underlying disease) can be used to complement or replace antimicrobials.

Veterinarians have practiced some form of antimicrobial stewardship for decades when making decisions about how and when to use antimicrobials, as well as through efforts to reduce the need for antimicrobials (e.g., preventive medicine). However, a more formal and comprehensive approach to antimicrobial stewardship is required.

Although veterinarians have practiced some form of stewardship, the overall field of antimicrobial stewardship is in its infancy in veterinary medicine. Fortunately, most aspects of antimicrobial stewardship are not complex, costly, or time consuming. There is no standard approach to antimicrobial stewardship, in part because of a lack of data but also because of the marked differences in needs, threats, and practical aspects between facilities. Some facilities may require few components while others (e.g., larger, tertiary care, greater prevalence of antimicrobial resistant pathogens) may require a more comprehensive program. Examples of potential stewardship practices are outlined in Box 46.4.

BOX 46.4

Prescribing and Other Practices That Can Be Used to Promote Stewardship of Antimicrobial Drugs

Antibiogram data collection and use
Cascading microbiology susceptibility reporting
Computerized decision support systems
Disease-specific treatment guidelines
Dose optimization
Formulary restriction with preauthorization
Computer-based identification of inappropriate pathogen-drug combinations
Improved diagnostics
Prescriber education
Prevention of treatment of noninfectious conditions
Prospective audit with feedback (clinician/service/facility)
Strategic microbiology results reporting
Therapeutic drug monitoring
Automatic stop orders
Checklists (e.g., surgical)
De-escalation and streaming
Surgical prophylaxis guidelines
Formulary restriction
Formulary restriction with authorization
Improved antimicrobial documentation
Intravenous to oral conversion
User (owner) education
Promotion of timely and appropriate microbiological sampling
Scheduled antimicrobial reassessments (antibiotic time-outs)
Targeted review for redundant therapy or therapeutic duplication

Management of Donor Animals

It is increasingly common to use animals owned by hospitals or veterinary personnel as donors for blood and ingesta (e.g., rumen fluid, equine feces) transfer to patients. Animals used for this purpose should be known to have a very low risk for contagious diseases (e.g., by virtue of their age, clinical status, facility origin), should be housed away from hospitalized patients, should be clinically healthy at the time of specimen recovery, and should be screened periodically for diseases that could be transmitted by use of transfer products. Diseases of concern that might be transferred by blood products from ruminants include bovine leukemia virus, bovine viral diarrhea and border disease viruses, and anaplasmosis; similarly, horses should be screened for equine infectious anemia infection. Bovine ingesta donors should be screened for Johne's disease *(Mycobacterium avium* subsp. *paratuberculosis)* and *S. enterica*, and equine fecal donors should be screened for *Salmonella* and potentially for other pathogens, such as *C. difficile*, equine coronavirus, and fecal parasites.

Prevention, Detection, and Response to Transboundary (Foreign) Animal Diseases

PAMELA J. HULLINGER, *Consulting Editor*
DANELLE A. BICKETT-WEDDLE

One of a private veterinary practitioner's most critical responsibilities is his or her role as the nation's front line of defense for detecting emerging, exotic, and transboundary animal diseases (TADs). TADs are important, transmissible diseases of livestock that are not present in the United States. If introduced, they would cause significant adverse economic or national animal, public, or environmental health consequences. Although many of these disease threats are known, new or "emerging" diseases may also impact the United States and affect human, animal, or ecosystem well-being. The U.S. Department of Agriculture (USDA) Animal and Plant Health Inspection Service (APHIS), Veterinary Services (VS) has primary responsibility for addressing foreign and emerging diseases of livestock and poultry and works closely with state animal health officials (SAHOs), private veterinary professionals, and the livestock industry to monitor for and to detect, control, eradicate, and mitigate the impacts of TADs on the livestock industries and the public. Box 47.1 shows a list of the diseases successfully eradicated from the United States. The *Code of Federal Regulations* (CFR), Title 9, part 53[1] details the federal government's list of reportable diseases of livestock and poultry and its policies and procedures for the diagnosis, appraisal, destruction, and disinfection of livestock and poultry infected with these diseases. The list specifically includes "Foot-and-mouth disease, rinderpest, contagious pleuropneumonia, Newcastle disease, highly pathogenic avian influenza, infectious salmon anemia, spring viremia of carp, or any other communicable disease of livestock or poultry that in the opinion of the Secretary constitutes an emergency and threatens the livestock or poultry of the United States."[1] In addition to the CFR reportable disease list, many states require the reporting of additional specific disease conditions. Additional diseases may include those of public health importance, such as equine encephalomyelitis, or other endemic diseases of industry concern, such as bovine trichomoniasis. Licensed veterinarians are responsible for maintaining a familiarity with the federal reportable disease list, as well as those of the states in which they practice. The reportable disease list for each state can be obtained through the office of the SAHO. States may also have more specific policies and procedures for the diagnosis, appraisal, euthanasia, and disinfection of livestock and poultry infected with such reportable diseases. Box 47.2 lists some reportable diseases of horses.

In an effort to create a standardized list of animal diseases, the U.S. National List of Reportable Animal Diseases has been proposed. This list, available at https://www.aphis.usda.gov/aphis/ourfocus/animalhealth/program-overview/ct_national_list_reportable_animal_diseases, is based on the OIE list while complementing the state reportable disease lists.

The World Organization for Animal Health or Office of International Epizootics (OIE)[2] is an international organization, representing more than 180 member countries, that seeks to provide leadership and guidelines to ensure transparency and solidarity in the management of the global animal disease situation. The OIE publishes health standards for international trade in animals and animal products, as well as criteria for the validation and certification of diagnostic assays. Policies and procedures that the federal government implements to manage the intrusion of TADs into the United States are often aligned with the OIE health standards and guidelines to help ensure the most rapid and efficient recovery of U.S. exports. Another equally important function of the OIE is to provide an early warning system for member countries to have rapid situational awareness and to act quickly to protect themselves when outbreaks of OIE-reportable diseases are confirmed in other member countries. More than 115 animal diseases are reportable to the OIE. It is important to remember that some of the domestic diseases that are present in the United States, such as bluetongue, are reportable to the OIE and have implications on U.S. trade with countries that are free of those diseases.

To protect the long-term overall health and viability of U.S. animal agriculture, any incursion of a TAD must be rapidly identified and controlled. In the United States, the goal is controlling the TAD outbreak with ultimate eradication and return to preoutbreak disease status. These TAD eradication efforts present significant short-term costs to affected industries, as well as the government and the public. In some cases these effects become long term, lasting for years, and industries may never fully recover. Most TAD incursions have significant economic costs associated with disease control and eradication efforts. Direct costs of disease control include paying personnel to manage and control the outbreak, indemnity costs (to buy diseased animals from producers for destruction), and the cost of necessary supplies and equipment for euthanasia, carcass management, and disinfection. In addition to these direct control costs, one of the most immediate consequences of a TAD occurrence in the United States would be the loss of export markets and disruption of normal industry business continuity in the United States. Indirect costs of TAD outbreaks result from control measures such as livestock movement restrictions and biosecurity that disrupt normal business continuity. These are likely to be the most significant economic costs. An example is the reduction or loss of income for a dairy

producer who is no longer able to ship raw milk across state lines to a milk processor due to movement restrictions. For all TADs, early detection and rapid application of situational awareness to assess the extent of the outbreak, followed by efficient implementation of necessary controls to limit further spread, will minimize the overall impact of the outbreak on the affected producers, the affected industries, and the U.S. economy as a whole.

The risk of a TAD incursion into the United States today is much greater than it has been in the past, for two main reasons. First, there has been a rapid expansion of international trade and travel. With a greater volume of people, animals, and animal products entering the United States on a daily basis, the opportunity for a TAD to be unintentionally introduced is much higher than previously. Second, in the wake of the terrorist attacks in the United States on September 11, 2001, there is heightened awareness and concern about the possibility of agroterrorism, or the deliberate introduction of a biologic agent targeting livestock for the purposes of inflicting economic damage and societal instability in the United States. Whether a TAD is intentionally or unintentionally introduced, the detection of the first case as soon as possible is critical to minimizing the overall impact of the resulting outbreak.

Private veterinary professionals need to be familiar with the clinical signs associated with TADs, especially those that can be easily confused with clinical signs of domestic or endemic diseases. When veterinary professionals are concerned about the possibility of a TAD in clients' animals, they need to contact a federal or state animal health official, who will consult with them on the history of the herd or flock. A Foreign Animal Disease Diagnostician (FADD) may be sent to examine the suspect animals and take and submit samples for testing at no expense to the producer or veterinarian. Testing will be prioritized by disease and level of concern. Both the livestock producer and private veterinarian should be contacted with regular updates as test results become available. Hundreds of TAD investigations occur annually in the United States, and fortunately most lead to the determination that a TAD is not involved. The TAD that goes undetected or unreported for some time because of lack of vigilance or reluctance to report will cause major economic harm to the livestock industry and the nation. Veterinary practitioners are encouraged to report a suspected TAD. It is better to investigate and rule out concerns. This not only tests the animal disease emergency response system to ensure that it is as efficient and effective as possible but could also prevent a catastrophic TAD outbreak.

U.S. Department of Agriculture National Veterinary Accreditation Program[3]

The USDA officially established the National Veterinary Accreditation Program (NVAP) in 1921 to provide a mechanism to enable private veterinary practitioners to work on behalf of the federal government to certify animals for certain types of interstate and international movement and to assist in controlling damaging animal diseases. The current mission of the NVAP is to provide accredited veterinarians with the information they need to ensure the health of the nation's livestock and animal population and to protect public health and well-being. NVAP's goal is to maintain the effective cooperation and use of private veterinary practitioners for regulatory work in a manner that is consistent with international trade requirements and enables the safeguarding of animal health. USDA's APHIS administers the NVAP. Participation in NVAP is voluntary and is not mandated by the federal government. Box 47.3 provides the eligibility requirements for a veterinarian planning to become accredited by the USDA. Accredited veterinarians participating in NVAP must carry out their duties according to the Standards for Accredited Veterinarian Duties described in CFR Title 9, Part 161.4. USDA veterinary accreditation is specific to a given state, so one needs to contact the USDA APHIS Veterinary Services District Office with oversight for the state(s) where he or she is practicing to obtain accreditation in that specific state. One requirement of the USDA for accredited veterinarians is prompt reporting of all suspected foreign animal and communicable animal diseases to state or federal animal health officials. Box 47.4 lists some of the clinical signs that should alert a private veterinarian that a TAD should be considered.

Accredited veterinarians are the backbone of U.S. regulatory programs for livestock and poultry diseases in the United States. The responsibilities of an accredited veterinarian are extraordinary. In fact, the United States depends extensively on accredited veterinarians for many official functions (e.g., inspecting, testing, and certifying animals for movement). Livestock producers who move animals domestically or internationally rely on the expertise of accredited veterinarians to help ensure that animals meet the requirements of the

VetBooks.ir

BOX 47.3

U.S. Department of Agriculture (USDA) NVAP Accreditation Eligibility Requirements

- Graduate with a doctor of veterinary medicine or equivalent degree.
- Licensed or legally able to practice veterinary medicine in the state in which accredited duties will be performed.
- Complete Initial Accreditation Training approved by Animal and Plant Health Inspection Service (APHIS).
- Complete an orientation program approved by the USDA Assistant Director for the state in which accredited duties will be performed, and document the training.
- Submit a signed application (VS Form 1-36A).
- Complete a state-specific orientation (if required by the state).
- Wait to perform accreditation duties until APHIS provides written approval.

BOX 47.4

Clinical Signs or Observations That Indicate a Foreign Animal Disease Should Be Considered

- Vesicles in oral cavity or around coronary bands
- Central nervous system signs
- Mucosal diseases
- Hemorrhagic septicemias
- Larvae in wounds
- Unusual (ornate) ticks
- High morbidity or mortality
- Unusual or unexplained illness or symptoms

destination and will not introduce diseases into the receiving state or country. The NVAP has served the animal industry well for many years and remains integral to the U.S. ability to trade internationally. There are currently more than 68,000 active accredited veterinarians in the national database, and these accredited veterinarians are instrumental in providing national capability to perform competent health certifications and to maintain extensive disease surveillance and monitoring. Today, more than 80% of all U.S. veterinarians are accredited and work cooperatively with federal and state animal health officials in NVAP.

The NVAP underwent changes to its overall process following the publishing of the Final Rule in the CFR in December 2009. As of 2010, NVAP has two species-based accreditation categories. Category I includes all animals except food and fiber species, horses, birds, farm-raised aquatic animals, all other livestock species, honeybees, and zoo animals that can transmit exotic animal diseases to livestock. Category II allows veterinarians to perform accredited duties on all animals. Category I veterinarians must complete three APHIS-Approved Supplemental Training (AAST) modules every 3 years; Category II veterinarians must complete six in the same time frame. Official AAST modules are offered free online (https://www.aphis.usda.gov/aphis/ourfocus/animalhealth/nvap/ct_aast), through presentations at state, regional, and national veterinary meetings (registration costs vary), or purchased as PDF files on a USB drive. Details about the NVAP can be found on the USDA APHIS website (http://www.aphis.usda.gov).[3]

Overview of Foreign Animal Disease Investigation and Response

Protecting the nation's livestock and poultry industries, and therefore a large segment of the U.S. agricultural economy from TADs, involves four basic principles or phases of emergency management: prevention, preparedness, response, and recovery. To be effectively executed, these phases require planning, cooperation, and communication among individuals, groups, and organizations at the local, state, tribal, regional, and national levels. Livestock and poultry owners; veterinarians in private clinical practice; industry groups; federal, state, tribal, and local governments; universities; veterinary diagnostic laboratories; and the consideration of public opinion and perception must all be included in emergency response preparation and planning. A response to a TAD outbreak will be carried out in accordance with the guidelines established by the National Response Framework (NRF) and using the National Incident Management System (NIMS) and the Incident Command System (ICS). Veterinarians who are interested in participating in either TAD emergency response or animal disaster response efforts, as either temporary employees or volunteers, must be familiar with these systems before an event occurs, in order to be effectively integrated into the response effort. There are both online and classroom-based training programs offered by federal, state, and local emergency response agencies to provide basic ICS training and certification. The Federal Emergency Management Agency offers several web-based, self-paced courses.[4]

Although the details of the clinical signs and epidemiology of the TADs themselves are discussed in detail in other sections of this book, many additional references and resources are available to practicing veterinarians to help them keep apprised of the clinical presentation and importance of these diseases, as well as to whom to report suspected cases. In the United States, veterinary students have access to the *Emerging and Exotic Diseases of Animals* web-based course that provides actual disease incursions, visual depictions of diseases, and the role of agencies involved in response. A portion of this course meets the USDA NVAP Initial Accreditation Training requirements. USDA also provides every U.S. graduating veterinarian with a copy of the "*Transboundary and Emerging Diseases of Animals*" text. The course and website are offered by the Center for Food Security and Public Health at Iowa State University,[5] along with a multitude of other resources available at: http://www.cfsph.iastate.edu. Another excellent resource is the text *Foreign Animal Diseases: "The Gray Book,"* revised in 2008[6] (available at http://www.usaha.org/upload/Disease%20Info/FAD.pdf).

Prevention and Preparedness

Early recognition of a TAD may be difficult because some domestic diseases seen by veterinarians have similar clinical signs or presentations (e.g., foot-and-mouth disease [FMD]). Some TADs may have mild clinical signs that could allow them to spread undetected for a period of time. Examples of both domestic and transboundary vesicular or ulcerative diseases, which may be difficult to distinguish clinically in cattle, are presented in Box 47.5. A similar list for small ruminants is provided in Box 47.6. The increased likelihood and severe consequences of an introduction of a TAD into the United States requires private veterinarians to be continually vigilant for unusual emerging animal health conditions or situations. This requires veterinarians understanding how TADs may manifest and what clinical signs they may possess. Participation in continuing education programs aimed at increasing awareness of the clinical signs and presentations of TADs can facilitate this necessary awareness. Education and awareness should also be extended to livestock producers and their employees who will likely be the first individuals to recognize an unusual problem in the herd or flock they work with daily.

An important component of the prevention programs for TAD incursions is USDA's implementation of policies and procedures related to the importation of live animal species or products into the United States. These import rules vary

by animal and product, as well as by country of origin. USDA monitors the OIE reports of the world animal health status and continually updates these importation requirements accordingly. These requirements may dictate the quarantine and possible testing of specified animal species for specific periods before animals are allowed to enter the United States. As of 2018, there were three animal import centers, located in New York, Miami, and Los Angeles, through which animals could legally enter the country. USDA port veterinarians at the importation stations are responsible for the examination of the animals, their identification, and evaluation of health certificates and permits for accuracy. If the requirements are not met or the animals are found to be diseased, the animals may be refused entry, sent back to their country of origin, or humanely destroyed. Once it has been determined that an animal is healthy, all the test results are negative, and all the requirements have been met, then the animal can be released to its owner and the state of destination is notified of the animal's movement into that state.

Detection

Historically, border controls and import procedures have been largely effective in keeping TADs out of the United States. There is always the possibility that a TAD could appear in the United States by either unintentional or intentional means. Illegal importation of animals and animal products via other channels poses a significant risk to U.S. agriculture. The responsibility for rapidly detecting, confirming, and effectively responding to incursions of TADs is primarily that of USDA APHIS in cooperation with livestock and poultry owners, veterinarians in private clinical practice, and SAHOs. An additional challenge for early detection of TADs is that few ongoing active surveillance programs exist that routinely test for TADs in targeted, high-risk livestock populations or in conjunction with screening for clinically indistinguishable domestic diseases in state or regional veterinary diagnostic laboratories. Because many of the TADs can mimic domestic diseases, a TAD may not be properly identified for some time if the condition is believed to be a domestic disease problem and if it is investigated with only that limited differential in mind. Even a single day's delay in identifying a TAD can result in significantly greater disease spread or economic impact owing to the large amount of daily livestock movement in the United States. Prompt reporting, investigation, and diagnosis can prevent a TAD from spreading further, can reduce the overall economic impact of the event, and can reduce the likelihood that the disease may become endemic in a wildlife or arthropod reservoir.

The most likely person to initially suspect a TAD is the producer or private veterinarian called by the producer to investigate an unusual disease condition. It is critical that any time a TAD is suspected, it is reported to state or federal animal health officials for expedited investigation and testing as needed. The SAHO and federal veterinarians working for the USDA routinely work to increase awareness of such conditions and reporting information among the state's private veterinarians and livestock producers. These activities require the support and assistance of state and university veterinary diagnostic laboratories, the Cooperative Extension Service, state and federal meat and poultry inspection services, universities, animal scientists, market operators, livestock and poultry producers, and private veterinarians.

For TAD outbreaks to be detected quickly, any suspicious signs or situations indicative of a TAD must be promptly reported to a state veterinarian and the USDA federal veterinarian for the state where the animal resides so that a TAD can be confirmed or ruled out. Private veterinarians are knowledgeable regarding the occurrence of various domestic animal diseases in their practice area and the history of such diseases on their clients' farms and ranches. This type of historical information and a herd's vaccination and animal movement history are critical to assessing the likelihood of a suspected TAD. Working with the herd veterinarian and the producer, the investigating state or federal, specially trained, FADD will use the herd history and clinical investigation to assess the likelihood that the situation involves a TAD and to determine the appropriate sample(s) to collect, the method of sample delivery, and what precautions must be taken at the site while test results are pending. Samples are submitted to the National Veterinary Services Laboratories (NVSL) in Ames, Iowa, or to the Foreign Animal Disease Diagnostic Laboratory (FADDL) at Plum Island, New York, to confirm the presence or absence of a TAD. On the basis of initial TAD investigation findings, often before the laboratory has completed testing of the samples, state and federal officials in the affected state may take action to quarantine affected animals at the site of the suspected case, increase surveillance in the area, and initiate steps to gather further information to assess the situation and characterize and control the outbreak if necessary.

In the United States, select laboratories that are members of the National Animal Health Laboratory Network (NAHLN) under USDA Veterinary Services Memorandum 580.4 have been trained and proficiency-tested to run tests for TADs. With the permission of the NVSL Director, the SAHO, and the USDA Assistant District Director, these select NAHLN laboratories may run designated tests in parallel with NVSL or FADDL. When approved, this parallel testing process can provide more timely "preliminary" results, which may facilitate local decision making. At present, assays for FMD, HPAI (highly pathogenic avian influenza), and END (exotic Newcastle Disease) have been successfully deployed to some NAHLN laboratories for use in national surveillance programs.

VetBooks.ir

Response, Management, and Control

A TAD response will be conducted according to the guidelines set forth in the NRF. This response framework incorporates best practices and procedures from various emergency management disciplines. It integrates them into a unified structure that forms the basis of how the federal government coordinates with state, tribal, and local governments and the private sector during all national response incidents including animal disease outbreaks. Under the NRF, the USDA is the lead agency coordinating the protection of agriculture and natural resources. All national responses are conducted in accordance with NIMS, which established a national emergency response framework to allow local, state, tribal, and federal agencies to more efficiently and quickly work together in an emergency. The NIMS uses the ICS to organize the response. The ICS is designed to be expandable and to meet the needs associated with incidents of all sizes, to allow individuals from a variety of agencies to meld more efficiently into a common management structure, to be cost-effective by reducing duplication of effort, and to provide needed logistic, administrative, and operational staff. There are five main management functions in the ICS: incident command, operations, planning, logistics, and finance. Most veterinarians work in the operations or planning sections during a TAD response. The operations section is where the bulk of the tactical field work is conducted, such as diagnosis, biosecurity, surveillance, disinfection, and depopulation.

Once a TAD has been confirmed by the USDA, the notification and coordination process for all involved parties begins. This includes international, federal, state, tribal, local, industrial, and public stakeholders. Conference calls, electronic notification, and press conferences may be used to communicate key messages. In addition, if agroterrorism is suspected, the Federal Bureau of Investigation and the Department of Homeland Security will be involved in the response efforts. If a zoonotic disease is suspected, the Centers for Disease Control and Prevention and state and local public health departments will also be involved. Federal officials will notify the OIE of the situation so that the international communities are made aware of the change in the nation's animal health status. Throughout the response, the goal will be to maintain accurate, timely communications regarding the status and progress of the eradication efforts.

Once the diagnosis of the initial case is confirmed, more information must be gathered to determine the true magnitude and extent of the situation. The species affected, history of the diseased herd or flock (including recent animal movements), and stage of disease in the affected animals will provide valuable information regarding the likely extent of disease. Outbreaks can be large or small, simple or complex, and localized or widespread. Timely development of situational awareness will be critical for mobilizing the necessary resources to effectively respond to the situation.

Tactical measures or procedures used to control an outbreak may include quarantine and/or animal movement restrictions; biosecurity; epidemiologic investigations; surveillance for disease in surrounding areas; vaccination, depopulation, or treatment of affected animals; carcass disposal; disinfection; vector control; and education campaigns. The exact approach to control will vary by disease, affected region, and extent of the outbreak. In rare cases, federal and state resources will be sufficient to respond to and control the situation quickly. However, if the outbreak is large or widespread, it will require the use of additional personnel resources.

In the past, when APHIS VS required temporary personnel to assist with disease eradication, it used the National Animal Health Emergency Response Corps (NAHERC),[7] a roster of preregistered private veterinarians and animal health technicians, to assist with the control efforts. USDA plans to phase out NAHERC, but there are numerous opportunities at the local and state level to become trained and part of a response. Private veterinarians may be enlisted to examine herds or flocks for clinical disease, vaccinate animals, collect laboratory samples, perform necropsies, collect epidemiologic data, and euthanize infected animals. During the United Kingdom's 2001 FMD epidemic, many private veterinarians found that their practices had little business because their clients stopped using routine services as a precaution to reduce the chances that their farms would become infected. In other situations, veterinarians found that their clients' animals were lost (depopulated) as a result of disease control efforts. In many cases, these private veterinarians joined the U.K. FMD task force as temporary veterinary inspectors (TVIs) working on behalf of the British government to assist in the control of the epidemic. Veterinarians in the United States who may be interested in participating in an animal health emergency should contact the office of the SAHO for more information.

Business Continuity

TADs can have devastating effects on the animals, livestock industry, and U.S. economy. Eradicating the disease without destroying the industry is complex. The goals of a USDA response are to detect, control, contain, and eradicate the TAD in a manner that stabilizes animal agriculture, the food supply, and the economy while protecting public health and the environment. Another goal is to facilitate business continuity for noninfected animals and their products. The 2014-2015 highly pathogenic avian influenza demonstrated how science and risk-based approaches could be used to achieve this using the guidance in the Secure Poultry Supply Plans. Similar plans have been developed for FMD response for the dairy, beef, and pork industries. More information about the livestock Secure Food Supply Plans can be found at www.securemilk.org, www.securebeef.org, and www.securepork.org. Opportunities exist for veterinary practitioners to help their clients prepare ahead of an outbreak to protect their animals and livelihood.

Recovery

The goal of recovery is to return the nation to a status equal to or better than what existed before a TAD outbreak. Full recovery can be a long and arduous process. Recovery activities include payment for animals and materials destroyed for disease control purposes, successful decontamination, clean-up and restocking of affected premises, renegotiation and reestablishment of international trading status, and government and industry's reassurance to consumers and the public that the outbreak has been managed successfully. The OIE's Terrestrial Animal Health Code sets the minimum standards that guide when a country may recover its disease-free status. The OIE standards, which are a key component to the resumption of international trade, serve to reassure the international community that trading with a previously affected country is now safe.

The ultimate cost of an outbreak for a country, its producers, affected industries, and the public can be quite high. Many indirect costs and impacts beyond those to the directly affected industries can be significant yet difficult to quantify.

Future of Foreign Animal Disease Detection and Response

A comprehensive review of the national framework for addressing animal diseases was conducted by a committee assembled by the National Academies and published in 2005.[8] The committee's findings and recommendations support the compelling need for significant changes to create a new future for animal health in the United States. Some of the key findings

VetBooks.ir

included the need for new tools for detection, diagnosis, and risk analysis and the expansion of the NAHLN's capabilities for both routine and emergency diagnostics. A report by the National Academies in 2012 described the many accomplishments of NAHLN as a timely surveillance and diagnostic component of early transboundary disease detection since its creation in 2002.[9] Another improvement to diagnostic capabilities and research is the National Bio and Agro-defense Facility (NBAF), which is currently under construction, with the goal of being operational in December 2022.[10] This state-of-the-art laboratory will replace the aging facilities at Plum Island and further enhance laboratory and discovery capabilities.

In 2005, the National Academies committee concluded that animal health has broad implications, ranging from the health of individual animals and the well-being of human communities to issues of global security and the adequacy of the global food supply. Planning carefully for the future is a significant need. That remains unchanged today. Given the changing nature of the risks to animal health in this country, it is unlikely that the current philosophy on how to protect animal health will be adequate in the future.

Extraordinary changes including continued globalization will continue to present new threats to U.S. agriculture and necessitate the continued vigilance of the veterinary and agricultural communities. Although state and federal governments are working to provide more targeted, active surveillance programs, private veterinary practitioners, who on a daily basis provide health care to the national herd, will remain the core of the nation's early warning system for TAD surveillance. Therefore their awareness of TADs and willingness to serve in the critical role of being part of the nation's early warning system for TADs will continue to be a cornerstone of national defense against the intrusion and devastating impact of such diseases.

Current Concepts in Equine Vaccination and Infectious Disease Control

Nicola Pusterla • W. David Wilson

General Considerations

Programs for controlling infectious diseases are important components of management practices directed toward maximizing the health, productivity, and performance of horses.[1] Infectious disease in an individual horse or outbreaks of infection in a group occur when horses experience challenge with an infectious agent at a dose sufficient to overcome resistance acquired through previous natural exposure to the disease or through vaccination. For this reason, programs for controlling infectious diseases should have the following three goals:

1. To reduce exposure to infectious agents in the horses' environment
2. To minimize factors that diminish resistance
3. To enhance resistance through the use of vaccines (vaccination alone cannot be expected to prevent disease; management practices must reduce the challenge from infectious pathogens)

The incidence of infectious disease in horse populations tends to rise with an increased number and stocking density of susceptible horses at a facility, with movement of horses on and off the facility, and with favorable external environmental and management influences. Other factors that influence the risk of acquiring infection and developing disease include the age, type, breed, gender, and use of the animals; geographic, climatic, and other environmental factors; facilities' layout and management practices; and history of exposure to or vaccination against individual diseases.

The conditions on breeding farms, in performance and show horse barns, and at racetracks are ideal for introduction and transmission of infectious diseases, particularly those of the respiratory tract. On breeding farms, the introduction and commingling of horses of various ages and origins and the high proportion of young susceptible horses and pregnant mares create a situation that poses special problems and demonstrates some important considerations in the practice of disease control. The risk of acquiring infection can be reduced by maintaining distinct groups by age and function. Resident mares and foals should be kept separate from weanlings, yearlings, horses in training, and visiting mares. Visiting mares and other horses entering the farm should have a negative test result for equine infectious anemia (EIA) virus, either by enzyme-linked immunosorbent assay (ELISA) or the Coggins AGID test, and should be appropriately vaccinated and dewormed before arrival. They should be received and maintained in barns and paddocks separate from the resident farm population. Preferably, a specific group of caretakers should attend to incoming horses, and footbaths, separate equipment, and a clean change of coveralls and boots should be used.

New arrivals should be quarantined for 30 days and monitored for signs of contagious disease. The rectal temperature should be recorded at least once daily, and any prophylactic procedures not done before arrival should be performed. Foaling mares being sent to a distant breeding farm for breeding should be transported 6 to 8 weeks before foaling; this permits timely exposure to resident pathogens at the destination farm, which allows the mare's immune system to mount a response and concentrate antibodies in the colostrum to improve passive protection to specific pathogens of the foal. Mares being shipped short distances for breeding can be transported during estrus and returned to the farm on the same day to reduce the risk of the foal acquiring infection.

Regardless of the type of equine facility, any horse that becomes ill with a possibly contagious disease should be isolated, preferably in an air space separate from the remainder of the herd, for at least 10 days beyond complete abatement of clinical signs. Separate equipment should be used, and if a separate group of caretakers is unavailable for these animals, workers should always complete their work with healthy horses before handling sick horses. Caretakers should wash their hands and boots thoroughly between horses and wear different outer clothing or coveralls. Stalls that have housed sick horses should be cleaned thoroughly, disinfected, allowed to dry, and left empty as long as possible. This approach is particularly important in dealing with organisms such as *Streptococcus equi* subspecies *(S. equi)* that can survive in a protected moist environment for several weeks.[2]

In most equine enterprises, vaccination is important to the overall management program for controlling infectious diseases. No "standard" vaccination program can be recommended for all horses; each situation must be evaluated individually by weighing the risk of acquiring infection and the medical and economic consequences of infection against the cost and expected efficacy of the product or products being considered for inclusion in the program, as well as their potential for inducing adverse reactions. Cost should include expenses incurred and money lost during the time the horses are out

VetBooks.ir

of competition, labor and medication expenses if the animals develop clinical disease and require treatment, and the expenses in time, labor, and vaccines required for proper immunization. The client's expectations should be realistic, and the veterinarian should explain the following points carefully:

- Vaccination minimizes the risk of infection but does not prevent disease in all circumstances.
- The primary series of vaccines and booster doses should be administered appropriately before likely exposure.
- Horses in a population are not all protected equally or for an equal duration after vaccination.
- Whenever possible, all horses in a herd should be vaccinated on the same schedule; this simplifies record keeping, minimizes replication and transmission of infectious agents in the herd, and optimizes herd immunity by protecting those animals that responded poorly to vaccination.

A properly administered licensed product should not be assumed to provide absolute effective protection during any given field epidemic. Copies of the vaccination and health maintenance records should accompany each horse leaving the facility for sales, training, or breeding. Similarly, owners of equine facilities should establish prerequisites for vaccination of all horses entering the facility and request that copies of the vaccination records accompany those horses.

Client expectations and the goals of disease control programs vary considerably. In performance horses, the general goal is to minimize time spent out of training and thereby maximize earning potential. In this case, an enforced period of rest owing to infectious disease has much more profound economic consequences than a similar recommendation for a barren broodmare or backyard horse. On the other hand, many owners of backyard horses diligently vaccinate against even low-risk diseases, despite the expense involved, to keep their horses healthy.

Only federally licensed vaccines should be used, and strict attention must be paid to the manufacturer's recommendations for storage, handling, and routes of administration to maximize the product's efficacy and safety. However, research or clinical experience may support alternate protocols for vaccination that will improve the vaccine's efficacy without increasing adverse effects. The length of time necessary to induce a protective immune response should be considered in relation to expected exposure. When inactivated (killed) vaccines are administered by intramuscular (IM) injection, for example, optimal protection is generally not achieved until 2 to 3 weeks after completion of the primary series, or 1 or more weeks after administration of a booster dose. Inactivated vaccines administered intramuscularly generally induce a greater serologic response when an initial series of three doses is given rather than the two-dose series recommended by most vaccine manufacturers. Whereas a 3- to 4-week interval between the first and second doses of vaccine is generally appropriate, a longer interval of 3 to 5 months between the second and third doses appears to optimize priming of the immune system and protection.

The primary role of authorities charged with licensing vaccines in North America has traditionally been to ensure vaccine purity and safety, with less emphasis placed on documentation of efficacy.[3-5] Consequently, little published information was available in the past documenting the efficacy of most vaccines licensed in North America. The situation has improved substantially in recent years, to the extent that published efficacy data are available for almost all equine vaccines licensed in North America since 1999. Field experience and some experimental evidence suggest that the efficacy of vaccines directed against different diseases varies considerably and that efficacy also varies among the vaccines from different manufacturers directed against the same disease.[6-8]

Vaccination is unlikely to confer protection more durable than that produced by recovery from natural disease, especially when the route of vaccination (usually IM) is different from the route of natural infection; this is because vaccines frequently do not evoke the full array of protective immune responses induced by natural infection.[9,10] For example, the efficacy and durability of protection induced by parenteral vaccines against respiratory tract pathogens are frequently questioned.[4,5,10] In part, this reflects the fact that parenterally administered vaccines are generally poor inducers of the local mucosal immune responses that are important for effective protection against infection of the respiratory tract.[4,9,10] In addition, immunity achieved after natural infection with some respiratory tract pathogens is short lived.

Considerations for Use of Vaccines in Broodmares

The primary goals of vaccination programs for broodmares are (1) prevention of diseases that pose a risk to the mare or her fetus and (2) maximizing the level of colostral antibodies that will be passively absorbed by the neonatal foal after nursing, thus providing it with protection against diseases that pose a risk during the first few months of life. Additional considerations in selecting vaccines for use in pregnant mares include (3) safety to the mare and fetus, (4) the potential for interference between multiple vaccines administered simultaneously, and (5) the influence of pregnancy on vaccine responses.

PROTECTING THE MARE AGAINST DISEASES THAT POSE A RISK TO THE MARE OR HER FETUS. Broodmares are at risk of exposure to the same diseases as performance and pleasure horses, so they should be regularly vaccinated against all core and specific risk-based diseases according to published recommendations. The high horse traffic and high concentration of foals and young horses that typify many breeding farms contribute to a high risk of exposure to contagious respiratory diseases, including equine herpesvirus (EHV)-4, EHV-1, influenza, and strangles. Inclusion of influenza in vaccination protocols for broodmares is routinely recommended, and addition of EHV-4 and strangles vaccines is frequently recommended when conditions of significant risk are anticipated. Vaccination of mares against equine viral arteritis (EVA) before breeding may be indicated when they are to be bred to a known or suspected EAV carrier stallion, by either natural cover or artificial insemination. Whereas protection of the broodmare, fetus, or herdmates against the abortifacient effects of EHV-1 or EAV is the primary goal underlying inclusion of these antigens in vaccination protocols for broodmares, the goal of protecting the foal features at least as prominently in the rationale for vaccinating mares against tetanus toxoid, West Nile virus (WNV), eastern equine encephalitis (EEE) virus, western equine encephalitis (WEE) virus, rabies virus, equine influenza virus, equine herpesvirus-1 (EHV-1), EHV-4, and *S. equi*. Inclusion of rotavirus and botulism vaccines in protocols for pregnant mares is directed almost exclusively at protecting the young foal against these diseases.

MAXIMIZING MATERNALLY DERIVED ANTIBODY TRANSFER. Maintaining consistent broodmare vaccination protocols, which typically include administration of booster doses of vaccines during the last 2 months of gestation, will not only protect the mare but also maximize the likelihood that a uniformly high level of maternally derived antibody (MDA) transfer and passive protection will be achieved within the foal crop. This is particularly important for diseases that pose a risk to the foal during the first few weeks of life. Whereas intranasally administered vaccines may afford good protection to the mare, they are typically less effective than parenterally administered inactivated vaccines in stimulating high levels of circulating immunoglobulin (Ig)G, the isotype that is passively transferred to the foal in highest concentration. Parenterally administered

VetBooks.ir

vaccines are preferred over intranasally administered vaccines for vaccination of mares during late gestation.

VACCINE SAFETY IN BROODMARES. Consideration of vaccine safety in broodmares must take into account risks to the pregnancy and safety to the fetus. Potential adverse effects of vaccines on pregnancy are difficult to document even when large numbers of mares are used, unless obvious problems occur. Because fetal organogenesis occurs early in gestation, and this period is also characterized by substantial embryonic loss, even in normal mares it is sound practice to avoid administering vaccines to mares during the first 60 days of gestation unless conditions of imminent risk prevail. Few vaccines carry specific label recommendations for use in pregnant mares, and little published data exist to specifically document the safety of equine vaccines during pregnancy. Licensed vaccines that carry label recommendations for use in pregnant mares include two inactivated EHV-1 vaccines (Pneumabort-K+1b [Zoetis, Parsippany, NJ] and Prodigy [Merck Animal Health, Madison, NJ]) marketed for use in pregnant mares as an aid in prevention of EHV-1 abortion, the Calvenza line of inactivated influenza (Calvenza-03 EIV [equine influenza virus]), EHV-1 (Calvenza EHV), and influenza/EHV-1 combination (Calvenza-03 EIV/EHV) vaccines from Boehringer Ingelheim (Ingelheim am Rhein, Germany), one multivalent vaccine (Vetera Gold) from Boehringer Ingelheim containing Eastern and Western Encephalomyelitis virus, WNV, tetanus toxoid, EHV-1, EHV-4 and equine influenza virus, one inactivated *Neorickettsia risticii* vaccine (Equine Potomavac [Merial, Lyon, France]), one vaccine licensed for prevention of type B botulism in foals (BotVaxB [Neogen, Lansing, Mich.]), and one *Leptospira pomona* vaccine (LEPTO EQ INNOVATOR [Zoetis]) for the prevention of leptospiremia. One conditionally licensed vaccine (Equine Rotavirus Vaccine [Zoetis]) for prevention of rotavirus infection in foals is labeled for use in pregnant mares. Although not specifically labeled for administration during pregnancy, widespread use in practice over many years has failed to document that any of the inactivated vaccines currently marketed for use in horses pose an unacceptable risk to pregnant mares. Therefore pregnant mares are routinely vaccinated with inactivated vaccines directed against tetanus toxoid, EEE virus, WEE virus, WNV, equine influenza virus, EHV-4, *Streptococcus equi* and, to a lesser extent, *Neorickettsia risticii*, rabies virus, and Venezuelan equine encephalitis (VEE) virus. Similarly, adverse impacts on pregnancy have not been documented for modified live, intranasally administered *S. equi* (Pinnacle I.N. [Zoetis]) and equine influenza virus (Flu-Avert [Merck Animal Health]) vaccines or the modified live, parenterally administered EHV-1 vaccine (Rhinomune [Boehringer Ingelheim]). Safety of the recombinant WNV and influenza vaccines (Recombitek [Merial]) should not be a significant concern, because the modified live canarypox vector lacks the ability to infect mammalian cells. In addition, the equivalent canarypox-vectored influenza vaccine (ProteqFlu [Merial]) marketed in the United Kingdom is labeled for use during pregnancy. Although the *Flavivirus* chimera WNV vaccine (PreveNile [Merck Animal Health]) was not specifically labeled for use during pregnancy while it was on the market, more than 300 pregnant mares were vaccinated during safety trials for licensing, without apparent adverse effects on the conceptus. In contrast, modified live virus (MLV) VEE vaccines and live anthrax spore vaccines should not be used in pregnant mares. Protection of mares against the potential abortigenic effects of EVA infection is best accomplished by completing the primary immunization series before the mare enters the broodmare band and by administering subsequent boosters during the open period before rebreeding.[11]

The practice of booster vaccinating mares against multiple equine pathogens to maximize colostral transfer of antibodies to the foal results in the typical broodmare receiving multiple doses of many vaccine antigens and adjuvants during her lifetime. In addition to stimulating high levels of antibody against a range of antigens, this practice may also predispose these mares to a higher rate of local and systemic adverse reactions, an issue that not only warrants further investigation but may force horse owners and veterinarians to carefully consider strategies for revaccination.

POTENTIAL INTERFERENCE BETWEEN MULTIPLE ANTIGENS ADMINISTERED CONCURRENTLY. The possibility that "competition" between multiple antigens will compromise the response to some or all of the administered antigens should be considered. When administration of multiple vaccines late in gestation is indicated, it is good practice to administer no more than four antigens at one time and to allow an interval of 3 to 4 weeks between administering different vaccines.

INFLUENCE OF PREGNANCY ON VACCINE RESPONSES. It is widely assumed that pregnant mares are fully capable of mounting appropriate cellular and humoral immune responses to vaccines, but this issue has received little research attention. Mares that have been primed before breeding appear to mount appropriate anamnestic responses to vaccines, but preliminary data suggest that the humoral response to primary vaccination with several inactivated vaccines, including WNV and rabies virus, may be downregulated during gestation, resulting in failure of some vaccinated mares to passively transfer specific antibodies to the foal via colostrum.

Vaccination of Foals and Influence of Maternal Antibodies on Vaccine Responses

MDAs and perhaps other immune effectors (e.g., lymphocytes) that are concentrated in colostrum and are passively transferred to the foal play a crucial role in defense against pathogens encountered during the first few months of life while endogenous immune function continues to mature. Passive transfer of MDAs should therefore be exploited in immunization programs for foals by consistently administering booster doses of selected vaccines to mares 4 to 8 weeks before foaling and by ensuring that foals ingest adequate amounts of high-quality colostrum within 24 hours of birth. Besides passively protecting the foal, MDAs may also exert a profound inhibitory effect on the active immune response of the foal to antigens, including those contained in vaccines. This phenomenon is known as *maternal antibody interference*.

Several studies reported during the 1990s brought this issue into focus by demonstrating that foals younger than 6 months of age consistently failed to mount serologic responses to inactivated influenza vaccines.[12-18] Of potentially greater concern was the finding that a high proportion of foals vaccinated under the cover of MDAs not only failed to seroconvert in response to the recommended primary series of two or three doses of influenza vaccine but also failed to respond to multiple additional doses administered during the next year, suggesting induction of a potentially detrimental immunotolerance-like phenomenon.[15,16,19] Our studies confirmed an apparent lack of response of foals to multiple doses of inactivated influenza vaccines when the hemagglutination inhibition (HI) test was used to detect serologic responses, but responses were detected when the same samples were assayed using a sensitive isotype-specific ELISA. Rather than representing true tolerance, it appears MDAs may cause misdirection of the immune response away from the more important virus neutralizing IgGa and IgGb subisotypes in favor of the less effective IgG(T) subisotype of IgG.[12] Subsequent studies in which titers of total rather than antigen-specific IgG subisotypes were determined documented that the age-related increase in concentrations of IgGb lagged significantly behind increases in concentrations of other isotypes and remained below adult levels beyond 6 months of age.[20]

VetBooks.ir

Maternal antibody interference has now been documented to be a significant issue for many other antigens, including tetanus toxoid, EEE virus, WEE virus, EHV-1, and EHV-4, contained in vaccines administered to foals.[12,21-25] Even low levels of antibody below those detectable by many routine serologic tests and below those thought to be protective can completely block the serologic response to some vaccines, resulting in a potentially prolonged period of susceptibility before the foal is capable of responding appropriately to vaccines.[24] These findings also indicate that it is not typically feasible to serologically test samples from foals to predict whether they will respond to particular vaccines. We now recommend that primary immunization with most vaccines containing inactivated antigens should be delayed until foals are 6 months of age or older, and with the exception of the rabies vaccine, three doses of vaccine should be included in the primary series rather the two doses routinely recommended by vaccine manufacturers. Typically, the third dose stimulates a serologic response of greater magnitude and durability than two doses and may also contribute to a higher "set point" for the response to subsequent booster doses.[12,24,26,27] In contrast to the results cited, maternal antibodies do not appear to exert a marked inhibitory effect on the immune response of foals to the inactivated, live recombinant, live chimera, or DNA WNV vaccines, thereby permitting antibody-positive foals as young as 3 months of age to be immunized successfully.[26,28,29] Similarly, the canarypox-vectored recombinant influenza vaccine has been shown to efficiently prime foals in the presence of MDA.[30]

Study results should be interpreted with caution because only humoral responses are typically assessed in MDA interference studies, and infectious challenge is not performed to confirm that lack of serologic response equates to lack of protection. Lack of a serologic response may correlate well with lack of protection for some diseases and some vaccines, whereas for others this may not be the case. In contrast, the presence of a serologic response may not correlate well with protection, as is frequently the case for respiratory tract pathogens. Because many commercially available vaccines are inactivated, adjuvanted, and administered by IM injection, they have limited potential to stimulate cellular and mucosal responses, so serologic responses induced by these vaccines likely correlate well with their potential to induce protection. In turn, MDA interference with serologic responses to inactivated vaccines likely equates to failure to induce protection. In contrast, failure to detect a serologic response to a modified live, vectored, DNA, or mucosally administered vaccine may not equate to lack of protection, because vaccines of these types induce a broader array of systemic and local responses that may not be affected by MDAs.

If MDA interference were not an issue, the approach to vaccination of foals would be greatly simplified because primary vaccination against all of the important diseases could be completed before MDAs had declined to nonprotective levels. In effect, the "window of susceptibility" would be eliminated. In reality, an attainable goal is to maximize the beneficial effects of MDAs while minimizing their negative impact on primary immunization. To best meet this goal, it is necessary to decide which one (or both) of the following is the primary focus: (1) to protect the foal and weanling against specific high-risk infectious diseases that affect this age group and have the potential to cause significant disease, either directly or by predisposing to other secondary infections, or (2) to initiate primary immunization to protect against disease later in life.

Assessing risk takes into account both the likelihood the foal will become infected and the risk of serious sequelae or death if the horse does become infected and does develop disease. If the disease affects the foal early in life, such as is the case with rotavirus (RV) infection, there is usually insufficient time to induce a protective immune response by actively immunizing the foal. Under these circumstances, the approach should be to maximize the degree of protection passively transferred from the dam via colostrum. Other diseases like rabies can affect horses of all ages, but the risk of acquiring infection is generally low.

Diseases of Moderate to High Risk to Young Foals but Low Risk to Adults

Diseases of moderate to high risk to young foals but low risk to adults include equine rotavirus infection (on certain breeding farms in certain years) and, in geographic areas such as Kentucky and some other Eastern states, type B botulism. For these diseases, the following approach is appropriate:

- Booster-vaccinate the dam before foaling to maximize uniformity of passive transfer.
- Ensure good passive transfer of maternal antibodies.
- Introduce management practices to reduce exposure to the infectious agent.
- Vaccinate the foal if risk continues beyond the first few months of life.

Diseases of Moderate to High Risk for Weanlings and Older Horses but Lower Risk to Young Foals Born to Vaccinated Mares

Diseases of moderate to high risk for weanlings and older horses but lower risk to young foals born to vaccinated mares include EHV-4, EHV-1, strangles, influenza, tetanus, EEE, and WNV infection. For these diseases, the following approach is appropriate:

- Vaccinate the dam before foaling to maximize uniformity of passive transfer.
- Ensure good passive transfer of maternal antibodies.
- Start foal vaccination after the risk of maternal antibody interference is no longer present in most foals. When several vaccine types are available for a particular disease, the vaccine that is least subject to MDA interference should be used. Introduce management practices to reduce exposure to the infectious agent while primary vaccination is being completed.
- If a two-dose primary series is recommended for adult horses, use three or more doses of vaccine in the primary series to improve the chances that foals that do not respond to earlier doses will respond to additional doses administered later.

Diseases of Low Risk to Foals

Diseases of low risk to foals in most circumstances include rabies, equine neorickettsiosis (EN), WEE, and EVA. For these diseases, the following approach is appropriate:

- Vaccinate the dam before foaling if the disease is a significant risk to adult horses and a vaccine shown to be safe for use in pregnant mares is available. If the available vaccines are not considered safe for use in pregnant mares, administer boosters before breeding.
- Ensure good passive transfer of maternal antibodies.
- Start foal vaccination after the risk of maternal antibody interference is no longer present in any foal (typically 9 months to 1 year of age)

Adverse Reactions to Vaccines

Though uncommon, the possibility always exists for adverse reactions (including anaphylaxis) associated with vaccine administration, so vaccines should be administered by or under the direct supervision of a veterinarian. Adverse reactions should be reported to the vaccine's manufacturer and the U.S. Department of Agriculture (USDA) (1-800-752-6255) or the U.S. Pharmacopeia (USP) Veterinary Practitioners Reporting Program (forms may be obtained or reports submitted by calling the USP at 1-800-487-7776). Anaphylaxis constitutes a life-threatening emergency requiring prompt treatment with epinephrine (1 mg/mL; equivalent to 5 to 10 mL of a

VetBooks.ir

1 mg/mL dilution IM for a 450-kg horse). Repeated doses of epinephrine can be administered at 15-minute intervals if necessary. It has recently been shown that horses vaccinated with viral vaccines can develop IgE responses to nontarget antigens, including bovine serum albumin (BSA), suggesting that subsequent administration of another viral vaccine containing the same component could elicit an adverse response, including anaphylaxis.[31]

Local irritant tissue reactions occur more frequently, particularly when polyvalent combination vaccines and injectable strangles vaccines are used. These reactions are usually self-limiting, but resolution can be promoted by parenteral or oral (PO) administration of nonsteroidal antiinflammatory drugs (NSAIDs), topical application of warm compresses or the cutaneously absorbed NSAID diclofenac (Surpass [IDEXX Pharmaceuticals, Greensboro, N.C.]), and gentle exercise. Significant reactions in the neck muscles may make the horse reluctant to lower or raise its head; feed and water buckets should be positioned accordingly. Occurrence of externally visible local reactions can be reduced by administration of the vaccine deep in the semimembranosus and semitendinosus muscles of the hindleg rather than in the neck and by allowing the horse to exercise after vaccination. Horses that repeatedly react to polyvalent vaccines may benefit from the administration of NSAIDs or antihistamines before vaccination, administration of the individual antigenic components separately in different sites, use of a different brand of vaccine, use of a vaccine that can be administered by a route other than IM, or use of a vaccine that contains a different adjuvant or no adjuvant at all.

Some horses develop transient self-limiting systemic signs that may include fever, anorexia, lethargy, colic, diarrhea, tachycardia, and congested mucous membranes after IM administration of vaccines. Systemic signs are perhaps more common with certain vaccines but can be associated with any vaccine.[32,33] In addition, inactivated Immune Stimulating Complex (ISCOM) and live recombinant vectored tetanus and influenza combination vaccines have been shown to elicit a prominent acute phase inflammatory response of several days' duration in vaccinated horses.[34] A similar response likely occurs with other vaccines. It is therefore inadvisable to give horses any injectable vaccine within 2 weeks before a show, performance event, sale, or prolonged transportation. It may also be beneficial to minimize environmental dust when vaccinating horses known to have allergic airway disease or hypersensitivity.[32]

If unacceptable reactions occur repeatedly, the need for continued annual or more frequent revaccination against individual antigens should be carefully reevaluated, taking into account risk of disease balanced against the risk of an adverse reaction. Many horses that experience adverse reactions have received numerous doses of multiple vaccine antigens, repeated over the years. In this situation, the vaccination protocol should be "pared down" so that only the most essential antigens are administered and the maximum possible interval between boosters is employed. For diseases like rabies and tetanus, for which resistance can reasonably be correlated with circulating antibody titer, one possible approach to define the maximum or optimal interval between booster doses would be to measure the antibody titer. Unfortunately, this approach is currently limited by the paucity of laboratories that offer this type of testing on a routine basis, inexpensively, and with a short turnaround time. Introduction of commercially available ELISA testing for antibodies to the SeM protein of *S. equi* (Equine Diagnostic Solutions, Lexington, Ky.) and neutralizing antibody testing for WNV virus (Cornell University, Colorado State University, the University of Florida, and the USDA Animal and Plant Health Inspection Service [APHIS] National Veterinary Services Laboratory) in recent years has made it possible to refine vaccination protocols for these diseases in horses that experience adverse reactions to vaccination. Testing for rabies antibodies is available through Kansas State University, and testing for antibodies to other pathogens may be available through state diagnostic laboratories.

Available Vaccines and the Concept of Core and Noncore Vaccines

Fully licensed vaccines are now available in North America as aids to the prevention of tetanus; viral encephalomyelitis (EEE, WEE, VEE); WNV infection; influenza; EHV-1 and EHV-4 infection; strangles; rabies; EVA; EN; and type B botulism. In addition, conditionally licensed vaccines are available to immunize horses against rotavirus, equine rhinitis A virus (ERAV), and *Corynebacterium pseudotuberculosis*. Tetanus, rabies, and viral encephalomyelitis caused by EEE, WEE, and WNV pose a threat to horses in all geographic areas and are therefore considered to be core diseases against which all horses in North America should be vaccinated. The abortigenic potential of EHV-1 warrants inclusion of this disease in the core for all pregnant broodmares. Although influenza is not routinely included as a core disease, vaccination against this highly contagious respiratory tract infection is strongly recommended for all horses likely to be colocated with horses from other facilities during transportation or at sales, shows, trail rides, races, or other events. The remaining diseases for which vaccines are available are considered "noncore" or "risk based." Indications for use of vaccines against these diseases are discussed in relevant sections that follow later in this chapter. Table 48.1 details the types of vaccines licensed for use in horses in the United States. Tables 48.2 through 48.4 provide general guidelines for use of the most frequently indicated equine vaccines in foals, weanlings, yearlings, and adult horses under various management conditions and in various geographic locations.

Vaccination Recommendations for Specific Diseases

Tetanus

All horses are at risk for developing tetanus, an often fatal disease caused by a potent neurotoxin elaborated by the anaerobic spore-forming bacterium *Clostridium tetani*. Infection of tissues typically occurs via puncture wounds (particularly those involving the foot or muscle), open lacerations, surgical incisions, exposed tissues like the umbilicus of foals, and the reproductive tract of the postpartum mare (especially in the event of trauma or retained placenta). *C. tetani* is present in the intestinal tract and feces of horses, other animals, and human beings, and spores are abundant, as well as ubiquitous, in soil. Spores of *C. tetani* survive in the environment for many years, resulting in an ever-present risk of exposure of horses and people on equine facilities. Because tetanus is expensive to treat and has a high mortality rate, all horses should be actively immunized using tetanus toxoid as part of the core vaccination program. Active immunization reduces the need to administer tetanus antitoxin, the use of which is associated with the risk of inducing potentially fatal serum hepatitis.

Protection against tetanus is mediated by circulating antibodies; toxin binding inhibition (ToBi) antibody titers of greater than 0.2 IU/mL are considered to be protective in the horse.[27,35] The many available vaccines are formalin-inactivated, adjuvanted toxoids that are inexpensive, safe, and potent antigens that induce an excellent serologic response and solid long-lasting immunity when administered according to manufacturer recommendations. Primary immunization involves administration of two doses of toxoid at 3- to 6-week intervals. Titers of specific antibody increase to protective levels within 14 days after administration of the second dose in the primary

TABLE 48.2

Guidelines for Vaccination of Adult Horses, Excluding Broodmares, Against Core and Noncore (Risk-Based) Diseases

Disease/Vaccine	Adult Horses (>1 Year of Age) Previously Vaccinated Against Disease Indicated	Adult Horses (>1 Year of Age) Not Previously Vaccinated Against Disease Indicated or Lacking Vaccination History	Comments
Core Diseases[a]			
Tetanus (toxoid)	Toxoid: annual revaccination	Toxoid: 2-dose primary series; second dose 4-6 weeks after first dose Revaccinate annually.	Booster at time of penetrating injury or surgery if last dose was administered >6 months previously
Eastern and Western equine encephalomyelitis (EEE, WEE)	Inactivated: annual revaccination in spring, before onset of vector season	Inactivated: 2-dose primary series; second dose 4-6 weeks after first dose Revaccinate annually before onset of next vector season.	Consider a 6-month revaccination interval for horses residing in endemic areas with a prolonged vector season (e.g., southeastern states).
West Nile virus (WNV)	Inactivated vaccine or live recombinant canarypox-vectored vaccine: annual revaccination in spring, before onset of vector season	Inactivated vaccine or live recombinant canarypox-vectored vaccine: 2-dose primary series; second dose 4-6 weeks after first dose Revaccinate annually before onset of next vector season. Inactivated *Flavivirus* chimera vaccine: 2-dose primary series; second dose 3-4 weeks after first dose Revaccinate annually before onset of next vector season. Live *Flavivirus* chimera vaccine: 1-dose primary series Revaccinate annually before onset of next vector season.	When using an inactivated product or live recombinant product, consider a 6-month revaccination interval for: • Horses residing in endemic areas with a prolonged vector season • Juvenile horses (<5 years of age) • Geriatric horses (>15 years of age) • Immunocompromised horses For naive horses being imported into an endemic area during vector season, preferred approach is to complete primary vaccination series before importation. If this approach is not feasible, protect horses from being bitten by mosquitoes if possible, and vaccinate them with one of the vaccines (canarypox-vectored or live *Flavivirus* chimera) that have most rapid onset of immunity.

VetBooks.ir

TABLE 48.2

Guidelines for Vaccination of Adult Horses, Excluding Broodmares, Against Core and Noncore (Risk-Based) Diseases—cont'd

Disease/Vaccine	Adult Horses (>1 Year of Age) Previously Vaccinated Against Disease Indicated	Adult Horses (>1 Year of Age) Not Previously Vaccinated Against Disease Indicated or Lacking Vaccination History	Comments
Rabies	Inactivated: annual revaccination	Inactivated: 1-dose primary series Annual revaccination	Booster vaccination induces persistently elevated levels of antirabies antibody.
Noncore (Risk-Based) Vaccines[b]			
Anthrax (rarely indicated)	Live spore vaccine: annual revaccination	Live spore vaccine: 2-dose primary series; second dose 3-4 weeks after first dose Annual revaccination	Use only in endemic areas or in the face of an outbreak. Antimicrobial drugs must not be given concurrently with this vaccine. Administer subcutaneously in neck. Use caution during storage, handling, and administration. Consult a physician immediately if human exposure to anthrax vaccine occurs by accidental injection, ingestion, or otherwise through conjunctivae or broken skin.
Botulism	Toxoid: annual revaccination	Toxoid: 3-dose primary series; second dose 4 weeks after first dose; third dose 4 weeks after second dose Annual revaccination	
Equine herpesvirus (EHV)	Inactivated or modified live: semiannual (6-month interval) to annual revaccination (see comments)	Inactivated or modified live: 3-dose primary series; second dose 4-6 weeks after first dose; third dose 4-6 weeks after second dose	A 6-month revaccination interval is recommended for: • Horses <5 years of age • Horses on breeding farms or in contact with pregnant mares • Horses housed at facilities with frequent equine movement on and off the premises • Performance or show horses at high risk
Equine influenza	Modified live cold-adapted intranasal, inactivated, or live canarypox-vectored recombinant vaccine: semiannual for horses with ongoing risk of exposure Annual for horses at low risk for exposure	Modified live cold-adapted intranasal vaccine: 1-dose primary series Revaccinate semiannually to annually. Inactivated vaccines: 3-dose primary series; second dose 4-6 weeks after first dose; third dose 3-6 months after second dose Revaccinate semiannually to annually. Live canarypox-vectored recombinant: 2-dose primary series; second dose 4-6 weeks after first dose Revaccinate semiannually to annually.	
Equine viral arteritis (EVA)	Modified live virus vaccine: annual revaccination. Stallions and teasers: vaccinate 3-4 weeks before start of breeding season. Mares: vaccinate when open.	Modified live virus vaccine: 1-dose primary series (see comments)	Before initial vaccination, intact males and any horses potentially intended for export should undergo serologic testing and be confirmed negative for antibodies to EAV. Samples for testing should be collected shortly before or, preferably, at the time of vaccination. All first-time vaccinated stallions should be isolated for 3 weeks after vaccination before being used for breeding.

TABLE 48.2

Guidelines for Vaccination of Adult Horses, Excluding Broodmares, Against Core and Noncore (Risk-Based) Diseases—cont'd

Disease/Vaccine	Adult Horses (>1 Year of Age) Previously Vaccinated Against Disease Indicated	Adult Horses (>1 Year of Age) Not Previously Vaccinated Against Disease Indicated or Lacking Vaccination History	Comments
Equine neorickettsiosis (Potomac horse fever)	Inactivated vaccines: semiannual to annual revaccination	Inactivated vaccines: 2-dose primary series; second dose 3-4 weeks after first dose Revaccinate semiannually to annually.	Because protection following vaccination is incomplete and short-lived, a revaccination interval of 3-4 months has been advocated in endemic areas when disease risk is high. However, strategic revaccination to maximize immunity before expected peak challenge in summer and fall is the preferred approach if vaccination is elected as an adjunct to strategic environmental control measures.
Rotavirus	Not applicable	Not applicable	
Strangles	Inactivated M-protein subunit or modified live intranasal vaccines: semiannual to annual revaccination	Inactivated M-protein subunit vaccines: 2- to 3-dose series; second dose 2-4 weeks after first dose; third dose (when recommended by manufacturer) 2-4 weeks after the second dose. Revaccinate semiannually. Modified live intranasal vaccine: 2-dose primary series administered IN; second dose 3-4 weeks after first dose Revaccinate semiannually to annually.	Vaccination is not recommended as a strategy in outbreak mitigation, but vaccination may be warranted on farms with endemic strangles, with the understanding that the risk of adverse vaccine reactions is higher in exposed horses.
Leptospirosis	Inactivated vaccines: annual revaccination	Inactivated vaccines: 2-dose primary series; second dose 3-4 weeks after first dose Revaccinate annually.	

[a]Core vaccines protect against diseases that are endemic to a region, are virulent or highly contagious, pose a risk of severe or fatal disease, have potential public health significance, and/or are required by law. Core vaccines have clearly demonstrable efficacy and have a sufficiently high level of patient benefit and low level of risk to justify their use in all equids in North America.

[b]Noncore (risk-based) vaccines are selected for use on the basis of assessment of risk performed by, or in consultation with, a licensed veterinarian. Use of noncore vaccines will vary among individuals, populations, and/or geographic regions.

Modified with permission from recommendations developed by the AAEP Infectious Disease Committee and posted on the AAEP website (aaep.org).

TABLE 48.3

Guidelines for Vaccination of Broodmares Against Core and Noncore (Risk-Based) Diseases

Disease/Vaccine	Previously Vaccinated Broodmares	Broodmares Not Previously Vaccinated or Lacking Vaccination History	Comments
Core Diseases[a]			
Tetanus	Toxoid: annual revaccination 4-6 weeks prepartum	2-dose primary series; second dose 4-6 weeks after first dose Revaccinate 4-6 weeks prepartum, depending on timing of second dose.	Booster at time of penetrating injury or surgery if last dose was administered more than 6 months previously
Eastern and Western equine encephalomyelitis (EEE, WEE)	Annual, 4-6 weeks prepartum	2-dose primary series; second dose 4 weeks after first dose Revaccinate 4-6 weeks prepartum, depending on timing of second dose.	Consider a 6-month revaccination interval for mares residing in endemic areas with a prolonged vector season (e.g., southeastern states).

VetBooks.ir

TABLE 48.3

Guidelines for Vaccination of Broodmares Against Core and Noncore (Risk-Based) Diseases—cont'd

Disease/Vaccine	Previously Vaccinated Broodmares	Broodmares Not Previously Vaccinated or Lacking Vaccination History	Comments
West Nile virus (WNV)	Annual, 4-6 weeks prepartum	It is preferable to vaccinate naive mares when open. When risk is high, initiate primary series as follows: Inactivated vaccine or live recombinant canarypox-vectored vaccine: 2-dose primary series; second dose 4-6 weeks after first dose Revaccinate 4-6 weeks prepartum, depending on timing of second dose. Inactivated *Flavivirus* chimera vaccine: 2-dose primary series; second dose 3-4 weeks after first dose Revaccinate annually, before onset of the next vector season. Live *Flavivirus* chimera vaccine: 1-dose primary series Revaccinate 4-6 weeks prepartum, depending on timing of first dose.	When using an inactivated product or live recombinant product, consider a 6-month revaccination interval for mares residing in endemic areas with a prolonged vector season. For naive mares being imported into an endemic area during the vector season, preferred approach is to complete the primary vaccination series before importation. If this approach is not feasible, protect them from being bitten by mosquitoes if possible, and vaccinate them with one of the vaccines (canarypox-vectored or live *Flavivirus* chimera) that have the most rapid onset of immunity.
Rabies	Annual, before breeding *OR* 4-6 weeks prepartum	1-dose primary series Annual revaccination before breeding *OR* 4-6 weeks prepartum	Booster vaccination induces persistently elevated levels of antirabies antibody. This vaccine may be given post foaling but before breeding to reduce the number of vaccines given to mares prepartum.
Equine herpesvirus (EHV)	3-dose series with product labeled for prevention of EHV-1 abortion Administer during fifth, seventh, and ninth months of gestation.	3-dose series with product labeled for prevention of EHV-1 abortion Administer during the fifth, seventh, and ninth months of gestation.	
Noncore (Risk-Based) Vaccines[b]			
Anthrax	Not recommended for use during gestation	Not recommended for use during gestation	
Botulism	Annual, 4-6 weeks prepartum	3-dose series: first dose during eighth month of gestation; second dose 4 weeks after first dose; third dose 4 weeks after the second dose	
Equine influenza	Inactivated vaccines: semiannual, with 1 dose administered 4-6 weeks prepartum Canarypox-vectored vaccine: semiannual, with one dose administered 4-6 weeks prepartum	Inactivated vaccine: 3-dose primary series; second dose 4-6 weeks after first dose; third dose 4-6 weeks prepartum Canarypox-vectored vaccine: 2-dose primary series; second dose 4-6 weeks after first dose but no later than 4 weeks prepartum	The MLV intranasal influenza vaccine can be used to protect pregnant mares against influenza, but its use for prepartum booster is not recommended because it does not reliably stimulate high levels of circulating antibody. Administration of an inactivated or canarypox-vectored vaccine for the prefoaling booster is the preferred approach.
Equine viral arteritis (EVA)	Administration during pregnancy is not recommended unless risk of exposure is high.	Administration during pregnancy is not recommended unless risk of exposure is high.	Mares potentially intended for export should undergo serologic testing immediately before initial vaccination and be confirmed negative for antibodies to EAV.

TABLE 48.3

Guidelines for Vaccination of Broodmares Against Core and Noncore (Risk-Based) Diseases—cont'd

Disease/Vaccine	Previously Vaccinated Broodmares	Broodmares Not Previously Vaccinated or Lacking Vaccination History	Comments
Equine neorickettsiosis (Potomac horse fever)	Semiannual, with one dose administered 4-6 weeks prepartum	2-dose primary series: first dose: 8-10 weeks prepartum; second dose 4-6 weeks prepartum	Strategic environmental control measures are important for effective control.
Rotavirus	3-dose series: first dose at 8 months' gestation; second dose 4 weeks after first dose; third dose 4 weeks after second dose	3-dose series: first dose at 8 months' gestation; second dose 4 weeks after first dose; third dose 4 weeks after second dose	Check serum concentration of immunoglobulin in foal to verify adequate passive transfer.
Strangles	Inactivated M-protein subunit vaccines: semiannual, with 1 dose given 4-6 weeks prepartum	Inactivated M-protein subunit vaccines: 3-dose primary series; second dose 2-4 weeks after the first dose; third dose 4-6 weeks prepartum	MLV intranasal strangles vaccine can be used to protect pregnant mares, but its use for the prepartum booster is not recommended because it does not reliably stimulate high levels of circulating antibody. Administration of an inactivated M-protein vaccine for the prefoaling booster is the preferred approach.
Leptospirosis	Inactivated vaccines: annual revaccination	Inactivated vaccines: 2-dose primary series; second dose 3-4 weeks after first dose Revaccinate annually.	Inactivated vaccine can be used in pregnant mares in all 3 trimesters of gestation.

[a]Core vaccines protect against diseases that are endemic to a region, are virulent or highly contagious, pose a risk of severe or fatal disease, have potential public health significance, and/or are required by law. Core vaccines have clearly demonstrable efficacy and have a sufficiently high level of patient benefit and low level of risk to justify their use in all equids in North America.

[b]Noncore (risk-based) vaccines are selected for use on the basis of assessment of risk performed by, or in consultation with, a licensed veterinarian. Use of noncore vaccines will vary among individuals, populations, and/or geographic regions.

TABLE 48.4

Guidelines for Vaccination of Foals, Weanlings, and Yearlings Against Core and Noncore (Risk-Based) Diseases—cont'd

Disease/Vaccine	Foals and Weanlings (<12 Months of Age) of Mares Vaccinated During Prepartum Period Against Disease Indicated	Foals and Weanlings (<12 Months of Age) of Mares Not Vaccinated During Prepartum Period	Yearlings	Comments
Eastern and Western equine encephalomyelitis (EEE, WEE)	Inactivated vaccine: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after first dose; third dose at 10-12 months of age, before onset of next vector season	Inactivated vaccine: 3-dose primary series; first dose at 3-4 months of age; second dose 4 weeks after first dose; third dose 4-8 weeks after second dose (shorter interval applies to foals receiving their primary series during mosquito season)	Annual in spring, before onset of vector season	Month of birth and geographic location influence risk of exposure to insect vectors at specific foal ages. Scheduling of primary immunization series may be amended by administration of EEE/WEE vaccines to foals at an earlier age if vectors are present. In the southeastern United States where vectors are present year-round, an additional dose should be added to primary series, beginning at 2-3 months of age. Fourth dose in the primary series should be administered at 10-12 months of age.
West Nile virus (WNV)	Inactivated vaccine or live recombinant canarypox-vectored vaccine: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after first dose; third dose at 10-12 months of age, before onset of next vector season	Inactivated vaccine or live recombinant canarypox-vectored vaccine: 3-dose primary series; first dose at 3-4 months of age; second dose 4 weeks after first dose; third dose 4-8 weeks after second dose (shorter interval applies to foals receiving their primary series during mosquito season)	Annual in spring, before onset of vector season	Month of birth and geographic location influence risk of exposure to insect vectors at specific foal ages. Scheduling of primary immunization series may be amended by administration of WNV vaccines to foals at an earlier age if vectors are present. In the southeastern United States where vectors are present year-round, primary vaccination series should be initiated at 3 months of age.
	Live *Flavivirus* chimera vaccine: 2-dose primary series; first dose at 5-6 months of age; second dose at 10-12 months of age, before onset of next vector season	Live *Flavivirus* chimera vaccine: 2-dose primary series; first dose at 5-6 months of age; second dose at 10-12 months of age before onset of next vector season		There are no published data regarding use of the live *Flavivirus* chimera product in foals <5 months of age. If administered to foals <5 months of age, the recommended schedule for primary vaccination should be completed by administration of a dose of vaccine at 5 months of age or older.

TABLE 48.4

Guidelines for Vaccination of Foals, Weanlings, and Yearlings Against Core and Noncore (Risk-Based) Diseases—cont'd

Disease/Vaccine	Foals and Weanlings (<12 Months of Age) of Mares Vaccinated During Prepartum Period Against Disease Indicated	Foals and Weanlings (<12 Months of Age) of Mares Not Vaccinated During Prepartum Period	Yearlings	Comments
Rabies	2-dose primary series: first dose at 6 months of age; second dose 4-6 weeks after first dose; next dose at 10-12 months of age	1- or 2-dose primary series: first dose at 3-4 months of age; second dose 4-6 weeks after first dose (not necessary if dam is seronegative); next dose at 10-12 months of age	Annual	For foals of mares with an unknown vaccination history, either follow approach outlined for foals of vaccinated mares or determine serologic status of foal (or mare) and use results to classify foal as either being from a vaccinated or unvaccinated mare.
Noncore (Risk-Based) Vaccines[b]				
Anthrax (rarely indicated)	Not applicable because vaccination of pregnant mares is not recommended	No age-specific guidelines are available for this vaccine. Manufacturer's recommendation is for primary series of 2 doses administered subcutaneously (in the neck) at a 2-3–week interval.	Annual, in spring	Anthrax vaccination is rarely indicated—only in focal endemic areas. Antimicrobial drugs must not be given concurrently with this vaccine. Exercise caution during storage, handling, and administration of this live bacterial product. Consult a physician immediately should accidental human exposure (via mucous membranes, conjunctivae, or broken skin) occur.
Botulism (type B toxoid)	3-dose primary series: first dose as early as 2-3 months of age; second dose 4 weeks after first dose; third dose 4 weeks after second dose	3-dose primary series: first dose as early as 1-3 months of age; second dose 4 weeks after first dose; third dose 4 weeks after second dose	Annual	Limited information suggests that maternal antibody does not interfere with vaccination, so foals at high risk may be vaccinated as early as 2 weeks of age.
Equine herpesvirus (EHV)	Inactivated EHV-1, EHV-1/4, or modified live EHV-1 vaccine: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after first dose; third dose 3-5 months after second dose (i.e., 10-12 months of age)	Inactivated EHV-1, EHV-1/4, or modified live EHV-1 vaccine: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after first dose; third dose 3-4 months after second dose (i.e., 10-12 months of age)	Semiannual (6-month interval)	The benefit of intensive vaccination programs directed against EHV-1 and EHV-4 in foals and young horses is not clearly defined because, despite frequent vaccination, infection and disease continue to occur. It is difficult to induce active immunity before weanlings experience field challenge.

TABLE 48.4

Guidelines for Vaccination of Foals, Weanlings, and Yearlings Against Core and Noncore (Risk-Based) Diseases—cont'd

Disease/Vaccine	Foals and Weanlings (<12 Months of Age) of Mares Vaccinated During Prepartum Period Against Disease Indicated	Foals and Weanlings (<12 Months of Age) of Mares Not Vaccinated During Prepartum Period	Yearlings	Comments
Equine influenza	Inactivated vaccine: 3-dose primary series; first dose at 6-7 months of age; second dose 4-6 weeks after first dose; third dose at 10-12 months of age Live canarypox-vectored recombinant vaccine: 3-dose primary series: first dose at 5-6 months of age; second dose 5 weeks after first dose; third dose at 10-12 months of age Modified live cold-adapted intranasal vaccine: 1-dose primary series: first dose at 11 months of age If vaccination earlier than 11 months is elected, use a 2-dose primary series: first dose at 6-10 months of age; second dose at 11-12 months of age	Inactivated vaccine: 3-dose primary series; first dose at 6-7 months of age; second dose 4-6 weeks after first dose; third dose at 10-12 months of age Live canarypox-vectored recombinant vaccine: 3-dose primary series; first dose at 5-6 months of age; second dose 5 weeks after first dose; third dose at 10-12 months of age Modified live cold-adapted intranasal vaccine: 1-dose primary series: first dose at 11 months of age If vaccination earlier than 11 months is elected, use a 2-dose primary series: first dose at 6-10 months of age second dose at 11-12 months of age	Semiannual (6-month interval) Semiannual (6-month interval) Semiannual (6-month interval)	An unusually high risk of exposure may warrant vaccination of younger foals. Because potentially interfering maternal anti-influenza antibody is likely to be present, a complete primary vaccination series should be given after 6 months of age. The modified live intranasal vaccine is licensed for administration to horses 11 months of age or older with a label recommendation of 1 dose for primary immunization. If vaccine is given before 11 months of age, a second dose should be administered at 11 months or older.
Equine viral arteritis (EVA)	Colt (male) foals: single dose at 6-12 months of age (see comments)	Colt (male) foals: single dose at 6-12 months of age (see comments)	Annual for colts intended for use as breeding stallions	Before initial vaccination, colt (male) foals should undergo serologic testing and be confirmed negative for antibodies to EAV. Maternally derived anti-EAV colostral antibodies can persist in foal for up to 6 months, so testing and vaccination should not be performed before 6 months of age. Keep colts isolated for 3 weeks after vaccination.
Equine neorickettsiosis (Potomac horse fever)	3-dose primary series: first dose at 5-6 months of age; second dose 3-4 weeks after first dose; third dose at 10-12 months of age	3-dose primary series: first dose at 5-6 months of age; second dose 3-4 weeks after first dose; third dose at 10-12 months of age	Semiannual to annual	If warranted by risk, vaccine may be administered to younger foals, in which case additional doses should be administered at 4-week intervals until foal is 6 months of age.
Rotavirus	Not recommended in foals	Not recommended in foals	Not applicable

TABLE 48.4

Guidelines for Vaccination of Foals, Weanlings, and Yearlings Against Core and Noncore (Risk-Based) Diseases—cont'd

Disease/Vaccine	Foals and Weanlings (<12 Months of Age) of Mares Vaccinated During Prepartum Period Against Disease Indicated	Foals and Weanlings (<12 Months of Age) of Mares Not Vaccinated During Prepartum Period	Yearlings	Comments
Strangles	Inactivated M-protein subunit vaccines: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after first dose; third dose 4-6 weeks after second dose Modified live intranasal vaccine: 3-dose primary series; first dose at 6-9 months of age; second dose 3-4 weeks after first dose; third dose at 11-12 months of age	Inactivated M-protein subunit vaccines: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after the first dose; third dose 4-6 weeks after second dose Modified live intranasal vaccine: 3-dose primary series; first dose at 6-9 months of age; second dose 3-4 weeks after first dose; third dose at 11-12 months of age	Semiannual	Vaccination is not routinely recommended as a strategy in outbreak mitigation but may be warranted on farms with endemic strangles, with the understanding that risk of adverse vaccine reactions is higher in exposed horses. If warranted by risk, the modified live vaccine (MLV) may be safely administered to foals as young as 6 weeks of age. However, vaccine efficacy in this age group has not been determined. If the MLV product is administered to foals <6 months of age, administration of third dose of vaccine should be timed 2-4 weeks before weaning if possible.
Leptospirosis	Inactivated vaccines: 2-dose primary series; second dose 3-4 weeks after first dose Revaccinate annually.	Inactivated vaccines: 2-dose primary series; second dose 3-4 weeks after first dose Revaccinate annually.	Annual	

[a]Core vaccines protect against diseases that are endemic to a region, are virulent or highly contagious, pose a risk of severe or fatal disease, have potential public health significance, and/or are required by law. Core vaccines have clearly demonstrable efficacy and have a sufficiently high level of patient benefit and low level of risk to justify their use in all equids in North America.

[b]Noncore (risk-based) vaccines are selected for use on the basis of the assessment of risk performed by, or in consultation with, a licensed veterinarian. Use of noncore vaccines will vary among individuals, populations, and/or geographic regions.

Modified with permission from recommendations developed by the AAEP Infectious Disease Committee and posted on the AAEP website (aaep.org).

series and, in adult horses, persist at detectable levels for 12 months or longer, depending on the adjuvant system used in the vaccine.[27,35-37] A recent study documented substantial differences between currently licensed combination tetanus-encephalomyelitis vaccines with regard to the magnitude of the vaccine-induced tetanus-specific IgGb and IgG(T) antibody responses.[8] The vaccine containing a Carbopol adjuvant induced substantially higher antibody titers than those containing either saponin or squaline combined with surfactants.[8] Revaccination once annually is recommended.

No published challenge studies are available to document the speed of onset or duration of protection induced by tetanus toxoid preparations currently licensed in North America. Conclusions regarding their efficacy are therefore based on the serologic response obtained in horses and laboratory animals and on field experience. However, a challenge study conducted in Europe over 60 years ago found that horses were resistant to challenge 8 days after receiving a single injection of tetanus toxoid, before antibody could be detected in their serum.[38] A second study demonstrated that a series of three doses of tetanus toxoid induced protection lasting for at least 8 years, and perhaps for life, even when antibodies could no longer be detected.[35] A recent study in Europe documented that protective levels of antibody (>0.2 IU/mL as measured by tetanus toxin-binding ELISA) persist for at least 18 months after revaccination of horses previously primed with a two-dose series of a tetanus toxoid/influenza ISCOM vaccine.[39] In contrast, tetanus has been documented in vaccinated horses in North America,[40] although survival was strongly associated with previous vaccination. Thus, it would not be prudent to recommend extension of the annual interval for revaccination with tetanus toxoid products available in North America, pending publication of data documenting duration of immunity (DOI). Vaccinated horses that sustain a wound or undergo surgery more than 6 months after receiving their previous tetanus booster should be revaccinated with tetanus toxoid immediately at the time of injury or surgery.

Annual revaccination of pregnant mares should be completed 4 to 8 weeks before foaling to protect the mare if she sustains foaling-induced trauma or retained placenta and to enhance

VetBooks.ir

concentrations of specific immunoglobulins in colostrum. Colostrum-derived antibodies significantly interfere with the immune response of foals vaccinated with tetanus toxoid until they are about 6 months old.[12,36]

Primary vaccination of foals that have received appropriate transfer of colostral antibodies from a vaccinated mare should include three doses of tetanus toxoid beginning at age 6 months or older. Optimally, the interval between the first two doses of vaccine should be approximately 4 weeks, and the interval between the second and third doses should be 3 to 5 months. The three-dose primary series is recommended for foals because a high proportion of foals fail to seroconvert in response to two doses of tetanus toxoid regardless of whether maternal antibodies are detectable at administration of the first dose.[12,36] For foals born to nonimmune mares, this initial three-dose series can start at 1 to 4 months of age.

Tetanus antitoxin is produced by hyperimmunization of donor horses with tetanus toxoid. Administration of 1 vial of antitoxin (1500 IU) to nonvaccinated horses induces immediate passive protection that lasts not more than 3 weeks.[36] More prolonged protection may be accomplished with higher doses. In addition to the use of high doses of tetanus antitoxin to treat tetanus, indications frequently cited include administration to newborn foals born to unvaccinated mares and to unvaccinated horses that sustain an injury. In these cases the concurrent administration of tetanus antitoxin and tetanus toxoid at different sites using separate syringes has been advocated, followed by administration of additional doses of toxoid at 4- to 6-week intervals to complete the primary series.[41] Because a small but significant number of horses experience serum sickness and fatal hepatic failure (serum hepatitis) several weeks after receiving tetanus antitoxin,[42,43] a preferred approach to the unvaccinated horse that sustains a puncture or deep laceration is to thoroughly clean and debride the wound, initiate active immunization by administering tetanus toxoid, and institute a course of antimicrobial treatment with penicillin or alternate antimicrobial that is active against *C. tetani*.

Equine Encephalomyelitis (Sleeping Sickness)

The equine encephalomyelitis viruses (EEE, WEE, and VEE) belong to the *Alphavirus* genus of the family Togaviridae. They are transmitted by mosquitoes (and infrequently by other bloodsucking insects) to horses from wild birds or rodents that serve as natural reservoirs for these viruses. Risk of exposure and geographic distribution of the encephalomyelitis viruses vary by season and from year to year with changes in distribution of insect vectors and wildlife reservoirs. The distribution of EEE has historically been restricted to the eastern, southeastern, and some southern states, with recent northward encroachment. WEE has caused minimal disease in horses in North America during the past 3 decades, but the virus continues to be detected in mosquitoes and birds throughout the western states. In the past, outbreaks of WEE have been recorded in the western and midwestern states, with sporadic cases in the northeastern and southeastern United States. Because EEE, WEE, or both are endemic in most areas of North America, vaccination against these diseases should be part of the core vaccination program for all horses. VEE is a reportable foreign animal disease. Epidemics of VEE occur when the virus undergoes genetic change and develops greater virulence for avian and mammalian hosts. These viral variants are able to multiply to high levels in the horse, and then the horse becomes a reservoir for infection in these outbreaks. VEE occurs in South and Central America but has not been diagnosed in the United States or Mexico for many years; routine vaccination of horses in these regions against VEE is not recommended at this time unless transportation to endemic areas is planned.

Available vaccines are formalin-inactivated, adjuvanted, bivalent or trivalent, whole-virus products containing EEE, WEE, and VEE virus, typically in combination products containing other antigens such as tetanus toxoid, influenza virus, WNV, or EHV-1/-4. Although correlates for protection against EEE, WEE, and VEE are not well established, circulating antibodies are assumed to be important because infection is acquired by vascular injection (mosquito bites), and current inactivated vaccines appear to have good efficacy.[44,45] A study evaluating the serologic response of horses to commercial encephalomyelitis-tetanus combination vaccines showed that the EEE neutralizing antibody responses to Encevac T (Merck Animal Health, Carbopol adjuvant) and Equiloid Innovator (Zoetis, squaline and surfactant adjuvant) were of greater magnitude and persistence than responses to Cephalovac EWT (Boehringer Ingelheim, saponin adjuvant).[8] However, no comparative randomized challenge studies have been performed using these vaccines to document whether differences in serologic responses equate to differences in efficacy. Early testing of bivalent (EEE/WEE) vaccines was performed by intracranial challenge with either EEE or WEE; the formalin-inactivated preparations demonstrated 100% protection.

Primary immunization of unvaccinated adult horses is accomplished by administering two doses of inactivated vaccine 3 to 6 weeks apart. In areas where EEE is not a threat and mosquito vectors are active for less than 6 months of the year, annual revaccination in the spring, before the peak insect vector season, is recommended. In areas like the Gulf States where EEE is endemic and mosquitoes are active virtually year-round, many veterinarians prefer to revaccinate horses semiannually to ensure more uniform protection throughout the year. Inactivated encephalomyelitis vaccines are considered safe for use during pregnancy, so booster vaccination of pregnant mares 4 to 8 weeks before foaling is routinely recommended to enhance colostral concentrations of specific immunoglobulins. Neutralizing antibodies to WEE and EEE are transferred passively to foals through colostrum and decline with an estimated half-life of 33 and 20 days, respectively. MDAs appear to confer protection and are detectable in the serum of many foals from vaccinated mares for at least 3 months and up to 7 months, depending on the postnursing titer.[23,46-48]

Several studies have shown that MDAs exert a profound inhibitory effect on the ability of foals to mount serologic responses to inactivated bivalent WEE/EEE vaccines, which likely accounts for some of the reported cases of vaccine failure and resultant clinical EEE in vaccinated horses, particularly those younger than 2 years of age.[19,23,24,46,47] Studies have shown that 3-month-old foals born to immune mares consistently failed to mount a serologic response to two doses of inactivated bivalent WEE/EEE vaccine, and the majority had not responded even after administration of a third dose.[24,26] Whereas many 6-month-old foals failed to seroconvert after administration of two doses of vaccine, most responded following administration of a third dose.[24] On the basis of these data, inclusion of a third dose in the primary series, 2 to 5 months after administration of the second dose, is strongly recommended for primary immunization of foals and yearlings.

WEE has a lower mortality rate than EEE, and prevalence of WEE in many western states is sufficiently low that the risk of foals acquiring infection during their first year of life is also low. Therefore primary vaccination of foals of vaccinated mares in areas where mosquitoes die off in the winter and the risk of infection is low is best completed when foals are 5 to 6 months of age or older in order to minimize the potential for MDA interference. Because foals born in the late spring and summer months are still younger than 6 months of age by the time the mosquito season comes to an end in many regions, primary vaccination of these foals can be delayed until the spring of the yearling year. In contrast, EEE is a highly fatal disease that poses a significant risk to foals during their first year of life, particularly in the Gulf States where competent vectors are present

year-round.[19,47,49] Most veterinarians in these regions recommend commencing primary vaccination of foals at 3 to 4 months of age using a three-dose primary series, followed by a fourth dose before the onset of the next mosquito season and semiannual boosters thereafter to maximize the chances of overcoming the inhibitory effects of MDAs and inducing protection.[47]

West Nile Virus

Only a few years after WNV infection was first diagnosed in horses in the northeastern United States in 1999, it had spread across the entire North American continent and is now considered endemic in all mainland areas of North America and Mexico, where it has become an important consideration in the differential diagnosis of horses presenting with signs of neurologic disease. Since 1999, the disease has been confirmed in more than 25,000 U.S. horses, about 35% of which have died or been euthanized. Roughly 40% of horses that survive acute illness caused by WNV exhibit residual effects (e.g., gait and behavioral abnormalities) 6 months post diagnosis.[50]

WNV, a member of the family Flaviviridae, is transmitted by mosquitoes and infrequently by other bloodsucking insects to horses, human beings, and a number of other mammals from avian hosts, which serve as natural reservoirs for these viruses. Horses and humans are considered to be "dead-end" hosts of WNV and therefore do not contribute to the transmission cycle. The virus is not directly contagious from horse to horse or from horse to human. Similarly, indirect transmission via mosquitoes from infected horses is highly unlikely because horses do not experience a significant level of viremia.[51] Risk of infection and death appears to increase with increasing age, but the disease has been confirmed in foals as young as 3 weeks of age. Although cases have been seen virtually year-round in the southeastern United States, the risk of acquiring infection is highest during those months in which mosquito activity peaks, typically July, August, September, and October in most areas of North America. WNV infection is a core disease against which all horses residing in the continental United States and Canada should be vaccinated.

As of April 2013, six WNV vaccines (West Nile-Innovator [Zoetis], Recombitek Equine rWNV vaccine [Merial], Equi-Nile [Merck Animal Health], Vetera WNV Vaccine [Boehringer Ingelheim], PreveNile [Merck Animal Health], and West Nile-Innovator DNA [Zoetis]) are licensed for use in horses in North America. All six vaccines have met USDA requirements for safety in tests, each involving more than 640 horses. West Nile-Innovator is an inactivated whole-virus vaccine that contains a metabolizable oil adjuvant.[52] This vaccine is available as either a monovalent (single-component) vaccine or as several multicomponent vaccines containing other encephalitis virus antigens (EEE, WEE, VEE) and tetanus. Recombitek Equine rWNV vaccine is a Carbopol-adjuvanted canarypox-vectored recombinant modified live vaccine,[53-55] which is also available as a multicomponent containing inactivated EEE, WEE, and tetanus antigens. PreveNile is a nonadjuvanted chimeric yellow fever 17D-vectored vaccine.[56-59] This vaccine was voluntarily withdrawn from the market in May of 2010 after an unacceptably high number of adverse reactions were reported and has not yet been reintroduced. Merck Animal Health has since produced and tested an inactivated version of this chimera vaccine, which was released in 2011 as a single-component vaccine (Equi-Nile), as well as several multicomponent vaccines that also contain EEE, WEE, tetanus, EHV-1, EHV-4, and influenza antigens (Encevac + WNV; Encevac T + WNV, and Prestige V + WNV). Similarly, the Vetera line of vaccines from Boehringer Ingelheim includes both single and multicomponent (up to 8 components) versions containing an inactivated WNV antigen. West Nile-Innovator DNA is a plasmid DNA vaccine with a metabolizable oil adjuvant.[28] It appears that Zoetis is not currently marketing this vaccine.

Needle and mosquito challenge models have shown that West Nile-Innovator, Recombitek, and West Nile-Innovator DNA all significantly reduce the magnitude of viremia in experimentally infected vaccinated horses compared with nonvaccinated control horses for as long as 12 months after primary vaccination with two doses of vaccine.[28,52,53] Although viremia was reliably induced in nonvaccinated control horses in these challenge models, clinical disease was not. Therefore these vaccines are labeled as aids to the prevention of viremia due to WNV infection. In contrast, an intrathecal challenge model that reliably induced severe clinical disease was used to test the efficacy of PreveNile in studies for licensure.[57] In this model, a single dose of PreveNile prevented clinical disease, as well as viremia in 4- to 6-month-old horses challenged 1 year after vaccination; therefore PreveNile was labeled for protection against viremia and as an aid in the prevention of disease and encephalitis caused by WNV.[57] Subsequently, Recombitek was shown to induce a high level of clinical protection when tested using this rigorous intrathecal challenge model in a placebo-controlled study in which horses were challenged 14 days after completion of a two-dose vaccination series.[54] The comparative efficacy of West Nile-Innovator, Recombitek, and PreveNile has now been tested in a randomized blinded, placebo-controlled intrathecal challenge study in which groups of 5 or 6 horses 6 months of age or older were challenged intrathecally 28 days after completion of the two-dose (West Nile-Innovator and Recombitek) or 1-dose (PreveNile) primary vaccination series.[60] In this study, all six unvaccinated control horses developed grave neurologic signs post challenge, whereas all vaccinated horses survived and none developed detectable viremia. Clinical disease was prevented in 100% of PreveNile-vaccinated horses, 80% of Recombitek-vaccinated horses, and 33% of Innovator-vaccinated horses.[60] These findings support the results of field studies that provide clear evidence that when used according to manufacturer recommendations, all available licensed WNV vaccines reduce the risk of disease and death after natural challenge, although clinical disease may not be fully prevented with all vaccines.[61-65]

Directions for primary immunization using inactivated whole virus, inactivated *Flavivirus* chimera, and recombinant vaccines include administration of two doses of vaccine 3 to 6 weeks apart (consult the specific label). Optimal protection cannot be expected until 2 weeks after administration of the second dose, although Recombitek has been shown to induce significant protection as early as 26 days after administration of the first dose when tested in both the mosquito challenge and intrathecal challenge models.[54,55] Primary immunization with PreveNile requires 1 dose. A challenge study in yearlings showed that 83% (5 of 6) were protected when challenged intrathecally 10 days after vaccination with one dose, indicating that onset of immunity is rapid.[57] Rapid onset of immunity is an important feature when faced with the challenge of protecting naive horses that are being introduced into an endemic area, as is the case when horses from Europe and other nonendemic countries are imported into North America.

Vaccine manufacturers recommend revaccination of previously vaccinated horses on an annual basis, or more frequently when local conditions are conducive to a prolonged period of potential exposure to infected mosquito vectors. Annual revaccination is best completed in the spring (late February through early April), before the onset of the insect vector season. In areas like the southeastern states, where the mosquito season is prolonged, revaccination twice annually, once in the spring and again in the late summer or early fall (late July through early September), has been advocated in the past to maximize protection, although the rationale for semiannual vaccination against WNV has not been tested in controlled studies.

None of the licensed vaccines currently marketed in the United States carry label recommendations for administration

VetBooks.ir

to pregnant mares, so mares are best vaccinated before breeding whenever possible. It is well recognized, however, that pregnant mares are at risk of acquiring infection from infected mosquitoes. Consequently, it has become accepted practice by many veterinarians to administer vaccines to pregnant mares on the reasonable assumption that the risk of adverse consequences of WNV infection far exceeds the reported adverse effects of use of vaccines in pregnant mares. Thousands of doses of West Nile-Innovator vaccine have been administered safely to pregnant mares, and a published study failed to document vaccine-associated adverse effects in a large population of pregnant mares.[66] Although the Recombitek vaccine is a live vectored vaccine, the canarypox vector is incapable of replication in mammals and does not induce a viremia that could infect a fetus. In addition, a canarypox-vectored influenza vaccine available in Europe is licensed for use in horses during pregnancy, so the vectored WNV vaccine is unlikely to be associated with an increased risk of adverse effects in pregnant mares. As with other vaccines, it is sound practice to avoid administering West Nile vaccines to mares during the first 60 days of gestation unless conditions of imminent risk prevail.

Booster vaccination of previously primed pregnant mares 4 to 8 weeks before foaling appears to induce a strong anamnestic serologic response that provides their foals with passive colostral protection lasting at least 3 to 4 months.[26] In contrast, a significant proportion of naive pregnant mares failed to seroconvert when the primary series of WNV-Innovator vaccine was administered during the second half of gestation, perhaps reflecting pregnancy-associated downregulation of Th2 responses.[26] This observation adds further justification to the recommendation that when inactivated West Nile-Innovator vaccine is used, the primary series is best completed before breeding. In a similar study, pregnancy did not appear to suppress the response of mares to primary immunization with Recombitek (Wilson WD and colleagues, unpublished observations, 2007).

In contrast to findings with many other vaccines in the foals of immune mares, MDAs do not block the response of foals as young as 3 months of age to vaccination with the inactivated West Nile Innovator vaccine or the recombinant, chimera, or DNA WNV vaccines.[26,29] Although this finding is somewhat surprising for the inactivated vaccine, it might reasonably have been expected for the other vaccines, because the vector systems accomplish transfection of cells and expression of the major E-peptide and M-peptide antigens of WNV on the surface of antigen-presenting cells (APCs) in association with major histocompatibility complex (MHC) class I and class II antigens. These peptide antigens are therefore not free in the tissues and circulation to be neutralized by MDAs. The impact of MDAs on the recently marketed inactivated whole virus (Vetera WNV Vaccine [Boehringer Ingelheim]) and inactivated chimera vaccines (Equi-Nile [Merck Animal Health]) is not known.

Primary vaccination of foals from properly vaccinated mares can be started by administration of the first dose of either an inactivated or recombinant vaccine as early as 3 to 6 months of age (consult the specific product label), followed by a second dose approximately 3 to 6 weeks later, and then a third dose 3 to 5 months after the second dose. This third dose increases the likelihood that foals with high MDA levels that may have attenuated the response to the first dose of vaccine will become primed and protected. Even in foals that have no maternally derived WNV antibodies after nursing, the third dose of inactivated vaccine in the primary series induces significantly higher and more persistent levels of antibody than two doses. A booster should be administered during the spring of the yearling year, after which the recommendations for vaccination of adult horses should be followed. Primary vaccination of foals from unvaccinated unexposed mares should commence at 3 months of age or younger (as early as 1 month of age), depending on month of birth and seasonal level of activity of mosquito vectors in the area. The three-dose primary vaccination protocol previously outlined should be followed. Revaccination should be performed before the onset of the next mosquito season.

The influence of MDAs on the response of foals to PreveNile was recently evaluated in 3-month-old and 5-month-old foals vaccinated with a single dose. Although significant titer responses were not observed post vaccination, sensitization of cell-mediated responses was accomplished, as evidenced by significant increases in expression of granzyme B, interleukin (IL)-2, perforin, and transforming growth factor (TGF)-β and nonsignificant increases in interferon (IFN)-γ expression in WNV-stimulated PBMC from foals vaccinated at 5 months of age.[29] Similar, although nonsignificant, trends were seen in 3-month-old foals.[29] When available, PreveNile was labeled for administration of a single priming dose to foals 5 months of age or older, primarily because 5 months was the minimum age of foals used in challenge trials for licensure. Results of the previously cited study suggest that foals younger than 5 months of age could be immunized successfully with PreveNile. Regardless, a second dose of vaccine should be administered before the onset of the next mosquito season. Preliminary data suggest that the plasmid West Nile-Innovator DNA vaccine is able to circumvent the potentially interfering effects of MDA, but the vaccine was labeled for use in horses 8 months of age or older.[28]

As with EEE, horses that have recovered from clinical WNV infection will likely be protected for the reminder of their lives and should not need to be revaccinated unless changes in their immune status, as might occur with prolonged corticosteroid administration, alter their susceptibility to infection.[67]

It is remarkable that in little more than 10 years after WNV disease was first encountered in the Americas, six vaccines with documented efficacy based on challenge studies were licensed for the benefit of horses, including three that apply the most modern technologies available for either animals or humans at the time.

Rabies

Rabies is an infrequently encountered neurologic disease of equids resulting from inoculation of the rabies virus through the bite of infected (rabid) wildlife. Wildlife species that serve as the natural reservoirs for rabies virus differ among regions of North America but include raccoons, foxes, skunks, and bats. Horses most often sustain bites on their muzzle, face, or lower limbs. The rabies virus then migrates via nerves to the brain, where it initiates rapidly progressive encephalitis. Even though the incidence of rabies in horses is low, the disease is invariably fatal and has considerable public health significance. All horses kept in areas where rabies is endemic in the wildlife population are at risk and should be vaccinated as part of the core vaccination program. Therefore vaccination of horses against rabies virus is recommended by, or under the direct supervision of, a veterinarian using one of the three inactivated tissue culture–derived products currently licensed for use in horses (Rabvac3 [Boehringer Ingelheim], RM Imrab3 [Merial], and EquiRab [Merck Animal Health]). These vaccines are potent immunogens that induce strong serologic responses that peak within 28 days after IM administration of a single dose.

Although correlates for protection against infection with rabies virus in horses are not well defined, it is logical to assume that protection correlates with titers of circulating antibody. In humans, postvaccination antibody titers are used to predict protection. In dogs, however, postvaccination serologic test results were not found to be completely predictive of resistance to challenge exposure during tests performed with certain inactivated vaccines.[68] Challenge studies demonstrating efficacy are required for licensing of all rabies vaccines, including those

VetBooks.ir

labeled for use in equids in the United States. The challenge studies are conducted by the vaccine manufacturers as outlined in the Code of Federal Regulations (CFR) from the USDA. These studies indicate a DOI of 12 months, and a minimum of 80% of vaccinated animals must be resistant to severe challenge with the rabies virus. A DOI of 14 months was documented in a placebo-controlled challenge study in which 4-month-old foals were vaccinated with one dose of EquiRab and challenged by masseter injection of virulent rabies virus 14 months later (see product data sheet).

For primary immunization, label directions on inactivated rabies vaccines licensed for use in horses suggest administration of one dose to horses aged 3 months or older followed by a second dose 1 year later. Thereafter, annual revaccination is recommended. Although none of the licensed vaccines carries a specific label approval for use in pregnant mares, it is important to acknowledge that only a limited number of equine vaccines are specifically licensed for use in pregnant mares and veterinarians do administer inactivated rabies vaccines to pregnant mares. Alternatively, veterinarians may recommend that mares be vaccinated against rabies before breeding in order to reduce the number and type of vaccines given in the period before foaling. Because rabies antibodies persist in serum for a prolonged period, foals born to mares that are revaccinated while open acquire substantial titers of rabies antibody after ingesting colostrum.

Documentation of rabies in supposedly vaccinated horses, most of which were younger than age 2, brought into question the efficacy of label recommendations for primary vaccination of foals against rabies.[69] Recent studies in our laboratory have shown that the serologic response of most 3-month-old foals from antibody-positive mares is completely blocked, even when a two-dose primary vaccination series is used. Although the response to the first dose of vaccine is typically blocked in 6-month-old foals from antibody-positive mares, these foals appear to seroconvert after administration of a second dose 4 weeks later. Primary vaccination of foals from vaccinated mares should therefore be delayed until they are 6 months of age or older and should include two doses of inactivated vaccine administered approximately 4 to 6 weeks apart, followed by a third dose at 1 year of age. For foals of mares known not to be vaccinated against rabies, the primary vaccination series can be started according to manufacturers' recommendations as early as 3 months of age and may comprise only 1 dose, followed by a second dose at 1 year of age. For foals from mares of unknown vaccinal history, either of the two following options is rational and can be used: (1) Assume the mare to be antibody positive, and follow the previous recommendation for foals from mares known to be vaccinated against rabies, starting at 6 months of age. (2) Document the serum antibody status of the foal by testing serum collected from the foal at 24 hours of age or older or from the dam during the periparturient period, and determine which of the approaches to follow on the basis of the presence or absence of rabies antibodies.

Equine Influenza

Infection of the respiratory tract of horses with the orthomyxovirus influenza A/equine/2 (H3N8) remains one of the most common causes of rapidly spreading outbreaks of respiratory disease. The influenza A/equine/1 subtype (H7N7) has not been recognized as a cause of clinical disease for many years and is likely extinct in nature. Influenza is endemic in the equine populations of the United States and much of the world. Evidence of influenza infection has never been documented in resident horses in New Zealand and Iceland. Whereas outbreaks of influenza have previously been reported in Singapore, Japan, South Africa, and Australia, rigorous control measures have apparently been successful in eliminating the virus from these countries. Rapid national and international transportation of horses facilitates spread of the virus. Concentrating young horses at racetracks, training facilities, boarding stables, breeding farms, shows, or similar athletic events increases the risk of infection, as does a low serum concentration of specific antibody.[70] Older horses are generally less susceptible to infection but may become ill when partial protection is overwhelmed by exposure to horses excreting large amounts of virus. Explosive outbreaks occur at intervals of several years when immunity of the equine population wanes and sufficient antigenic drift has occurred to generate a new viral strain. In contrast to herpesviruses, EIV is not maintained in asymptomatic carrier horses and does not circulate constantly, even within large groups of horses. Rather, the disease is introduced sporadically by a symptomatic or an asymptomatic infected horse. This epidemiologic finding and rapid elimination of the virus by the equine immune response suggest that infection can be avoided by preventing entry of the virus into an equine population (e.g., quarantine of newly arriving horses for at least 14 days) and appropriate vaccination.[71]

EIV is highly contagious and spreads rapidly through groups of horses in aerosolized droplets dispersed by coughing. Contaminated buckets, grooming or feeding equipment, tack, and transport vehicles may serve as fomites because the virus can survive for hours on such objects. Severity of clinical signs of influenza, which include nasal discharge, fever, lethargy, anorexia, cough, and myalgia, depends on the degree of existing immunity and other factors. Infected horses shed virus for up to 10 days in their nasal secretions. Inactivated vaccines do not induce sterile immunity, so recently vaccinated horses can become infected, shed virus, and contribute to interepidemic persistence of infection within the equine population and propagation of infection during outbreaks.[6]

Immunity to the same (homologous) strain of H3N8 virus after natural infection persists for more than a year and involves both local and systemic humoral and cellular mechanisms. These include induction of large amounts of virus-specific neutralizing IgG and secretory IgA antibody in nasal secretions, high levels of circulating IgG antibodies, and genetically restricted antigen-specific cytotoxic T lymphocytes (CTLs) that kill infected cells.[72-76] Memory CTLs can be detected in peripheral blood for at least 6 months after infection, and solid immunity persists even when circulating antibody titers have declined to low or undetectable levels.[73,74,77,78] Similarly, protection induced by the licensed modified live intranasal (IN) influenza vaccine (Flu-Avert I.N. [Merck Animal Health]) is presumably mediated through induction of local immune responses in the respiratory tract because this vaccine does not typically induce high levels of circulating antibodies.[7,79] With the exception of ISCOM vaccines, inactivated vaccines administered by IM injection have limited potential to induce CTL or nasal secretory IgA responses and induce only low levels of neutralizing antibody in nasal secretions.[72,78,80,81] The degree of protection induced by inactivated influenza vaccines is highly correlated with postvaccination titers of circulating antibody, predominantly of the IgGa and IgGb subisotypes, as measured by HI or single radial hemolysis (SRH) tests.[70,82-84] SRH levels of 100 mm^2 or greater are considered to be at least partially protective, but levels above 140 mm^2 are required for successful prevention of disease.[82] The partial protection induced by inactivated vaccines is of limited duration (up to about 7 months, depending on the vaccine) and is manifested as a reduction in clinical signs and attenuation of viral shedding in horses exposed to infection.[71,72]

The magnitude of the serologic response to inactivated influenza vaccines depends on many factors, the most important of which are the quality and quantity (mass) of the viral antigen and choice of the adjuvant.[82,85,86] Carboxypolymer-based compounds (carbomer, Carbopol) and ISCOMs are contained in some of the most efficacious inactivated influenza vaccines,

VetBooks.ir

whereas some commonly used adjuvants (e.g., alum) have been associated with induction of a nonproductive immune response.[72,85] History of previous vaccination or infection, interval since the last dose of vaccine, antibody titer at the time of vaccination, age, maternal antibody status, and relatedness of the vaccine strain to circulating field strains of influenza virus are other important determinants of efficacy, at least for inactivated influenza vaccines.[84,87,88]

Antigenic drift of the A/equine/2 subtype has resulted from point mutations in the genes encoding the amino acid sequences of the hemagglutinin (H) and neuraminidase (N) glycoprotein antigens on the surface of the virus. The result is emergence of viral strains representing two antigenic lineages, American and Eurasian, of the H3N8 virus. Further antigenic drift within each lineage has generated variants that, as with the prototypical strain A/equine 2/Miami 63, are named according to the location and year in which they were first isolated. The American lineage further evolved during the 1990s into Kentucky, Florida, and South American sublineages.[89] For the Florida sublineage, two clades have been identified: clade I, represented by Ohio 03 and South Africa 03, and clade II, represented by Richmond 07. According to the 2017 report of the OIE expert surveillance panel on EIV, only clades I and II Florida sublineage EIV strains are circulating worldwide. Clade I representatives of the Florida sublineage are present in North America, Europe, South Africa, and Japan, and clade II representatives are present in Europe, India, and China.[89]

Antigenic drift, by generating antigenically heterologous viruses, reduces the degree and duration of protection conferred by previous infection or vaccination because of the specificity of immunoglobulins, and it allows horses with high titers to become infected and develop clinical signs of disease if the vaccine strain is not closely related to the drifted infectious field strain.[90] Although antigenic drift of EIV is slower than that of human influenza viruses, it is recommended that inactivated equine influenza vaccines include viral antigens from isolates obtained within the most recent 5 years. An expert surveillance panel meets annually to recommend strains that should be included in influenza vaccines in subsequent years (www.equiflunet.org.uk). In the past, federal U.S. regulations made updating of equine influenza vaccines through inclusion of recently isolated strains so costly and time-consuming that vaccines typically lagged more than the recommended 5 years behind the antigenic drift of field viruses, resulting in suboptimal protection. Recent changes in vaccine licensing regulations should make more frequent updating of equine influenza vaccines feasible. Even though Flu-Avert I.N. contains only a 1991 H3N8 strain of North American lineage, it has been shown to be protective against challenge with Eurasian strains and recently isolated North American strains.

The short-lived immunity after vaccination with inactivated equine influenza vaccines was the impetus for past recommendations for frequent revaccination, at intervals as short as 2 months. However, too short an interval may compromise efficacy because an optimal anamnestic response to influenza vaccination is inhibited in horses with a high antibody titer.[91] An additional consideration that potentially limits the efficacy of influenza vaccines is the phenomenon termed *original antigenic sin*, whereby horses exposed to a drifted field A/equine/2 virus will mount an anamnestic immune response directed more strongly against the strain with which they were vaccinated initially than against the drifted field virus.[86]

A considerable amount of published efficacy data based on both challenge studies and field epidemiology studies has been available for many years in Europe to support the use of influenza vaccines. In contrast, information regarding the efficacy of influenza vaccines marketed in North America has remained sparse until recently. Furthermore, studies conducted in North America during the late 1990s showed that the inactivated influenza vaccines in use at the time failed to provide much benefit in terms of reducing the risk of infection and clinical disease during field outbreaks.[6,70] Serologic testing performed during these and other studies indicated that vaccine failure was caused by failure of the influenza vaccines in use at the time to induce protective antibody titers.[6,70,92]

Fortunately, vaccine manufacturers in North America have responded to the challenge of producing more efficacious equine influenza vaccines during the past 15 years by incorporating more relevant recent viral strains, increasing antigenic mass of relevant strains, eliminating the seemingly irrelevant H7N7 strain, modifying adjuvant systems, and introducing novel technologies. An important advance occurred in 1999 when Heska Corporation marketed an attenuated live cold-adapted influenza vaccine (Flu-Avert I.N. [Merck Animal Health]) for IN administration. This vaccine, which contains a Kentucky/1991 strain of North American lineage, was found to be highly efficacious in blinded controlled challenge studies conducted 5 weeks, 6 months, and 1 year after administration of a single dose to naive horses.[7] Subsequently, Flu-Avert I.N. was shown to cross protect against European H3N8 strains, as well as against North American strains isolated during the late 1990s and early 2000s, and to induce a rapid onset of protection within 7 days of administration of a single dose to naive horses.[79,93] Although horses challenged 1 year after administration of a single dose showed a significant but only partial reduction in severity of clinical signs and virus shedding, a more marked reduction in clinical signs and viral shedding was found when the challenge was performed 6 months after vaccination.[7] On the basis of these results, revaccination at 6-month intervals is recommended. Field experience indicates that this regimen induces solid clinical protection after natural challenge. Currently, Flu-Avert I.N. is licensed for use in nonpregnant horses 11 months of age or older, primarily because this was the youngest age of the horses used in the challenge studies for licensing. Horses may shed small amounts of vaccinal virus for several days after vaccination with Flu-Avert I.N., but the amount of virus shed is so low that in-contact horses will not generally become infected or immunized with vaccinal virus shed by recently vaccinated horses, and the likelihood of reversion to virulence is extremely low.[94]

In recent years, several vaccine manufacturers in North America have updated their inactivated vaccines and demonstrated efficacy in challenge studies. Inactivated influenza vaccines containing one or more relevant H3N8 strains are currently marketed by Boehringer Ingelheim (Calvenza EIV), Zoetis (Fluvac Innovator), and Merck Animal Health (Prestige II). These companies also market a large number of multicomponent combination vaccines that contain the same inactivated influenza antigens as in their single-component products but also contain tetanus, WEE and EEE virus, EHV, or WNV antigens.

A study in which naive 9-month-old horses were challenged by aerosol with a recent influenza H3N8 strain (KY/99) 16 weeks after the last dose of a three-dose vaccination series (0, 4, and 16 weeks) documented that Calvenza EIV and two EIV/EHV combination vaccines (Prestige II and Fluvac EHV-4/1) reduced clinical signs and viral shedding in vaccinated horses compared with nonvaccinated control horses.[96] The group vaccinated with Calvenza EIV developed significantly higher serum antibody titers after vaccination and experienced less fever, nasal discharge, and viral shedding than horses vaccinated with either Prestige II or Fluvac EHV-4/1. On the basis of these findings, the authors concluded that Calvenza EIV, a vaccine developed, formulated, and efficacy tested according to European Union guidelines, was the most effective inactivated influenza vaccine available in North America at that time. This vaccine is adjuvanted with Carbopol and contains the KY/95 and Ohio 03 North American strains and the Newmarket 93

VetBooks.ir

Eurasian H3N8 strains. The initial two doses of this vaccine are administered intramuscularly; subsequent doses may be administered intramuscularly or intranasally. It is proposed, but not proved, that administration of booster doses by the IN route may provide a stronger local mucosal immune response. This vaccine is licensed for use in horses older than 6 months of age, including pregnant mares. Only two commercially available EIV vaccines commercially available in North America (Vetera 2^{XP} [Boehringer Ingelheim] and Prestige II [Merck Animal Health]) do follow the OIE recommendations by including contemporary relevant clades I and II EIV strains. Vetera 2^{XP} contains representatives of both clade I (A/eq/Ohio/03) and clade II (A/eq/Richmond/1/07) Florida sublineage EIV, as well as an American lineage EIV strain (A/eq/Kentucky/95). The newly formulated Prestige II is the most recently updated EIV vaccine available in North America and contains A/eq/Florida/13 (Florida sublineage clade I), A/eq/Richmond/1/07 (Florida sublineage clade II), and A/eq/Kentucky/02 (American lineage). The metabolizable oil (MetaStim) adjuvanted Fluvac vaccine evaluated in the challenge study mentioned previously contained the KY/92 strain of the H3N8 virus. This strain has since been replaced with a KY/97 strain, and the product is now named Fluvac Innovator.

In 2006, Merial was granted a North American license to market an injectable canarypox-vectored recombinant equine influenza vaccine that has been used with success in Europe for several years. This vaccine, Recombitek Equine Influenza Virus vaccine, has been shown to induce strong protection in challenge studies and has the potential to positively impact influenza prevention in North America.[95] The vaccine incorporates the HA gene from the Ohio 03 and Newmarket 93 H3N8 strains into the same vector delivery platform as the efficacious WNV virus vaccine (Recombitek) and contains a carbomer polymer adjuvant in the diluent.[95] Consequently, this vaccine invokes a broad array of humoral and cellular immune responses. Challenge studies document onset of protection as soon as 2 weeks after completion of a two-dose primary series and persistence of solid protection for at least 5 months. Administration of a booster dose at 5 months induced a strong anamnestic response that provided solid protection persisting for at least 12 months.[96] This vectored influenza vaccine can circumvent the inhibitory effect of maternal antibodies, an issue that significantly impacts primary immunization of foals using inactivated influenza vaccines.[30] Recombitek Equine Influenza Virus vaccine is licensed for vaccination of healthy horses as young as 5 months of age.

VACCINATION PROTOCOLS FOR INFLUENZA. Influenza should be considered a core vaccine on all facilities that are not totally closed so as to preclude contact with "outside" horses from other locations. As with other diseases, the full benefit of vaccination against influenza can be realized only if the primary vaccination series is completed, or if booster doses of vaccine are administered, several weeks before anticipated exposure. The following issues should be considered when planning an influenza vaccination program: (1) primary vaccination of adult horses, (2) routine revaccination, (3) vaccination of pregnant mares, (4) primary vaccination of foals, and (5) vaccination in an outbreak.

Primary Vaccination of Adult Horses

The following are options for primary vaccination of adult horses that have not previously been vaccinated:

- Flu-Avert: administer a single dose intranasally. A second dose administered 3 months later may be beneficial, particularly for horses vaccinated at younger than age 11 months.
- Inactivated intramuscularly administered vaccines: administer two doses 3 to 6 weeks apart according to label directions. Although not specifically recommended by some manufacturers, administration of a third dose of vaccine 3 to 5 months after the second dose is indicated because it significantly enhances the magnitude of the primary response and duration of persistence of antibodies at protective levels.
- Recombitek Equine Influenza Virus vaccine: administer two doses 4 to 6 weeks apart, and revaccinate 5 months later.

Routine Revaccination

Improvements in injectable vaccines and introduction of new vaccine types during the past 10 years has extended the duration of clinical protection achievable through vaccination. A routine revaccination interval of 6 months appears to be appropriate for most of the influenza vaccines currently marketed in North America. This routine protocol should be customized by adjusting timing of boosters or inclusion of an additional booster to achieve maximum protection during periods when the risk of exposure is high. For example, strategic revaccination 1 month before being placed at high risk of exposure, such as at a show or sale or being transferred to a training or boarding facility, is justified to maximize protection.

Vaccination of Pregnant Mares

For the mare to produce colostrum that contains a high level of antibodies against equine influenza, she should be revaccinated 4 to 8 weeks before foaling with a vaccine that stimulates a robust serologic response. Although the intranasally administered Flu-Avert I.N. vaccine induces good protection, it does not routinely stimulate high levels of circulating antibody, at least when used for primary immunization. An inactivated injectable vaccine is therefore recommended for prefoaling booster vaccination of pregnant mares at this time.[26]

Vaccination of Foals

The antibody status of a mare at the time of foaling is the main determinant of the postnursing circulating antibody titer in her foal and therefore has a profound impact on the ability of the foal or weanling to respond to influenza vaccines administered during the first year of life. Foals born to seronegative nonvaccinated mares respond appropriately to influenza vaccines, so primary vaccination can commence at 3 months of age or younger if significant risk of exposure to influenza exists. In contrast, maternal antibodies have been shown to completely block the serologic response of foals to a primary immunization series comprising two or more doses of inactivated influenza vaccines when the first dose is administered at 6 months of age or younger.[12-18,24] Interference from MDA may persist until 9 months of age or beyond for foals with high antibody titers post nursing.[12-18,24,26] Studies in Newmarket, United Kingdom, have shown that influenza virus infection is rare in Thoroughbred yearlings before they enter training, suggesting that the risk of influenza is low in horses younger than age 1 year born to mares in herds that are well vaccinated.[88,97,98] There appears to be little justification to vaccinate young foals from vaccinated mares against influenza, as was recommended in the past.[48,99,100]

The IN modified live vaccine (Flu-Avert I.N.) is licensed for vaccination of horses 11 months of age or older. Whereas this vaccine has been shown to be safe in foals as young as 2 months of age,[101] published data regarding the potential for MDAs to interfere with the response are lacking. Unpublished observations suggest that MDA interferes with the response of foals between 3 and 6 months of age, whereas foals with maternal antibody vaccinated at 7 months of age were protected against virulent challenge (Holland and Chambers, personal communication). Pending publication of well-controlled studies, it is recommended that if the first dose of Flu-Avert I.N. vaccine is administered before 11 months of age, a second dose should be administered at 11 months of age or older.[102]

The European-licensed live canarypox-vectored recombinant influenza is labeled for use in pregnant mares and foals as

VetBooks.ir

young as 4 months.[78] The North American–licensed Recombitek EIV vaccine has been shown to be safe in foals as young as 4 months, but the minimum age recommended for vaccination of foals from immunized dams is 5 months. The recombinant vaccine has been shown to efficiently prime foals aged 10 to 20 weeks that had detectable MDA at the time of vaccination.[30] These foals showed clear evidence of an anamnestic antibody response when a secondary vaccination with the same vaccine was performed. The canarypox-vectored recombinant influenza vaccine therefore offers a unique opportunity to overcome the limitations of early-life vaccination in the face of maternally derived immunity in foals.[30] If the foal experiences failure of passive transfer of maternal antibodies, or if the mare is seronegative for influenza, the manufacturer recommends commencing vaccination at 4 months of age and including an additional dose in the primary series.

Vaccination in an Outbreak

Definitive diagnosis of equine influenza infection should be pursued during outbreaks of suspected viral respiratory disease because specific measures can then be instituted to contain spread of the disease. Rapid (same-day) diagnosis of influenza can be accomplished using the highly sensitive and specific polymerase chain reaction (PCR) or antigen-capture ELISA tests. In addition, virus isolation should be pursued during outbreaks to characterize new isolates and assess efficacy of current vaccines. The decision to vaccinate in an outbreak is dependent on many factors, the most important of which are the age, vaccination status, and size of the population of horses at risk; the elapsed time since onset of the outbreak; the rapidity with which a diagnosis can be confirmed; the layout of the physical facilities; and availability of personnel. Outbreaks of influenza at racetracks and similar large facilities typically take 1 month or more to spread through the entire population. Therefore sufficient time exists to enhance immune protection of many at-risk horses while implementing other management strategies to minimize disease spread.[93] It is prudent to booster-vaccinate those horses that have been on a regular influenza vaccination program but have not been revaccinated within the previous 3 months. It is also important to induce protection as quickly as possible in horses that have not previously been vaccinated. Of the vaccines currently available, Flu-Avert I.N. induces protection most rapidly, within 7 days of administration of a single IN dose. This is currently the product of choice for vaccination of naive horses and those of unknown vaccination status in the face of an outbreak.[93] Adverse effects have not been reported when Flu-Avert I.N. is administered to horses that are incubating infection, although vaccination of horses that are already clinically ill is not recommended. Alternatively, an accelerated vaccination schedule using the canarypox-vectored vaccine with a primary intervaccination interval of 14 days and booster at 105 days has been shown to quickly confer long-lasting protective antibody levels.[103] All 14 vaccinates demonstrated high SRH antibody titers 14 days following V2, thereby achieving 100% herd immunity to homologous viral challenge. Rapid induction of high levels of acquired herd immunity is critical in containing an outbreak of such a highly contagious pathogen as EIV.[103] In addition to reducing clinical and economic impacts, early vaccination clearly played an important role, together with biosecurity measures and movement restrictions, in containing the 2007 equine influenza outbreak in Australia, as well as ultimate eradication of the disease from that country.[104]

FUTURE INFLUENZA VACCINES. A recombinant modified vaccinia Ankara (rMVA) vector that delivers genetic material encoding for relevant hemagglutinin (H) antigens of an H3N8 influenza virus has been developed.[105,106] The rMVA system is designed to focus the CTL response on the recombinant antigen and was initially tested in a prime-boost strategy in which the priming dose consisted of a DNA plasmid encoding for expression of the H antigen. The intent of this DNA prime-rMVA boost regimen was to invoke both cellular and humoral immune responses involved in protection.[106] A subsequent study showed that the rMVA system was capable of inducing virus-specific lymphoproliferative and IFN-γ messenger ribonucleic acid (mRNA) responses; antigen-specific IgGa, IgGb, and IgA antibodies; and protection from challenge, both with and without a priming dose of the DNA vaccine.[105] These data indicate that vaccination of horses with rMVA alone or as part of a prime-boost regimen is an effective means of inducing protective immunity to influenza virus infection.[105] Considerable research has been performed to document the efficacy of the DNA vaccine used in the previously mentioned studies against equine influenza. However, the delivery system used (multiple sublingual, conjunctival, and subcutaneous [SC] injections delivered with a gene gun under general anesthesia) is impractical for use in the field.[105,107] Recent licensing of a naked plasmid DNA vaccine that can be conveniently administered to horses by IM injection to prevent WNV infection clearly documents the potential for development of a DNA vaccine to prevent influenza in horses in the future. In addition, a DNA vaccine expressing the hemagglutinin protein of H3N8 influenza virus was recently shown to protect ponies against challenge when administered subdermally using a needle-free delivery system.[108]

Equine Herpesvirus (Rhinopneumonitis)

The respiratory tract is the primary route of infection for EHV-1 and EHV-4, both of which cause respiratory tract disease that varies in severity from subclinical to severe and is characterized by fever, lethargy, anorexia, nasal discharge, and cough.[109] Seroepidemiologic studies indicate that the vast majority of foals become infected with EHV-1 and EHV-4 during the first year of life, but the clinical disease syndromes resulting from these infections are not always well defined, perhaps reflecting the modulating effect of MDAs.[110-112] Recurrent or recrudescent clinically apparent infections are seen in weanlings, yearlings, and young horses entering training, especially when horses from different sources are commingled.[109,113] In contrast, surveillance studies involving racehorses document that seroconversion to both EHV-1 and EHV-4 occurs sporadically during the course of a racing season, but these seroconversions are often not clearly associated with outbreaks of respiratory disease that follow an epidemiologic pattern consistent with an infectious agent.[114,115] EHV-1 and EHV-4 are spread by direct and indirect (fomite) contact with nasal secretions, by aerosolized secretions from infected horses, and in the case of EHV-1, by aborted fetuses, fetal fluids, and placentae associated with abortions. Management practices are therefore of primary importance for control of clinical disease caused by equine herpesviruses.

Viremia occurs frequently after infection with EHV-1, potentially leading to paralytic neurologic disease (equine herpes myeloencephalopathy [EHM]) secondary to vasculitis of the spinal cord and brain, abortion of virus-infected fetuses, or birth of infected nonviable foals. In contrast, manifestations of infection with EHV-4 (rhinopneumonitis) are generally confined to the respiratory tract, because EHV-4 does not typically infect endothelial cells or produce a cell-associated viremia.[116] As with herpesvirus infections in other species, horses typically fail to clear primary infections with either EHV-1 or EHV-4, the result being that most horses in the population remain latently infected with both viruses.[109,112,117] Latently infected horses do not show clinical signs but may experience recrudescence of infection with or without clinical signs, an increase in antibody titer, and shedding of the virus when stressed. Consequently, many horses have detectable levels of SN antibody to both EHV-1 and EHV-4 in their serum.[109,112,117]

VetBooks.ir

These features of the epidemiology of herpesvirus infections seriously compromise efforts to control these diseases and explain why outbreaks of EHV-1 or EHV-4 can occur in closed populations of horses. Whereas most mature horses have developed some immunity to EHV-1 and EHV-4 through repeated natural exposure and do not typically show respiratory signs when they become reinfected, horses do not appear to become resistant to the abortigenic or neurologic forms of infection with EHV-1 even after repeated exposure.[118] In fact, previously exposed mature horses are more likely than juvenile horses to develop the neurologic form of the disease.[119,120]

The genetic basis underlying the apparent increased likelihood that some EHV-1 isolates will cause EHM appears to involve a single-point mutation in the DNA polymerase *(DNApol)* gene.[121] This mutation results in the presence of either aspartic acid (D) or an asparagine (N) residue at position 752 of the DNA polymerase. More than 80% of EHV-1 isolates associated with EHM are of the D_{752} genotype, whereas less than 20% are of the N_{752} genotype.[121] Isolates of the D_{752} genotype have been designated as "neuropathogenic strains" in recent publications, lay articles, and laboratory PCR result reports, whereas N_{752} isolates have been designated as "wild-type," "abortigenic," or "non-neuropathogenic" strains. The latter terminology is unfortunate because both the D_{752} and N_{752} isolates are capable of inducing all syndromes (i.e., respiratory disease, abortion, neonatal death, and EHM).

Correlates for protection against EHV-1 and EHV-4 infection have been investigated extensively but are not yet fully defined. Infection with EHV-1 induces a strong humoral response, but protection from reinfection is short-lived and is not achieved until the horse has experienced multiple infections with homotypic virus.[109,116] No clear relationship exists between protection from EHV-1 or EHV-4 infection and concentrations of circulating antibody induced by vaccination or infection, but clinical manifestations of disease and the duration and amount of virus shedding from the nasopharynx are reduced in animals with high levels of circulating neutralizing antibody.[116,122-126] Mucosal immunity and cell-mediated responses likely play a role at least as important as circulating neutralizing antibodies in protection against EHV-1 infection[127] because the presence of MHC class 1–restricted CTL precursors in peripheral blood is correlated with protection.[116] Because EHV-4 replication is largely confined to epithelial cells of the upper respiratory tract, mucosal immunity is likely important in protection.[116]

Currently available vaccines include inactivated vaccines containing only EHV-1 or both EHV-1 and EHV-4 and one MLV EHV-1 (Rhinomune [Boehringer Ingelheim]). Several inactivated products are licensed only for protection against respiratory disease; currently, all contain a low antigen load. Two inactivated products (Pneumabort-K + 1b [Zoetis] and Prodigy [Merck Animal Health]) that contain a high antigen load are licensed for protection against both abortion and respiratory disease. Performance of the killed low-antigen-load respiratory vaccines is variable, with some vaccines outperforming others. Performance of the killed high-antigen-load abortion/respiratory vaccines is superior, resulting in higher antibody responses and some evidence of cellular responses to vaccination. This factor may provide good reason to choose the high-antigen-load abortion/respiratory vaccines when the slightly higher cost is not a decision factor. Alternatively, the Calvenza EIV/EHV (Boehringer Ingelheim) respiratory vaccine induces high titers of VN antibody comparable with those induced by the high-antigen-load abortion/respiratory vaccines.[8] The MLV EHV-1 vaccine (Rhinomune [Boehringer Ingelheim]) has been shown to induce a level of clinical protection and reduction in viral shedding of similar magnitude to that provided by an inactivated high-antigen-load vaccine (Pneumabort-K + 1b) and of greater magnitude than is provided by one of the killed low-antigen-load respiratory vaccines.[128] Whereas vaccination with either EHV-1 or EHV-4 can provide partial protection against the heterologous strain, vaccines containing EHV-1 may be superior in this regard.

The principal indication for use of equine herpesvirus vaccines is prevention of EHV-1–induced abortion in pregnant mares and reduction of signs and spread of respiratory tract disease (rhinopneumonitis) in foals, weanlings, yearlings, and young performance and show horses that are at high risk of exposure. Many horses do produce postvaccinal antibodies against EHV, but the presence of those antibodies does not ensure complete protection. Consistent vaccination appears to reduce the frequency and severity of herpesvirus-induced disease. Although convincing evidence is lacking, field experience suggests that whereas the incidence of sporadic EHV-1–induced abortion in individual mares has not changed, the incidence of abortion storms caused by EHV-1 has declined significantly since the introduction and widespread use of EHV-1 vaccines in the United States.[117,118] Outbreaks of abortion and associated perinatal foal death, however, do continue to occur on occasion in herds of vaccinated mares.

Of the vaccines currently licensed for use in pregnant mares in North America, only inactivated monovalent EHV-1 vaccines (Pneumabort-K + 1b [Parsippany-Troy Hills, NJ] and Prodigy [Merck Animal Health, Madison, NJ]) containing abortigenic strains of EHV-1 carry a label claim for preventing abortion, whereas at least one bivalent EHV-1/4 vaccine is licensed for prevention of abortion in Europe (Duvaxyn EHV-1/4 [Intervet]). One of the vaccines available in North America, Pneumabort-K + 1b, incorporates both the 1p and 1b subtypes of EHV-1 to reflect the documented increase in the proportion of EHV-1 abortions caused by the 1b subtype that occurred during the 1980s as compared with earlier years.[129] Pregnant mares should be vaccinated during the fifth, seventh, and ninth months of gestation. Some veterinarians also recommend a dose during the third month of gestation. Similarly, vaccination of mares with an inactivated EHV-1/-4 vaccine at the time of breeding and again 4 to 6 weeks before foaling is commonly practiced to enhance concentrations of colostral immunoglobulin for transfer to the foal. However, no published reports document the effectiveness of this approach in raising titers of specific antibody in mares that have already been vaccinated against EHV-1 3 times during the previous 5 months. Vaccination of barren mares and stallions with either a bivalent EHV-1/-4 vaccine or a monovalent EHV-1 vaccine before the start of the breeding season and thereafter at 6-month intervals is recommended, with the goal of increasing herd immunity in an attempt to reduce viral shedding and challenge to pregnant mares on breeding farms.[117]

An MLV EHV-1 vaccine (Rhinomune) has been used as an aid in prevention of EHV-1 abortion by some practitioners for many years,[130] even though this vaccine is not currently labeled for this use. Several recent developments have created renewed interest in the potential for use of MLV vaccines to protect horses against manifestations of EHV-1 and EHV-4 infection. Sequencing of the EHV-1 genome has made it possible to document the nature of the mutation encoding for attenuation, mediated through truncation of the gp2 glycoprotein of the KyA strain.[131] Similar studies may soon yield information regarding the mutation underlying attenuation of the RAC-H strain from which Rhinomune was derived.

Because currently available inactivated vaccines do not block infection with equine herpesviruses, the most we can hope for when using inactivated vaccines is reduction of severity of clinical signs and attenuation of virus shedding to help protect herdmates. Challenge studies in weanlings aged 5 to 8 months have clearly demonstrated the efficacy of an inactivated whole virus EHV-1/-4 vaccine in reducing clinical manifestations and virus shedding induced by virulent EHV-1 challenge administered 2 weeks after completion of the two-dose primary

series.[125] Efficacy was clearly correlated with vaccine-induced antibody levels at the time of challenge in this study.[125]

Specific antibodies against both EHV-1 and EHV-4 are passed in colostrum.[22,25,132-134] Field studies with EHV-1 MLVs indicate that colostral antibodies exert a profound inhibitory effect on serologic responses to vaccination up to at least 5 months of age.[21,135,136] However, a cytotoxic cellular immune response to both EHV-1 and EHV-4 was induced in a substantial percentage of foals vaccinated with an EHV-1 MLV in the presence of maternal antibody, even though humoral responses were often absent.[137] It is uncertain whether these responses would provide protection against natural challenge. Recent studies with two different commercially available inactivated bivalent EHV-1/-4 vaccines and one inactivated EHV-4/EIV vaccine have shown that the majority of foals from EHV-vaccinated mares do not mount a detectable neutralizing antibody response to vaccines administered at 3 and 4 months of age, even when three doses are administered in the primary series.[22,24,25] An increased proportion of foals responded when vaccinated with a three-dose series starting at 5 or 6 months of age, but a substantial number still failed to seroconvert.[24,25] Some foals with low or undetectable levels of SN antibody at the time of vaccination failed to mount a serologic response, suggesting that low levels of antibody, below the lower limit of detection of the SN test based on EHV-1 antigen, are capable of inhibiting the serologic response to inactivated EHV-1/-4 vaccines.[25] The failure of a large proportion of foals younger than 6 months of age to mount serologic responses to inactivated EHV-1/-4 vaccines and the influence of antibody titer at the time of vaccination on failure to respond has been confirmed using sensitive gD and gG ELISAs in studies on commercial stud farms in Australia.[138] In parallel studies, these researchers concluded that mares were the source of infection for foals, and intensive use of inactivated EHV-1/-4 vaccines on breeding farms in Australia had a minimal impact on the infection rate of young foals and weanlings with EHV-1 and EHV-4.[110,112,139]

Considering the uncertainty regarding the role of EHV-1 and EHV-4 as causes of clinically important respiratory disease, the lack of published data regarding the efficacy of available vaccines in preventing infection and establishment of latency, and results of a recent study documenting the poor serologic responses of naive horses to a number of killed low-antigen-load EHV respiratory vaccines currently marketed in North America,[8] there appears to be little rationale to support the common practice of frequent revaccination of foals, weanlings, yearlings, and young performance horses against EHV-1 and EHV-4.[5] Furthermore, an obvious dilemma in designing a vaccination strategy to prevent EHV-1 and EHV-4 infection in foals and weanlings is that if primary immunization is delayed until 6 months of age or older to reduce the likelihood of MDA interference, foals are likely to encounter field infection before the three-dose primary series can be completed. It is therefore unreasonable to expect a high degree of efficacy for vaccination programs designed to protect foals and weanlings against EHV infection using available vaccines. Despite these uncertainties, many practitioners elect to vaccinate against both EHV-1 and EHV-4. Under these circumstances, a reasonable compromise would be to start foal vaccination at 4 to 6 months of age using two doses of an inactivated bivalent vaccine or an EHV-1 MLV administered 3 to 4 weeks apart, followed by administration of a third dose 2 to 5 months later. Revaccination at 4- to 6-month intervals, thereafter using either an inactivated bivalent EHV-1/-4 vaccine or a modified live EHV-1 vaccine, appears appropriate for yearlings and young performance or show horses that experience contact with other horses. Frequent vaccination of nonpregnant mature horses (except those on breeding farms) with EHV vaccines is generally not indicated.

Available vaccines make no labeled claim to prevent EHM, and there is no evidence that current vaccines can prevent EHM in the field. Frequent revaccination of mature horses to help prevent EHM is not justified in most circumstances because EHM is a relatively rare disease from a population standpoint, and most mature horses have previously been infected with EHV-1 and are latent carriers. Currently available vaccines do not reliably block infection, development of viremia, or establishment of latency, and EHM has been observed in horses vaccinated against EHV-1 regularly at 3- to 5-month intervals with inactivated or modified live vaccines.[119,120,140,141]

On the basis of the presumed similar pathogenic mechanism between EHV-1 abortion and neurologic disease,[142,143] parallels likely exist in terms of the requirement for immunologic protection. The control of cell-associated viremia is thought to be critical for preventing EHV-1 abortion and, presumably, neurologic disease. Therefore the goal of any vaccination program aimed at the prevention of EHV-1 abortion or neurologic disease is to stimulate those immune responses that can reduce or eliminate cell-associated viremia. Two recent studies have investigated the protective effect of commercially available killed and MLV vaccines against experimental challenge with neurotropic EHV-1 strains 24 or 29 days after completion of a three-dose vaccination series.[122,123] A significant reduction in the level of viremia was noted in ponies challenged after vaccination with either Calvenza or Pneumabort-K + 1b, both of which are inactivated vaccines.[122,123] Reduction in viremia post challenge was not observed in ponies vaccinated with another inactivated vaccine (Prodigy) or the MLV vaccine (Rhinomune).

A challenge study performed almost 30 years ago to test the efficacy of Pneumabort-K + 1b in preventing abortion and a recent study to test the efficacy of Rhinomune against challenge with a "neuropathogenic" strain of EHV-1 provided some evidence that these vaccines may have a place in control of outbreaks of EHM.[126,128] Interestingly, the Army 183 EHV-1 strain used as the challenge virus in the Pneumabort-K + 1b efficacy study has now been shown to carry the D_{752} mutation, as has the Findlay 03 strain used in the Rhinomune study. However, the low numbers of horses used in these studies, the failure of either vaccine to prevent infection or significantly reduce the level of viremia, the lack of statistical significance of results pertaining to prevention of neurologic signs, and the well-known difficulties encountered in accomplishing a consistent and reproducible challenge model for neurologic EHV-1 infection justify caution in interpretation.

The significant reduction in viral shedding observed in vaccinated horses provides reasonable justification for booster vaccination of nonexposed horses at risk for infection to reduce viral shedding in the event they do become exposed to EHV-1. By enhancing herd immunity, it is hoped that the level of infectious virus circulating in the at-risk population will be reduced, and in turn the risk that individual horses in the population will develop disease may be reduced.[140] This approach also relies on the assumption that the immune system of most mature horses has already been "primed" by prior exposure to EHV-1 antigens through field infection or vaccination and can therefore be "boosted" within 7 to 10 days of administration of a single dose of vaccine. Although the validity of this approach has not been critically evaluated for prevention of EHV-1 neurologic disease, its implementation seems rational when faced with one or more horses with confirmed clinical EHV-1 infection (any form) at a particular facility. Whereas booster vaccination of horses likely to have already been exposed is not recommended, it is rational to booster vaccinate nonexposed horses, as well as those that must enter the premises, if they have not been vaccinated against EHV-1 during the previous 90 days. Use of the Rhinomune MLV or one of the inactivated EHV-1 vaccines known to stimulate high circulating titers of neutralizing antibody appears justified for this purpose. Horse owners must develop an understanding of the concept of boosting herd immunity to help protect the group of horses

VetBooks.ir

VetBooks.ir

rather than focusing on the as yet unattainable expectation that the veterinarian can reliably protect an individual horse from developing potentially fatal EHM by administering one of the vaccines currently marketed as aids to prevention of clinical manifestations of EHV-1 infection. Ultimately, enforcement of strict biosecurity measures and hygiene practices are likely to be more effective than widespread vaccination in reducing the risk of acquiring infection.

FUTURE VACCINATION STRATEGIES TO PREVENT HERPESVIRUS INFECTION. To be completely effective in blocking primary infection and establishing a lifelong carrier state with EHV-1 and EHV-4, future vaccination strategies should be directed at inducing a strong mucosal immune response in the upper respiratory tract during the first few weeks of life, at a time when high levels of maternal antibodies are present. Promising progress toward this goal was reported by Patel and colleagues,[144] who documented that IN administration of a single dose of temperature-sensitive modified live EHV-1 vaccine to maternal antibody-positive foals aged 1.4 to 3.5 months afforded partial but significant protection against febrile respiratory disease, viremia, and virus shedding after IN challenge with virulent EHV-1 performed 8 weeks after vaccination. This vaccine has also been shown to provide significant protection against abortion in challenge studies, and because it is capable of preventing the development of viremia, it shows potential to prevent EHM.[127,145] Recent studies with vaccinia and canarypox-vectored recombinant vaccines and DNA vaccines have generated promising results, but more research is necessary to identify the immunodominant protective antigens of EHV-1 and their interaction with the equine immune system before these approaches will be applicable for use in the field.[146-150]

The recent Third International Havemeyer Workshop on Equine Herpesvirus Type 1 highlighted the need to improve vaccines, with MLV being identified as the vaccine type most likely to be successful in inducing a protective immune response.[151] The identified goals of future vaccine candidates will be to stimulate both humoral and cell-mediated immunity, differentiate infected from vaccinated animals (DIVA), provide minimal gaps in immunity, induce a rapid onset and long-lasting immunity, be effective in the presence of MDAs to prevent infection early in life, provide a wide clinical and virologic cross-protection, be safe and effective against the development of EHM, suppress reactivation of latent EHV-1 infection, and be safe when used in the face of an outbreak.[151]

Streptococcus equi subsp. *equi* Infection (Strangles)

Strangles is a highly contagious disease caused by the bacterium *Streptococcus equi* subsp. *equi (S. equi)*. Strangles primarily affects young horses (weanlings and yearlings), although horses of any age can become infected if not protected by previous exposure to the organism or vaccination. The organism is transmitted by direct contact with infected horses or subclinical carriers or indirect contact with water troughs, feed bunks, pastures, stalls, trailers, tack, or grooming equipment contaminated with nasal discharge or pus draining from lymph nodes of infected horses. The organism survives for several weeks in the environment, particularly in aquatic locations and when protected from exposure to sunlight and disinfectants, and can be a source of infection for new additions to the herd. Because *S. equi* is a clonal organism, there is minimal antigenic variation between different isolates even though isolates vary in their pathogenicity.

Most horses develop a solid immunity during recovery from strangles, which persists in over 75% of animals for 5 years or longer,[152] indicating that induction of durable protection through vaccination is biologically feasible if the protective antigens can be identified and presented in an appropriate manner.[153] Although the basis for acquired resistance to strangles is not completely understood, the finding that recovered horses rapidly clear intranasally inoculated *S. equi* despite not making circulating antibody to its surface proteins indicates that to be highly effective a strangles vaccine must stimulate local nasopharyngeal tonsillar immune clearance responses and that serum antibody is of lesser importance.[154] This conclusion is further supported by the finding that ponies with high levels of circulating antibody to multiple unique surface-exposed and secreted proteins after systemic vaccination remained susceptible to challenge with *S. equi*.[154] The cell wall M protein of *S. equi* (SeM) is recognized in the acquired immune response to *S. equi* infection, a response that involves both production of local antibodies in the nasopharynx and circulating opsonophagocytic antibodies.[155-157] The predominant opsonophagocytic antibodies are of the IgGb subisotype but also include IgGa and IgA, whereas IgGb and later mucosal IgA predominate in nasopharyngeal secretions.[156,158]

Strangles vaccines licensed and marketed for use in North America include one inactivated adjuvanted M-protein cell wall extract (Strepvax II [Boehringer Ingelheim]) and one attenuated live vaccine (Pinnacle I.N. [Zoetis]) derived from a nonencapsulated mutant of *S. equi* for IN administration.[159] Infection of horses with *S. equi* continues to cause troublesome outbreaks of strangles throughout North America, despite the availability and widespread use of these vaccines, indicating that their efficacy is suboptimal.[160] M-protein vaccines induce a good opsonophagocytic antibody response in serum but a minimal mucosal IgA response, which likely accounts for the incomplete protection observed when they are used in the field.[156,161] However, data do exist to document that vaccination using injectable SeM vaccines reduces the attack rate and severity of strangles in herds with endemic infection.[161-163] The live IN vaccine has been shown to induce a relevant mucosal immune response and partial or complete protection but may do so without inducing a strong serologic response.[160,164] Because vaccinal organisms in the IN vaccine must reach the inductive sites for immunity in the pharyngeal and lingual tonsils, accurate vaccine delivery is critical to vaccine efficacy.

Vaccination against *S. equi* is not routinely recommended for pleasure or performance horses kept in low-risk situations, but it is a consideration for horses that are resident on or being transported to premises like breeding farms, where strangles is a persistent endemic problem or where a high risk of exposure is anticipated. The bacterial MLV is generally preferred over the inactivated injectable vaccine for primary vaccination of foals and weanlings and for routine use in older horses at high risk for infection. On breeding farms, efforts should be concentrated on preventing infection of foals and weanlings by booster-vaccinating broodmares 4 to 6 weeks before foaling to maximize colostral content of antibodies. Whereas the IN vaccine has been shown to be safe for use in mares at all stages of pregnancy and can be used in mares in the face of an outbreak, it does not reliably stimulate high levels of circulating antibody. For this reason, the intramuscularly administered inactivated SeM product is preferred for prefoaling booster immunization of mares. Antibodies of the IgG and IgA class recognizing the SeM are passively transferred to the foal through colostrum and are also present in the milk of immune mares.[165] Antibodies of predominantly the IgGb isotype are absorbed from colostrum and redistribute to the nasopharyngeal mucosa.[158] These IgGb antibodies, along with the SeM-specific IgA antibodies that are present in milk and passively coat the pharyngeal mucosa of nursing foals, provide protection to most nursing foals up to the time of weaning.[157,158,165] Resistance of nursing foals to strangles during the first few months of life appears to be mediated by IgGb antibodies in nasal secretions and milk and not by IgA.[165] Serologic (ELISA) responses to M-protein

vaccines are poor in foals, most likely owing to the inhibitory effect of maternal antibodies.

Whereas the IN MLV may be less susceptible than the inactivated extract vaccines to MDA interference, this issue has not been investigated and the manufacturer does not recommend administration of this vaccine to horses younger than 9 months of age. Considering that on farms where strangles is endemic, foals often become infected around the time of weaning (age 4 to 8 months), it is difficult to protect them if vaccination is delayed until age 9 months. A reasonable compromise on breeding farms where the risk of strangles infection is high and mares are on a regular vaccination program would be to begin primary vaccination of foals using the IN live vaccine as early as 4 months of age. The recommended two-dose primary series administered 2 to 3 weeks apart should be followed by a third dose 3 to 4 months later and boosters at 6- to 12-month intervals thereafter, depending on risk of infection. The IN vaccine has been administered to foals as young as 5 or 6 weeks of age during outbreaks. If a vaccine is used in this manner, a third dose of the vaccine should be administered 2 to 4 weeks before the foal is weaned to optimize protection during this high-risk period. Although there are few reports of adverse effects attributable to use of the IN strangles vaccine in young foals, the inability of foals to mount an adequate mucosal IgA response during the first month of life and the potential for interference by maternal antibodies suggests that foals are unlikely to fully benefit from IN strangles vaccine administered before 4 months of age. When an inactivated M-protein vaccine is used for primary vaccination of foals, it is recommended that the initial series begin at 4 to 6 months of age, using three doses administered at 4- to 6-week intervals, followed by semiannual boosters for as long as high-risk conditions prevail.

Strangles vaccines should be administered only to healthy, nonfebrile horses free of nasal discharge and should not be administered to those that are known to have had recent direct exposure to clinically ill animals.[153] However, outbreaks of strangles generally persist for several months to more than 1 year, particularly on breeding farms where each foal crop adds new susceptible animals to the population. Thus, strangles vaccines are frequently administered in the face of an outbreak as an adjunct to management practices designed to bring outbreaks under control, and it is not always possible to accurately determine the exposure status of each horse. Under these circumstances, the likelihood of preventing strangles is greatest for horses that have not yet been exposed and can be kept isolated from infected horses until 2 weeks after the vaccination protocol can be completed. Horses that have been vaccinated previously will generate a response more rapidly than naive horses. Similarly, the IN MLV is preferred over inactivated vaccines for immunization of naive horses in an outbreak because it is likely to generate a protective immune response more rapidly.

Injectable strangles vaccines tend to cause local reactions at the site of injection more often than other equine vaccines. Injection in the gluteal muscles is not recommended because gravitational drainage along fascial planes can prove troublesome in the event an abscess develops at the injection site. In addition, purpura hemorrhagica, a serious and sometimes life-threatening systemic immune complex (Arthus-type) vasculitis manifested as edema with or without petechial hemorrhages on mucosal surfaces, has been observed with low frequency in the weeks after administration of strangles vaccines. Inactivated extract vaccines are implicated more often than the IN MLV, but all strangles vaccines have the potential to induce purpura hemorrhagica. The antigen present in immune complexes is SeM, along with antibodies of the IgA class. Because a high serum IgG titer against *S. equi* appears to be associated with an increased risk of developing purpura, routine testing for specific IgG antibodies using a commercially available ELISA test has been recommended as a means of preventing vaccine-associated purpura hemorrhagica.[160] Horses with titers of 3200 or greater in the SeM ELISA and those known to have had strangles during the previous year should not be vaccinated.[160] Recent studies investigated the factors associated with likelihood of horses having a high serum *S. equi* SeM-specific antibody titer.[166,167] This study indicated that older horses, horses other than Thoroughbreds and warmbloods, and horses that had been vaccinated with an attenuated live IN *S. equi* vaccine between 1 and 3 years previously had an increased likelihood of having a serum SeM-specific antibody titer of 3200 or higher. Recommendations of when to vaccinate horses after an *S. equi* outbreak largely depend on how long horses maintain a serum SeM-specific antibody titer of 3200 or higher, which can range from 9 to 27 months. Therefore the recommendation is to wait at least 1 year after an outbreak before vaccinating horses against *S. equi* and to test for *S. equi* SeM-specific antibody titer 12 to 24 months following the outbreak.[167]

The bacterial modified live vaccine for IN administration will cause injection site abscesses if inadvertently injected intramuscularly. To avoid inadvertent contamination of other vaccines, syringes, and needles, it is advisable and considered good practice to administer all parenteral vaccines before handling and administering the IN strangles modified live vaccine. Other reported adverse responses after administration of the IN modified live vaccine include nasal discharge, submandibular or retropharyngeal lymphadenopathy with or without abscessation, limb edema, internal abscesses (bastard strangles), and purpura hemorrhagica. The overall frequency of adverse events is low but appears to be higher than reported to the manufacturer (4.8 per 10,000 doses). The majority of reported adverse events, including the development of nasal discharge, lymph node abscesses, and purpura hemorrhagica, occurs in horses on farms with endemic or epidemic strangles, so it is often uncertain whether the adverse event was caused by the vaccine or by a wild strain of *S. equi*.

RECENT DEVELOPMENTS IN STRANGLES VACCINES. The nonspecifically attenuated Pinnacle strain of *S. equi* was produced by chemical mutagenesis to induce random mutations throughout the bacterial genome.[157,168] Because the point mutations responsible for attenuation have not been specifically defined, the potential exists for back mutation and reversion to full virulence.[168] In contrast, the live attenuated vaccine strain TW 928 contained in a strangles vaccine (Equilis StrepE [Intervet]) formerly licensed in Europe was stably attenuated by targeted deletion of the *aroA* gene.[169] This allowed development of a companion PCR test that was used in molecular epidemiologic studies to determine whether strangles in vaccinated horses was caused by the vaccine or wild-type strains.[170] Although this development proves that targeted gene deletion is a promising route for generating stable candidate mutants for inclusion in future vaccines, the high residual virulence, unconventional route of administration (submucosal in the upper lip), and short duration of immunity induced by Equilis StrepE limited its use to the extent that the vaccine was recently withdrawn from the market.

The incomplete protection afforded by bacterins and SeM extracts administered parenterally or by attenuated live vaccines administered intranasally or submucosally, as well as the undesirable side effects associated with some of these products, has prompted research to investigate other potential vaccine antigens and vaccination strategies. Promising results have recently been achieved in challenge studies involving horses vaccinated intramuscularly and intranasally with combinations of up to seven recombinant antigens including EAG (a protein that binds α_2-macroglobulin, albumin, and IgG), CNE (a

collagen-binding protein), SclC (a collagen-like protein), and two IgG endopeptidases, IdeE and IdeE2.[171,172]

Equine Neorickettsiosis (formerly termed *Potomac horse fever*)

Equine neorickettsiosis (EN), formerly known as *Potomac horse fever* (PHF), is caused by *Neorickettsia risticii* (formerly *Ehrlichia risticii*). Originally described in 1979 as a sporadic disease affecting horses residing in the northeastern United States near the Potomac River, the disease has since occurred in horses in 43 U.S. states, three Canadian provinces (Nova Scotia, Ontario, Alberta), South America (Uruguay, Brazil), Europe (The Netherlands, France), and India. The disease does not appear to be directly contagious, and it now appears that accidental ingestion of aquatic insects harboring metacercaria infected with *N. risticii* is at least one documented mode of transmission.[173] EN is seasonal, occurring between late spring and early fall in temperate areas of the northern hemisphere, with most cases in July, August, and September at the onset of hot weather. The disease may sporadically affect individual horses or cause outbreaks involving multiple horses. Foals appear to be at low risk for the disease. If EN has been confirmed on a farm or in a particular geographic area, cases will likely occur in future years. Documentation of the involvement of operculate freshwater snails and aquatic insects like caddis flies and mayflies in the life cycle of *N. risticii* has permitted formulation of focused control measures directed at minimizing exposure of horses to the habitats occupied by these species during the summer and fall months, when disease risk is highest in endemic areas.[173] Risk reduction is best accomplished by turning off barn lights at night, covering hay or storing it indoors, preventing horses from drinking at natural water sources like ponds or streams, and staying informed about local hatches of aquatic insects.[174]

Recovery after natural infection with *N. risticii* induces a strong antibody response and durable protection from reinfection lasting 20 months or longer. However, the presence of antibodies does not necessarily correlate with protection, and cell-mediated responses likely play a crucial role.[175] A β-propiolactone inactivated host cell-free *N. risticii* vaccine protects mice against homologous challenge.[176] Only one inactivated vaccine against *N. risticii* for IM administration (Equine Potomavac [Boehringer Ingelheim]) is licensed and available for use in horses as an aid in prevention of PHF. The high rate of serious complications and mortality associated with this disease has been considered adequate justification for vaccinating horses residing in or traveling to endemic areas. In a series of studies in which ponies were challenged intravenously with *N. risticii* approximately 4 weeks after completion of the two-dose primary vaccination series using a formalin-inactivated aluminum hydroxide–adjuvanted vaccine (PHF-Vax [Schering-Plough, Union, N.J.]) that is no longer marketed, Ristic's group (1988) reported that 78% of experimentally infected ponies were protected against all clinical manifestations of disease except fever and 33% were protected against all signs including fever.[177] A published noncontrolled field study involving the same vaccine documented induction of serologic responses in most vaccinated horses and a substantial reduction in disease prevalence, morbidity, and mortality compared with data collected in a previous year when horses were not vaccinated.[175,178]

In contrast to the results of the studies cited, epidemiologic investigations involving a large number of horses failed to demonstrate any clinical benefit from annual vaccination with currently available vaccines in the states of New York, Indiana, and Kentucky.[179,180] Failure of a substantial number of individual horses to mount an immune response to inactivated vaccines against *N. risticii*, heterogeneity of *N. risticii* isolates, the presence of only one *N. risticii* strain in vaccines, and much more rapid waning of immunity after vaccination than after natural infection likely account for the observed failure of vaccines to provide protection against field infection.[175,181] Despite the lack of documented efficacy of approved vaccines to prevent infection in the field setting, many practitioners who work in endemic areas believe that severity of disease is attenuated and mortality is reduced in vaccinated horses when vaccines are administered at 4- to 6-month intervals, with administration of one booster timed to precede the anticipated period of peak challenge.

If vaccination is elected, a primary series of two doses should be administered 3 to 4 weeks apart. The manufacturer recommends revaccination at 6- to 12-month intervals, but some veterinarians encourage a shorter revaccination interval. Because the disease has a distinct seasonal pattern, revaccination in the late spring, about 1 month before the first cases are expected, followed by a second dose 4 months later, appears to be a reasonable approach for strategic immunization to maximize the chances of protection during the period of peak challenge. The available vaccine is licensed for use in stallions and pregnant mares and can be administered to gestating mares 4 to 8 weeks before foaling to maximize passive transfer of specific antibodies to foals through colostrum. Whereas about 67% of foals from antibody-positive mares were antibody negative by 12 weeks of age, antibody was detectable in 33% of foals up to 5 months of age. On the basis of these findings, the low risk of clinical disease in young foals, and the apparent susceptibility to infection of two foals vaccinated earlier than 12 weeks of age, primary vaccination of foals from antibody-positive dams should begin with a two-dose primary series starting at age 5 months or older, followed by administration of one subsequent booster dose 8 to 12 weeks later.[178] However, the efficacy of this recommended regimen requires further study. If the primary series of two vaccinations is initiated before age 5 months, additional doses should be administered at monthly intervals up to 5 months of age to maximize the likelihood that an immunologic response is achieved. Vaccination of foals in endemic areas is further complicated by the distinct seasonal incidence of disease in July, August, and September, a time when most foals are between 2 and 6 months old and may be subject to maternal antibody interference with vaccination.

Botulism

Botulism is a neuromuscular paralytic disorder caused by one of eight distinct neurotoxins (A, B, Ca, Cb, D, E, F, G) produced by *Clostridium botulinum*, a soilborne, spore-forming, saprophytic, anaerobic, gram-positive bacterium.[182] Botulinum toxins are among the most potent biological toxins known and act by blocking transmission of impulses at motor end plates, resulting in weakness progressing to paralysis, inability to swallow, and frequently death. Of the seven serogroups (A through G) of *C. botulinum*, types A, B, C, and D have been reported to cause disease in horses, with types B and C responsible for most cases.[182] Three forms of botulism—toxicoinfectious botulism (shaker foal syndrome), forage poisoning, and wound botulism—have been observed in horses. Forage poisoning results from ingestion of preformed toxin produced by decaying plant material or animal carcasses present in feed, whereas wound botulism results from vegetation of spores of *C. botulinum* and subsequent production of toxin in contaminated wounds. Shaker foal syndrome, almost all cases of which are caused by *C. botulinum* type B, results from toxin produced by vegetation of ingested spores in the intestinal tract. This syndrome is a significant problem in foals between the ages of 2 weeks and 8 months in Kentucky and the Mid-Atlantic seaboard states and occurs sporadically in other areas.[183-185] Toxicoinfection with *C. botulinum* type C is currently being investigated as a cause of equine grass sickness, a largely fatal pasture-associated dysautonomia mainly affecting horses in Great Britain, continental Europe, and Australia, with reports of isolated U.S. cases.

VetBooks.ir

A toxoid vaccine (BotVax-B [Neogen Corporation, Tampa, Fla.]) directed against *C. botulinum* type B is licensed for use in horses in the United States. Its primary indication is prevention of shaker foal syndrome via colostral transfer of antibodies induced by vaccination of the mare. For primary vaccination, mares should be vaccinated during gestation with a series of three doses administered 4 weeks apart, scheduled so that the last dose will be administered 4 to 6 weeks before foaling to enhance concentrations of specific immunoglobulin in colostrum (i.e., months 8, 9, and 10 of gestation). Subsequently, mares should be revaccinated annually with a single dose 4 to 6 weeks before foaling. A similar type B toxoid is available to protect foals in endemic areas in Australia.[186]

Passively derived colostral antibodies appear to protect most foals for 8 to 12 weeks, although foals from properly vaccinated dams can present with botulism.[184-186] Insufficient production of specific antibody by the dam in response to the vaccination, failure of passive transfer of specific immunity to botulinum toxin, overwhelming toxin production, and loss of passive immunity by the time exposure to the toxin occurs may be reasons for vaccine failure. The clinician should be aware of the status of MDA transfer of each foal.

Maternal antibodies do not appear to interfere with the response of foals to primary immunization against botulism,[187] so a primary series of three doses of vaccine administered 4 weeks apart can be started when foals in endemic areas are 2 to 3 months of age or older. Other horses can be immunized using a primary series of three doses of vaccine administered at 4-week intervals, followed by annual revaccination. No licensed vaccines are available at present for preventing botulism due to *C. botulinum* type C or other subtypes, and because cross-protection between the B and C subtypes does not occur, routine vaccination against *C. botulinum* type C is not currently practiced. A type C toxoid approved for use in mink was administered to horses under special license to protect them during an outbreak of forage poisoning caused by contaminated alfalfa cubes in southern California in 1989. The C-terminal part of the heavy chains of botulinum neurotoxin types C and D (HcBoNT/C and D) has been expressed in *Escherichia coli* and has been shown to effectively immunize horses when administered as a recombinant monovalent or bivalent vaccine.[188,189] These vaccines are not yet licensed.

Horses and foals with clinical botulism may be treated with botulinum antitoxin administered intravenously. Antitoxin is not effective against toxin that has been translocated to motor end plates, so clinical signs may progress for 12 to 24 hours after administration of the antitoxin or until all internalized toxin has attached to motor end plates. The dose of botulinum type B antitoxin recommended for treating a foal is 30,000 IU and for an adult is 70,000 IU. Foals of unvaccinated mares born in or being moved to endemic areas may benefit from transfusion with plasma from a vaccinated horse or from administration of *C. botulinum* type B antitoxin. The efficacy of these practices warrants further study. Vaccination with type B toxoid as described earlier is an alternative to passive immunization.

Equine Viral Arteritis

Equine viral arteritis (EVA) is a contagious disease of equids caused by equine arteritis virus (EAV), an RNA virus found in the horse populations of many countries. EAV is the prototype virus in the family Arteriviridae of the genus *Arterivirus*, order Nidovirales. Although all horse breeds appear to be equally susceptible to EAV, the prevalence of infection, as determined by seroconversion, is much higher in some breeds (notably Standardbreds and warmbloods) than in others. Despite the high seroprevalence of infection in Standardbreds, clinical disease is rarely observed in this breed, indicating that subclinical infection is common.[11,190] Conversely, Thoroughbreds and most other breeds have a low seroprevalence of infection but are more likely to show fulminant clinical signs when they become infected. Most primary EAV infections are subclinical or asymptomatic. Clinical signs, if they occur, typically develop 3 to 7 days post infection and vary in severity, both within and between outbreaks, but may include some or all of the following: fever, anorexia, depression, localized or generalized urticaria, supraorbital or periorbital edema, conjunctivitis, lacrimation, serous or mucoid nasal discharge, and dependent edema involving the limbs, prepuce, scrotum, mammary glands, or ventrum. EVA is of special concern because abortion is a frequent sequel to infection in the unprotected pregnant mare. EAV can also cause life-threatening pneumonia or pneumoenteritis in young foals, and infection of the postpubertal colt or stallion may establish a long-term carrier state.[11,191] Transmission most frequently occurs through direct or aerosol contact with virus-infective respiratory secretions, leading to widespread dissemination of the virus among susceptible horses in close proximity. Indirect transmission, though less significant, can occur through contact with virus-contaminated fomites. Venereal transmission from infected carrier stallions to mares via semen during natural breeding or artificial insemination with fresh, chilled, or frozen semen can play a significant role in introduction and spread of infection on or between breeding farms or other equine facilities. The virus can persist in the reproductive tract of stallions for many years and possibly result in lifelong infection.

Historically, large-scale outbreaks of EVA have been relatively infrequent. However, the number of confirmed occurrences appears to be increasing, likely because of increased global movement of horses, increased accessibility of carrier stallions, and increased utilization of shipped cooled or frozen virus-infected semen. Outbreaks can be associated with serious economic consequences, as clearly exemplified by the 2006 multistate outbreak in Quarter Horses that was propagated by widespread shipment of semen from the index cases, two inapparently infected carrier stallions in New Mexico. Because the carrier stallion is widely accepted as the natural reservoir of EAV and the source of diversity among naturally occurring strains of the virus, identifying these individuals through serologic testing followed by PCR testing or virus isolation from semen forms the cornerstone of eradication measures. Vaccination also constitutes an important means of controlling spread and minimizing the consequences of infection.

A modified live vaccine based on an attenuated strain of EVA virus was developed by researchers in Kentucky in 1969.[192] This vaccine (Arvac [Zoetis]) was first used extensively in the field during the 1984 outbreak of EVA in Kentucky and proved safe and effective in bringing the outbreak under control.[11] This vaccine was developed further and licensed for use in North America. Vaccination of stallions, nonpregnant mares, and prepubertal colts has been shown to be a safe and effective means of controlling EVA. Strategic use of the MLV has formed the cornerstone of a highly successful program to control EVA in the Kentucky Thoroughbred breeding population for many years.[11] Indications for vaccination against EVA are to:

- Protect stallions against infection and subsequent development of the carrier state
- Immunize seronegative mares before being bred with EAV-infective semen
- Curtail outbreaks in nonbreeding populations. Vaccination in the face of an EVA outbreak in concentrated populations of performance horses at racetracks has been successful in controlling horizontal disease dissemination within 7 to 10 days.

Primary immunization with the modified live vaccine involves IM administration of a single dose, with a booster administered annually thereafter. Virus-neutralizing antibodies are induced within 5 to 8 days after vaccination and persist for at least 2

VetBooks.ir

years.[11,193] Revaccination induces high VN antibody titers that persist for several breeding seasons.[194] Although the current modified live vaccine is highly attenuated and has been shown to be safe and effective in stallions and nonpregnant mares, a small proportion of first-time vaccinated horses develop mild febrile reactions and transient lymphopenia after vaccination, and vaccine virus may be isolated sporadically from the nasopharynx and buffy coat for 7 days (occasionally up to 32 days) after vaccination.[11,193,195,196] Vaccinated stallions do not shed vaccine virus in either semen or urine.[194]

Primary vaccination provides sustained clinical protection against EVA but does not prevent reinfection and subsequent limited replication and shedding of field strains of virus.[197] However, the frequency, duration, and amount of viral shedding via the respiratory tract are significantly reduced in vaccinates. Vaccinated mares may transiently shed field virus after being bred to carrier stallions, so isolation of these individuals for 21 days after breeding is recommended.[11]

Annual revaccination of breeding stallions 28 days before the start of breeding season is highly recommended as a means of preventing establishment of the carrier state.[11] Annual revaccination of mares being bred to carrier stallions should occur at least 21 days before breeding. The modified live vaccine is not recommended for use in pregnant mares, especially during the last 2 months of gestation, or in foals younger than 6 weeks of age, except in emergency situations when there is a high risk of exposure. Apparent fetal infection with the modified live vaccine strain after vaccination of pregnant mares has been documented in rare instances.[193,198] A recently published study in which 73 pregnant mares were vaccinated during midgestation to late gestation concluded that it is safe to vaccinate healthy pregnant mares up to 3 months before foaling and during the immediate postpartum period. Vaccinating mares during the last 2 months of gestation was associated with an increased risk of abortion.[199] The authors concluded that when faced with a substantial risk of natural exposure to EAV, the risk associated with vaccination must be weighed against the much greater risk of widespread abortions in unprotected populations of pregnant mares.[199]

Foals born to seropositive mares become seropositive after ingesting colostrum. MDAs decay with a mean half-life of approximately 32 days, with the result that foals become seronegative between 2 and 7 months of age.[200,201] Maternal antibodies are unlikely to interfere with the response to vaccine administered at 7 months of age or older.[200] However, when foals younger than 6 months are vaccinated during conditions of high risk, they should be revaccinated after age 6 months. Establishment of the carrier state appears to depend on the high levels of androgens circulating in intact stallions and can be prevented by vaccinating colts, preferably before puberty and before they are used for breeding.[11] Vaccination of prepubertal colts at age 6 to 12 months is therefore central to effective control of the spread of EAV infection and should be strongly encouraged in breeds like Standardbreds and warmbloods in which EVA is prevalent and on facilities where risk of infection is high. Persistent infection has never been documented in a stallion properly vaccinated with the licensed modified live vaccine before exposure.[11]

REGULATORY AND EXPORTATION CONSIDERATIONS WITH VACCINATION AGAINST EVA. Horses vaccinated with the MLV can be expected to become seropositive for life. Titers resulting from vaccination cannot be distinguished from titers resulting from natural infection, so vaccination may complicate testing of horses for export. When planning a vaccination program against EVA, it is important to consult with state and/or federal animal health officials to ensure that any such program is in compliance with the state's control program for EVA if one exists. It is strongly recommended that before vaccination, all first-time male vaccinates be tested and confirmed negative for antibodies to EAV by a USDA-approved laboratory (http://www.aphis.usda.gov/cvbapps/Labs.jsp). Mares intended for export should be similarly tested. In instances where there is uncertainty or concern over whether vaccination against EVA could prevent export of a horse to a particular country, it is advisable to consult the federal area veterinarian (http://www.aphis.usda.gov/vs/area_offices.htm#CO) in charge in the state to determine the specific import requirements of that country. Several countries bar entry of any equid that is serologically positive for antibodies to EAV, regardless of vaccination history. Countries that do accept EVA vaccinated horses typically require stallions or colts to have a certified vaccination history and confirmation of prevaccination negative serologic status.

FUTURE DIRECTIONS. Development and marketing of a marker vaccine that not only affords protection but also allows vaccinated horses to be distinguished serologically from inapparently infected carriers would greatly facilitate control and even eradication of EAV from horse populations. Several new-generation EAV vaccines that potentially meet these criteria have been developed in recent years. These include an MLV DIVA vaccine with a deletion in the GP5 ectodomain,[202,203] a DNA vaccine that incorporates open reading frames (ORFs) 2b, 5, and 7,[204,205] and a subunit EAV vaccine using recombinant replicon particles derived from a vaccine strain of VEE virus that includes genes encoding both major envelope proteins (GP5 and M) of EAV.[206,207]

Rotaviral Diarrhea

Equine rotavirus (ER), a nonenveloped icosahedral RNA virus possessing a genome comprising 11 segments of dsRNA, is one of the most important causes of infectious diarrhea in foals during the first few weeks of life and often causes outbreaks involving the majority of the foal crop on individual farms.[208-210] Older foals and adult horses are more resistant to infection. Equine RV is transmitted via fecal-oral contamination and causes diarrhea by damaging the tips of villi in the small intestine, resulting in cellular destruction, maldigestion, malabsorption, and diarrhea. The genus *Rotavirus* is one of five genera of the family Reoviridae and is divided into seven serogroups (A through G) based on differences in the inner capsid protein, VP6.[210,211] All equine rotavirus isolates to date are in group A, which is further subdivided using neutralizing antibodies to the VP4 and VP7 outer capsid proteins into P (protease-sensitive, VP4-positive) and G (glycoprotein, VP7-positive) serotypes, respectively.[211] Five P serotypes (P1, P6, P7, P12, and P18) and eight G serotypes (G1, G3, G5, G8, G10, G13, G14, G16) have been identified and characterized in horses.[212-214] Molecular genome analysis strongly suggests that the vast majority of the currently circulating equine group A rotavirus strains are highly conserved, with only limited genetic diversity.[215] Most are of the P12 and G3 serotype and include two subtypes (A and B).[216]

An inactivated rotavirus A vaccine (Equine Rotavirus Vaccine [Zoetis]) containing the P12, G3 serotype (H2 strain) in a metabolizable oil-in-water emulsion is conditionally licensed in the United States and is indicated for administration to pregnant mares in endemic areas as an aid for preventing diarrhea in their foals caused by infection with ERs of serogroup A. Foal vaccination is not indicated; no data suggest that vaccinating the newborn foal with inactivated rotavirus A vaccine has any benefit in preventing or reducing infection severity. Label recommendations call for a three-dose vaccine series to be administered to mares during each pregnancy at 8, 9, and 10 months' gestation. This protocol has been shown to induce significant increases in serum concentrations of neutralizing antibody in vaccinated mares and in antibody concentrations of the IgG (but not IgA) subclass in colostrum and milk of

VetBooks.ir

vaccinated mares.[217,218] It is essential that the newborn foal receive an adequate amount of good-quality colostrum so that it absorbs sufficient anti-ER antibodies. After nursing from vaccinated mares, the concentration of passively derived ER-specific antibody of the IgG subclass in the serum of foals up to 90 days of age is significantly higher than that measured in serum of foals born to unvaccinated mares.[217,218] A field study showed this vaccine to be safe when administered to pregnant mares and provided circumstantial evidence of at least partial efficacy. An approximately twofold higher incidence of rotaviral diarrhea was found in foals from unvaccinated mares compared with those from vaccinated mares, although this difference did not prove to be statistically significant.[217] Similarly, a controlled field study in Argentina in which an inactivated aluminum hydroxide–adjuvanted vaccine containing the SA11 (G3P2), H2 (G3P12), and Lincoln (G6P1) strains of equine rotavirus was administered to 100 mares at 60 days before foaling and again 30 days later demonstrated a substantial reduction in the incidence and severity of rotaviral disease in foals from vaccinated mares compared with foals from unvaccinated mares.[219] As MDA titers wane at about 60 days of age, foals may develop rotaviral diarrhea, but the severity of diarrhea is generally milder and of shorter duration than in foals that become infected during the first 30 days of life.

Challenge studies involving two inactivated rotavirus vaccines administered in a similar manner to pregnant mares in Japan showed that their foals were not completely protected against infection but had a substantial reduction in severity of clinical signs after challenge.[214] The major correlate for protection against rotaviral infection appears to be mucosal immunity, predominantly mucosal IgA, in the gastrointestinal tract. Studies of the immunoglobulin isotype responses of mares after parenteral vaccination with inactivated ER vaccines, and of antibodies passively transferred to their foals via colostrum, indicate that this approach is unlikely to provide foals with intestinal mucosal protection in the form of IgA.[218] Consequently, it is not surprising that current protocols do not provide complete protection. In addition, because the conditionally licensed vaccine available in the United States contains only the G3 serotype of the A serogroup, it cannot be expected to protect against infection with all field strains.

Equine Rhinitis A Virus

Two rhinitis viruses, equine rhinitis A virus (ERAV; formerly known as equine rhinovirus 1, genus *Aphthovirus*, family Picornaviridae) and equine rhinitis B virus (ERBV; formerly known as equine rhinovirus 2, genus *Erbovirus*, family Picornaviridae), have been identified in horses.[220-225] Seroprevalence studies confirm that both viruses are active in horse populations worldwide, with prevalence ranging from 20% to 90%, depending on the age group and use of the horses sampled.[221,222,226] The rhinitis viruses have been largely overlooked as potential causes of clinically apparent respiratory disease for many years, but recently investigated outbreaks of contagious respiratory disease, as well as challenge studies, suggest that ERAV and ERBV may indeed be important pathogens of horses, causing both lower and upper respiratory tract disease.[223,225,226] Clinical manifestations include pyrexia, nasal discharge, cough, lethargy, anorexia, pharyngitis, and submandibular lymphadenopathy.[223,225] It has also been suggested that ERAV may play a causative role in inflammatory airway disease.[226] A unique feature of ERAV is persistent shedding in urine but only short shedding in nasal secretions after respiratory tract infection.[220]

An inactivated ERAV vaccine (Equine Rhinitis A Vaccine [Boehringer Ingelheim]) was granted a conditional license in late 2012; efficacy and potency tests are in progress. The vaccine is labeled for vaccination of healthy horses 4 months of age or older. The manufacturer recommends a primary vaccination series of three 1-mL doses administered IM at 3- to 4-week intervals, followed by revaccination annually or before anticipated exposure. Pending publication of more data regarding vaccine efficacy, as well as the role of ERAV as a cause of respiratory disease, these authors are unable to provide recommendations regarding use of this vaccine at the present time.

Anthrax

Anthrax is a serious and rapidly fatal septicemic disease caused by proliferation and spread of the vegetative form of *Bacillus anthracis* in the body. *B. anthracis* is acquired through ingestion, inhalation, or skin penetration through contamination of wounds by soilborne spores of the organism. Anthrax is encountered only in limited geographic areas where moist alkaline soils, particularly those with high organic content, favor survival, germination, and sporulation of the organism. Vaccination is indicated only for horses pastured in endemic areas.

The only vaccine currently licensed for vaccination of livestock, including horses, contains viable live Sterne's strain 34F2 nonencapsulated spores in saponin (Anthrax Spore Vaccine [Colorado Serum Company, Denver, Colo.]). A primary series consisting of two doses of that vaccine should be administered SC 2 to 3 weeks apart, followed by annual revaccination. Mild to moderate swelling at the injection site is common, and adverse systemic reactions may occur occasionally, particularly in young and miniature horses. Little objective information is available regarding use of this vaccine in horses, but clinical evidence suggests that it provides protection. Vaccination of pregnant mares is not recommended.[227] Because it is a live bacterial product, appropriate caution should be used during storage, handling, and administration of the vaccine to prevent accidental inoculation of people and maintain vaccine potency. Concurrent administration of antimicrobial drugs effective against *B. anthracis* is contraindicated if the vaccine is to function as intended.

Leptospirosis

Leptospirosis is a bacterial disease with a worldwide distribution caused by spirochetes of the genus *Leptospira*. Classification of *Leptospira* spp. is fairly complex and is performed either via the traditional phenotypic classification based on serotyping or via genotypic classification based on DNA homology.[228] In North America the most prominent pathologic serovar associated with disease of equids is *Leptospira interrogans* serovar Pomona type kennewicki.[229] Opossums, raccoons, skunks, foxes, and deer are believed to be the most common maintenance host of this serovar. In horses *Leptospira* infection has most often been associated with abortion, equine recurrent uveitis, and renal and hepatic disease.[230] Horses are typically exposed to *Leptospira* by ingestion of wet vegetation or water that has been contaminated by urine of a carrier or reservoir host, after which *Leptospira* spirochetes penetrate mucous membranes or breaches of skin, although other routes of exposure include contact with aborted fetuses, placentas, uterine discharge, or milk or with water contaminated by any of these materials.[230] A diagnosis of leptospirosis in horses can be challenging due to the difficulty in identifying *Leptospira* spp. and the high seroprevalence in the equine population.[231] A combination of serology, culture, direct detection, and qPCR testing is used to support a diagnosis of leptospirosis. A single leptospirosis vaccine (LEPTO EQ INNOVATOR [Zoetis]) is licensed for horses in the United States. The vaccine contains a whole-cell monovalent *Leptospira* bacterin with a label claim to use as an aid in prevention of leptospiremia caused by *Leptospira interrogans* serovar Pomona in healthy animals 6 months of age or older, as well as in pregnant mares in all three trimesters of gestation. The manufacturer recommends a primary vaccination series of two 1-mL doses administered IM at 3- to 4-week intervals, followed by revaccination annually.

Corynebacterium pseudotuberculosis Infection (Pigeon fever)

C. pseudotuberculosis, an agent of pigeon fever or dryland distemper, is a gram-positive, intracellular, facultative anaerobic bacterium. Flies act as a mechanical vector for this microorganism, and transmission occurs generally through abrasions or wounds in the skin or mucous membranes.[232] Pigeon fever has a seasonal incidence with the highest number of cases occurring during the dry months of the year, which is late summer and fall in the southwestern United States.[233] In recent years, pigeon fever cases have been diagnosed with increased frequency outside the western states. There are three forms of the disease, which are external infection, internal infection, and ulcerative lymphangitis. A diagnosis of pigeon fever infection is based on clinical signs, clinicopathologic data, diagnostic imaging, bacterial culture of an aspirate, and serology.[234] A conditionally licensed inactivated *C. pseudotuberculosis* bacterin-toxoid (*C. pseudotuberculosis* bacterin-toxoid [Boehringer Ingelheim]) is available in the United States. The vaccine is labeled to be used in horses 12 months of age or older for the immunization against disease caused by *C. pseudotuberculosis*. The manufacturer recommends a primary vaccination series of two 1-mL doses administered IM at 3- to 4-week intervals, followed by revaccination annually. Pending publication of more data regarding vaccine efficacy, these authors are unable to provide recommendations regarding use of this vaccine at the present time.

Ovine and Caprine Vaccination Programs

Factors Affecting Vaccine Availability, Choice, and Usage

Labeled vaccines for several important diseases of sheep and goats are currently available for use in the United States, but the small market share for small ruminant vaccines has negatively affected the funding available for vaccine research and development compared with other domestic species. As a consequence of low funding and difficulties in recouping development costs, vaccines currently being produced for small ruminants in the United States, except for the modified live vaccine for bluetongue virus and the anthrax spore vaccine, are either killed bacterin products or virulent live products. These products are more basic to develop and cheaper to produce and market. Modified live products typically require increased costs related to development and production and thus are not widely available for small ruminant–specific diseases. A current list of vaccine targets available for labeled use in sheep and goats in the United States is presented in Table 48.5, and example vaccination schedules for sheep (Table 48.6) and goats (Table 48.7) are also provided. All vaccines must pass basic efficacy and safety testing by the USDA Center for Biologics; however, for the majority of vaccines currently marketed, there is an overall lack of field-based comparative vaccine efficacy data available for the practitioner's use to determine which vaccines to select. Because the value of individual animals in flocks may be low and the cost associated with vaccination for certain diseases high, a cost/benefit analysis should be performed before developing a vaccine program for a particular herd. This analysis should include not only the cost of the vaccine itself but also the high cost of labor associated with administration, as compared with the anticipated risk of infection of the herd and direct costs associated with the disease.

Most available vaccines are bacterins, so avoiding maternal antibody interference and ensuring timely booster administration are key concepts for developing effective vaccine programs. Similar to other food animal species, proper vaccine administration and adherence to meat quality assurance are important. Vaccines should be administered subcutaneously whenever possible, either in the neck or behind the shoulder in the axillary region. Confusion over vaccine reactions that can lead to swellings that resemble lymph nodes infected with *C. pseudotuberculosis* should be kept in mind when choosing a vaccination location. Compared with sheep, goats are known to exhibit more severe vaccine reactions. If vaccines labeled for other species are to be used off label in goats, it is recommended that a small number of animals be vaccinated first to observe for reactions before vaccinating the entire flock.

Clostridial Vaccines

The only vaccine currently recommended for routine use in all small ruminants is yearly administration of a *Clostridium perfringens* C and D plus tetanus toxoid. Vaccination or protection via passive immunity (colostrum or antitoxin administration) is particularly important before common husbandry tasks like tail docking and castration (tetanus), as well as introduction to high-grain diets (*C. perfringens* type D). Ideally, all ewes and does should receive a booster vaccination 3 to 4 weeks before parturition; previous research in sheep indicates that passive immunity acquired from properly immunized ewes confers protection for up to 12 weeks in lambs.[1] Current recommendations for vaccination include an initial series of two doses 3 to 4 weeks apart, followed by yearly boosters. Appropriate timing of the booster in the first series of immunizations is essential in the formation of an adequate immune response for the remainder of the animal's life. When to initiate the first series of vaccinations is a topic of debate because there is little evidence-based literature on which to form a decision. The following guidelines are used by the authors in clinical practice. Lambs and kids from vaccinated dams with no evidence or suspicion of failure of passive transfer (FPT) may be vaccinated starting at 8 to 12 weeks of age. In animals born to unvaccinated dams or those with suspected FPT, we recommend earlier use of the initial dose; these animals should be vaccinated starting at 1 to 3 weeks of age, with a booster in 3 to 4 weeks and consideration for an additional booster 1 month later. It is relatively common for producers to vaccinate ewes/does before parturition and then still initiate the vaccination of kids/lambs at 1 to 2 weeks of age. In such cases the practitioner should discuss the implications of passive maternal immunity on the immune response elicited by the kid/lamb and should consider either additional boosters (after the period of maternal antibody wane) or delaying initiation of the vaccines. In cases of puncture wounds or injury, a tetanus booster should be administered if it has been longer than 6 months since the last vaccination. An additional booster may also be given to animals entering a feedlot or to those on a high-grain ration year-round (e.g., dairy animals) to aid in prevention of enterotoxemia.

Multiple combination commercial products are available, including *C. perfringens* C/D only, stand-alone tetanus toxoid, and seven-way or eight-way clostridial combination products. There is little evidence that vaccination with multivalent clostridial products is routinely beneficial, but these may frequently be chosen to decrease cost or in herds with a history of disease caused by other Clostridial species. If multivalent clostridial vaccines are selected, care should be taken to ensure the vaccine contains a tetanus toxoid; in some vaccines, *C. sordellii* may be substituted in place of *C. tetani*.

Rabies Vaccines

Highly efficacious vaccines for the rabies virus are commercially available for sheep in the United States. Vaccination for rabies

FPT, Failure of passive transfer.

is recommended in endemic areas, especially in animals with increased human exposure, such as pets, show animals, and petting zoo exhibits. Vaccination of valuable animals is also recommended. Despite the availability of highly effective vaccines, administration to all small ruminants is not routinely recommended, owing to the high cost associated with vaccination and the overall low rates of infection. In addition, unlike rabies vaccination in cats and dogs, previous vaccination of small ruminants does not necessarily constitute protection in regard to quarantine versus destruction of exposed animals. None of the currently available vaccines are labeled for goats, but they are considered relatively safe to use in this species in similar instances as with sheep. Initial vaccination after 3 months of age, followed by yearly revaccination, is recommended; after the initial yearly booster, vaccination frequency can be decreased to every 3 years in some cases, depending on vaccine label.

Foot Rot Vaccines

Commercial bacterin vaccines labeled for foot rot in sheep and targeting 10 strains of *Dichelobacter nodosus* and *Fusobacterium necrophorum* were once available in the United States. These vaccines are no longer commercially available in the United States, but the *D. nodosus* vaccine may be imported with USDA approval on a case-by-case basis. Localized vaccine reactions were common in both sheep and goats, and vaccine efficacy on a large scale has long been debated. Available evidence suggests that antigenic competition may reduce the effectiveness of simultaneous vaccination against multiple serogroups of *D. nodosus*.[2,3]

Current research performed in regions other than North America suggests newer approaches to vaccination for this disease may be more beneficial. In areas or flocks where only one or two strains may be present, targeted use of monovalent or bivalent autogenous vaccines in combination with culling of nonresponders may be of benefit in eradicating the disease.[4-6] However, it is considered uncommon for only one or two strains to be present; instead, multistrain infections are thought to more commonly occur.[7] Use of multiple bivalent autogenous vaccines with sequential administration staggered every 3 months may help avoid antigenic competition while allowing for prolonged protection against multiple serotypes.[8] Development of a "universal" vaccine through comparative genomics, transcriptional profiling, and serologic screening for potential candidate antigens has also shown promising results.[9] When these newer technologies will be commercially available in the United States remains to be seen. Given the difficulties and limited availability of vaccines for foot rot, veterinary practitioners are encouraged to consider alternate management strategies that include antibiotic therapy and potentially footbaths.

Reproductive Disorder Vaccines

Commercial vaccines are currently available for sheep only to aid in control of some of the important infectious abortion diseases and contagious epididymitis in the United States. Again, many of these vaccines lack comparative or published field efficacy data, so blanket recommendations for use cannot be made. For additional information on vaccination strategies in reproductive diseases, two excellent reviews have recently been written with a more in-depth discussion of each of the following diseases.[10,11]

An inactivated *Brucella ovis* vaccine is licensed in the United States for use in rams to aid in prevention of epididymitis, but at this time it is no longer being produced by the company other than on a special order basis. Inactivated vaccines are not believed to confer protective immunity to this organism but are known to interfere with serologic testing to detect carrier animals; therefore it is not recommended for routine use. In countries where *Brucella melitensis* is present, the Rev-1 live mutant vaccine may be useful in controlling both diseases; however, in *B. melitensis*–free countries like the United States and Canada, its use is prohibited.

There are currently two commercially available bivalent bacterin vaccines for abortion due to *Campylobacter fetus* subsp. *fetus* and *C. jejuni* in the United States. In general, there is minimal cross-protection between these organisms, and sheep appear to be much more susceptible than goats to abortions caused by these agents. Recommendations for use on farms with diagnosed abortions due to *Campylobacter* spp. include an initial series of two doses in ewe lambs, followed by administration of an annual booster; exact timing varies on the basis of the vaccine chosen. Recently a new tetracycline-resistant strain of *C. jejuni* (sheep abortion clone IA3902) has emerged in the

United States and is now thought to be the leading cause of *Campylobacter*-associated abortion in sheep.[12] Studies in guinea pig abortion models suggest that vaccination with certain commercial vaccines may be more beneficial than others in providing cross-protection to prevent abortion associated with this sheep abortion strain.[13] Following an abortion storm, herd immunity may initially be high, and in future breeding seasons the extent of disease may be limited to naive animals. Over time, immunity may wane, and infections may reoccur.

Chlamydophila abortus (formerly *Chlamydia psittaci*) is a common cause of abortion in both sheep and goats worldwide. Following abortion, ewes and does will develop immunity to future abortion but will often continue to shed the organism and infect other naive animals. Currently, only an inactivated culture vaccine (bacterin) is available in North America for use in sheep. Some producers have used this vaccine in goats, and it appears to be generally safe in this species. Vaccination with this type of vaccine will not prevent shedding of the organism but may decrease the rate of abortions. Vaccine efficacy is unpredictable, owing to variation in the amount of antigen present and loss of antigenicity following in vitro culture during vaccine production. Strain variation from farm to farm may also play a role in perceived vaccine failures. An attenuated live vaccine is available in other countries and is thought to be more efficacious in preventing abortion and shedding but is not without drawbacks. Live attenuated *C. abortus* organisms can be infective to humans handling the vaccine, and the vaccine strain has recently been identified in aborted placentas in the United Kingdom.[14] Newer vaccine technologies such as DNA vaccines or bacteriophage-delivered DNA may eventually offer a solution to the problems identified with current vaccine strategies.[15,16]

Vaccines for other important reproductive diseases like Q fever *(Coxiella burnetii)* and toxoplasmosis *(Toxoplasma gondii)* are not available in the United States even though they remain important causes of abortion in sheep and goats. A phase I inactivated *C. burnetii* vaccine is commonly used in many areas of Europe, with observed reductions in shedding and decreased abortion rates. This vaccine is currently part of the mandatory vaccination program in The Netherlands.[17] This vaccine is neither marketed nor approved for importation into the United States at present by the USDA. A modified live toxoplasmosis vaccine consisting of freeze-dried tachyzooites is available in Europe and New Zealand; it provides excellent long-term immunity. Both of these vaccines are potentially zoonotic and therefore must be handled carefully. Licensing of the *C. burnetii* vaccine has been considered in North America but may be hindered by licensing cost and market size. A vaccine for toxoplasmosis is not likely to become available in the United States in the near future, owing to the small market compared with overseas.

Caseous Lymphadenitis Vaccines

Vaccination for *C. pseudotuberculosis* has been attempted with a number of different vaccine modalities; all currently marketed products in the United States are bacterin-toxoids sold as either separate or combination products. Experimental trials have demonstrated a decrease in the occurrence of both internal and external abscesses following inoculation in vaccinated animals.[18] On the basis of these and other data, the vaccine may have a place in some herds to decrease disease prevalence. Although a large amount of research into vaccines has been done overseas,[19,20] little other U.S. vaccine research for this disease has been done. The available vaccines will not prevent all animals from developing abscesses, and animals must be vaccinated before exposure. Vaccine reactions (lameness, lethargy, depression) may occur and can be significant. Despite frequent use in goats, the fully licensed vaccine is not labeled for use in this species and may result in severe injection site reactions that can lead to decreased milk production and poor appetite. Recently, a new conditionally licensed vaccine specific for goats has come on the market. At the time of this writing, little data are available regarding its clinical use. It is not approved for use in all states, so practitioners should consult their state veterinarian or the manufacturer for more information. Initial vaccination requires a two-dose series 2 to 4 weeks apart, with annual revaccination required. Producers must be aware that vaccination will lead to a positive result on serologic testing.

Contagious Ecthyma Vaccines

Virulent live virus vaccines are available in the United States and labeled for use in both sheep and goats to decrease the severity of disease caused by contagious ecthyma virus (soremouth, orf). Use of these vaccines should be limited to herds where endemic disease is present or in outbreak situations where the disease has been newly introduced to the farm. Use of the vaccine on a farm without previous evidence of infection will result in contamination of the farm with live virulent vaccine virus. The goal of vaccination is to induce mild disease while creating immunity to future exposure. An area free of wool or hair is selected (axilla, flank, inner thigh) and a 1-in^2 area is scarified with a provided instrument, followed by application of vaccine. Development of a scab in the region of scarification is an indication of successful vaccination. The vaccine is a virulent live virus, so care should be taken with administration as it poses a zoonotic risk of infection. Vaccination failures are known to occur, and it has been suggested that the increased occurrence of vaccine failures, particularly in goats, may be due to strain variation between sheep and goat isolates. Efforts are under way to develop goat-specific vaccine strains.[21]

Respiratory Vaccines

Despite the long list of bacterial and viral organisms thought to play a role in respiratory disease in small ruminants, the only available labeled vaccines for sheep and goats in the United States for respiratory disease are combination killed bacterins of *Mannheimia haemolytica* and *Pasteurella multocida*. Most vaccine strains of these organisms are derived from bovine isolates; small ruminant strains, particularly for *M. haemolytica*, are not the same as those found in bovine cases.[22] Cross-reactivity among strains is variable, so the efficacy of these vaccines in small ruminants is inconsistent. In addition, many previously reported cases of *P. multocida* may instead have been caused by the newly classified *Bibersteinia trehalosi* (formerly *P. multocida* type T). None of the currently labeled respiratory vaccines for sheep and goats (or cattle) contain any strain of *B. trehalosi* at this time, and experimental results investigating the efficacy of vaccination for *M. haemolytica* and/or *P. multocida* in controlling disease cause by *B. trehalosi* are mixed at best.[23,24] There are currently no labeled vaccines for viral agents of respiratory disease in small ruminants, and there are no published studies evaluating the safety and efficacy of the use of bovine vaccines in these species.

Other Vaccines

An MLV vaccine is available for bluetongue virus in the United States, but it is thought to be of limited efficacy in the field because it contains only one of the six serotypes known to circulate in North America. Cross-protection among serotypes is thought to be limited, so vaccination will only offer protection against the vaccine strain (serotype 10). The vaccine is known to cause fetal malformations in pregnant ewes and has the potential to be transmitted to unvaccinated animals during vector season.

An avirulent live culture anthrax vaccine is available for domestic livestock including sheep and goats in the United States. Although rare, sporadic outbreaks and epizootics do

VetBooks.ir

occur among U.S. livestock, and premises with previous diagnosis of anthrax are considered susceptible to future outbreaks when soil and weather conditions are appropriate, such as during the 2005 epizootic in North Dakota. In endemic areas, vaccination in the spring of all livestock within 3 miles of a diagnosed case is recommended for a minimum of 5 years following the last diagnosed case.[25]

A conditionally approved (California only) endotoxin vaccine is labeled for use in milking goats to decrease the severity of toxic mastitis caused by *E. coli*. In other areas of the country, some of the endotoxin vaccines commonly administered in dairy cattle are used off label in milking goat herds. Because of the low incidence of toxic mastitis in this species, routine use is not recommended. If these vaccines are used, administration will not prevent infection but will decrease disease severity.

At present, there are no additional vaccines licensed for mastitis in milking sheep or goats in the United States. However, there is a vaccine currently licensed in multiple European countries for reduction of the incidence of subclinical mastitis cause by *Staphylococcus aureus* (sheep and goats) and coagulase-negative *Staphylococcus* (goats only) and the company is currently exploring approval for this vaccine in the United States. This vaccine is an inactivated product derived from a biofilm-expressing strain of *S. aureus*. Internal research reports by the company suggest efficacy in decreasing the incidence and severity of mastitis associated with staphylococcal infections, but no peer-reviewed research has been published to date. Previously published research has demonstrated that bacterins derived from strong biofilm producing strains of *Staphylococcus* provided the highest protection against intramammary infection and subsequent mastitis in sheep.[26] As mastitis caused by *Staphylococcus* species remains a major cause for production loss in milking sheep and goat herds, approval of an efficacious vaccine for this purpose in the United States would be beneficial.

BOX 48.1

Bovine Vaccines Seldom Needed on Most U.S. Ranches and Farms[a]

Anthrax vaccine
Clostridium septicum (malignant edema) bacterins
Leptospira grippotyphosa bacterins
Leptospira icterohaemorrhagiae bacterins
Leptospira canicola bacterins
Clostridium botulinum toxoids
Clostridium novyi bacterins
Rabies vaccine
Tetanus toxoids
Erysipelas bacterins
Clostridium sordellii (malignant edema) bacterins

BOX 48.2

Bovine Vaccines for Ranch- and Farm-Specific (Soilborne) Diseases

Blackleg bacterins
Clostridium haemolyticum (redwater) bacterins
Anthrax vaccine
Clostridium novyi (infectious necrotic hepatitis) bacterins

Bovine Vaccines and Herd Vaccination Programs

Victor S. Cortese

With the increasing size of today's cattle operations and the extensive movement of cattle, disease exposure continues to occur at a high rate. These exposures often put pressure on the efficacy of the vaccines used and may give field experience as to how well they can protect cattle. The wide diversity in uses of cattle and management practices makes a single vaccination protocol impossible for all cattle production systems. Today it is even more important to scientifically choose a vaccine or design a vaccination program based on good information. When designing programs, several variables must be considered[1]:

- The presence and degree of challenge of the particular diseases on the farm or ranch (Boxes 48.1 and 48.2)
- Management practices on the facility that support or hinder vaccination programs
- The times or ages when disease problems occur and whether the diseases are associated with any stressors
- The immune system components necessary to afford protection against various diseases
- Some basic immunologic concepts
- The information available on products being considered and the source and quality of the information
- Required vaccines for a particular use of the animal (e.g., 4-H shows)

Challenge

The level of disease challenge and degree of protection continually fluctuate. Biological variability makes the degree of protection different in every vaccinated animal. The same is true for the level of exposure to a pathogen. Overwhelming challenge can override immunity and lead to disease even in well-vaccinated animals.[2]

Timing of Disease

On many farms, certain diseases occur at consistent times. Timing may give some insight into stresses that occur in the management of the cattle. Correcting these stresses can have a positive impact on vaccination and lessen animals' susceptibility to disease. This type of history is also helpful in determining the timing of vaccinations, a concept that is often underused in veterinary medicine. Knowing when a problem historically has occurred allows vaccinations to be scheduled when they will induce maximum immune responses in preparation for expected challenges.

Assessing Vaccine Efficacy

The efficacy of a vaccine can be extremely difficult for the practitioner to assess. Traditionally, serologic data showing prevaccination and postvaccination titers have been equated with protection. For many diseases, however, the correlation is poor between the antibody measured and the protection generated by the vaccine in the animal.[3] Recently a study comparing BVDV protection showed an inverse relationship between antibody levels and the ability of the vaccines to prevent development of persistently infected calves.[4] Cell-mediated immune function tests have been added to show a more complete stimulation of the immune response after vaccination.[5] Although these tests provide more information about the vaccine, they still do not answer the basic question of how well a vaccine truly protects. This question can be answered only by well-designed challenge studies. Many examples of well-designed studies involve both viral[6,7] and bacterial[8,9] agents. To assess a challenge study, the following information is necessary:

1. Trial design, including animal characteristics
2. Statistical analysis of the results

[c]Heifer and bull replacements only.

3. Determination of whether statistical differences are biologically important
4. Route of administration of the challenge
5. Characteristics of the challenge organism
6. Consistency of the challenge model with the desired protection sought (e.g., respiratory vs. reproductive protection)
7. Method of clinical score assignment
8. Level of disease seen in the control unvaccinated cattle
9. Publication of the results in a peer-reviewed article

Unfortunately, the challenge model is not well established for many diseases. Field trials are even harder to assess but are valuable for judging the effectiveness (i.e., efficacy in a particular situation) and efficiency (i.e., cost-effectiveness) of a vaccine[10] (Boxes 48.3 to 48.12; also see Boxes 48.1 and 48.2). Several good references on field trial analysis are available.[11,12] Recently the Center for Veterinary Biologics (CVB) began giving vaccines different labels depending on the strength of the efficacy data submitted to them in the licensing trials.

Cattle Vaccines

Bovine vaccines tailored for use against 8 viral diseases, more than 28 bacterial pathogens, and 1 protozoal disease (trichomoniasis) are currently federally licensed in the United States (Table 48.8). These vaccines have been designed to aid in preventing a myriad of diseases in cattle, including reproductive, respiratory, generalized septicemic, and toxic (endotoxic and exotoxic) diseases. The vaccines have demonstrated some degree of protection against the pathogen for which they were designed, but they may not have proved protective against all the various syndromes known to be caused by a specific infectious agent. The challenge models for each pathogen and the release requirements for each vaccine are monitored by the Veterinary Biologics division of the USDA's Animal and Plant Health Inspection Service (USDA/APHIS) and can be found in Book 9 of the Code of Federal Regulations.

During gestation the bovine reproductive system, with its multilayered placenta, leaves the fetus in a naive environment susceptible to infection. Abortions may be due to infection of the placenta, inflammation of the ovary, death of the fetus, or disruption of the cervical plug. It is therefore difficult to achieve protection against reproductive diseases. Vaccination must minimize the amount or duration (or both) of the viremia or septicemia, or it must prevent the pathogen from moving through the cervix or crossing the placenta. Only a few currently licensed vaccines have proved protective against the reproductive forms of various diseases, and the duration of immunity they afford has not been established.

Each manufacturer's development and production of cattle vaccines is different, so the composition of vaccines varies

Fusobacterium necrophorum (foot rot) bacterin
Clostridium septicum (malignant edema) bacterins
Clostridium sordellii (malignant edema) bacterins

substantially among manufacturers. Outlines of production are proprietary for each manufacturer, but some information can be found in technical and marketing materials. For example, some viral vaccines are grown on bovine-derived kidney cell lines and others are grown on porcine-derived kidney cells. Some vaccines are grown only on calf serum, whereas others are grown on both calf and fetal calf serum. Variability is seen in the strain or strains chosen for the vaccine, number of growth cycle passages chosen for attenuation, growth medium, and number of viral or bacterial particles in the vaccine.

Three types of vaccines represent the basic technologies currently available in cattle viral and bacterial vaccines[2,13–17]:

1. *Modified live (attenuated) vaccines* contain living bacterial or viral organisms. These organisms usually are collected from a field disease case and then grown in abnormal host cells

Clostridium septicum (malignant edema) bacterins
Clostridium sordellii (malignant edema) bacterins

[a]Anavac (BioLOGIC Laboratories, Davis, Calif. 95616) is the preferred vaccine for use in dairy herds where adult cows are grazing in an endemic area.

(viruses) or media (bacteria) to change or attenuate the pathogen. Each completed replication cycle is known as a *passage*, and the changed pathogen is then administered back to the animal to determine if it is still virulent. After several passages the pathogen begins to lose virulence factors because it cannot cause "disease" in the unnatural host cells. Once the pathogen can no longer cause "disease" in the target species, it is tested to see if it can confer protection. The final vaccine is usually passed a number of times beyond the passage where virulence disappears in order to reduce the risk of reversion to a virulent pathogen. These vaccines require good quality control to reduce the risk of a contaminant entering the vaccine.

2. *Inactivated (killed) vaccines* are easier to develop because virulence after growth is not a problem. The same pathogen is isolated from a disease outbreak. The pathogen is grown and then chemically or physically killed. The inactivation is usually achieved by either adding a chemical to the pathogen or using ultraviolet rays. The major concern with inactivation is the potential loss of important epitopes. An adjuvant is normally added to inactivated vaccines to heighten the immune response. The vaccine is then tested for efficacy.
3. *Genetically engineered vaccines* have been genetically altered, usually through a mutation. This mutation may be induced by several different methods, but the resulting bacterium or virus has different properties that may alter virulence or growth characteristics. Most of these vaccines are modified live mutants (e.g., temperature-sensitive viral vaccines or streptomycin-dependent *Mannheimia/Pasteurella* vaccines), but inactivated marker vaccines are also genetically engineered. These vaccines have been engineered to delete a gene and cause an immune response deficient in antibodies to a certain epitope; this allows diagnostic methods to distinguish between vaccine and natural exposure responses (e.g., gene-deleted infectious bovine rhinotracheitis [IBR] vaccines).

	Anaplasmosis	*Anaplasma marginale* (not federally licensed)

[a]Licensed by the Animal and Plant Health Inspection Service, U.S. Department of Agriculture.

TEME, Thromboembolic meningoencephalitis.

Modified from Bayley AJ: *Compendium of veterinary products*, ed 5, Iowa City, IA, 1999, Iowa State University Press.

Once its efficacy has been established, the vaccine is put through a series of experiments to determine the minimum dose required to achieve adequate protection, called the *minimum immunizing dose* (MID). The vaccine will contain more than the MID to ensure that it contains at least the MID at the expiration date found on the label. In effect, a vaccine's efficacy is not determined by the final product used by the veterinarian, but at a reduced level of immunogens from the amount contained in the final vaccine.

Autogenous Vaccines

In addition to the vaccines licensed by the USDA, several companies will make autogenous vaccines for use by veterinarians and cattle owners. These vaccines do not fall under any particular USDA/APHIS guidelines and are usually derived from cultures (e.g., viral or bacterial) isolated from specimens submitted by the particular farm. Such vaccines can be used only on that particular facility and cannot be sold for use on other farms. These vaccines are not tested for efficacy or safety, and the components found in the vaccines may vary from batch to batch; this adds some element of risk when they are used. Nevertheless, this type of vaccine may be an option to consider when federally licensed vaccines are unavailable for a specific farm problem.

Maternal Antibody Interference Revisited

It is an accepted belief that maternal antibodies can block immune responses from vaccination. This belief has been based on a procedure of vaccination followed by a titer evaluation in the vaccinates. Many studies have shown that vaccinated

VetBooks.ir

animals may not display increased antibody levels if high levels of maternal antibody to that antigen are present. However, recent studies have shown that both B-cell memory responses and cell-mediated responses can be stimulated despite high maternal antibody for the same antigens.[18-20] Seropositive calves vaccinated at a young age with modified live (MLV) bovine herpesvirus type 1 (BHV-1), parainfluenza type 3 (PI-3), and/or bovine respiratory syncytial virus (BRSV) vaccines have shown higher antibody responses on revaccination than control calves vaccinated only at the second date. These young vaccinates typically do not show increased antibody responses after the initial vaccination in the presence of high maternal antibody. Cell-mediated immune responses, as indicated by antigen-specific T-cell blastogenesis, have been demonstrated in the face of high maternal antibody levels[21] when attenuated BRSV and BHV-1 vaccines were used. Similar responses have been reported in laboratory animals as well.[22-24] One study also demonstrated higher levels of protection at challenge if calves were vaccinated with a modified live BRSV vaccine.[20] It is clear from these studies that maternal antibody interference with vaccines is not as absolute as once thought. The animal's immune status, specific antigen, and presentation of that antigen should be considered when designing vaccination programs in which maternal antibody may be a factor.

Impact of Stress

Stress affects the immune system of all cattle, as can a number of other factors. The release of corticosteroid that occurs during the birthing process has a dramatic impact on the newborn's immune system. Newborns also have a higher number of suppressor T cells than adults.[2] These factors and others dramatically diminish systemic immune responses for the first week of life.[25] Other stresses should be avoided at vaccination time to maintain the integrity of the immune system. Procedures like castration, dehorning, weaning, and movement have to be considered as stressors in cattle, and all have the potential to temporarily diminish immune system functioning.[26-28]

Systemic vaccinations should be avoided during high-stress times because of these diminished responses and because vaccination at such times may even have undesired effects.

Booster Importance

It is important to follow the label directions for administering vaccines. Many inactivated vaccines and some modified live BRSV vaccines require a booster before protection is complete. The first time an inactivated vaccine is administered, the primary response occurs. This response is not strong, is fairly short-lived, and is predominantly composed of IgM antibodies (Fig. 48.1). The response seen after a booster vaccination is called the *secondary* or *anamnestic response*. This response is much stronger, of longer duration, and is primarily composed of IgG antibodies.[2,12] If the booster is given too early, the anamnestic response does not occur, and if too much time elapses before the booster is given, it acts as an initial dose, not as a booster.

With most MLV vaccines (except for some BRSV vaccines), the primary vaccination also stimulates the secondary response without the necessity of a booster because the virus or bacterium is replicating in the animal.

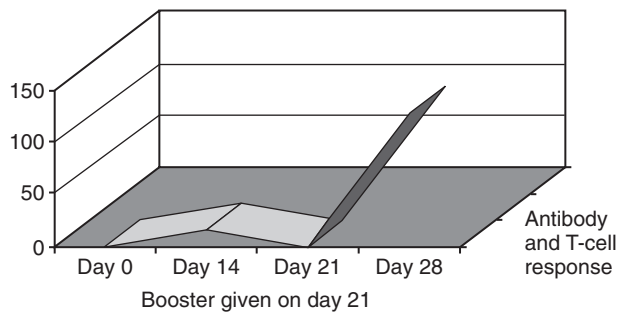

FIG. 48.1 Anamnestic response seen after booster dose is administered to vaccinates.

Adverse Reactions

Adverse reactions are a risk with any vaccination and can be categorized as one of the following two primary types of hypersensitivities[2,4,29-34]:

1. *Type I (immediate) hypersensitivity* is mediated by IgE stimulation and release of granules from basophils and mast cells. This reaction is seen within minutes of vaccination and often begins with shaking or sweating. Most of these animals respond to intravenous (IV) injection of epinephrine. Every vaccine can occasionally elicit an anaphylactic reaction. Cattle should always be kept under observation for at least 30 minutes after administration of a vaccine. Epinephrine should be administered at a dosage of 1 mL of 1:1000 solution per 50 kg of body weight, preferably by IV injection, at the first sign of weakness, staggering, or dyspnea. With most vaccines, anaphylactic reactions occur no more often than 1 case per 5000 to 10,000 doses administered. The rate of occurrence may be much higher after administration of *Salmonella*, *E. coli*, and some *Moraxella bovis* bacterins, which may have high levels of endotoxin.
2. *Type III (immune complex) hypersensitivity* is mediated by attachment of an antibody-antigen complex to complement and the ensuing activation of the complement cascade. The resultant reaction may occur locally or systemically. The reaction may be delayed, as the complexes form and the cascade begins, or subsequent, as products begin to exert their effects. The signs are similar to those of an immediate hypersensitivity reaction, and the treatment is administration of epinephrine.

One of the more common reactions seen in cattle has been associated with the endotoxin and other bacterial components found in most gram-negative vaccines.[32-35] Currently, there are no requirements for monitoring or reporting the amount of endotoxin found in cattle vaccines, and the level of endotoxin may vary dramatically between vaccines and between serials of the same vaccine. Furthermore, the potency of endotoxin varies among different gram-negative bacteria. This type of reaction is seen primarily in Holsteins because of a genetic predisposition and may be seen after administration of any gram-negative bacterin. The signs vary depending on the farm's or individual's sensitivity to gram-negative bacterial components. The number or potency of the gram-negative fractions in vaccinations administered simultaneously are also instrumental in causing these reactions. As a general rule, no more than two gram-negative vaccines should be administered to dairy cattle on the same day because of the possibility of adverse reactions, which may include anorexia and transient decreases in milk production, early embryonic death, abortion, and gram-negative bacterial shock (endotoxic shock), which requires treatment with flunixin or ketoprofen, steroids, antihistamines, and fluids.

Site reactions are common sequelae to many vaccines. These granulomas are usually caused by overreaction to the adjuvants, but they may also be directly aimed at the antigen or antigens. This has been a major focus of beef quality programs and has generated a push to have all vaccines labeled and to have them administered subcutaneously to avoid damaging the muscle.

Finally, some vaccines may affect appetites post vaccination. This impact continues to be an area of concern and active research, particularly in stressed cattle and neonates.[36-41]

VetBooks.ir

Read the Labels

The vaccine label is a wealth of information that is approved by the CVB/APHIS. The CVB evaluates the supportive efficacy data supplied by the vaccine manufacturer and decides whether the vaccine can be licensed or not. They also determine what type of efficacy claim can appear on the vaccine labels and in advertising. Included are dosage, route of administration, precautions, timing, indications, storage information, withdrawal period, and shelf life. As found in Veterinary Services Memorandum 800.202 (June 2002), the CVB also does some preliminary rating of vaccine efficacy by granting one of five level of protection statements (in order of highest efficacy to lowest): Prevention of Infection, Prevention of Disease, Aid in the Prevention of Infection, Aid in Disease Control, and Other Miscellaneous Claims. The label can be a good starting point for comparing vaccines.

Newer Immunologic Concepts in Cattle Vaccination

The terms *dominant antigen*, *antigen interference*, and *immunodominance* have been used interchangeably to describe a unique phenomena of the immune system. The term *immunodominance* has become the accepted term in human immunology, and textbooks have been written on the subject.[42] Immunodomination is defined as the process whereby immune expression or recognition of one epitope or antigen influences the recognition of a second distinct epitope or antigen.[43] This prioritization of epitopes by the immune system has been widely studied, and many articles have been published. Although most studies have focused on the occurrence of immunodominance in immune responses to the multitude of epitopes within a specific antigen (virus or bacteria), there are continued studies on the interactions between different antigens. On any bacteria or virus, only 0.2% of the possible epitopes have any measurable immune response.[44] This also extends to interactions between concurrent administration of different vaccines.[45,46]

Immunodominance has been shown to occur via several different mechanisms. These include:

1. Dominant epitope processing block antigen presenting cells from the antigen presentation of subdominant epitopes[43]
2. Dominant epitope T cells block expansion of subdominant T cells (CD4+ and CD8+)[3]
3. Dominant epitope processing using T-cell synaptic molecules to be used and exhausted and/or the release of defective synaptic molecules, thereby blocking attachment of subdominant T cells[42]
4. Shifting of subsets of CD4+ subsets toward antiviral or antibody formation[45,46]

One of the first published cattle studies demonstrating the potential for interactions between cattle vaccines was published in the *Canadian Journal of Veterinary Medicine* in 1992.[47] The authors demonstrated that vaccination with a modified live bovine herpesvirus 1 (infectious bovine rhinotracheitis virus, BHV-1) vaccine blocked the *M. haemolytica* vaccine response. The same phenomena of modified live BHV-1 vaccine over *M. haemolytica* vaccine response was observed in a vaccine field trial performed by Kansas State University.[48] More recent studies that have compared the serologic responses to *M. hemolyica* bacterins with coadministration of attenuated BHV-1 (MLV and temperature sensitive [TS]) supported the earlier findings; however, immunodominance was not shown if the BHV-1 vaccine was administered intranasally or on subsequent vaccination.[49-50] Antigen interaction has been shown with several other vaccines as well.[51-53] More research is necessary to continue to understand these interactions and how they pertain to developing vaccine program strategies.

Another new immunologic concept that also started in human immunology and is now being researched in veterinary immunology is the prime boost vaccine strategy. This concept involves priming the immune system to a target antigen delivered by one vector, route, or mechanism and then selectively boosting this immunity by readministration of the antigen in the context of a second and distinct method.[54] This is considered heterologous versus traditional homologous boostering.

Several papers have highlighted the power of prime-boost strategies in eliciting protective cellular immunity to a variety of pathogens and have demonstrated efficacy in humans.[55] The key strength of this strategy is that greater levels of immunity are established by heterologous prime boost than can be attained by a single-vaccine administration or homologous boost strategies. Recent studies in veterinary medicine have demonstrated the prime boost concept.[56-59] These and other studies indicate that this area of vaccination strategy is poised to make tremendous progress.

Summary

Designing a vaccination program requires a good history of the individual farm and a basic understanding of the immune system. Vaccines that should be considered for routine or optional use in various classes of pastured beef cattle, feedlot cattle, and dairy cattle are listed in Boxes 44.3 to 44.12. The vaccines chosen should be supported by good, solid efficacy studies (and by effectiveness and efficiency studies if possible) to ensure that the product can fulfill the needs of the farm or ranch (see Table 44.8). Management decisions that do not maximize the potential of the product chosen may be made, and realistic expectations of all products should be well explained to the producer before the vaccines are administered. The owner should be involved in the vaccine decision-making process, and all information on the product should be shared.

Establishing good baseline immunity of replacement heifers and the foundation vaccination program can have dramatic effects on the health and profitability of the herd, so such programs must be well planned.

Bovine Herpesvirus Type 1: Infectious Bovine Rhinotracheitis Virus

Bovine Herpesvirus Type 1 Vaccines

Robert W. Fulton

In 2018 more than 100 vaccines against BHV-1 were available in the United States for use in cattle.[1] These vaccines were either monovalent or in combination with other viral and/or bacterial immunogens. Vaccination protocols for beef and dairy cattle in the United States routinely incorporate use of one or more vaccines against BHV-1. These vaccines are classified into four types: (1) MLV vaccines for parenteral administration (IM and/or subcutaneous); (2) MLV, IN administered vaccines; (3) chemically altered, live virus, TS vaccine for parenteral use and/or IN use; and 4) inactivated viral (killed [KV] vaccines for parenteral use. These vaccines may be single-component (monovalent) vaccines (e.g., BHV-1 alone) or may contain several immunogens, including various combinations of bovine

viral diarrhea (BVD) viruses types 1 and 2; bovine parainfluenza type 3 (PI-3) virus, bovine respiratory syncytial virus (BRSV), *Leptospira* spp., *Histophilus somni*, *M. haemolytica*, *P. multocida*, and/or *Campylobacter* spp.[1] BHV-1 vaccines in the United States are principally derived from the Cooper/Colorado 1 strain, and in some cases the temperature sensitive mutant, RLB106.[1] The characteristics of the BHV-1 vaccines are described as follows.

BHV-1 MLV parenteral vaccines induce both B-cell (humoral) and T-cell (cell-mediated) active immune responses after administration of MLV vaccine.[2,3] Calves born to dams with circulating BHV-1 antibodies may absorb the colostrally derived maternal antibodies to BHV-1 and other viruses.[4] The mean half-life of viral antibodies to BHV-1 in calves receiving maternal immunity was 21.2 days.[4] Potentially, calves receiving passive immunity to BHV-1 may have a reduced response to BHV-1.[5] Calves seronegative to BHV-1 were given BHV-1 neutralizing antibody intramuscularly and subsequently given MLV BHV-1 intranasally. The passive BHV-1 immunity via BHV Ig had a reduction on the efficacy of MLV BHV-1.[5] The passively administered BHV-1 antibodies protected against viral shedding in viral-challenged calves.[5]

Modified Live Virus Parenteral Vaccines

The MLV parenteral vaccines were the initial vaccines licensed for use in cattle for protection against BHV-1.[6] Vaccines are attenuated by multiple passages in cell culture and often retain their ability to replicate in a susceptible animal, possibly causing viremia. MLV parenteral vaccines are relatively inexpensive, offer a convenient route of administration, and stimulate a rapid onset of immunity (i.e., within 3 to 5 days of administration).[7-12] In general, one dose given to a susceptible animal stimulates protective immunity, which varies in duration depending on the clinical form of the disease challenge.[3,12] Duration of immunity studies are important to determine length of protection after initial vaccination. Calves receiving a combination MLV vaccine with BHV-1 were protected for at least 126 days after vaccination as measured by protection against infection.[13] Licensure of BHV-1 vaccines in the United States requires efficacy studies using a standard challenge with the BHV-1 USDA Cooper strain. In addition, administration of a combination modified live BHV-1 vaccine yielded protection against virulent field strains of BHV-1.[14] The MLV parenteral vaccines may cross the placenta and infect the fetus, causing abortion.[15] Most MLV BHV-1 parenteral vaccines are not approved for use in pregnant heifers/cows or nursing calves.[1] However, companies have received label claim for BHV-1 and BVDV MLV vaccine use in pregnant cows providing they were vaccinated before breeding initially with that line of vaccines and within 12 months thereafter and to nursing calves provided their dams were vaccinated within 12 months as described earlier.[1,16] The impact of MLV BHV-1 and concurrent *M. haemolytica* vaccines has potential negative interactions. Administration of an MLV vaccine containing BHV-1 and PI3V in combination with a *M. haemolytica* vaccine reduced the efficacy of the *M. haemolytica* vaccine in preventing respiratory disease morbidity, respiratory disease mortality, and fibrinous pneumonia mortality and reduced the antibody response to *M. haemolytica* leukotoxin antibody response in a feedlot study.[17] In another study, coadministration of MLV BHV-1 and *M. haemolytica* immunogen interfered with the serologic response to *M. haemolytica* leukotoxin serum antibody response.[18]

Modified Live Virus Intranasal Vaccines

MLV IN vaccines generally can be divided into two types, based on the attenuation process: (1) those modified by passage in a cell culture[19,20] and (2) those modified by treatment such that they become "temperature sensitive"[21] (i.e., they do not replicate at internal body temperature). MLV IN vaccines stimulate protection in susceptible animals with only one dose, in contrast to chemically altered MLV parenteral vaccines. Calves receiving a temperature-sensitive IN BHV-1 vaccine were protected against virulent BHV-1 challenge.[22] The label directions for selected, but not all, MLV IN vaccines may indicate that they can be safely used in pregnant cattle.[1] These vaccines induce a rapid onset of protection (within 3 days of administration), possibly through interferon in the nasal secretions.[19] One benefit of the MLV IN vaccines is that they stimulate immunity at the upper respiratory tract, the portal of entry of the virus. Another benefit is their potential to immunize calves that are already seropositive because of maternal (humoral) antibodies passively transferred through the colostrum.[22,23] Animals vaccinated with the MLV IN vaccines may transiently shed virus in the nasal secretions and therefore might infect susceptible contact animals.[22,24]

Chemically Altered Live Virus Vaccines

The chemically altered BHV-1 vaccine strain was modified by nitrous acid treatment, which caused changes in the viral genome that resulted in a strain (RLB 106) that is TS, meaning that it has limited replication at internal body temperature.[25] Presumably, because of the limited viral replication, the vaccine requires two doses to stimulate immunity. Because it is TS, the vaccine can be used in pregnant cattle.[1,25,26] This vaccine containing the TS protected cattle against respiratory disease in challenged calves and abortions and stillbirths in challenged females.[26] In one study heifers received two doses of the vaccine and were challenged with BHV-1 seven months later (at 6 months' gestation). These heifers showed a significant reduction in the number of abortions and stillbirths compared with controls.[26]

Inactivated Viral Vaccines

Inactivated viral vaccines are prepared by growing virus in cell cultures and then inactivating them with chemicals. An adjuvant is added to the inactivated strain to help stimulate an immune response. Inactivated BHV-1 vaccines require two doses (14 to 28 days apart) when used for the initial vaccination of susceptible cattle. Historically it has been thought that inactivated vaccines against viruses did not induce as long duration of immunity as the MLV vaccines, nor did they confer protection against mucosal infections. Experiments have shown inactivated BHV-1 vaccine protected calves against BHV-1 in a respiratory disease study and also against against BHV-1 experimentally induced abortions.[27-29] Controlled studies should be performed to determine the duration of immunity induced by inactivated BHV-1 vaccines and MLV vaccines, both for respiratory disease and fetal infections. A disadvantage of inactivated vaccines is that the onset of protection may not be as rapid as with MLV parenteral or MLV IN vaccines. An advantage of the inactivated vaccines is that they can be used in pregnant cows and nursing calves.

Use of Vaccines to Prevent and Control BHV-1 Diseases

Many vaccines are available for preventing and controlling the different forms of BHV-1 disease, and each vaccine has certain characteristics that should be considered when designing a vaccination program. Each vaccine also has both benefits and limitations. Probably more important is management of the cattle for which the vaccines are used.

Pregnant Animals or Animals Nearing Breeding Season

The MLV parenteral vaccines may infect the fetus if pregnant susceptible heifers or cows are vaccinated. Abortions have been

VetBooks.ir

reported subsequent to vaccination with MLV parenteral vaccines.[15] In many cases the abortions may have occurred to the inadvertent use of the MLV vaccines in pregnant cows.[30,31] However, there has been a report of BHV-1 abortions in pregnant cows after MLV BHV-1 in late gestations in cows vaccinated according to the label (three doses including two as calves and one before breeding).[32] This study indicates that some animals may not develop required immunity despite following protocol. At the time of the diagnosis there was no way to differentiate field from vaccine BHV-1 strains. In recent years using modern genomic testing including PCR and sequencing the products, MLV vaccines have unique single nucleotide polymorphisms (SNPs) for each virus strain in the vaccine. The isolates from aborted fetuses can be differentiated from field strains on the basis of the SNP profile. In recent years BHV-1 isolates from aborted fetuses have been identified as MLV vaccine strains.[31,33-35] The MLV vaccine virus may also result in corpus luteum infection or disease.[30,36,37] Experimental studies have indicated a reduced conception rate in susceptible cattle that received an MLV parenteral vaccine 3 to 4 days before or 14 days after breeding.[36,37] It has been reported that pregnant cattle raised in contact with calves recently vaccinated with MLV parenteral vaccines had a greater incidence of BHV-1 abortion than those that did not have contact with vaccinates.[38] Consequently, the labels of MLV parenteral vaccines have usually stated that the vaccine should not be used in calves nursing pregnant cows. Recent studies have shown that calves given an MLV parenteral vaccine did not shed virus in their nasal secretions, nor did contact animals become infected with the vaccine virus.[39-41] However, in a recent study of calves pulled for BRD treatment in feedlots, the BHV-1 vaccine strains were isolated from nasal secretions and necropsy tissues of calves within 35 days of vaccination.[42] Similar duration of isolation of field strains of BHV-1 was noted (35 days). Multiple companies have received label claim from the MLV vaccine containing BHV-1 and BVDV for pregnant cows provided the cows had received the same line of vaccines with the MLV BHV-1 and BVDV before breeding and within 12 months thereafter.[1] Likewise, that vaccine could be used in nursing calves if cows were previously vaccinated with that line of vaccines within 12 months.[1] Another concern is that the MLV vaccine virus may recrudesce, with resulting shedding of virus in cattle either stressed or receiving corticosteroids.[43] Realistically, concern about transmission of BHV-1 to animals in contact with those receiving MLV parenteral vaccines would be negligible if the contact animals were properly immunized and immune to BHV-1.

Until the vaccine labels on many MLV parenteral vaccines are changed, MLV IN vaccines or the inactivated or chemically altered live virus vaccines are usually recommended for pregnant cattle or those near breeding. The exceptions are the approved vaccines cited.[1] Vaccine recommendations should be weighed, with the benefits of vaccination as a guide and especially with the realization that properly vaccinated cattle are better protected when exposed to either field (virulent) or vaccine strains shed by vaccinated animals. In a meta-analysis of publications to determine efficacy of BHV-1 vaccination to prevent abortion in pregnant cattle, both inactivated and MLV vaccines decreased abortion risk.[44] Because of the potential of some vaccinated animals to not respond to MLV vaccines used according to label and being susceptible to MLV vaccine causing abortion if given in late gestation, a recent study indicated protection if the previously MLV-vaccinated cows were given an MLV strain with the temperature-sensitive strain at late gestation.[45] A recent publication indicated that large-scale field studies demonstrated that conception was highest in animals previously vaccinated and revaccinated with inactivated vaccine compared with animals revaccinated with MLV.[30]

Rapid Onset of Immunity

Cattle that are susceptible and likely to be exposed to BHV-1 should receive either an MLV parenteral vaccine or MLV IN vaccine because both types induce immunity within 3 days of the initial dose. Rapid onset of immunity is desirable in such situations as stocker calf and feedlot operations, in which calves are transported long distances to pastures or feedlots, which stresses the animals and makes them more susceptible to infection. Such calves also are exposed to infection with BHV-1 from contact cattle in the markets. The drawback to inactivated vaccines is that two doses are required to obtain good immunity.

Duration of Immunity

Controlled studies on the duration of immunity are limited, and there was variation of the duration of immunity. A degree of protection against challenge existed at 6 to 9 months after vaccination with an MLV IN vaccine or an inactivated vaccine.[46,47] A parenteral MLV BHV-1 MLV vaccine provided protection up to 126 days after vaccination.[13] In a subsequent study, a parenteral BHV-1 vaccine provided protection in calves after 97 days' vaccination when challenged with virulent field BHV-1 strains and the antibodies induced by the MLV vaccine neutralized the field BHV-1 strains.[48] An additional study reported that BHV-1 MLV vaccination provided a 1-year-long duration of immunity following vaccination of seronegative calves, and the challenge was by the respiratory route.[49] Challenge studies for licensure are usually performed on calves within days of vaccination, at the time of peak immunity. Also, the challenge may be for only one form of disease, usually the respiratory type and often with the USDA virulent Cooper strain as challenge. Such challenges may detect only protection against a severe form of the respiratory disease. However, an MLV vaccine containing BHV-1 administered 8 or 13 months before challenge provided significant protection against fetal infection resulting from a severe challenge (intravenous challenge with the USDA Cooper strain).[50] BHV-1 manifests itself in other forms, such as abortions, neonatal disease, genital disease (male and female), and conjunctivitis. Yet little or no data are available about the efficacy of vaccines against these other forms of disease. For example, in one case the genital form of BHV-1 disease (infectious pustular vulvovaginitis) occurred in heifers that had received an MLV parenteral vaccine 5 months earlier.[51] Given the lack of duration of immunity studies for all BHV-1 vaccines individually and the cost of vaccines, breeding animals are usually vaccinated at least annually. In selected feedyards the animals may be revaccinated during the feeding period. In these feedlot cattle processing protocols, cattle receive a monovalent BHV-1 or multivalent viral combination MLV parenteral vaccine at reimplant time at approximately 100 days after arrival. There have been field reports of BHV-1 respiratory disease (IBR) in feedlot cattle after a few months of entry/processing at which time they received MLV vaccines containing BHV-1.[52]

Vaccination of Calves With Maternal Antibody

The possibility exists that maternal BHV-1 antibodies acquired by the calf through ingestion and absorption of colostrum may interfere with vaccination. The level of these serum BHV-1 antibodies in the calf depend on the amount in the colostrum, the amount absorbed, and the half-life of the particular antibody—for BHV-1, this is 21.2 days.[4] Some calves receive no BHV-1 antibodies through the colostrum, or they may lose them within 1 month. Some calves, however, may have serum BHV-1 antibodies for up to 6 months after birth.[4,43]

VetBooks.ir

Vaccination recommendations for neonatal calves include use of multiple doses of an MLV parenteral, an inactivated, or a chemically altered live TS virus vaccine or administration of an MLV IN vaccine. The maternal antibodies may block the parenterally administered MLV or inactivated vaccine. However, the MLV IN vaccine may induce BHV-1 antibody immunity.[23] Calves given a TS IN MLV vaccine and possessing maternal antibodies were able to override the maternal antibody when later challenged by the respiratory route with virulent virus.[22] To date, there are limited if any studies on the use of parenteral MLV BHV-1 in challenge studies to determine efficacy of the parenteral MLV BHV-1 to override maternal antibody in the calves. However, in studies on calves with BVDV maternal antibodies, BVDV MLV stimulated protective immunity when the calves were later challenged with BVDV.[53] Calves often are revaccinated at 6 to 8 months of age regardless of their prior vaccination history.

Advances in Vaccines

Molecular techniques of biotechnology have been applied to the study of vaccines and the response to vaccination (vaccinology). These advances are especially noted for herpesviruses, including BHV-1. In addition to conventional vaccines manufactured via propagation of MLV and inactivated BHV-1 strains, current and future technologies offer opportunities for other vaccines.[54,55] These include subunit vaccines with a portion of the virus, deletion mutants with specific viral genomic fragments deleted, live vectored strains, DNA vaccines using plasmids, and plant-based vaccines. DNA vaccines comprising combinations of plasmids encoding for genes along with immunostimulatory CpG motifs have been evaluated for safety and efficacy in vaccinated cattle.[56] Deletion mutant BHV-1 vaccines as marker vaccines with selected glycoprotein genes deleted along with diagnostic tests for the deleted genes may permit identification of vaccinates under control programs.[57,58] Needle-free delivery of vaccines has been developed and implemented.[55] By high-pressure gas delivery, vaccines may penetrate the skin and be administered intradermally, subcutaneously, or intramuscularly.[54] Such delivery is designed to minimize damage resulting from IM injections. Two studies compared needle-free intramuscular injection of multivalent MLV vaccine containing BHV-1 with conventional subcutaneous injection via syringe in dairy calves and feedlot cattle. In both studies antibody titers to BHV-1 were higher at day 21 postvaccination than conventional needle injection.[59,60]

Vaccination Programs

The best possible vaccine provides protective immunity in the host against infection (viral replication) when challenged; protects the animal against all forms of disease, including multiple organ and systemic forms; and provides lifelong mucosal and systemic immunity. Ideally, the vaccine recommendations would incorporate the results of field trials that are carefully designed to show the efficacy of the vaccine against a pathogen. Information is available, as can be seen by a review of the literature, for evaluating the field efficacy of the respiratory disease vaccines.[61,62] The summary of results was mixed for BHV-1 vaccines and for other respiratory viral and bacterial vaccines. Such studies use reduction in general BRD production measures such as morbidity, mortality, reduction of clinical signs, and economic benefit without regard to immunity to a specific agent. However, vaccines evaluated under field conditions may be used in cattle already incubating the virulent infectious agent at time of vaccination or that may be stressed and unable to mount an effective immune response. Animals receiving vaccines before commingling and before feedlot entry developed immunity, which provided protection against respiratory disease, resulting in less morbidity and mortality and treatment costs, and often resulted in greater economic return to the producer.[63,64]

Veterinarians therefore must make recommendations based on (1) experimental studies of vaccination followed by challenge under controlled laboratory conditions apart from the field conditions of normal cattle management and (2) clinical experience with vaccines. Data from challenge studies often are under the control of universities, the federal government, or a biologic manufacturer and may not be published. Government licensure studies require efficacy and safety evaluations, but these studies may not be available in scientific publications for review by those making recommendations. For these reasons, the veterinarian may not have access to all the data needed to make a good decision on vaccines.

The veterinarian's dilemma is confounded by other factors. First, licensure may be granted for vaccination efficacy that demonstrated protection against one form of disease, such as respiratory type. However, the virus may be just as important a pathogen of other organs, such as the developing fetus, as is the case with BHV-1. Second, information is not available or limited about the duration of immunity induced by each BHV-1 viral vaccine commercially available. Licensure studies may use challenge of vaccinated animals within 2 to 4 weeks of initial vaccination, yet cattle may be in feedyards (months) or breeding herds (years) after vaccination. Third, vaccines may induce a strong parenteral immunity, yet the surface mucosal defenses at the portal of entry may still be susceptible to infection even in presumably well-vaccinated animals. Thus, it is entirely possible that natural infections could still occur in these vaccinated animals. Ecologically this point is reinforced because viruses, for which there are good immunization products, are still circulating in cattle populations after years of vaccination.

The veterinarian therefore must weigh both the benefits provided by vaccines and their limitations. This is probably best done by focusing on the real economic effects of certain disease manifestations, including morbidity, mortality, and treatment and prevention costs. Historically, this approach has been applied to two important forms of BHV-1 disease: the respiratory form, singularly or in combination with pneumonic bacterial diseases; and the fetal disease (abortions). As a result, most vaccine regimens focus on preventing respiratory disease in both young and adult animals and on protecting the pregnant breeding herd of cows and heifers against abortions. Another fact to be considered is that many vaccines may have multiple viral or bacterial components (or both), which may require multiple doses for an immunogen mixed with one that requires only one dose.

Guidelines

CALVES. Calves may be vaccinated at branding, weaning, or 30 days before weaning. Calves vaccinated before 6 months of age should be revaccinated because the earlier vaccination may have been blocked by maternal antibodies. The MLV parenteral and IN vaccines require only one dose in susceptible calves, whereas the chemically altered live virus or inactivated vaccines require two doses. Although the labels for most MLV parenteral vaccines state that the vaccine should not be used if the calf is nursing a pregnant cow, the likelihood of infection of the pregnant cow may be minimal, especially if she is already immune. Yet as described earlier, MLV parenteral vaccines are available for use in pregnant cows and nursing calves.

BREEDING COWS AND HEIFERS. Yearling heifers (12 to 14 months of age) should be vaccinated at least 1 month before breeding. Any of the vaccines may be used, but if two doses are required, the second dose should be given at least 1 month before breeding.

VetBooks.ir

Pregnant cows may be vaccinated with a vaccine that has a label description warranting such use; these include MLV IN vaccines, chemically altered live virus vaccines, inactivated vaccines, and approved MLV parenteral vaccines. Generally one dose is used, primarily because of management considerations. However, following the vaccine label for number of doses and safety for pregnant cow use is important. Administering booster doses of the BHV-1 vaccines may have two conflicting outcomes as a result of booster dose stimulation of an increase in colostral BHV-1 antibodies, which are transferred to the newborn calf in the colostrums; consequently, (1) it may be beneficial to the calf to have increased BHV-1 serum antibodies for protection against BHV-1 disease, or (2) the calf may have longer duration of BHV-1 antibodies, which may block BHV-1 immunization. There are no published multiyear duration of immunity studies in vaccinated cattle challenged with virulent BHV-1. Because of the relatively low cost of BHV-1 vaccines and the need to vaccinate against other pathogens, many breeding cows are given a BHV-1 vaccine annually.

STOCKER AND FEEDER CATTLE. Cattle to be shipped to forage pasture after weaning (wheat pasture or native grass) or to feedyards should be vaccinated 2 to 3 weeks before shipment. However, management practices and marketing may only permit vaccination at initial collection point, market site, or stocker/feedlot delivery. All the major types of BHV-1 vaccines may be used, but those that require only one dose have two advantages: rapid onset of immunity and less handling required (one dose vs. two).

Cattle presented for purchase immediately before shipment, with no known vaccination history, pose a challenge. Presumably healthy cattle may be candidates for the 1-dose MLV parenteral or MLV IN vaccines because these calves may benefit from rapid immunity. Cattle already infected with BHV-1 may not be protected by vaccination.

Cattle entering the feedyard usually receive either the MLV parenteral or MLV IN vaccine, particularly for the rapid onset of immunity.[65] Cattle are often revaccinated during the feeding period in some operations to ensure protection against BHV-1 disease later in the feedyard.[52] Recently studies have shown that delaying MLV vaccination (BHV-1, PI3V, BVDV1, BVDV2, and BRSV) 30 days after processing in stressed auction market calves resulted in a significant decrease in the number of calves requiring additional treatment for BRD.[66]

Breeding Services

Veterinarians should consult the breeding bull center for vaccination requirements for bulls, especially relating to export shipment and collection for artificial insemination (AI). MLV IN vaccines have been used in AI bulls because these vaccines are less likely to cause latent infections than MLV parenteral vaccines.[67,68] The MLV parenteral vaccines cause latent infections that may recrudesce with stress after administration of corticosteroids, which means the virus may be present in semen.[43,65]

Advances in Diagnostic Medicine and Future Research

In recent years, diagnostic laboratories have moved to newer technologies including immunohistochemistry and genomic tests for infectious agents including viruses.[69] The genomic tests focus on real-time PCR (RT-PCR) and sequencing of the viral genome by whole genomic testing and/or sequencing of PCR products. Reliance on genomic testing has often replaced traditional isolation attempts in cell culture, which are more laborious and time consuming. Sequencing of the viral nucleic material permits the differentiation of field strains from vaccine strains due to the SNPs' pattern. This is important as BHV-1 strains are often isolated from cattle with prior MLV vaccination. BHV-1 parenteral MLV strains may migrate to other sites such as the respiratory tract (nasal passage and lung) with shedding and the fetus from the injection site. The MLV and field strains may initially be identified by RT-PCR; however, the primers for the PCR do not differentiate field from MLV strains. Thus, genomic sequencing is required to differentiate the strains.

Future research should include developing live virus seed stocks for BHV-1 vaccines that are nonabortifacient and do not induce latency in vaccinated animals. Possibly MLV BHV-1 latent infections may remain in the herd for some time (years perhaps) and then be shed, exposing other susceptible animals including susceptible heifers/cows resulting in BHV-1 fetal disease (abortions).

Bovine Virus Diarrhea Virus Vaccines

Victor S. Cortese

Our knowledge of the different vaccines' ability to protect against infection with BVDV is rapidly increasing. Currently, three kinds of BVDV vaccines are available: MLV vaccines, temperature-sensitive vaccines (available only in Europe), and inactivated virus vaccines (Table 48.9). MLV BVDV vaccines have demonstrated advantages over the newer inactivated vaccines. Most of these advantages are common to all MLV vaccines[1,2]: (1) MLV vaccines are less expensive, (2) postvaccination anaphylactic reactions occur less often than after administration of some inactivated vaccines, (3) immunity is achieved more rapidly after administration of a single dose (within 7 to 10 days), (4) MLV vaccines produce much higher levels of serum-neutralizing antibodies,[3] (5) immunity lasts longer,[4-6] (6) MLV vaccines are effective against a broader spectrum of viral strains,[3] and (7) MLV BVDV vaccines are better able to protect the developing fetus from infection.[7]

On the other hand, MLV BVDV vaccines have certain disadvantages compared with inactivated BVDV vaccines: (1) some MLV vaccines can produce mild immunosuppression for brief periods after administration,[5] (2) some have been associated with what is usually a rather low incidence of a highly fatal disease syndrome, postvaccinal mucosal disease[8,9] (see later), and (3) until recently, MLV vaccines were not ordinarily recommended for routine use in pregnant cattle.

Studies have shown that the duration of cross-neutralizing antibodies stimulated by inactivated BVDV vaccines depends on the antigenic similarity between the vaccine strain and the wild-type virus to which the cow is exposed.[10,11] If there are few common proteins, the ability to neutralize can be as short as 4 months; if there are many common antigenic sites, neutralization may last a year. MLV BVDV vaccines stimulate cross-neutralizing antibodies that can still be detected 18 months after vaccination.[3] This longer duration was further demonstrated by a modified live BVDV vaccine receiving a USDA label containing a 1-year duration of immunity against the birth of both type 1 and type 2 persistently infected calves.[12]

Recent studies have demonstrated the ability of both modified live[13,14] and inactivated type 1 vaccines[15] to provide protection against type 2 BVDV strains, although the protection afforded by the MLV vaccine was more complete. The USDA/APHIS has established a licensing protocol for BVDV vaccines to obtain a type 2 BVDV protection claim. Most of the vaccines licensed against both BVDV type 1 and type 2 contain BVDV type 1 and type 2 isolates. The question of current vaccines' ability to cross-protect against BVDV type 1b strains has been raised,[16] and further studies are needed to determine the level of protection afforded by current vaccine strains.

[b]MLV licensed for use in pregnant cattle when used according to label.

[c]Licensed by the Animal and Plant Health Inspection Service, U.S. Department of Agriculture.

Vaccination and Mucosal Disease

Mucosal disease (MD) is seen when an animal that is persistently infected is exposed to another closely related cytopathic strain of BVDV. Also, theoretically a noncytopathic BVDV strain can mutate spontaneously into a cytopathic strain, resulting in MD without any subsequent exposure. High stress and immunodepression may be involved in this mutation.[17,18]

A major concern with the MLV vaccines is whether they can cause MD.[10,19,20] For MD to occur, the cytopathic strain in the MLV vaccine must be closely related to the noncytopathic strain in the persistently infected animal. With the degree of attenuation of MLV vaccines today, an animal must be nutritionally deficient or severely stressed, or both, to face an increased likelihood of developing MD from the vaccine. This suggests that a specific set of circumstances is required and that MD caused by vaccination, when it occurs, is rare.

Bovine Virus Diarrhea Virus Vaccines and Reproductive Control

Control of BVDV centers on prevention of persistent infection and elimination of persistently infected cattle; this means identifying and removing persistently infected animals and continued vaccination to prevent persistent infection are necessary for effective control. Persistent infections occur through in utero infection of the fetus (up to roughly 125 days' gestation) with a noncytopathic strain of BVDV.[3,17] Although the mechanism of transplacental transfer of BVDV is unknown, small amounts of virus in the dam's bloodstream appear to be sufficient to produce these immunotolerant cattle. Protection of the dam may or may not correlate with protection of the fetus from subsequent persistent infection if viremia of the dam occurs. To break the cycle of in utero infection and persistent infection, it is essential that vaccination provide fetal protection.

Several studies have been performed to assess the ability of vaccines to protect the fetus against either natural or artificial challenge. Results of these studies showed that most inactivated vaccines failed to provide much fetal protection,[7,10,21-26] except for one experimental vaccine, which is reported to give a high level of fetal protection. With the experimental vaccine, inability to isolate the virus from offspring of vaccinated animals indicated good protection.[27] However, the challenge of controls resulted in only about a 50% rate of persistent infection. Only one inactivated vaccine has demonstrated a high level of fetal protection and was given the appropriate label by the USDA (see Table 48.8). Other published reports demonstrated that

VetBooks.ir

MLV BVDV vaccines were more effective at protecting the fetus[7,28-30] and that inclusion of a type 2 vaccine broadened the strains against which vaccinates were protected.[31] To date, vaccines licensed in the United States have not been required to provide fetal protection. However, label indications are being granted by the USDA to vaccines that demonstrated the ability to prevent development of persistently infected calves. Several vaccines have achieved this label claim (see Table 48.8).

Bovine Virus Diarrhea Virus Vaccination Programs

Because BVDV infections can cause severe death loss and immunosuppression, all herds of cattle should be vaccinated against BVDV. Although it was once thought that BVDV vaccines would not immunize calves that were passively immune to BVDV,[32,33] recent studies have shown that immunization can occur with certain inactivated vaccines[34] and with MLV vaccines (when the passive antibody titer against BVDV is ≤1:64).[13,35] When required, BVDV vaccines can be administered to young calves, with the possibility of gaining some degree of protection. In most calves the maternal antibodies against BVDV drop below the 1:64 level by 5 to 6 months of age. If an early BVDV problem does not exist, waiting to administer the first BVDV vaccine until at least 6 months of age increases the number of animals that respond to vaccination.

Among cows given MLV BVDV vaccines in the last trimester of pregnancy, 86% of the calves from seronegative cows[36] and some calves (0[36] to 52%[37]) from seropositive dams were actively immune at birth. In addition, the calves' level of passive immunity to BVDV was enhanced, in that seronegative cows seroconverted and serum antibody titers were boostered in 52% of the seropositive cows. The rate of occurrence of BVD in neonatal calves was reduced.[38] Administration of an MLV BVDV vaccine to seronegative cows after day 118 of gestation did not result in adverse effects.[38,39] However, vaccination with an MLV noncytopathic virus vaccine before day 118 resulted in fetal resorption, abortion, congenital defects, and the birth of undersized, weak, persistently infected calves. Several authors have recommended vaccination of cows with an MLV BVDV vaccine during the last trimester of pregnancy.[22] Three MLV BVDV vaccines are now labeled for use in pregnant animals. To ensure the safety of these vaccination schedules, label directions must be adhered to.

It is important to consider the epidemiologic nonresponse rate to any vaccine when designing a BVDV vaccination program. Therefore even though MLV BVDV vaccines do not require a booster dose, a second dose may be advised to stimulate protection in animals that did not respond to the initial vaccination. BVDV vaccination programs should include the following features:

1. A virus isolation and cull program should be instituted, along with a vaccination program that includes administration of at least one dose of an MLV BVDV vaccine to all replacement animals.
2. Vaccination with killed vaccines should be increased to 2 or 3 times a year, or an MLV BVDV vaccine should be given to open cows 3 weeks before breeding or turning in the bull.
3. The vaccines used should have been proved to stimulate protection against BVDV type 1 and type 2.

Bovine Respiratory Syncytial Virus Vaccines

John A. Ellis

Bovine respiratory syncytial virus (BRSV) is a pneumovirus in the paramyxovirus family that endemically infects cattle populations worldwide. Although the virus can cause disease in all ages of cattle, it primarily occurs in recurrent seasonal outbreaks in calves with decayed concentrations of maternal antibodies.[1-3] Resulting respiratory disease is characterized by pyrexia, coughing, and tachypnea, which can progress rapidly to severe expiratory dyspnea.[2,4] BRSV is also considered one of the viral agents that predisposes animals to secondary bacterial infections in the bovine respiratory disease complex (BRDC); however, secondary infections are often absent in fatal BRSV-associated respiratory disease.[2,5,6] Subclinical BRSV infection or mild respiratory disease due to BRSV infection in dairy cattle may have a negative impact on milk production.[7]

Parenteral Vaccines

MLV and inactivated parenteral BRSV vaccines have been commercially available since the 1980s.[8] Most of these vaccines are formulated in combination with other viral respiratory pathogens, including PI-3, BHV-1, and BVDVs. The efficacy of commercial MLV nonadjuvanted and adjuvanted combination BRSV vaccines in conferring significant disease sparing subsequent to experimental infection with a virulent field isolate has been demonstrated[8], despite a meta-analysis that reported no differences in morbidity or mortality comparing vaccinees with unvaccinated controls.[9] Most vaccinated calves shed virus, but the peak virus titer was suppressed compared with unvaccinated controls, indicating immunity is not sterilizing. Viral clearance was coincident with the simultaneous appearance of mucosal antibody, cytotoxic T cells in the lungs, and anamnestic or primary serum antibody responses. In contrast, virus clearance in unvaccinated calves was coincident with the appearance of BRSV-specific cytotoxic cells before mucosal antibody was detected.[8]

The efficacy of parenterally delivered MLV vaccines in calves with MDAs, the most relevant candidates for vaccination in the field, remains controversial and incompletely resolved.[8,10] In classical studies conducted in small numbers of calves in the 1980s, administration of attenuated BRSV by the IM route to passively immune calves reportedly did not elicit mucosal memory IgA or serum antibody responses or even prime for such responses.[11] In contrast, several studies have documented a variety of BRSV-specific T-cell responses after parenteral vaccination in passively immune calves.[8] However, it has not been determined in a challenge experiment whether these in vitro responses are associated with a protective cell-mediated memory response once maternal antibodies have decayed. Available data from one challenge study conducted with a representative commercial combination parenteral MLV BRSV vaccine given to young BRSV-seropositive calves indicated that priming for protective immunity was blocked by MDA concentrations typical of good passive transfer.[12] Although the ability of parenteral modified live BRSV vaccines to prime for protective immunity in the context of MDAs is likely to vary with the concentration of MDA, the antigenic mass of the vaccine, and/or vaccine formulation,[13] it is probably most prudent, in the absence of serologic data on individual calves, to assume that a biologically significant amount of inhibition of priming will occur in the face of MDA and use mucosal (IN) vaccines in young BRSV-seropositive calves.[14]

Disease-sparing efficacy similar to that demonstrated for parenteral MLV BRSV vaccines has also been documented in the case of some combination inactivated vaccines containing BRSV formulated with different adjuvants[8] when tested in a disease-producing challenge model in young BRSV-seronegative calves. Clinical protection was associated with serum concentrations of BRSV-specific IgG as determined by ELISA,[8] and in one case[8] the presence of IFN-γ–secreting BRSV-specific $CD4^+$ T lymphocytes in the blood of vaccinated calves. There are conflicting data concerning the ability of commercial inactivated

VetBooks.ir

BRSV vaccines to override maternal antibodies and stimulate protective responses after parenteral immunization, which may be related to the vaccine formulation and adjuvant, as well as whether disease was produced in the challenge model used in testing.[8,10] Relevant to the importance of vaccine formulation in affecting efficacy in the context of MDAs, some studies with experimental vaccines have demonstrated clinical protection following experimental challenge of seropositive calves[8]; however, whether or not these or future novel vaccines will become commercialized remains to be determined.

Most experimental studies concerning the efficacy of commercial BRSV vaccines are consistent with previous field trials, demonstrating the safety and efficacy of parenterally administered vaccines.[8] In addition, one study suggested the usefulness of combination vaccines in reducing the impact of subclinical BRSV infections.[7]

As alluded to, protection against BRSV infection and disease is immunologically multifactorial. Certainly, IgA is part of that response,[1-3,8] but serum IgG acquired from either passive or active immunization can significantly reduce the severity of clinical respiratory disease that results from BRSV infection.[8] Several studies have reported that the incidence and severity of disease in calves were inversely related to maternal antibody titers.[2,8] In the case of herd immunity, passive antibodies were detectable in 50% of the calves for 3 months after birth and were present in some calves until 7 months of age.[15] Therefore administration of BRSV vaccines to cows in late gestation to booster colostral antibody titers is a rational strategy to deal with BRSV-induced respiratory disease in young calves (1 to 3 months of age) in problem herds, without having to be concerned about the immunizing potential of particular parenteral vaccines in young seropositive calves.

Intranasal Vaccines

Because BRSV is an endemic infection in most cow herds, most young calves will have BRSV-specific maternal antibodies unless there is failure of passive transfer. Given the endemic nature of BRSV, many calves are likely exposed to BRSV early in life and will contract BRSV-associated respiratory disease if their passive protection is poor or has waned. These biological factors, together with the mixed results with parenteral administration of BRSV vaccines to young seropositive calves, stimulated interest in IN vaccines for BRSV. Combination IN vaccines containing ML BRSV are commercially available in North America and Europe.[8]

Conceptually, it was demonstrated in the late 1980s that IN inoculation of tissue culture–attenuated BRSV to passively immune calves primed the calves for immunologic memory, as evinced by anamnestic local IgA and systemic IgG responses after challenge.[16] Subsequent studies with culture-attenuated BRSV, then with single-component and combination parenteral BRSV vaccines administered intranasally and, finally, with commercial IN BRSV vaccines confirmed these phenomenona. Importantly, in addition, these studies documented an association between immunologic responses and significant disease-sparing.[8]

As epidemiologic studies suggest is the case in nature,[1,2,8] iatrogenic mucosal exposure to BRSV IN vaccines is capable of "overriding" MDA, resulting in effective priming of young calves.[8] This has been confirmed by experimental challenge studies and documenting enhanced BRSV-specific antibody responses, compared with nonintranasally vaccinated controls, following parenteral administration of commercial vaccines at approximately 2 months of age to commercially reared beef calves.[8] However, the duration of immunity to neonatal IN vaccination is apparently short, probably less than 4 months.[14] Therefore the current focus of applied research in BRSV vaccines is determining an optimal protocol for boosting of neonatally, mucosally primed immunity. One study[17] suggests that parenteral inactivated BRSV vaccines, used in a "heterologous prime-boost" protocol[18] at 2 months of age, may be superior to similar modified live vaccines, used in the same way, in conferring clinical immunity. Further data are required to provide a better evidence-based foundation for recommendations on the use of BRSV vaccines.

Adverse Reactions to Bovine Respiratory Syncytial Virus Vaccines

A major factor hampering development of a vaccine for human respiratory syncytial virus (HRSV) is the dramatic HRSV vaccine failure in the 1960s, in which vaccination with a formalin-inactivated (FI), alum-adjuvanted HRSV predisposed children to more severe disease after subsequent HRSV infection.[1] Historically, deriving primarily from these observations, there has been a concern about the use of inactivated BRSV vaccines in cattle.[8] Although this same disease-enhancing phenomenon has been demonstrated in some studies of experimental FI-BRSV vaccines in cattle,[8] it is unlikely that modern manufacturing practices would use formalin inactivation of BRSV or other viral vaccines in cattle. Moreover, there are documented cases of apparent enhancement of BRSV-associated respiratory disease in cattle that received *either* inactivated *or* MLV vaccine in the field, indicating that some commercial vaccine formulations may stimulate potentially pathogenic immune responses in some cattle, but that it is not necessarily a strict function of inactivation per se.[8] The immunologic mechanisms responsible for vaccine-associated disease enhancement in pneumovirus infections are not completely understood; it may have more to do with the timing between vaccination and BRSV infection than being completely a function of vaccine formulation.[8] However, it is unlikely that the current hypothesis applied in studies of vaccine enhancement of disease in HRSV infections, namely a strict dichomotization between protective T-helper cell (Th1)-like responses versus pathogenic Th2-like responses involving IgE and/or "hypersensitivity " reactions in response to BRSV vaccines, is particularly relevant to cattle.[8] Nevertheless, given the history of adverse reaction to RSV vaccines in humans and, to a lesser extent, cattle, care should be taken in making assumptions about the efficacy and safety of BRSV vaccines. Data from the laboratory and field use situations should be evaluated before using a particular BRSV vaccine to best avoid adverse reactions.

Parainfluenza Type 3 Virus Vaccines

John A. Ellis

Parainfluenza virus type 3 (PI-3V) is a ubiquitous paramyxovirus in cattle populations worldwide.[1] In uncomplicated experimental PI-3V infections, clinical signs of coughing, tachypnea, and fever have been observed from 4 to 12 days after infection.[1] Although the virus was originally detected in calves with respiratory disease (often in the absence of other agents), it has been used to experimentally reproduce respiratory disease, and exposure to the virus has been detected by seroconversion in animals with BRD complex, its importance as a pathogen has been somewhat controversial.[1,] Generally PI-3V has been viewed as a potentiating agent in mixed infections, predisposing the animal to bacterial pneumonia by altering bacterial clearance in the upper and lower airways and infecting both respiratory epithelia and alveolar macrophages.[1] Although, as originally described,[1] the PI-3V quasispecies exists as one serotype, recently three serologically distinct genotypes of the virus

have been molecularly defined.[2-4] This has raised unresolved questions about differences in virulence among PI-3V isolates, as well as possible genotype-specific variation in vaccine efficacy.[2-4]

Five types of PI-3V vaccines are currently available commercially: (1) MLV IM vaccines, (2) MLV temperature-sensitive IM vaccines, (3) MLV IN vaccines, (4) MLV temperature-sensitive IN vaccines, and (5) inactivated virus vaccines. All PI-3V vaccines available in North America are combined with at least a BHV-1 vaccine.[1] A single-antigen MLV PI-3V IN vaccine that was available in Europe had demonstrated efficacy in a challenge model that produced severe disease typical of that reported in the original descriptions of the virus.[1,5] However, generally, the challenge models previously and currently used result in minimal if any clinical disease, making it difficult to assess the clinical immunity induced by PI-3V vaccines.[1] In most vaccine efficacy studies, the use of attenuated virus resulted in minimal disease,[1] yielding a lack of differences in morbidity and mortality between vaccinees and controls in a meta-analysis of published vaccine studies.[6] This probably contributes to the impression that PI-3V is not a significant pathogen. The latter assumption was also commonly made about BRSV before more robust challenge models were developed and used.[7]

Opinions have been divided as to the relative importance of mucosal versus systemic immune responses in achieving protection from PI-3V–associated respiratory disease and, by extension, the comparative efficacy of IN and IM vaccines.[1] Some comparative studies reported that IN vaccination resulted in better protection against experimental challenge; others were unable to demonstrate any advantage to the use of one vaccine or route of administration over the other.[1] A notable exception, however, was young calves with maternal antibodies, in which IN administration was thought to produce a more effective immune response. Passive antibodies may persist in calves until 8 months of age and may interfere with active immunization.[1] Consequently, calves vaccinated parenterally before 6 months of age should be revaccinated after reaching 8 or 9 months of age.[1]

Although not experimentally documented, as in the case of BRSV, it is likely that given the similar biology of PI-3V infection, a mucosal (IgA) response is necessary to prevent PI-3V infection, but that passively (maternal) or actively acquired serum IgG is likely to mediate significant sparing of clinical disease subsequent to infection. The cell-mediated (cytotoxic T-cell) response in the clearance of PI-3V is a poorly documented but probably important effector mechanism stimulated by MLV vaccines, as is the case with BRSV.[1]

There is debate about the overall utility and economic benefit of using PI-3V (and BRSV) vaccines in the field.[1,6] Much of the uncertainty is undoubtedly related to the difficulties involved in determining the relative importance of a particular agent in a multifactorial disease process such as BRD complex.[8] Few studies[1] address the economic impact of subclinical paramyxovirus infections in cattle. No recent studies (in the past 5 years) directly address the economic impact of inclusion of PI-3V in combination vaccines. There are conflicting data from studies conducted under commercial feedlot conditions as to the economic benefit of including PI-3V in a vaccination program.[1] One study found no decrease in morbidity or mortality when two versus one dose of a combination viral vaccine containing PI-3V was used in a feedlot environment.[1] A limitation of these studies and such studies in general is the difficulty in obtaining, or failure to attempt to obtain, specific etiologic diagnoses, making it difficult to determine whether an immune response against one or more antigens was responsible for any disease sparing. Although an increased use of PCR[9] can partially address this, it does not directly associate a particular pathogen with actual lesions in affected organs.

Mannheimia haemolytica, *Pasteurella multocida*, *Histophilus somni*, and *Bibersteinia trehalosi*

Jared D. Taylor

Mannheimia haemolytica Vaccines

M. haemolytica, serotype 1 (formerly *Pasteurella haemolytica* A1) is the main bacteria responsible for the clinical signs and lesions of severe bovine fibrinous pleuropneumonia (shipping fever).[1,2] The bacterium is a gram-negative commensal of the bovine upper respiratory tract (URT), whose presence in the nasopharynx is not predictive of impending disease.[3,4] Historically, it has been hypothesized that immunosuppression resulting from stress or viral infections permits the bacterium to proliferate initially in the URT, evade clearance by normal protective mechanisms, and subsequently establish infection within the lungs. It is now recognized that the lower respiratory tract (LRT) is not sterile, and *M. haemolytica* and other pathogenic bacteria can be present in the lung in the absence of disease.[98,99,101] Processes and factors that allow the organisms to proliferate and progress to induction of disease are not fully understood. Regardless, once *M. haemolytica* initiates a disease process, it stimulates a series of pathologic events leading to acute, severe fibrinopurulent inflammation and necrosis. The bacterium was renamed *M. haemolytica* due to substantial genomic differences between it and other members of the *Pasteurella* genus; however, commercial vaccines may still refer to by its previous name, *P. haemolytica*.[5]

Immunity to *Mannheimia haemolytica*

Twelve serotypes of *M. haemolytica* occur (A1, A2, A5, A6, A7, A8, A9, A12, A13, A14, A16, and A17), and only partial cross-serotypic protection is seen following vaccination.[6] Serotypes A1, A2, and A6 are the most prevalent.[7-9] Because *M. haemolytica* is strictly an extracellular organism, humoral immunity is far more important to controlling infection than is cell-mediated immunity. Indeed, there is substantial evidence that cattle entering a feedlot with preexisting serum antibody titers to *M. haemolytica* have less respiratory disease and fewer deaths than do those without serum antibodies.[10,11] Maternal antibodies to *M. haemolytica* and *P. multocida* can be found in both dairy and beef cattle but decline to undetectable levels between 30 and 90 days of age.[12] Most calves subsequently and spontaneously develop antibodies to these bacteria due to natural exposure to the nasal flora.[12] Unfortunately, this antibody response is typically short lived, and calves seem to become more susceptible to disease following their decline. Antibody responses following natural exposure target numerous cellular components and secreted products. Those with the most potential for stimulating immunity include capsular polysaccharide, lipopolysaccharide (LPS), outer membrane proteins (OMPs), iron-regulated OMPs, a secreted leukotoxin (LKT), a serotype-specific antigen, and several other secreted enzymes including neuraminidase, a sialoglycoprotease, and bovine immunoglobulin-specific proteases.[13,14] The central dogma of *M. haemolytica* vaccination is that immunity to the organism requires stimulation of antibodies that neutralize LKT and antibodies that bind to surface antigens, allowing for complement-mediated killing and/or phagocytosis of the bacterium.[15] There is no agreement as to what are the most important surface antigens. However, OMPs and iron-regulated OMPs are the major candidates based on many in vitro and in vivo studies.[16-20] Capsular polysaccharide is theoretically an important surface antigen because it is the first surface molecule encountered by cellular and humoral components of the immune

system, and its presence enhances *M. haemolytica* resistance to phagocytosis and complement-mediated killing.[21] However, antibody responses to *M. haemolytica* capsular polysaccharide do not always correlate with resistance, and vaccination with purified capsular polysaccharide failed to protect against challenge.[22,23] LPS is also a surface antigen; however, antibodies to *M. haemolytica* LPS failed to correlate with resistance to experimental challenge, and passive antibodies to *M. haemolytica* LPS were not protective in experimentally challenged calves.[24,25]

Use of *Mannheimia haemolytica* Vaccines in Beef Calves

Several studies have examined how rapidly various commercial *M. haemolytica* vaccines induce antibody response and how long after vaccination antibodies remain detectable. Antibody responses reach their maximum quickly (typically within 14 days after vaccination) and abruptly wane (significantly lower by day 28, and sometimes returning to baseline by day 42).[26-28] Revaccination an extended period after the initial vaccination (140 days in one case) may stimulate rapid anamnestic responses.[27] However, it is unclear if this suggests efficacy in protecting against disease.

When designing a vaccination program for prevention of bovine respiratory disease, four questions should be addressed: (1) Should calves be vaccinated for *M. haemolytica*? (2) What type of *M. haemolytica* vaccine should be used? (3) How many doses of *M. haemolytica* vaccine should be given? And (4) When should the vaccination be administered? We will attempt to provide a basis for answering some of these, but the clinician ultimately must make decisions in consideration of the type of operation (cow-calf, stocker, dairy, or feedlot); management practices; interpretation of published literature; consultations with colleagues; and personal experience.

1. Should an *M. haemolytica* vaccine be used?
   This may be the most difficult question for the practitioner to answer. Vaccine efficacy has been demonstrated primarily with experimental models of pneumonia using one of several challenge methods including direct *M. haemolytica* challenge via intratracheal, intrabronchial, or transthoracic routes or using a combination viral (usually BHV-1) and *M. haemolytica* challenge.[13] The majority of published reports examining vaccination efficacy through experimental challenge have used experimental vaccines and not commercial ones. There are few published reports of efficacy of individual commercial vaccines against experimental *M. haemolytica* challenge. Nonetheless, the studies published have, in general, supported efficacy of commercial vaccines, although not in all cases.[29-31] Of course, one must consider the potential of bias favoring publication of positive results accounting for some or all of this difference (either because of simple publication or due to influence of pharmaceutical companies over dissemination of information related to their product).
   Clinical studies examining field efficacy of vaccines are abundant and frustratingly inconsistent. Numerous studies have found a protective factor from vaccinating.[32-36] Similar numbers of studies found vaccination to be ineffective or inconclusive.[37-39] Perino and Hunsaker[40] reviewed 10 published studies of several commercial live and subunit *M. haemolytica* vaccines with respect to their efficacies in field studies of feedlot cattle. Their report concluded that commercial *M. haemolytica* vaccines available at the time did not consistently reduce morbidity or mortality or increase weight gains. Of those studies, five showed positive outcomes based on reduced morbidity, mortality, or increased weight gain, whereas five studies demonstrated no positive outcome. Three of those studies demonstrating positive outcomes involved the same *M. haemolytica* bacterin-toxoid given at arrival in the feedlot; however, two clinical trials with the same vaccine showed no significant differences when given at arrival and/or 3 weeks before shipment. A more recent, rigorous review of *M. haemolytica* vaccines trials using feedlot cattle found that conclusions remain conflicting at times. However, their meta-analysis determined vaccination against *M. haemolytica* offers a modest reduction in morbidity but not mortality.[41] An observational trial also found vaccination at the ranch of origin to be associated with decreased morbidity.[96] It is important to note that the study was performed in Australia, and the vaccine examined is only available in that country.
   When examining efficacy of vaccines in field trials, it is relevant to note that diagnosis and treatment in such studies is based on undifferentiated BRD (rather than disease solely attributable to *M. haemolytica*). Although *M. haemolytica* is the predominant bacterial isolate associated with BRD, it is not the sole pathogen. In order to conclude that an *M. haemolytica* vaccine is efficacious in reducing BRD, a study would need to have a high power (large number of cattle enrolled), a relatively high incidence of BRD, and a large proportion of that disease attributable to *M. haemolytica*. This may play a role in the lack of definitive evidence of vaccine efficacy. Given these considerations, if a clinician chooses to recommend vaccination, questions 2 to 4 from earlier need addressed.
2. What type of *M. haemolytica* vaccine should be used?
   Numerous commercially available bovine biologicals contain *M. haemolytica* antigens.[42] *M. haemolytica* vaccines are often in combination with viral vaccines, *H. somni* or *P. multocida* bacterins, and occasionally *Clostridium* spp. biologicals. Despite the various licensed *M. haemolytica* biologicals available, formulations of *M. haemolytica* vaccines fall into one of nine categories, seven of which are nonliving vaccines. These are described by their manufacturers as follows: (1) bacterin with aluminum hydroxide adjuvant, (2) bacterin with water-in-oil adjuvant, (3) outer membrane extract, (4) bacterin-toxoid (leukotoxin toxoid), (5) toxoid-cell-associated antigen, (6) adjuvanted toxoid (culture supernatant), (7) recombinant leukotoxin-extracted OMP vaccine, (8) autogenous (herd-specific) bacterins produced from isolates submitted by practicing veterinarians, and (9) live streptomycin-dependent mutant. The latter vaccine is the only currently licensed live *M. haemolytica* biological. In the past, several live *M. haemolytica* vaccines were commercially available, and those vaccines showed potential efficacy; however, untoward side effects such as severe local and systemic reactions often occurred after vaccination. Studies have occasionally compared commercially available vaccine products under field conditions.[43,44] Unfortunately, they often are supported by industry funding (creating a potential conflict of interest) and typically do not include a negative control group. Thus, the significance and validity of the findings from these studies are unclear.
   Most studies comparing commercial vaccines have relied on antibody titers (typically to LKT and/or whole bacterial cell preparations) as outcome of interest. Although antibodies appear important to protection, it is unclear what antigens are most important, what titer is sufficient for protection, or if a higher titer is always better. Therefore conclusions from those studies are difficult to interpret. Direct comparisons of two or more commercial *M. haemolytica* vaccines against experimental or natural challenge have rarely been published. In one such comparison between a commercial *M. haemolytica* bacterin-toxoid and the live streptomycin-dependent mutant vaccines, the bacterin-toxoid elicited the greatest serologic responses and significantly reduced lung lesions after experimental challenge.[31] Calves receiving the live mutant vaccine had lesions that were not significantly lower than for control cattle. Demonstration of protection against experimental challenge, however, may not necessarily

indicate that the vaccine will be efficacious against natural disease under field conditions.

3. How many doses of *M. haemolytica* vaccine should be given? Although many of the currently available *M. haemolytica* biologicals are licensed for only one injection, manufacturers recommend a booster if possible. Of course, administration of two doses of a *M. haemolytica* vaccine is not practical for most cow-calf operations. Shewen[45] demonstrated that one of the reasons one dose of *M. haemolytica* vaccine often stimulates adequate antibody response is because most cattle carry *M. haemolytica* in their nasopharynx and have a primed immune system that can produce a rapid anamnestic response to vaccination. However, as mentioned earlier, it is unclear if this suggests continued efficacy in protecting against disease.
4. When should an *M. haemolytica* vaccine be given? Given the short persistence of elevated titers following vaccination, administering a *M. haemolytica* vaccine at the appropriate time becomes critical.[46-48] Manufacturers of *M. haemolytica* biologicals usually recommend vaccination between 15 and 21 days before "weaning, shipping or exposure."[42] If vaccination was more than 2 to 3 weeks before time of greatest risk, a booster should be given before shipment. This protocol is incompatible with routine management of most cow-calf operations, making it difficult to recommend vaccination as a standard practice in this segment of the industry. Further adding to the challenge of identifying an optimal time for vaccination is the possibility that concurrent administration of MLV vaccines may interfere with response to *M. haemolytica* vaccination. Cortese and colleagues[28] examined serologic response to vaccination with four commercially available *M. haemolytica* vaccines in calves naïve to bovine herpesvirus 1 (BHV-1) and *M. haemolytica*. When the vaccines were given concurrent with an MLV product, the antibody response against LKT was consistently lower than when the *M. haemolytica* product was administered alone. It is unclear whether this would impact the efficacy of the vaccines in reducing disease, although previous work with an experimental vaccine suggests it could.[49] Work examining different products found no evidence of BHV-1 interference with response to a bacterin product,[100] but this study examined response to *P. multocida* vaccination, not *M. haemolytica*. Moreover, assessments were directed at CMI response to vaccination, not antibody titers.

A negative effect of BHV-1 vaccination on anti-LKT titers was not seen with IN administration of an MLV vaccine, although only one product was examined in this study.[50] Concurrent vaccination with IN MLV and *M. haemolytica* vaccines resulted in an initial anti-LKT titer equivalent to that produced by the *M. haemolytica* vaccine alone. Moreover, a robust anamnestic response occurred when a booster of the *M. haemolytica* vaccine was given 90 days later, in conjunction with a parenteral MLV. Similarly, no negative effect on response to *P. multocida* vaccine was observed to result from concurrent IN BHV-1[100] (although, as mentioned earlier, there was also no negative effect from parenteral administration of BHV-1, either). Thus, it appears that some of the negative effect of concurrent MLV vaccination may exist. This effect may be muted if calves are not naïve for BHV-1 and/or other viral agents or if an IN route is used.

Vaccination of cattle against pneumonic mannheimiosis on arrival at the feedlot is somewhat controversial, for numerous reasons. Most importantly, it may not allow enough time for development of adequate protection before the period of highest morbidity.[51] Secondly, if cattle have been vaccinated 2 to 3 weeks before shipment and had an appropriate immunologic response, antibody titers may be adequate, making revaccination not cost effective. Finally, vaccination with an MLV vaccine at arrival is nearly universal, which may interfere with response to the *M. haemolytica* vaccine, if the calves have not previously been vaccinated or exposed to respiratory viruses.[28] Since the vaccination history is rarely known for cattle entering a feedlot, it may be impossible to make an informed decision regarding these considerations. Nonetheless, vaccination with a *M. haemolytica* product on feedlot entry is often practiced.[46-48] Results in several field trials indicate that this practice can potentially afford some protection against shipping fever during the first 14 days in the feedlot.[46] Selective use of *M. haemolytica* vaccines has also been advocated. Some feedlots designate cattle as high risk and low risk for respiratory disease. Managers may be more willing to vaccinate low-risk cattle because high-risk cattle are either sick on arrival or can break with disease soon after entry into the feedlot.[47] Therefore high-risk cattle would not have time to mount an immune response to vaccination before disease. However, low-risk cattle are less likely to break with disease soon after entry into the feedlot, and when they are vaccinated there is often adequate time for immunity to develop before a respiratory outbreak occurs.[47] While this is arguably rational, research to support or refute its effectiveness is lacking. As stated earlier, a meta-analysis of vaccination for *M. haemolytica* in feedlot cattle found a modest reduction in morbidity (relative risk 0.93, 95% confidence interval of 0.89 to 0.98), but no significant reduction in mortality (RR 0.75, 95% CI 0.56 to 1.04).

In summary, there is some evidence that use of *M. haemolytica* vaccination can be beneficial. However, *M. haemolytica* vaccination is not warranted or appropriate in all situations. It would likely provide the most benefit when employed by cow-calf producers, but doing so correctly would require administration at an appropriate time (2 to 3 weeks before shipping). It would also be preferable to not perform MLV vaccination concurrently (unless an IN product is used or the MLV is a booster of previous administration). It would be questionable whether the additional cost and effort are justified, as weaning for at least 40 days seems more important in reducing disease than is vaccination.[52] For stocker/backgrounder and feedlot operations, use of *M. haemolytica* may offer less benefit. Usage is particularly questionable in lightweight, high-risk calves. These calves are likely to develop disease before vaccination could produce an immune response, and the resulting inflammatory response to endotoxin and other innate immune stimulators may have negative effects, including decreased feed intake. Usage may be justified in backgrounded or yearling cattle that are more likely to respond to vaccination before the period of greatest risk for disease.

Use of *M. haemolytica* Vaccination in Dairy and Veal Calves

Management differences between dairy and beef calves could be expected to impact disease incidence and severity, as well as immune status in these two classes of cattle. In addition, evidence suggests that purebred Holstein calves may not respond immunologically as well as beef or Holstein crossbred cattle.[53] Thus, it would seem prudent to consider this population separately. Unfortunately, studies of *M. haemolytica* vaccination in dairy and veal calves have been published less frequently than those in beef calves. In general, vaccination of young dairy calves has failed to produce significant antibody responses.[54,55] This is probably due to interference by colostral antibodies. As passive immunity wanes, calves develop anti–*M. haemolytica* antibodies as a result of natural exposure.[55] In terms of protection against natural disease, vaccinated calves had similar incidences of respiratory disease as did unvaccinated controls.[56,57] In another study, a *M. haemolytica* bacterin-toxoid was found to be less effective than a commercial streptomycin-dependent mutant *M. haemolytica* and *P. multocida* vaccine in reducing respiratory disease in veal calves.[58] Failure of *M. haemolytica* vaccines to provide protection in dairy and veal

calves could be because *P. multocida* is usually the most common isolate from dairy calf pneumonia.

Vaccination for *Pasteurella multocida*

P. multocida, particularly serogroup A, serotype 3 isolates, is the second most common bacteria associated with pneumonia in beef cattle and the most common isolated from pneumonia in dairy calves.[2] Although *M. haemolytica* has traditionally been the major pathogenic bacterium associated with shipping fever, some studies have suggested that the incidence of *P. multocida* in BRD has increased in beef cattle.[1,48,99]

The antigenic makeup of nonliving *P. multocida* vaccines presently available are proprietary and are described in the *Compendium of Veterinary Products* as bacterial extracts, cell-associated antigens, soluble antigens, and/or bacterins. Conventional formalin-inactivated, whole-cell, aluminum hydroxide-adsorbed bacterins have been the industry standard and are not considered highly efficacious.[42] A commercial live streptomycin-dependent mutant *P. multocida* and *M. haemolytica* vaccine is available. One study that examined this product found no difference in immune response compared with nonvaccinated controls.[100] However, only CMI responses were assessed rather than antibody levels.

The immune mechanisms involved in resistance to *P. multocida* lung infections in cattle are poorly understood. Antibodies are presumed to be important in protecting against disease, and serum antibody levels have been correlated with severity of lesions following challenge,[59,60] as well as decreased risk of natural disease.[10] However, there are few peer-reviewed studies examining efficacy of vaccination in field conditions, and those that have been published suffer from severe shortcomings (typically sponsored by a manufacturer and often lacking a nonvaccinated control group). A meta-analysis[41] reported three trials of vaccination of feedlot cattle with products containing *P. multocida* along with *M. haemolytica*. The results of these trials were not examined separately but instead were combined with results of studies examining only *M. haemolytica*. Nonetheless, the reported results are not compelling (one reduced BRD, one increased BRD, and one trial showed no effect). Little work has been done regarding commercial *P. multocida* vaccines in dairy calves, despite the prevalence of *P. multocida* in respiratory disease in that population. In the one trial identified, a combined *M. haemolytica–P. multocida* vaccine was no better than control.[56] There is more published work related to vaccines against *P. multocida* serogroups B and E, which cause hemorrhagic septicemia in cattle and water buffalo,[61] but those have limited or no relevance to BRD.

Studies suggest that *P. multocida* OMPs or iron-regulated OMPs could be important immunogens for protecting cattle against pneumonia, and vaccination of calves with outer membrane preparations substantially enhanced resistance against experimental challenge.[13,62,63] Work on specific OMPs and cell surface antigens continues, but results have not been incorporated into commercial vaccines as of yet. Although the *P. multocida* toxin, which is produced primarily by serogroup D isolates, is an important virulence factor and immunogen for *P. multocida* in atrophic rhinitis of swine, there is no evidence that this toxin is important in pneumonia of cattle, nor would it be beneficial to include the toxin in a cattle vaccine.[13]

In summary, significantly less is known about the immunogenicity and vaccinology of *P. multocida* than for *M. haemolytica*. Products currently available are generally unrefined and have limited evidence of efficacy. As such, it is difficult to make recommendations regarding their usage. It seems reasonable to presume that these products will work no better than *M. haemolytica* vaccines and suffer from many of the same challenges. Thus, their usefulness (if any) is likely restricted to vaccination at least several weeks before maximum risk. Vaccination of lightweight, high-risk calves is probably of limited benefit and should be avoided due to the potential negative impact of innate immune system stimulators (such as endotoxin) contained within vaccine preparations. Inadequate information exists to comment on potential usefulness of *P. multocida* vaccination in dairy and veal calves.

Vaccination for *Histophilus somni (Haemophilus somnus)*

Histophilus somni (formerly *Haemophilus somnus*) is the cause of thrombotic meningoencephalitis (TME), septicemia, and reproductive disorders in cattle. In addition, it is the third most common bacterial isolate from beef cattle pneumonia in most epidemiologic surveys.[1,2] Cases of *H. somni*–induced pneumonia are often associated with concurrent myocardial necrosis. Potential immunogens have been experimentally studied in *H. somni* and consist of lipooligosaccharide (LOS),[64] several OMPs including immunoglobulin-binding proteins that bind the Fc receptor of bovine immunoglobulin and are associated with serum resistance of pathogenic strains,[65,66] and iron-regulated OMPs.[67] As in most gram-negative bacteria, *H. somni* LOS is a dominant antigen that stimulates an antibody response to the polysaccharide moiety following natural or experimental exposure. Interestingly, *H. somni* LOS has been demonstrated to exhibit phase variation in its epitopes (i.e., antigenic drift), thus allowing the bacterium to escape the immune response.[64] Currently, there is no evidence that those anti-LOS antibodies are protective.[68] Likewise, several OMPs and iron-regulated OMPs have been shown to be immunogenic in cattle. The major *H. somni* outer membrane protein (MOMP) is weakly immunogenic and shows strain antigenic variability.[69] Given the weak immunologic reactivity and its antigenic variability, MOMP is likely of limited utility in diagnostics or subunit vaccine development. Immunoglobulin-binding protein A (IbpA) not only binds immunoglobulins but is cytotoxic for bovine alveolar type II epithelium.[70] In addition, vaccination of calves with recombinant subunits of IbpA enhanced resistance against experimental intrabronchial *H. somni* challenge.[71] Unfortunately, sera from calves that received a commercially available vaccine showed no antibody reactivity to IbpA, suggesting a bacterin vaccine does not stimulate a response to this important virulence factor.[97]

Several approved *H. somni* biologicals are available, often in combination with respiratory viruses or other bacterial pathogens (*Clostridial* spp.). Currently licensed *H. somni* biologicals are formalin-killed bacterins with aluminum hydroxide as adjuvant. Efficacy of *H. somni* bacterins has been generally favorable in stimulating protection against experimental pneumonia, against intravenous and intracisternal *H. somni* challenge as a model of TME, and against natural TME. Overall, vaccine-induced immunity has been best against experimental and natural TME.[41,51,72,73] Using an experimental challenge model of *H. somni*-induced pneumonia, significant protection was afforded calves vaccinated twice with an *H. somni* bacterin.[74] Resistance correlated with a high serum antibody response to the bacterium. One study demonstrated a reduced risk for respiratory disease in cattle that had high antibodies titers to *H. somni* on arrival in a feedlot.[75] Therefore the potential would appear to exist for stimulating resistance to *H. somni*–associated pneumonia. Unfortunately, commercial *H. somni* vaccines can stimulate IgE antibodies and thus potentially increase the risk for type I hypersensitivity.[76] Administration of a commercial *H. somni* vaccine concurrent with a formalin inactivated bovine respiratory syncytial virus (BRSV) vaccine resulted in increased morbidity and pathology following co-infection, compared with vaccination with experimental subunit vaccines.[94] The authors attributed this negative outcome to IgE response to both agents. The negative

VetBooks.ir

outcomes were despite a strong IgG1 and IgG2 response in calves receiving the commercial *H. somni* vaccine. However, the co-vaccination/co-infection nature of the study precludes conclusions about effects of the *H. somni* vaccine alone.

Under field conditions, commercial *H. somni* bacterins have had limited success in inducing a protective immune response against respiratory disease.[40] In the three trials reviewed by Perino and Hunsaker, *H. somni* vaccination resulted in reduced treatment rate,[77] an increased rate of cattle being treated for respiratory disease,[78] and no significant difference from nonvaccinated controls.[79] In a more recent study, partial reduction in feedlot respiratory disease was associated with vaccinating for *H. somni*, whereas a significant reduction in respiratory disease was associated with *H. somni* vaccine in combination with *M. haemolytica* or *M. haemolytica* vaccine alone.[80] Ribble and colleagues[81] demonstrated reduced steer mortality following *H. somni* vaccination but not heifer mortality. A meta-analysis demonstrated no benefit associated with *H. somni* vaccines in beef cattle,[41] but the authors acknowledged that the few published trials offered little power to find a benefit, if it existed.

Vaccination for *Bibersteinia trehalosi*

B. trehalosi was originally classified as *Pasteurella haemolytica* Biotype T and consists of four serotypes (T3, T4, T10, and T15).[6,82] In 2007, Blackall and colleagues[82] proposed the new classification of the bacterium using phenotypic and molecular characteristics of 43 European isolates, of which 14 were from cattle and 9 of those were isolated from lung (the authors did not indicate if those isolates were from pneumonic lungs). Traditionally, *B. trehalosi* has been associated with diseases of sheep, primarily septicemia in domestic sheep and fatal pneumonia in Bighorn sheep.[83] In recent years, *B. trehalosi* has been isolated from bovine pneumonia, and there is concern among cattlemen, dairymen, and veterinarians that the bacterium is an emerging pathogen.[84] *B. trehalosi* has been isolated sporadically from bovine pneumonia as early as 1971 with occasional subsequent descriptions of isolations.[85-89] Much of the currently available information about prevalence of *B. trehalosi* in bovine pneumonia is anecdotal and not well documented in the scientific literature. What little data are documented, however, indicate a low prevalence of the bacterium. The Veterinary Laboratories Agency (VLA) laboratories in the United Kingdom documented 65 isolates of *B. trehalosi* from bovine pneumonia cases since four initial cases were recorded in 2003.[90] Isolations ranged from 0 (2005) to 22 (2009) with over two thirds of the isolates occurring in the last 3 years of the study. Isolates have been from both beef and dairy cattle, and all ages have been affected. In 72% of the cases, *B. trehalosi* was isolated in combination with one or more other bacterial or viral respiratory pathogens. From 2007 and 2009, *B. trehalosi* was isolated from approximately 20 to 45 cases of respiratory disease in dairy cattle annually.[84] That report also documented multiple case of respiratory disease in two dairies and one beef cattle operation. A challenge study evaluated clinical disease and lung lesions following experimental challenge with multiple strains of *B. trehalosi* isolates (including leukotoxin positive and leukotoxin negative strains) found little evidence of pathogenicity of *B. trehalosi*.[95] There were no clinical signs observed following inoculation with only *Bibersteinia*, and lung lesions were no different from negative control calves. The findings were notably different from challenge with *M. haemolytica* or combination of *B. trehalosi* and *M. haemolytica*, which produced clinical signs and mortality. These authors concluded that *B. trehalosi* may not be a primary pathogen of respiratory disease in cattle.

Little is known about immunity against *B. trehalosi*, and commercial vaccines specifically targeting this agent are not currently available. There is only approximately 35% homology between the genomes of *B. trehalosi* and *M. haemolytica*.[91] Some *B. trehalosi* strains are hemolytic and produce leukotoxin that is antigenically related to *M. haemolytica* leukotoxin and can be neutralized by anti-*M. haemolytica* leukotoxin antibodies.[45] This suggests that vaccination of cattle with a *M. haemolytica* vaccine that stimulates antileukotoxin antibodies may provide some level of immunity against leukotoxin-positive *B. trehalosi* strains. Indeed, one study found that a commercially available *M. haemolytica* toxoid reduced clinical signs, mortality, and lung lesions to intratracheal challenge with *B. trehalosi* isolate with leukotoxin genes.[93] The authors of this study referred to unpublished findings of leukotoxin genes being present in up to 45% of *B. trehalosi* isolates. However, an earlier publication found only approximately 15% of the bovine isolates produce leukotoxin.[82] Other potential antigens, such as outer membrane proteins, appear to be substantially different from those of *M. haemolytica*.[92] Thus, while there is some evidence for use of commercial *M. haemolytica* vaccine for protection from *B. trehalosi*, the resulting immunity may well be inadequate for complete protection.

Bovine Reproductive Disease Vaccines

Victor S. Cortese • Carole A. Bolin

As discussed earlier, cows have a multilayered placenta that leaves the fetus susceptible to infection. Infection of the placenta, inflammation of the ovary, death of the fetus, or disruption of the cervical plug all may cause abortion. Reproductive disease is therefore the most difficult disorder to achieve protection against. Vaccination must minimize the amount or duration (or both) of the viremia or septicemia, or it must prevent the pathogen from moving through the cervix or crossing the placenta.

Reproductive diseases and protection against them through vaccination are areas of active research. With current research, a vaccination program can be designed to help control reproductive diseases, but there is little or no research on the efficacy of many vaccines currently used to prevent reproductive disease. Given that the causes of reproductive failure are so numerous (infectious agents account for only a small percentage), vaccination to prevent infectious reproductive losses may not appear to be effective. This is often because diagnostic testing has not been attempted or has not determined the cause of reproductive inefficiencies. A vaccination program may be inappropriately instituted when the cause is not infectious, or the current program may unfairly be deemed ineffective. Use of viral vaccines to help prevent reproductive diseases was discussed earlier in the chapter.

Brucella abortus Vaccine

Brucella vaccination has best shown the effectiveness of vaccination in controlling a reproductive disease. Successful control and even eradication of *Brucella abortus* in many areas of North America are a testament to the ability of a program involving testing, culling, and vaccination to control a reproductive disease with zoonotic consequences; vaccination with either strain 19 or strain RB51 *Brucella* has proved to be effective. However, many herd owners have stopped vaccinating against this disease as states have been declared *Brucella* free.

Abortions caused by *B. abortus* are usually seen after 5 months' gestation. Retained placentae and subsequent metritis usually follow. The abortion is due to severe placentitis. *Brucella* infections have also been associated with a decrease in conception rates and an increase in services per conception. A higher number of dead and weak calves has also been demonstrated in infected herds. Orchitis, seminal vesiculitis, or both may characterize infections in bulls.

VetBooks.ir

Only heifer calves can be vaccinated for brucellosis. Both of the two licensed *B. abortus* vaccines are modified live bacterins, and vaccination of bulls may lead to orchitis.[1] Legal use of the vaccines is usually confined to heifer calves 4 to 12 months of age, because vaccination of older animals with the strain 19 vaccine may lead to false-positive results on routine *Brucella* screening tests. Because the strain 19 vaccine may cause septicemia, clinical illness, and occasionally death,[2] sick, unhealthy, or stressed cattle should not be vaccinated. The RB51 strain vaccine is an O antigen–deficient mutant of the *B. abortus* strain 2308. The RB51 vaccine has three primary advantages:

1. Antibodies induced by this vaccine do not react with the serologic tests routinely done to diagnose *Brucella* infections.
2. The vaccine can be used in adult cattle at a lower dosage under special circumstances and with USDA permission.
3. The vaccine tends to cause less postvaccination fever and stress than the traditional strain 19 vaccines.

The long-term immunity conferred by *Brucella* vaccination is the cell-mediated type.[3,4] Calfhood vaccination does not prevent a herd of cattle from becoming infected with *B. abortus*, but it does largely prevent abortions and protects 65% to 75% of the cattle in the herd from infection while infected reactors are identified and slaughtered.[5] For these reasons, in addition to vaccination, a control program should include testing and culling of all animals that test positive.

Leptospira Bacterins

Leptospirosis occurs worldwide and is caused by infection with the spirochete *Leptospira*. The pathogenic leptospires were formerly classified as members of the species *Leptospira interrogans;* the genus has recently been reorganized, and pathogenic leptospires are now identified in seven species of *Leptospira*.[6] As part of this reclassification, the serovar names have remained the same, but some of the common leptospiral pathogens of cattle have different species names than before. The key changes for this discussion include (1) *L. interrogans* serovar *grippotyphosa* is now *L. kirschneri* serovar *grippotyphosa*; and (2) the two types of serovar *hardjo* have been formally split into two species: serovar *hardjo* type *hardjobovis* (found in the United States and much of the world) is now *L. borgpetersenii* serovar *hardjo*, and the less common serovar *hardjo* type *hardjoprajitno* (found primarily in the United Kingdom) is now *L. interrogans* serovar *hardjo*.

Although traditionally associated with abortions, infection with various serovars of *Leptospira* is associated with a variety of clinical signs, including severe systemic disease (most often in young animals), decreased milk production, birth of weak calves, and infertility. In addition, infected cattle are known to present a risk of zoonotic transmission of the infection to humans. Many different serovars of *Leptospira* have been shown to cause reproductive failure and abortions in cattle. Of these serovars, *hardjo*, *pomona*, and *grippotyphosa*[7-10] are more common, with serovars *canicola*, *icterohaemorrhagiae*, and *bratislava* occasionally implicated. The epidemiology of infection of cattle with these serovars differs with cattle serving as the reservoir or maintenance host for serovar *hardjo* and as an incidental host for the other serovars. In general, maintenance host infections are associated with a high prevalence of infection, a poor immune response, and long-term infection and shedding, whereas incidental host infections are characterized by low overall prevalence of infection with epidemics recognized, a vigorous immune response, and short-term infection and shedding. These differences in the epidemiology of leptospirosis caused by different serovars of *Leptospira* require different strategies for prevention.

Leptospirosis can cause abortion storms in which a high number of cattle may abort within a short period. There may also be an increased number of stillbirths and births of premature and weak calves during these periods.[11] Although serovars *pomona* and *grippotyphosa* tend to cause abortions in the last trimester of pregnancy, serovar *hardjo* can cause abortions at any stage of pregnancy. Abortions are usually due to fetal infection and subsequent fetal death, although placentitis may also occur. Serovar *hardjo* can also colonize the oviducts and uterus,[8,2-13] diminishing fertility. After an initial serovar *hardjo* infection, cattle may remain infected and shed the spirochete for long periods,[14-15] whereas infection and shedding of the other serovars is relatively brief.

Current bacterins generally contain combinations of leptospiral serovar *pomona*, *grippotyphosa*, *canicola*, *icterohaemorrhagiae*, and either *L. interrogans* serovar *hardjo* type *hardjoprajitno* or *L. borgpetersenii* serovar *hardjo* type *hardjobovis*. A monovalent *L. borgpetersenii* serovar *hardjo* type *hardjobovis* vaccine is also available. There has been considerable debate in recent years regarding the efficacy of leptospiral bacterins for cattle. The bacterins have label claims that indicate they are to be used as an "aid in the prevention of disease." These bacterins should therefore be expected to decrease the severity of clinical signs, including abortion, associated with infection. In general, the evidence supports such claims for serovars for which cattle are an incidental host (i.e., serovars *pomona*, *grippotyphosa*, *canicola*, and *icterohaemorrhagiae*). Protection mediated by bacterins for these serovars is thought to occur because of induction of antibodies directed against the LPS on the surface of the *Leptospira*.[16] However, vaccination does not always prevent infection and leptospiruria caused by serovar *pomona*.[17-19]

The efficacy of bacterins for prevention of infection, leptospiruria, and clinical signs associated with serovar *hardjo* infection is significantly more controversial. Evidence that the efficacy of traditional serovar *hardjo* vaccines is less than optimal includes induction of a relatively poor antibody response in vaccinated animals, the common presence of *hardjo* infection in herds despite routine vaccination, and experimental trials that did not demonstrate protection afforded by these traditional vaccines for prevention of infection, colonization of the renal or genital tract, or transplacental infection on challenge with *L. borgpetersenii* serovar *hardjo* type *hardjobovis*.[20-22] In these studies, cattle were not protected from infection despite the induction of antibody directed against serovar *hardjo* LPS. Further investigation and evaluation of other serovar *hardjo* bacterins has led to a hypothesis that cell-mediated immunity may play a role in protective immunity against serovar *hardjo* in cattle.[23-27] Newer serovar *hardjo* bacterins have been introduced in monovalent and polyvalent formats, and there is evidence these bacterins provide significant protection of cattle against infection, tissue colonization, shedding, and transplacental infection.[23,28,29] Other new bacterins for serovar *hardjo* are also entering the marketplace, but as of this writing, extensive data regarding the performance of these products for reproductive protection are unavailable in the literature.

Some *Leptospira* bacterins are labeled as single initial dose products, but a booster dose is recommended approximately 1 month after the first dose.[18] *Leptospira* bacterins must be administered by IM or SC injection. Although some manufacturers specify revaccination at 12-month intervals, this duration of immunity has been questioned and more frequent revaccination is often necessary to control *Leptospira* abortions.[19-21] A 1-year duration of immunity has been documented for two of the newer serovar *hardjo* bacterins, but this duration has not been documented for other *hardjo* vaccines or for the other serovars, making vaccination every 6 months a reasonable recommendation in many circumstances. Nevertheless, because leptospiral abortions are uncommon during the first half of pregnancy, it may be possible to use an annual vaccination schedule (serovar *hardjo* excepted) in seasonally calving herds like beef herds. Cattle in such herds can be vaccinated when they are 2 to 4 months pregnant, usually at the time pregnancy is diagnosed, and protected through the remainder of the pregnancy with a single annual dose.[19]

Prevention of leptospirosis caused by serovar *hardjo* requires a somewhat different approach. Prebreeding vaccination of heifers that is effective in managing reproductive sequelae of other types of leptospirosis may be too late to prevent the consequences of serovar *hardjo* infection. Heifers exposed early in life may remain infected well into the time of breeding. Therefore efforts to control serovar *hardjo* infection should be targeted at preventing the initial infection and are best done by vaccinating young stock well before the time when they are mixed with older animals. In addition, bulls can carry serovar *hardjo* and transmit the infection quite readily during breeding.[29] Therefore bulls should be fully included in efforts to control serovar *hardjo* infection by vaccination.

Bovine Genital Campylobacteriosis Vaccines

Originally classified as *Vibrio*, *Campylobacter fetus* subsp. *veneralis* causes a venereal infection of cattle. The bacteria are introduced during natural breeding by infected bulls or artificial insemination (AI) with infected semen. Bulls are usually infected by breeding with infected cows, but contact with infected bedding may also be a cause. Older bulls (>4 years of age) are more likely to be infected. After deposition in the vagina, the bacteria rapidly colonize the vagina and cervix and in 25% of these cows are found in the oviducts. The organism can persist for months after infection of these sites. It has been shown that fertility never returns to normal in some infected animals, and some may be permanently sterile because of the damage caused by salpingitis.

Vaccination with *Campylobacter* vaccines has been shown to be effective in protecting heifers even when vaginal cultures test positive for the bacteria.[30] It appears that the uterus is resistant to the bacteria after vaccination. Studies have demonstrated improved breeding efficiency in vaccinated herds.[30] Vaccination of bulls with oil-adjuvant vaccines not only prevents infection of bulls for up to 1 year[31] but also aids in prevention of mechanical transfer of organisms during natural service.[32] Vaccination with two doses has been shown to be effective at clearing infections from carrier bulls.[33,34]

Vaccination

Use of *C. fetus* bacterins is recommended in all breeding herds that use bulls, even if only on selected cows. In heifer herds using virgin bulls or in 100% AI-bred herds, vaccination against *Vibrio* organisms is not necessary.

Several different *C. fetus* vaccines are available, including oil-adjuvanted and aluminum hydroxide–adsorbed types. Oil-adjuvant *C. fetus* bacterins have proved to be more effective[35] and provide longer lasting protection after a single dose.[36] Unfortunately, oil-adjuvant vaccines cause localized granuloma formation and fibrosis at the site of injection. This may cause visible blemishes, which may be objectionable in registered stock or show cattle. Administration no earlier than 4 months before the breeding season is preferred.[36] When aluminum hydroxide–adsorbed *C. fetus* bacterins are used, a priming dose should be administered at least 6 weeks before the immunizing (booster) dose and the booster should be administered 10 days before the beginning of the breeding season.[37] After administration of an aluminum hydroxide–adsorbed bacterin, serum antibody concentrations peak rapidly and decline precipitously, falling to susceptible levels by 4 weeks after one dose or 11 weeks after two doses.[39] Some aluminum hydroxide–adsorbed bacterins do not require an initial booster.

Campylobacteriosis (vibriosis) is most effectively controlled when all breeding-age animals, including bulls, are included in the vaccination program.[32] Vibrin (Zoetis) is the only *C. fetus* bacterin available in the United States that has been evaluated in bulls.[30] Two 5-mL doses are administered to breeding bulls at 4-week intervals beginning 8 weeks before the start of the breeding season.[30] In subsequent years, a single booster dose is administered 4 weeks before the start of the breeding season.[33] This dosage is 2.5 times that recommended for vaccination of cows.

Bovine Trichomoniasis Vaccines

Bovine trichomoniasis is a venereal infection of cattle caused by the protozoal agent *Tritrichomonas foetus.* Early in the course of the disease, abortions with pyometra may be seen in 5% of infected cows; these abortions occur early in gestation.[38] However, infertility is the most common sign, with long interservice intervals.[39,40] Early embryonic death is followed by a period of conception failure. Some natural resistance develops after infection, but carrier cows may be an important component of the epidemiology of this disease. In rare cases, uterine destruction may leave a cow sterile after an infection.[41]

The efficacy of *Tritrichomonas* vaccines is questionable,[42-45] but the vaccines do appear to reduce actual reproductive losses.[46] Heifers, cows, and breeding bulls should be vaccinated twice at 2- to 4-week intervals, the second dose given 4 weeks before the beginning of the breeding season[46]; SC administration is recommended. In subsequent years a single annual booster vaccination should be given 4 weeks before the beginning of the breeding season.

In a problem herd, trichomoniasis vaccination must be coupled with other control measures like culturing, culling, and treatment to effectively control the disease.

Neonatal Calf Enteric Disease Vaccines

Gerald E. Duhamel

Neonatal calf enteric diseases (NCEDs) can have a devastating impact on the profitability of beef cow-calf and dairy operations. In addition to mortality, medical, and labor costs, NCED can significantly reduce body weight of beef calves at weaning and performance of replacement dairy heifers.[1]

Several well-characterized infectious causes of NCED have been described.[2] Some of the more common infectious agents are group A RVs, coronavirus (CV), enterotoxigenic *E. coli* (ETEC), salmonellae, and *Cryptosporidium* spp.[3-9] Sporadic outbreaks of necrohemorrhagic enteritis affecting 3- to 10-day-old calves have been associated with infection with *C. perfringens* type C.[10] Other less well-characterized viruses (group B RV, calicivirus, torovirus, astrovirus); bacteria (enterotoxigenic *Bacteroides fragilis*, attaching-effacing enteropathogenic and enterohemorrhagic *E. coli*, *Enterococcus durans*); and protozoans *(Giardia duodenalis)* have also been associated with NCED.

Because of the continuous calving and constant introduction of replacement heifers on dairy farms and the continuous flow of susceptible calves on veal calf operations, infections caused by more than one agent should be suspected in these types of operations.[3-9,11-13] In addition to different infectious agents, mixed infections with different groups and serotypes or genotypes of viruses and bacteria can also occur. Consequently the severity, duration, and spread of clinical disease associated with complicated infections are usually greater than with a single agent, and control may be more challenging. When scours occurs in a herd that has been vaccinated against enteric diseases, possible contributing factors should be considered, including concurrent infection with pathogens not present in the vaccine (e.g., *Cryptosporidium* spp., salmonellae, nongroup A RVs, other pathogens), suboptimal management of colostrum feeding, and poor control of environmental contamination. Under these conditions, strategic improvement in husbandry practices might

VetBooks.ir

be sufficient to reduce the infectious threshold for NCED and obtain the full benefit of pathogen-specific vaccination. In any situation, thorough laboratory diagnostic investigation is essential to identify the primary cause of NCED and any other possible contributing factors and to serve as a basis for implementation of appropriate control strategies for present and future calf crops.[14]

Management practices and risk factors associated with development of NCED are sufficiently different between dairy and beef herds that control measures can be tailored according to the type of production. For example, in dairy herds, high turnover of older cows and continuous introduction of replacement heifers pose a higher risk of introducing new enteric disease pathogens in a susceptible population than in closed beef herds. Similarly, continuous calving and proximity of susceptible calves on dairy farms creates an ideal environment for recirculation of enteric disease agents back into the adult population. This in turn may increase and broaden herd immunity such that the efficacy of a vaccine might be enhanced partly because of the booster effect vaccine can have on preexisting immunity. Beef cattle herds, in contrast, are generally relatively closed, and a susceptible calf population is present only for a relatively short period annually during the calving season. Introduction of new pathogens or new strains of enteric disease agents, particularly during the calving season, can have a devastating effect because of the potential for exposure of a high number of susceptible animals over a relatively short period of time. Conversely, after an outbreak, herd immunity might be more stable and the occurrence of NCED might be reduced during the following calving seasons.

Under both types of production systems, vaccination for NCED is rarely successful without reasonably good management programs aimed at providing adequate intake of high-quality colostrum and minimizing environmental contamination through effective sanitation. General herd health management steps that can affect the success of a vaccination program for NCED should include a calving cow-calf care plan aimed at minimizing exposure of newborn calves to infectious agents that can overwhelm innate or passively acquired immunity. This is accomplished by careful monitoring of colostrum intake, eliminating all potential means of NCED transmission, and reducing the load and duration of exposure to pathogens present in the calving environment. The following are eight simple recommendations to accomplish these goals:

1. Establish a sound biosecurity program, including purchase of replacement animals only from reputable sources and a complete ban on the introduction of foster calves, which pose a high risk of introducing new NCED agents.
2. Provide adequate protein and energy feed, including proper concentrations of vitamin and micronutrients (e.g., copper and selenium) and abundant clean drinking water throughout gestation and calving to ensure heifers and cows have optimal body condition scores at calving, produce adequate volume of high-quality colostrum and milk, and deliver healthy and vigorous calves at birth that have a fully developed and functional immune system.[15]
3. Avoid crowding and keep the calving area and equipment clean, dry, and protected from the elements, particularly cold winter wind or wet muddy conditions. Provide sufficient bedding in calving pens so that calves are not born in a wet, manure-contaminated environment. Separate feeding and bedding grounds should be available in the calving area. Similarly, to minimize infectious disease transmission, use separate equipment for feeding and manure handling.
4. Limit the spread of infectious disease agents from younger, more susceptible, and potentially shedding animals to the main herd by segregating first-calf heifer pairs from the mature cow herd during the calving season until the youngest calf is at least 4 weeks old. Because of potential problems associated with nursing in first-calf heifers, newborn calves in this group should be monitored closely for colostrum intake and early detection of failure of passive transfer so that rapid intervention can be implemented.[15-17] Because first-calf heifers are at a competitive disadvantage with mature cows, segregation of pregnant first-calf heifers also ensures free access to feed and water at all times.
5. Ensure that each calf ingests roughly 10% of its body weight (at least 4 L [1 gallon]) of colostrum divided into half as soon as possible and preferably within the first 2 to 3 hours of birth, then the rest 4 to 6 hours later, but always before the calf is 24 hours old. Consider heat-treating colostrum at 60° C for 60 minutes to reduce total coliform count, and thus, reduce risk of illness (including scours) as a function of improved passive transfer of maternal immunity.[18] In dairy herds, do not rely on the calf nursing the dam for adequate colostrum intake; instead, routinely use nipple/bottle or bucket feeding and esophageal tubing. If a calf is unable to suckle or is at risk for failure of passive transfer of maternal immunity, force-feed fresh or freshly thawed frozen colostrum from the calf's dam or from a mature cow in the same herd or a neighboring herd. First-milking colostrum is optimal for passive transfer of immunity to the calf; however, feeding calves colostrum from day 1 and day 2 milking can provide long-term health benefits.
6. Thoroughly rinse and soak with hot water, and vigorously scrub and disinfect all equipment with detergent and bleach, and let them completely dry between uses for feeding colostrum and treating sick calves. This includes such items as nipple bottles, esophageal tubes, buckets, balling guns, and calf carts. For more difficult pathogens to kill such as *Cryptosporidium* spp., consider using chlorine dioxide (ClO_2) disinfectant.
7. Move cow-calf pairs away from the calving area as soon as possible after birth in dairy herds. In beef herds, segregate calves by age by scheduled movement of dams that have not calved to new calving pastures—the so-called Sandhills Calving System (http://veterinaryextension.colostate.edu/menu2/Cattle/Calf%20Scours%20101.pdf).
8. Develop a calf-care program including rapid identification and isolation protocols for scouring calves from healthy calves in dairy herds, or sick cow-calf pairs from healthy pairs in beef herds, to minimize environmental buildup of infectious disease agents.[15]

Giving calves a healthy start maximizes their genetic potential and reduces costs and labor associated with treating sick animals while minimizing production losses.

Rotavirus and Coronavirus Vaccines

RVs and CVs are ubiquitous in the cattle population; most adult cattle have VN serum antibodies.[19-23] RV infections are widespread in both dairy and beef cow-calf production systems, whereas infection with CV most often occurs as sporadic outbreaks of severe diarrhea in beef cow-calf herds or chronic low-grade diarrhea in dairy and veal calf operations. In addition to causing NCED, infection with CV causes winter dysentery in adult cattle[24] and respiratory tract infection in calves,[25] and it also contributes to BRD complex in feedlot cattle.[26] Fecal shedding of RV and CV is common among adult cattle,[27-30] providing a constant source of challenge for naive newborn calves and allowing persistence of these viral agents at the herd level.

Although only one type of CV is known to cause NCED,[31] different subtypes of CVs can be identified on the basis of minor genomic and antigenic differences.[31-35] On a herd basis, however, affected calves can display a range of clinical signs from enteric only to mixed enteric and respiratory signs. A molecular epidemiologic investigation based on comparative

VetBooks.ir

analyses of a gene encoding a major structural protein of bovine CV revealed (1) identical CV strains in different animals from the same herd and from paired nasal and fecal samples from the same animals, suggesting herd outbreaks are associated with a single strain circulating among susceptible cattle; (2) identical CV strains in affected cattle from different herds in the same region, suggesting transmission between herds; and (3) different CV strains in cattle affected during different outbreaks occurring over several years in the same herd, suggesting herd outbreaks are associated with the introduction of new strains in a recovered herd.[36]

Currently, RVs are classified into at least eight distinct groups, A through H.[37] Although RVs that belong to groups A, B, and C naturally infect cattle,[30,37-41] members of group A RV are by far the most prevalent.[39,41] The group A RVs are further classified according to sequence differences in two genes encoding the corresponding outer protein layer of the virus, namely viral protein 7 (VP7) or G (for glycoprotein) serotype and the protease-activated attachment protein VP4 or P (for protease sensitive) serotype.[42-44] Because both the G and the P proteins are involved in neutralization of virus infectivity in vitro and protection in vivo,[45-47] and each protein can segregate independently in progeny viruses during mixed infections leading to wide variations in relative frequency of individual G/P antigenic combinations according to geographic locations and individual farm, consideration of the G/P configuration of RVs is critical to development of effective vaccination programs for prevention of NCED.

Although a good correlation between the antigenicity of the G proteins and their corresponding gene sequences is well established, a similar relationship has not been found for the P proteins. Nevertheless, the binary G/P serotyping of group A RVs classification has largely been replaced by a G/P genotyping system based on nucleotide sequence of the corresponding genes.[48] Globally, 27 different G genotypes (G1 to G27) and 35 P genotypes (P1 to P35) are found among group A RVs infecting animals and humans.[48] At least eight distinct G types (G1, G2, G3, G6, G8, G10, G11, and untypeable) are known to infect cattle in the United States[49,50]; however, G6 appears to be the most widespread, while G8 and G10 account for fewer infections.[23,50-55] Similarly, RVs with any of four P types (P1, P5, P11, and untypeable) are known to infect cattle in the United States, but P5 appears most prevalent.[50,53,56]

The genome of RVs is composed of 11 gene segments that can be exchanged among RV strains when animals are infected by more than one virus differing in G/P types at the same time.[43] Therefore mixed infections produce progeny RV with a genetic makeup derived from either parental strain by a mechanism called *gene reassortment*. Because the G and P proteins are independently involved in generation of specific VN antibodies, reassortment of the genes encoding these proteins during mixed infections can generate new progeny viruses that can evade what once was a protective immune response.[55] Genetic reassortment is a well-characterized mechanism of immune evasion that allows persistence of RVs in susceptible populations but can also promote interspecies transmission.[57] Some RV strains appear to be host specific; however, zoonotic spread of bovine RVs to humans is increasingly recognized.[57-60] In the case of bovine group A RVs, the potential for emergence of virus strains carrying any of 36 possible antigenic configurations (4 Ps × 8 Gs = 32 potential types) underscores the limitation of vaccination programs and also the importance of sound management practices designed to minimize exposure by limiting environmental contamination.

Vaccination Programs

Two approaches are widely used in an attempt to protect calves against RV and CV infection and diarrhea. The most common approach involves passive protection of the suckling neonate by transfer of high levels of specific VN colostral antibodies induced by parenteral vaccination of the pregnant dam.[21,61-69] The mechanism of passive protection with this approach is due to the continuing presence of an amount of specific VN antibodies in the intestinal lumen sufficient to neutralize infectious virus before infection of the intestinal villous enterocytes.[19,66,70-74] The continuous presence of VN antibodies in the gut lumen may also reduce the severity of the disease if infection has already developed. In addition, some of the VN colostral antibodies that are absorbed into the bloodstream are secreted onto mucous membranes and may provide local immunity later in life.[75] However, colostral transfer of immunity is less efficient in ruminants than in other species; high concentrations of maternal antibodies are present for less than 3 days postpartum, and these concentrations often fall below protective levels within 1 week of parturition.*

A delicate balance exists between passive protection afforded by lactogenic immunity and development of the calf's own innate and adaptive local immunity to RV and CV. Because most calves' level of resistance to the adverse clinical effects of RV and CV infection increases with age, disease caused by these agents can be controlled under certain circumstances by continuous hand-feeding of fresh, frozen, or fermented colostrum from vaccinated cows throughout the first 3 to 4 weeks of life.† The goal with this approach is to allow development of subclinical infection while the milk VN antibody concentration is partially protective.[63,74,79] Conversely, lactogenic immunity might interfere with development of adaptive immunity, or some calves might not be exposed to RV and CV infection until after milk antibody concentrations have fallen below protective levels, leaving the calf fully susceptible to infection.[61,63,80]

There are currently five safe and effective USDA-approved vaccines on the market for prevention of neonatal calf diarrhea caused by group A RV and CV. The first RV and CV vaccine for parenteral administration to pregnant cows (Calf-Guard [Zoetis]) became commercially available in 1979. This vaccine contains a single live attenuated G6:P1 strain of group A RV. However, because precalving parenteral vaccination of cows with this vaccine resulted in low VN antibody concentrations in the colostrum and milk,[21,22,63,81] this product was later reformulated to a more potent parenteral preparation that contains inactivated G6 and G10 strains of group A RV and CV (ScourGuard 4KC [Zoetis]). Other inactivated vaccines that contain either three strains of group A RV and a strain of CV (Scour Bos 4 and 9 [Elanco U.S. Inc., Larchwood, Iowa]) or two strains of group A RV and two strains of CV (Guardian [Merck Animal Health, Madison, N.J.]) have also been licensed for use in pregnant cattle in the United States. The latter product can also be combined with a modified live CV vaccine (Bovilis [Merck]) for IN administration to healthy calves 3 days of age or older.

Vaccination of pregnant cows with inactivated RV and CV vaccine can raise the level of VN antibodies in the colostrum.[21,61-70,82] Although there are reports of successful protection of calves against NCED by parenteral vaccination of pregnant cows with RV and CV,‡ negative results have also been reported. Failure of this vaccination strategy is generally attributed to failure of passive transfer of colostral antibodies to the calf or overwhelming virus challenge. An alternative explanation might be that the serotypic specificity of the passively transferred maternal antibodies may affect the protective efficacy of the RV vaccine.[91]

Information on protective immunity against infection of calves with group A RVs having the same or a different G/P serotype

VetBooks.ir

configuration as the vaccine strain is incomplete.[51,82,92-96] Although immunity to RV appears to be G/P serotype specific with some strains,[51,82,92,95] there is some indication that immunity directed against certain strains can neutralize in vitro[51,96] and protect challenge-exposed calves in vivo[51,95] against RV strains with different G/P configurations. Also, parenteral vaccination of seropositive cows with a single strain of RV can elicit serum VN antibodies to a broad spectrum of RV serotypes and genotypes, suggesting that this strategy may provide a means of enhancing passive protection against other potential RV serotype challenges.[83,93,95] However, a difference in the P protein of a vaccine RV and the infecting RV was suggested as the basis for failure of an inactivated monovalent RV and CV vaccine in beef cow-calf herds.[97,98]

Although antigenic and genotypic variations are documented among bovine CVs,[31-35] reduced protection of nursing calves after challenge with a strain of bovine CV different from the vaccine strain has not been demonstrated. Consequently, addition of more than one strain of bovine CV in certain vaccines might not be justified at this time.

Another approach for preventing NCED caused by RV and CV involves oral vaccination of calves with an MLV vaccine that contain attenuated G6:P1 strain of group A RV (Calf-Guard) or IN vaccination with an MLV attenuated CV vaccine (Bovilis).[99-109] The mechanism of disease prevention with these vaccines is unknown, but interference with infection by virulent virus, followed by development of secretory IgM and IgA and/or CMI in the intestinal mucosa, has been proposed for the group A RV vaccine.[80,102] To achieve adequate protection, the manufacturer recommends that the group A RV vaccine be given immediately after birth, before the calf has nursed. This regimen might be applicable to calves whose dams have not been vaccinated. However, because the colostrum of most heifers and cows contains some level of VN antibodies arising from natural exposure,* administration of colostrum should be delayed for several hours after vaccination to avoid inactivation of the vaccine virus. Under commercial conditions, it is nearly impossible to administer vaccine within minutes of birth or to effectively regulate colostrum intake in relation to the time of vaccination. Therefore infection before vaccination, neutralization of the vaccine virus by colostral antibodies, and overwhelming challenge with infectious RV shed by unvaccinated diseased calves might explain a lack of field efficacy with this approach.[64,104-107] This is evident from the data obtained in vaccine efficacy evaluation studies in which only a portion of the calves on a farm or a ranch are vaccinated in double-blind or odd/even-day vaccination trials.[76,108,109] When all calves are either vaccinated or not vaccinated in sequential comparisons, morbidity and mortality rates from NCED are significantly reduced by this vaccination strategy,[70,99-101,108,109] but the design and statistical validity of the latter kinds of trials have been questioned.[90,105]

Although not recommended by the manufacturer, the oral attenuated RV vaccine has been administered to calves with unknown immune status that were raised as veal calves or replacements in heifer development operations.[6] Under these circumstances, vaccination might provide active immunity and protection against potential virus challenge when calves from several different sources are commingled.

The manufacturer recommends administration of the IN MLV attenuated CV vaccine in calves 3 days of age and older, after colostrum intake on the first day of age.

Rotavirus and Coronavirus Vaccination Products

ScourGuard 4KC

ScourGuard 4KC consists of inactivated bovine G6 and G10 strains of group A RV and a bovine CV strain combined with K99 *E. coli* bacterin and *C. perfringens* type C toxoid. For first-calf heifers and mature cows that have not previously been vaccinated, a two-dose series of vaccine should be administered by IM injection into the neck of pregnant cows and heifers 3 weeks apart, starting 6 to 9 weeks precalving. The second dose should be given 3 to 6 weeks before the expected calving date. A single annual booster dose should be administered 3 to 6 weeks before each subsequent calving.

Scour Bos 9

Scour Bos 9 consists of inactivated bovine group A RV strains G6, G8, and G10 and a CV strain combined with bacterins from four *E. coli* K99 serotypes and *C. perfringens* type C toxoid. The first vaccine should be administered by IM injection into the neck of pregnant cows and heifers 8 to 16 weeks before the expected calving date, with a booster dose of vaccine 4 weeks before the expected calving. Only one annual dose at 8 to 10 weeks before calving is required thereafter.

Guardian

Guardian consists of inactivated bovine group A RV G6 and G10 strains together with type 1 and type 3 bovine CV strains combined with cell-free extract of enriched K99 pili from *E. coli* and bacterin-toxoid from *C. perfringens* types C and D. The vaccine should be administered by SC injection of pregnant cows and heifers up to 12 weeks before the expected calving date. A booster dose of vaccine is given approximately 3 to 6 weeks following initial vaccination. One annual dose administered 5 to 7 weeks before expected calving is required thereafter.

Bovilis

Bovilis is a modified live bovine CV recommended for IN administration to calves 3 days of age and older.

Calf-Guard

Calf-Guard is a modified live bovine G6 strain of group A RV and bovine CV recommended for oral vaccination of newborn calves. The vaccine should be administered immediately after birth, before the calf has nursed. As indicated earlier, interference by maternal antibodies may limit the efficacy of the vaccine, so vaccination of calves older than 1 day may be ineffective.

Bacterial Scours Vaccines

Gerald E. Duhamel • Victor S. Cortese

Enterotoxigenic *Escherichia coli* (Calf Scours) Bacterins

Neonatal calf diarrhea associated with enterotoxigenic *E. coli* (ETEC) usually occurs within the first 72 hours of life. The majority of ETEC-associated NCEDs are associated with strains that produce the F5 (K99) fimbrial adhesin mediating adherence to specific receptors located on the brush border of small intestinal villous enterocytes, thereby resisting normal peristaltic clearance mechanisms, and thus, promoting bacterial colonization of the intestinal mucosa.[1-3] Adherent ETEC produce enterotoxins that stimulate water and electrolyte loss into the intestinal lumen, leading to dehydration and electrolyte imbalance that can be fatal. These ETEC strains may also express other types of fimbriae, including F41 and F1 (type 1), sometimes in combinations with the same strain of ETEC.[1,4] Intestinal colonization and villous attachment by strains of ETEC expressing adhesive fimbriae can be prevented by precalving vaccination of the dam with a bacterin that contains a single fimbrial antigen in common with the challenge strain.[1,4]

*References 19, 21-23, 61-69, 73, 77, 81, 82, 86, 88, 90, 94, and 103.

VetBooks.ir

However, disease may occasionally be caused by ETEC expressing fimbrial antigens different from the most common, $F5^+$; therefore typing of *E. coli* isolates obtained from diarrheic calves can assist with proper selection of an ETEC fimbriae-based vaccination program.[5,6]

Because calf scours associated with ETEC strains occurs so early in life, there is not enough time for a newborn calf to mount a protective immune response through vaccination. Therefore control of ETEC-induced calf scours is aimed at (1) limiting calf exposure to bacterial pathogens, (2) vaccinating dams to provide high levels of fimbriae-specific colostral antibodies (i.e., usually against the F5 antigen), and (3) providing adequate volume of colostrum as soon as possible after birth to prevent bacterial colonization of the calf intestinal tract.[3] Pregnant cows are vaccinated in late gestation to ensure high concentrations of anti-F5 colostral antibodies. When colostrum from vaccinated cows is fed to newborn calves, the antibodies prevent bacteria expressing fimbrial adhesin from binding to specific host cell receptors located on the brush border of small intestinal villous enterocytes, mostly in the jejunum and ileum.[1,8] Unbound ETEC bacteria are passed into the feces by intestinal peristalsis and, thus, prevented from colonizing the small intestine and causing disease. By 72 to 96 hours of age, calves are highly resistant to ETEC infection and will rarely show clinical signs of diarrhea.[1,9] Thus, feeding calves colostrum with a high concentration of antibodies against F5 fimbrial antigen, even though restricted to the first day of life, is often sufficient to prevent severe diarrheal disease.[4] Passive circulating serum antibodies that are absorbed into the bloodstream from the intestinal tract are thought to play little or no role in protective immunity against NCED caused by ETEC.[1] However, for maximum efficacy of ETEC vaccine programs, a concurrent well-managed colostrum program should be in place.

Nearly all strains of ETEC that have been isolated from neonatal calves have F5 fimbriae. Currently there is no evidence that a bacterin with multiple types of fimbrial antigens is more effective than products with only F5, so long as the vaccine and challenge strains share a common fimbrial antigen.[1] However, vaccines with multiple fimbrial antigens are more likely to have at least one of the antigens expressed by the challenge ETEC strain. Besides non-F5 ETEC strains potentially causing calf scours, a lack of efficacy of fimbriae-based ETEC vaccines may be due to *E. coli* belonging to a pathotype other than ETEC, including attaching and effacing *E. coli* (AEEC) and Shiga toxin–producing *E. coli* (STEC), which cause hemorrhagic enterocolitis in 1- to 6-week-old calves. Given that AEEC and STEC strains do not produce fimbrial adhesins, fimbriae-based ETEC bacterins will not protect against these strains.[6,7] Unfortunately, commercially available vaccines for prevention of calf scours associated with AEEC and STEC are not currently available.

Escherichia coli Vaccination Programs

The general recommendations for use of fimbriae-based ETEC vaccines (bacterins) are summarized in Table 48.10. ETEC bacterins are offered as single-antigen vaccines and in combination with other antigens designed to protect against other diseases in addition to ETEC infection. Oil-adjuvanted ETEC bacterins are administered by IM injection in a single dose 2 weeks to 6 months before calving, and administration is repeated annually.[10] Non–oil-adjuvanted ETEC bacterins are recommended for IM or SC injection in two doses administered at a 2- to 4-week interval, with the second dose given 3 to 6 weeks before calving. In subsequent years a single booster dose should be administered 3 to 6 weeks before calving. ETEC bacterins do not protect calves that do not ingest adequate amounts of colostrum soon after birth. Also, because this

VetBooks.ir

protection is based on passive immunity, high environmental challenge levels may overwhelm the limited amount of antibodies present in the lumen of the calf's small intestine. This is consistent with the higher prevalence and severity of clinical ETEC infections in the offspring of replacement dairy heifers kept in overcrowded closed confinement than in less intensive cow-calf beef operations. Environmental control of bacterial contamination is paramount to effective NCED management.

Salmonella Vaccines

Salmonellosis is due to infection by various pathogenic *Salmonella enterica* serotypes (see Chapter 32). Disease severity varies according to serotypes and strain-specific virulence determinants, but also according to the number of infective organisms, route of entry, and host natural and acquired resistance mechanisms. Bovine salmonellosis is caused predominantly by *S. enterica* serotypes Typhimurium (*S.* Typhimurium) and Dublin (*S.* Dublin), and although both serotypes can cause enteritis, clinical disease associated with each serotype is different.[11] Disease caused by *S.* Typhimurium, a ubiquitous group B *Salmonella* serotype, is most often associated with enteritis resulting in diarrhea in young calves. The host-restricted serotype group D *S.* Dublin most often causes systemic infections that may result in asymptomatic shedding or abortion in pregnant cows. Consequently, commercially available *Salmonella* vaccines contain single or combinations of *S.* Typhimurium and Dublin. Because *Salmonella* serotype Newport and other group C *Salmonella* have increased in prevalence, serotyping of *Salmonella* is critical to implementing an effective vaccination program. All currently licensed products are formalin-inactivated, whole-cell, aluminum hydroxide–absorbed bacterins, except for a genetically altered, stable, nonreverting, aromatic-dependent (*aroA* mutant) modified live *S.* Dublin vaccine (Entervene-D [Boehringer Ingelheim Vetmedica Inc., St. Joseph, Mo.]) and a siderophore receptor protein (SRP)-based vaccine (SRP *S.* Newport Vaccine, Conditional USDA License [Zoetis, Parsippany, NJ]). One *S.* Typhimurium and three *E. coli* mutant lipopolysaccharide (LPS) core antigen vaccines can provide protection from morbidity and mortality associated with salmonellosis.

A modified live and genetically altered (via deletion of *aroA*) *S.* Dublin vaccine marketed for parenteral use is effective in 2-week-old calves against challenge with *S.* Dublin, but it also provides cross-protection to challenge with *S.* Typhimurium.[12,13] As with many gram-negative bacterial vaccines, adverse reactions to this vaccine have been reported. Anecdotal reports of effective oral use in calves younger than 2 weeks old indicate that this route may help avoid some adverse reactions associated with injection of an endotoxin-containing product. Killed *Salmonella* bacterins can produce measurable serum antibody responses to bacterial proteins in calves and adult cattle. However, calves vaccinated with a killed bacterin are unable to produce anti-LPS antibodies until 12 weeks of age,[14] and optimum responsiveness does not occur until a year old.[15] Most controlled studies in which calves were vaccinated with a killed *Salmonella* bacterin and orally challenged have reported a lack of protection.[16-18] One small study that reported good protection after vaccination of 3- to 6-week-old calves with two doses of killed bacterin used IM challenge.[19] Another study in 6-month-old cattle found that a single intradermal dose of heat-killed *S.* Dublin protected against IV challenge.[20] Vaccination of cattle 3 months of age or older with two doses of killed *Salmonella* bacterins can prevent salmonellosis. Although little has been published on the efficacy of a conditionally USDA-licensed SRP *S.* Newport vaccine, the clinical impression is that it is safe and effective at reducing fecal shedding of *Salmonella* but also capable of controlling disease caused by different serotypes of *Salmonella*.

Vaccination of adult cows, with passive transfer of antibody to calves through colostrum, is frequently used in dairies to control salmonellosis in neonates. Controlled trials evaluating passive protection have produced mixed results, with some indicating a lack of protection[18,21] and others demonstrating some protection in 5-day-old calves.[22] Vaccination of dry cows may be useful for control of salmonellosis in calves younger than 3 weeks of age but is minimally effective for controlling salmonellosis in calves older than 3 weeks. There are anecdotal reports of protection against salmonellosis by repeated vaccination of calves with an *S.* Typhimurium mutant LPS core antigen vaccine (ENDOVAC [IMMVAC Inc., Columbia, Mo.]). A J-5 *E. coli* Rc-mutant LPS core antigen–based bacterin (J-VAC [Merial Ltd., Athens, Ga.], ENVIRACOR J-5 [Zoetis], and Hygieia [Biological Laboratories, Woodland, Calif.]) improve survival and reduce morbidity rate from naturally occurring bacterial infections in dairy calves vaccinated at 3 and 17 days of age.[23]

Gram-Negative Mutant Lipopolysaccharide Core Antigen Bacterins

All genera and species of gram-negative bacteria share a common set of LPS core antigens that are present within the inner layer of the bacterial cell wall.[24] Endotoxin from gram-negative bacteria is thought to play an important role in producing clinical signs, biochemical and hematologic alterations, and lesions associated with a wide variety of bovine diseases caused by gram-negative bacteria,[24] including salmonellosis and coliform mastitis, variously caused by *E. coli*, *Klebsiella* spp., *Enterobacter aerogenes*, and *Serratia* spp. Vaccines based on *S.* Typhimurium or *E. coli* with mutated LPS core antigen are designed to provide broad protection against related gram-negative infections by reducing the severity of clinical signs associated with sepsis and endotoxemia.

General Considerations

Several gram-negative mutant LPS core antigen oil-adjuvanted vaccines are currently marketed. Three vaccines use a J-5 Rc-mutant strain of *E. coli* that lacks the serotype-specific O-chain LPS components that ordinarily prevent deeper cell wall antigens from eliciting adaptive host immune response and production of antibodies against gram-negative core antigens.[24] Another commercial vaccine uses an Re-mutant strain of *Salmonella* Typhimurium.

Theoretically, gram-negative mutant LPS core antigen vaccines are expected to reduce the severity of disease, but not the rate of occurrence of infection. In four different clinical trials, however, the incidence of clinical coliform mastitis in dairy cows was reduced by 69%, 72%, 80%, and 82%, respectively, by vaccination with a J-5 *E. coli* vaccine.[25-27] Data are consistent with the hypothesis that antibodies induced against gram-negative LPS core antigens assist in either the control of bacterial infection, neutralization of bacterial endotoxin, or a combination of both. In the trial where clinical coliform mastitis was reduced by 82%, however, vaccination did not reduce the incidence of subclinical intramammary coliform infections that were present at the time of calving.[27]

Vaccination Programs

Recommendations for use of bacterins to prevent disease associated with salmonellosis are summarized in Table 48.11. Cows should not receive other vaccines containing gram-negative organisms (*Pasteurella*, *Salmonella*, *Brucella*, *Campylobacter [Vibrio]*, *Histophilus somnus*, *E. coli*, or *M. bovis* bacterins) within 5 days of vaccination with J-5 *E. coli* bacterin.

A J-5 *E. coli* bacterin has also successfully reduced morbidity and mortality in experimental *S.* Typhimurium infection in calves.[28] However, because of the short half-life of passively acquired antibodies stimulated by mutant LPS core antigen vaccines,[29] vaccination of dry cows is unlikely to be an effective control measure for salmonellosis in calves except when calves

are exposed to and infected with *Salmonella* in the first week or two after birth. Salmonellosis in dairy calves often occurs after 2 weeks of age. However, when vaccinated at age 3 and 10 days with an oil-adjuvant J-5 *E. coli* bacterin, calves do develop strong antibody responses by 17 days of age; this strong antibody response occurs even in the presence of passively acquired antibodies to LPS core antigens.[30] Consequently, a combined program in which both dry cows and neonatal calves are immunized against LPS core antigens might be a useful approach for reducing the severity of salmonellosis in neonatal dairy calves.

Clostridial Vaccines

Francisco A. Uzal and J. Glenn Songer

Clostridial infections cause mostly acute and frequently fatal disease in cattle. The pathogenesis of most clostridial diseases is mediated by powerful toxins,[1,2] and prevention is therefore based on immunoprophylactic amelioration of the effects of these molecules. Unfortunately, the ready availability of mostly inexpensive and efficacious bacterins, toxoids, and bacterin-toxoids has not eliminated clostridial infections, mainly because these

VetBooks.ir

immunoprophylactic products are sometimes used poorly or not at all. Duration of immunity is poor in some cases, and frequent revaccination is required if adequate immunity is to be achieved. Accurate diagnosis remains an important component in management of clostridial diseases as it provides vital information on type of vaccines to use in a given area or herd.[3-5] Immunization of cattle against clostridial diseases can be complicated by the development of site reactions, leading to trimming at slaughter.[6] These problems are exacerbated with some of the multivalent modern clostridial vaccines and have stimulated the biologics industry to seek a new paradigm for preparation and delivery of vaccines. Approaches have included concentration of the antigen into smaller doses and use of alternate adjuvants. Recombinant proteins delivered by conventional means, application of slow-release media, in vivo expression from attenuated bacterial delivery systems, and production in vivo by replicon particles from alpha viruses will likely be a major focus of effort.

Clostridium chauvoei (Blackleg) Bacterins

Blackleg occurs frequently despite long-term availability of generally effective bacterins.[10] The most common route of exposure in cattle is likely ingestion, and dormant spores seeded within macrophages in the skeletal or cardiac muscle germinate when muscle damage provides appropriate conditions of lack of oxygen. Signs in affected animals, when observed, include fever, anorexia, depression, and lameness. Sudden death is common. Lesions are characterized by extensive, dry, and emphysematous to edematous, hemorrhagic, and necrotic myositis with or without subcutaneous edema. In diagnosis, differentiation between blackleg and gas gangrene edema is important as both clinical signs and lesions may overlap.[7]

Vaccination against blackleg is universally advocated, especially in cattle younger than 2 years. Dogma holds that protection arises from the immune response to a heat-labile soluble antigen, but *C. chauvoei* produces alpha toxin and several other toxic factors that may be equally important targets.[8-11] Recommendations for immunization are summarized in Table 48.12.

TABLE 48.12

General Considerations for Use of Clostridial Seven-Way and Eight-Way Bacterin-Toxoids[a]

Protection, by Species	Coverage Designation[a]	
	Seven-Way	Eight-Way
Clostridium chauvoei	x	X
Clostridium septicum	x	X
Clostridium novyi B	x	x
Clostridium sordellii	x	x
Clostridium perfringens type C	x	x
Clostridium perfringens type D	x	x
Clostridium perfringens type B[b]	x	x
Clostridium haemolyticum (novyi type D)	x	
Dose (mL)	2-5	5
Recommended boosters	After 2-4 weeks for *C. sordellii* and *C. perfringens* C and D; after 5-6 months for *C. novyi* type B and *C. haemolyticum*. Calves initially vaccinated at <3 months of age should be revaccinated at 4-6 months (or at weaning).	
Comment	No use <21 days preslaughter	

[a]Note that many combinations are available commercially, including some that also contain immunogens against nonclostridial diseases. Some of these combinations also include tetanus toxoid.

[b]No currently licensed product is produced by use of cultures of *C. perfringens* type B, but protection against type B infection is implied by the inclusion of toxoid prepared against type C (beta toxin) and type D (epsilon toxin) strains.

Gas Gangrene Bacterins

Gas gangrene, historically called *malignant edema*, is a wound infection most frequently caused by *C. septicum*,[12,13] although other microorganisms, including *Clostridium novyi* type A, *Clostridium chauvoei*, *Clostridium sordellii*, and more rarely *C. perfringens* type A can also be involved. The infection usually follows direct contamination of a wound, including accidental trauma, iatrogenic injuries, and genital tract lacerations during delivery. Infection spreads mostly along fascial planes, and lesions that are initially warm and pitting become crepitant and cold. The clinical signs and lesions are similar to those of blackleg, except that subcutaneous and interstitial tissue is more frequently involved than muscle.[13] "Braxy" or "Bradsot" is a form of *C. septicum* alimentary infection characterized by necrotizing abomasitis, which occurs most commonly in calves and lambs.[14]

Cattle are protected by two initial doses of the corresponding bacterin, 4 to 6 weeks apart, followed by an annual booster. Vaccination is recommended in areas with a substantial incidence of the disease[13] (see Table 48.9). Vaccines elicit antibody responses to both somatic and toxin antigens, and research findings suggest a central role for *C. septicum* alpha toxin.[11,15,16] Several bacterins contain immunogens to most or all the components of the gas gangrene complex.

Clostridium haemolyticum (formerly called *Clostridium novyi* type D) (Bacillary Hemoglobinuria) and *Clostridium novyi* type B (infectious necrotic hepatitis or black disease) Bacterins

Bacillary hemoglobinuria, also called *redwater*, is caused by *Clostridium haemolyticum* and it occurs mostly in cattle, although occasional cases in sheep have been reported. *C. novyi* type B causes infectious necrotic hepatitis (black disease) of sheep, with occasional cases being reported in cattle.[17,18]

The hallmark lesion of both diseases is acute focal or multifocal liver necrosis. Dormant spores in Kupffer cells germinate when liver injury provides appropriate anaerobic conditions, most frequently associated with migration of larvae of *Fasciola hepatica* through the liver parenchyma, although cases of both diseases may occur in animals free of this parasite.[17,18]

Beta toxin, a homolog of *C. perfringens* alpha toxin (CPA), mediates the pathogenesis of bacillary hemoglobinuria, and *C. novyi* alpha toxin seems to be the main virulence factor involved in the pathogenesis of infectious necrotic hepatitis. Both diseases usually occur in well-nourished animals, with bacillary hemoglobinuria occurring mostly in animals 1 year of age or older,[17,18] and infectious necrotic hepatitis affecting mainly adult animals.[19] Tissue damage caused by migrating liver fluke larvae or other less understood factors allows germination of dormant spores in Kupffer cells. Vegetative growth yields focal or multifocal hepatic necrosis with local production of a large amount of toxins. In cattle with bacillary hemoglobinuria, systemic dissemination of beta toxin via the bloodstream results in intravascular hemolysis, hemorrhage, and hemoglobinuria.[17] When urine takes on the color of port wine, about 50% of the red cells have lysed and death ultimately results from anoxia. Because the pathogenesis of infectious necrotic hepatitis is thought to be mediated mostly by *C. novyi* alpha toxin with much less involvement of beta toxin, jaundice and hemoglobinuria are not usually observed in animals with this disease.[19]

A vaccination program is essential for herds pastured in endemic areas. When heavy exposure to fluke metacercariae is expected, an initial double dose, 4 to 6 weeks apart, of

VetBooks.ir

bacterin-toxoid should be administered to all cattle older than age 6 months, before they are pastured in the spring. This should be followed by a single annual booster a few weeks before the season when heavy exposure to flukes is expected. Liver fluke control also helps prevent cases of both bacillary hemoglobinuria and infectious necrotic hepatitis.

Clostridium botulinum (Botulism) and *Clostridium tetani* (Tetanus) Toxoids

Botulism is caused by *C. botulinum* neurotoxins, which block acetylcholine release from cholinergic nerve endings.[20] Cattle in the United States are most commonly affected by type C, and this is commonly associated with an infected animal carcass in the feed. Clinical signs include incoordination, flaccid paralysis, and difficulty in swallowing; respiratory paralysis causes eventual death.[20,21]

Toxoids of botulinum toxins can be employed for immunoprophylaxis, but vaccination is usually practiced only in populations at immediate risk, such as beef cattle grazed on phosphorus-deficient range land, where cattle tend to chew on bones of carcasses left in the field, increasing the risk of contamination.[22] Feeding of poultry litter poses a similar problem, in that it may contain animal remains, but this practice has now been suspended in the United States.

Spores of *C. tetani* are found in soil, and animal hosts are usually infected in association with some traumatic event. Spores introduced to tissue under proper conditions of anaerobiosis germinate and produce tetanus neurotoxin.[23] Tetanus can develop after several different interventions in cattle including, but not limited to, calves after castration by the elastrator method.[24,25] Cases may also occur in postparturient dairy cows.[23] Toxin moves retrograde, binding to presynaptic axonal terminals and resulting in muscular tremor and increased stimulus response; continued motor neuron hyperactivity causes sustained tetanic spasms in the innervated muscles and then permanent rigidity. Death is due to respiratory failure.[23]

Acquired resistance to tetanus is based on circulating antitoxin, and widespread vaccination with toxoid in populations at risk has dramatically lessened the impact of tetanus on animal production. Neonatal passive immunity acquired from the dam is followed by active immunization with toxoid at 2 to 3 months of age followed by a booster 4 to 6 weeks later. Single annual boosters are commonly recommended at 1- to 5-year intervals. Passive immunotherapy is intended to neutralize preformed toxin, although it is much more effective when used prophylactically than therapeutically. Vaccination is recommended in endemic areas, but universal vaccination is not usually recommended as a cost-effective means for control of tetanus.

Clostridium perfringens Toxoids

C. perfringens causes various diseases in domestic animals, and those of greatest importance affect the gastrointestinal tract[4] (Table 48.13) (see ruminant section of Chapter 32). This organism has been historically classified into 5 types (A, B, C, D, and E) on the basis of the production of one or more of the following toxins: alpha, beta, epsilon, and iota. Two additional types (i.e., F and G), have been recently added on the basis of the production of enterotoxin and and necrotic B-like toxins (see Table 48.13).[26]

C. perfringens type A is present in the intestine of most clinically healthy animals. Although this microorganism has been associated with gastroenteric syndromes in many mammals including, among others, cattle, final proof of involvement of *C. perfringens* type A in these syndromes is lacking and there are currently no accepted criteria to establish a diagnosis of *C. perfringens* type A enteritis in cattle.[4]

Type B disease is a rare disease that affects mostly sheep, and it has not been diagnosed in the United States. Pathogenesis is thought to be mediated by beta and epsilon toxins.[27] Type C strains affect several mammalian species including cattle. Because beta toxin, the main virulence factor of *C. perfringens* type C, is exquisitely sensitive to trypsin and other intestinal proteases, type C disease occurs mostly in neonatal animals in which trypsin is naturally inhibited by colostrum present in the intestine. In the absence of trypsin activity, beta toxin accumulates and produces local hemorrhage and necrosis, as well as systemic effects.[28,29] Type D produces enterotoxemia in sheep and goats and rarely in cattle. Epsilon toxin is the main virulence factor of type D strains; this toxin facilitates its own absorption through the intestinal wall and, in circulation, damages the central nervous system and other systems distant from the gut.[30] *C. perfringens* type E has been associated, albeit infrequently, with cases of enterotoxemia in lambs, calves, and rabbits. However, the few diagnoses of this condition reported so far were based on isolation of *C. perfringens* type E from the intestinal content of sick animals, which is not considered a diagnostic criterion for *C. perfringens* intestinal diseases because this organism is found in most healthy animals.[4]

C. perfringens types F and G are not involved in diseases of cattle.[26]

Although a few commercial vaccines including type A toxoid are currently available, because type A disease has not been definitely proved to occur in cattle, the use of such vaccines has not been fully evaluated.

Vaccination against type C enterotoxemia is recommended only in herds where the disease has been documented. Because the disease affects mostly neonates, vaccination of all dams before calving is required, and immunity is provided to calves via immune colostrum. Initial immunization should be followed by a booster after 3 to 4 weeks, with the second dose (and subsequent boosters precalving) administered approximately 2 to 3 weeks before parturition.

Type D enterotoxemia occurs sufficiently infrequently in cattle that vaccination may not be cost-effective. No commercial products are licensed in the United States for use against infections by strains of type E. Although production of

autogenous toxoids or bacterin-toxoids have been used, these have not been scientifically evaluated and information about their efficacy is lacking.

Miscellaneous Bovine Rickettsial, Bacterial, and Viral Disease Vaccines

Derek A. Mosier

A number of bovine vaccines are available for anaplasmosis, infectious bovine keratoconjunctivitis, staphylococcal mastitis, anthrax, interdigital necrobacillosis (foot rot), papillomatous digital dermatitis (foot warts), rabies, and fibropapillomas. These are discussed individually next and summarized in Table 48.14.

Anaplasmosis

Anaplasmosis is a vectorborne or mechanically transmitted disease caused by the rickettsia *Anaplasma marginale*.[1,2] The disease occurs worldwide and is most prevalent in tropical and semitropical areas. Anaplasmosis is the only major tickborne disease of cattle in North America, being enzootic in the southeastern and some midwestern and western states and sporadic in the northern states and Canada.[1-3] In enzootic areas with adequate numbers of arthropod vectors, most adult cattle become naturally immune through repeated exposure. Maternal antibodies protect calves until they also become subclinically infected and develop immunity. Disease is more severe in older cattle than in calves, and nonimmune older cattle are particularly at risk when they are moved into an endemic area.[1,4] Susceptibility to disease occurs when there is a lack of arthropod vectors to maintain natural infection and immunity or when a nonimmune adult is introduced into an enzootic area. In these situations or when vector or environmental conditions suggest an increased risk of disease, vaccination can be beneficial.

No widely marketed commercial vaccines against anaplasmosis were available as of 2012 in North America. A killed vaccine (Anaplasmosis Vaccine, University Products LLC, Baton Rouge, La.) is available in some states, including Arkansas, California, Florida, Indiana, Illinois, Iowa, Kansas, Kentucky, Louisiana, Mississippi, Missouri, Nevada, Oklahoma, Oregon, Tennessee, Texas, and Wisconsin, and in Puerto Rico. The vaccine consists of an emulsion of concentrated inactivated *A. marginale* antigens and adjuvant suspended in 10% oil, similar to the last widely available commercial vaccine that was discontinued in 1999 (Plazvax [Schering-Plough Animal Health]). The killed vaccine is not USDA licensed, but it is USDA approved for use as an experimental vaccine. The vaccine has reportedly been used successfully in cows at all stages of pregnancy without an episode of neonatal isoerythrolysis. In endemic areas the vaccine is recommended for use just before the onset of the vector season. Vaccine-induced immunity does not generally occur until 2 weeks after administration of the second dose of an initial series or 2 weeks after a booster dose in previously immunized cattle.[5,6] Vaccination does not prevent infection or clinical disease and does not eliminate *A. marginale* from a herd, but it does reduce the severity and incidence of disease.[1,6] Inactivated vaccines could be used in conjunction with oxytetracycline in the face of outbreaks to provide both temporary and more prolonged protection.

A sheep-passaged modified live vaccine (Anavac [PHL Associates, Davis, Calif.]) has been used in California and Latin America.[7] Because this vaccine causes mild clinical disease, it has limited use for vaccination of mature susceptible cattle.[1,7] If the vaccine is administered to cattle older than 2 years of age, anemia, severe clinical disease, and death may occur, especially in bulls and heavily lactating cows.[7] The vaccine is recommended for use in healthy cattle between age 1 month and 2 years and is most commonly administered to 7- to 24-month-old cattle in herds in endemic areas. Concurrent use of certain antibiotics or other live or MLV vaccines is contraindicated.

A live vaccine (Frozen Anaplasmosis [Tick-borne gallsickness] vaccine for cattle [Onderstepoort Biological Products, Onderstepoort, South Africa]) composed of *A. marginale* subsp. *centrale*, a less pathogenic species or subspecies of *A. marginale*, is used in some countries including Africa, Australia, Israel, and Latin America but not in North America.[6,8,9] This vaccine consists of standardized and frozen red blood cells from splenectomized cattle that were infected with *A. marginale* subsp. *centrale*. The vaccine is recommended for use in 4- to 9-month-old cattle; older cattle have an increased risk of severe vaccine-induced disease. The vaccine produces mild disease but protects against subsequent severe disease caused by *A. marginale*. Immunity is considered long term or possibly for life if subsequent natural exposure occurs to ensure development of durable immunity.

Immunity to *A. marginale* is proposed to involve humoral responses to a variety of major surface proteins and enhanced macrophage phagocytosis and killing, both mediated by IFN-γ–producing $CD4^+$ T lymphocytes.[1,10,11] Inadequate protection from vaccines during field use can result from antigenic variability of the organism, geographic differences in the organism that result in a lack of cross-reactivity between *A. marginale* strains, and weak immune responses to protective *A. marginale* antigens.[1,4,12-14] Purified native, recombinant, and tick culture–derived *A. marginale* immunogens and DNA vaccines are being investigated for possible commercial use in the future.[6,9,12,13,15-17]

Infectious Bovine Keratoconjunctivitis

The most common infectious agent associated with infectious bovine keratoconjunctivitis (IBK) is *M. bovis*.[1] Vaccination is most effective when done before fly season in herds with a history of problems. Certain breeds (e.g., Herefords, Hereford crosses) are particularly susceptible and may benefit from vaccination.[1,2] Commercial vaccines used to help prevent the disease consist of inactivated cultures of various strains of *M. bovis*.[3] Some products recommend two doses given 3 weeks apart for initial vaccination, beginning as early as 3 weeks of age to no earlier than 5 months of age. Other products recommend a single dose administered 3 to 6 weeks before the predicted onset of the disease season, with annual vaccination thereafter. *M. bovis* bacterins are also available in combination with seven-way clostridial bacterin-toxoids.[4] Although multivalent *M. bovis* bacterins can provide some protection in field use, efficacy varies depending on the *M. bovis* strains present in the bacterin and those responsible for disease.[1,5-7] Seven different disease-producing serogroups of *M. bovis* are recognized on the basis of differences in pili, and there is variable cross-reactivity between serogroups.[3] Pilin gene rearrangements and pilin-type switching can allow *M. bovis* to switch from expression of one type of pilus antigen to another, making it difficult to predict what serogroup(s) may be necessary for protection.[2,3,6] Monovalent bacterins are generally ineffective in field use, and multivalent bacterins provide neither consistent nor reliable protection.[3,5-7] Vaccines must incorporate pili from all major serogroups or conserved immunogenic portions of all serogroups to provide optimum protection.[3,6,7] Experimental recombinant vaccines containing cloned pili of various serogroups have demonstrated some promise for future vaccines.[5,6] Another immunogen considered important for protection is *M. bovis* β-hemolytic corneotoxic and leukotoxic cytotoxin.[1-3] Experimental vaccines containing hemolytic cytotoxin preparations alone or in combination with pilus antigens have shown some efficacy in experimental trials.[1,3,8-10] Other potential immunogens include iron-regulated OMPs, proteases, fibrinolysins, and phospholipases.[1-3] Vaccine-induced protection is

correlated predominantly with a suitable lacrimal immune response (predominantly IgA but also IgM and IgG) and not with serum antibody levels to *M. bovis* antigens.[1-3] Therefore an antigen delivery system that enhances lacrimal and mucosal immunity is an important feature of an effective vaccine.[11] The presence of other agents contributing to IBK (e.g., *Moraxella [Branhamella] ovis*, *Mycoplasma bovoculi*, or BHV-1) should also be considered when there is poor *M. bovis* vaccine efficacy.[12] Autogenous *M. bovis* or *M. bovis* plus *M. bovoculi* vaccines have not been consistently effective against the disease.[1,13,14] Use of MLV vaccines for IBR is contraindicated in the presence of an outbreak of IBK because it may exacerbate the IBK.[1]

Staphylococcal Mastitis

S. aureus is considered one of the most important causative agents of bovine mastitis.[1] Vaccination against *S. aureus* may be beneficial in dairy herds that have an existing mastitis problem,[1,2] but vaccination in well-managed dairy herds with a low level of staphylococcal mastitis may not provide much economic benefit.[2] Staphylococcal bacterins contain conserved antigens or antigens from multiple strains or serotypes of *S. aureus*.[3-5] The typical recommended vaccination protocol is two doses given 2 weeks apart, followed by revaccination at 6-month intervals. Vaccination can start at 6 months of age, and one of the semiannual doses should be given 3 to 4 weeks before calving. Vaccination with *S. aureus* bacterins does not generally eliminate disease but can substantially reduce clinical mastitis and the incidence of subclinical and chronic staphylococcal infection.[1,2,5,6] Vaccination may be more effective in heifers because of their initial lower basal immunity compared with older cows.[6] The benefits of immunity induced early in life include the abilities to clear the organism and resist chronic infection on initial natural exposure. Vaccination during the dry period may be more effective than vaccination during lactation. In some but not all studies, vaccination has reduced somatic cell counts in milk.[5,6] Vaccination in combination with antimicrobial therapy has been successfully used to eliminate chronic staphylococcal mastitis.[7]

In considering the use of staphylococcal vaccines, the prevalence of various pathogens that can cause mastitis must be considered. For mastitis caused by *S. aureus*, differences between the *S. aureus* strains in vaccines and the strains specifically responsible for the disease may diminish vaccine efficacy.[1,4,8] Both long-standing bacterins and some newer-technology vaccines have achieved positive results.[1,9] Experimental trials suggest that more effective vaccines may be derived by stimulating immune responses to combinations of *S. aureus* capsular polysaccharide.[10] A vaccine based on technologies used for human staphylococcal vaccines that incorporates capsular polysaccharide from the three *S. aureus* serotypes most commonly associated with mastitis stimulated immunologic parameters necessary for protection.[11] Other vaccines have used highly conserved membrane proteins, iron-regulated proteins, a staphylococcal superantigen conserved by many mastitis strains, and DNA vaccines directed against adhesin proteins in attempts to achieve the "universal" *S. aureus* vaccine.[5,12-14]

In herds where other pathogens are a major cause of mastitis, *S. aureus* vaccines may be of minimal benefit.[2] Other important causes of bovine mastitis include *Streptococcus* spp. (e.g., *Streptococcus uberis*, *Streptococcus dysgalactiae*, and *Streptococcus agalactiae*) and coliform bacteria (e.g., *E. coli*). Recombinant vaccines containing *S. aureus* and *S. agalactiae* have shown some promise in experimental models.[15] Experimental vaccines composed of bacterial proteins derived from *S. uberis* and *S. dysgalactiae* reduced somatic cell counts compared with controls after challenge.[16,17] *E. coli* J5 vaccines have also been used to successfully reduce the severity of mastitis (reviewed elsewhere in this section).

Anthrax

Anthrax is an acute, highly fatal disease caused by *Bacillus anthracis*.[1] Vaccination has proven to be an effective means of controlling the disease in endemic areas and in the face of outbreaks.[1-3] Bovine anthrax vaccines are derived from the live toxigenic, nonencapsulated spore vaccine developed by Sterne and consist of spores suspended in a diluent containing saponin and glycerin.[1] Annual vaccination of livestock in areas of endemic anthrax is recommended 4 weeks before outbreaks are expected, typically in the spring to provide protection during the summer months.[1] A single dose generally provides adequate immunity for about a year, but a second dose given 2 to 4 weeks after the first is sometimes recommended. Cattle should not be vaccinated within 42 days of slaughter. Antibiotics should not be administered within 7 days of vaccination to avoid interference with in vivo growth of the vaccine organism. Outbreaks can occur sporadically but often occur in areas with a history of flooding followed by drought.[4,5] Vaccination in the face of an outbreak does not protect all cattle, but the spread of infection and the number of new cases generally declines within 10 days.[3,5] Localized subcutaneous edema can develop at the injection site within 24 hours; it may last for several days and is sometimes severe.[2] Since the intentional release of *B. anthracis* via the mail system in 2001, there has been increased interest in technologies for the development of an efficacious long-acting human vaccine for anthrax.[2,6-8] Some of these technologies could hold promise to reduce some of the localized side effects of the current bovine vaccine,[9] but it is unlikely a new bovine vaccine will match the safety, efficacy, and cost-effectiveness of the Sterne strain vaccine in the foreseeable future. All anthrax outbreaks should be reported to local regulatory and public health officials, and appropriate guidelines for vaccination should be followed, including quarantine and vaccination of all susceptible livestock on affected and surrounding premises.

Interdigital Necrobacillosis (Foot Rot)

Interdigital necrobacillosis (foot rot) in cattle results from interdigital infection with *Fusobacterium necrophorum*, with lesser contributions from *Porphyromonas levii* (previously classified as a subspecies of *Prevotella [Bacterioides] melaninogenica*) and sometimes *Dichelobacter (Bacterioides) nodosus* (the most common cause of foot rot in sheep) and other bacteria.[1-3] Commercial *F. necrophorum* bacterins to aid in the prevention of foot rot (and hepatic necrobacillosis) are available for use in cattle. Recommendations for initial vaccination are two doses given 3 to 4 weeks apart, followed by annual revaccination. Vaccination is also recommended when endemic conditions exist or when exposure is imminent. The efficacy of *F. necrophorum* vaccines is unclear because hepatic abscesses are sometimes the study focus, but some benefit for foot rot has been demonstrated in experimental studies and field trials.[4] Vaccination is especially recommended in herds with a high incidence of disease. Protective immunity most closely correlates with the level of antileukotoxin antibodies.[5] In experimental models, truncated recombinant leukotoxin proteins provide protection and presumably would have some benefit against interdigital *F. necrophorum* infection.[6,7] Most foot rot infections involve single rather than multiple strains of *F. necrophorum*, so a vaccine that targets the specific strain involved should be effective.[8]

Papillomatous Digital Dermatitis (Foot Warts)

Papillomatous digital dermatitis, or foot warts, can be a serious problem in dairy cattle.[1] The disease is characterized by ulcerative to proliferative digital lesions that most often occur in replacement heifers and younger cows after introduction into a milking herd.[1,2] Risk is greatest in larger dairy breeds in herds of greater than 500 head. *Treponema* spp. are most

VetBooks.ir

commonly isolated from lesions and are considered the most important cause of foot warts. A wide variety of *Treponema* are incriminated, including *T. phagedensis*, *T. denticola*, *T. vincentii/T. medium*, and *T. pedis*.[3-5] No virus was seen in biopsies from multiple warts from dairy cattle in two herds.[6] Several bacterial species have also been isolated from lesions, including *Fusobacterium necrophorum*, *Serpens* spp., and *Porphyromonas levii*.[7,8] However, the precise combinations of these agents necessary to produce disease remain unclear. Commercial bacterins are available for use as preventives and/or aids to treatment and consist of killed cultures of *Serpens* spp. or *Treponema* spp. organisms. Recommendations are for three doses administered SC at 3- to 4-week intervals, followed by revaccination every 4 to 6 months. Company field trials report reduced onset of new infections and sometimes more rapid resolution of existing infections in vaccinated cattle. However, some trials failed to show significant improvement in vaccinated cows compared with unvaccinated ones.[8,9] The requirement for frequent boosters and the high recurrence rates of natural infection suggest that immunity to the disease is short lived or weak.[2]

Rabies

Rabies is a highly fatal zoonotic neurologic disease caused by a rhabdovirus.[1] Bovine rabies in North America is generally uncommon, and routine vaccination of cattle is not recommended in most situations.[2] However, vaccination may be a consideration in rural areas of Latin America, where vampire bats are important sylvatic vectors, or Africa, where exposure to infected dogs is a major cause of bovine rabies.[3,4] In endemic areas, vaccination of valuable cattle or herds may be a reasonable precautionary measure. This is particularly true in situations where cattle are in frequent contact with human beings, in order to reduce the anxiety of animal workers and minimize the likelihood of human exposure. Currently licensed rabies vaccines for cattle contain inactivated cell culture–derived virus.[5] The recommended regimen is initial vaccination at 3 months of age followed by annual vaccination thereafter. Because the duration of protective neutralizing antibody levels after initial vaccination can vary, some experts have suggested that a second booster dose be given either 1 month after initial vaccination or at 6 months of age.[6] Subsequent annual revaccination induces strong anamnestic responses that persist for 1 year or longer.[6] In Latin America, modified live vaccines are sometimes used but do not stimulate the same level of immunity as inactivated virus vaccines. A Capripoxvirus vector expressing rabies virus glycoprotein has shown promise in providing long-term protection against rabies (and lumpy skin disease) and may be a cost-effective mechanism for rabies control in cattle in some developing countries.[7,8]

Fibropapillomas (Warts)

Fibropapillomas (warts) are manifested in a variety of forms and locations, each caused by 1 of over 13 different types of bovine papillomaviruses (BPV).[1,2] Lesions associated with papillomaviruses can occur in the epidermis of the head, face, neck, and legs (BPV-1 and BPV-22); upper alimentary and urinary tracts (BPV-4); teats and udder (BPV-1, BPV-3, BPV-5, and BPV-6); and genital epithelium (BPV-1).[1,2] Immunity after infection or vaccination is virus type specific and is induced by viral structural proteins.[1] Therefore the efficacy of both autogenous and commercial vaccines depends on which viral antigens are incorporated into the vaccine and which virus type is responsible for the disease. Vaccines containing BPV-1 and BPV-2 are generally effective for prevention, with some reports that BPV-2 also aids in regression of existing lesions.[1,3] Vaccines are usually ineffective for treatment or prevention of disease caused by BPV-3 and BPV-5.[3] Vaccination with structural capsid proteins of BPV-4 generally induces long-lasting immunity and is effective in preventing papillomas caused by BPV-4.[1] However, in immunocompromised cattle (e.g., those ingesting bracken fern), papillomas may spread and can progress to squamous cell carcinoma.[2,4] Interpreting the response to vaccination against fibropapilloma can be complicated by spontaneous regression of some lesions. Lesions associated with BPV-1, BPV-2, and BPV-4 usually regress spontaneously within 1 to 12 months, whereas lesions caused by BPV-3 and BPV-5 do not normally regress spontaneously.[2,3]

Commercial vaccines consist of inactivated virus-laden tissue extracts derived from bovine papillomas.[5] The recommended regimen is an initial dose divided and given in at least two different sites, followed by a second dose in 3 to 5 weeks. Vaccination should continue for at least 1 year after elimination of disease from the herd. Autogenous vaccines can be made by homogenization and inactivation (0.3% formalin) of excised wart tissue, followed by dilution of the homogenate in physiologic saline and filtration through gauze. Three 1- to 5-mL intradermal injections given at 1-week intervals are recommended. Because autogenous vaccines generally contain the virus type associated with the disease, these often provide favorable results for both regression and prevention.[6] Vaccination is most commonly used with valuable animals destined for competitive shows or overseas sale.[3] Recombinant or native BPV proteins derived from multiple virus types have shown promise in experimental studies and could form the basis for a vaccine that protects against all BPV types.[7]
