Urethral catheterization and retrograde flushing may dislodge urethral calculi and restore urine flow, but successful clearance of the urethra is rarely achieved and retrograde flushing under pressure may result in urethral rupture or may simply flush stones back into the urethral diverticulum rather than the bladder. Retrograde passage of a catheter may allow for localization of the urethral obstruction, potentially guiding further surgical treatment. Passage of a catheter into the bladder of ruminants and camelids is exceedingly difficult as the catheter typically becomes lodged in the urethral diverticulum near the ischial arch.

Surgical options range from standing procedures in a field setting to surgery under general anesthesia in a hospital. All of the factors mentioned earlier contribute to the wide range of procedures that have been developed, and surgeon preference, case selection, and owner compliance are critical to the success of a technique.

In sheep and goats, *amputation of an obstructed urethral process* is a simple procedure that may at least temporarily restore

urethral patency. The urethral process can be removed without detrimental effects on breeding soundness. Recurrence of urethral obstruction is extremely common, and urethral patency is often maintained for only hours to days before reobstruction occurs.[28] This may provide enough time to allow feeder lambs and kids to survive until slaughter.

Penectomy is an option for animals intended for slaughter and is similar to the perineal urethrostomy for risk of stricture formation. *Prepubic urethrostomy*, *perineal urethrostomy*, and *modified proximal perineal urethrostomy* are surgical options for ruminants not intended to be used for breeding.[29,30] In small ruminants, postoperative stricture of the stoma or recurrent obstruction with additional calculi is a long-term risk with urethrostomy procedures. *Ischial urethrostomy* with placement of a Foley catheter into the bladder has been used as a treatment for urolithiasis in heavy feedlot steers and bulls.[31] If urethral damage is not severe, this procedure allows the breeding ability of bulls to be maintained.[31]

Urethrotomy can be used to remove the obstructing calculi followed by primary closure of urethra; however, there is a risk of urethral stricture, adhesions resulting in phimosis in breeding males, and reobstruction with additional calculi.

A *vesicopreputial anastomosis* procedure has recently been described in a small number of goats as an option for management of recurrent obstructions.[32]

Cystotomy can be used to remove calculi from the bladder and maintain breeding soundness. In small ruminants and camelids, bidirectional (normograde and retrograde) flushing is used to restore urethral patency.[28] Even if the urethra is successfully cleared of calculi, traumatic urethritis may cause significant postoperative dysuria in these animals. Therefore, some surgeons prefer to also perform a tube cystostomy to allow for rest and healing of the irritated urethra.

Tube cystostomy (surgical or percutaneous placement) allows urine to exit the bladder through a temporary Foley or other type of suprapubic catheter, which is anchored in the bladder lumen and exits the ventral abdomen.[33-35] Urethral patency is restored when calculi are spontaneously expelled from the urethra, dissolved, refluxed into the bladder, or removed via urethrotomy. Spontaneous resolution of urethral obstruction after tube cystostomy may take several weeks or longer, and urethral rupture at the site of obstruction due to pressure necrosis can occur. To judge when removal of the catheter is appropriate, the catheter can be clamped shut and the animal observed for urination through the urethra. Fewer complications of tube cystostomy have been reported with surgically placed tube cystostomies versus percutaneously placed cystic catheters.[33,35] The primary complication is a dislodged catheter, followed by tears of the bladder, leakage of urine into the abdomen, adhesions of the bladder to intestine or body wall, and obstruction of the catheter.

In cases of urethral rupture where patency of the entire urethra is the preferred outcome, tube cystostomy is often the sole feasible option. Primary repair of the urethral defect is rarely successful because of swelling and maceration of the damaged mucosa and risk of stricture formation. Contrast medium can be introduced into the bladder through the catheter to monitor urethral patency, locate urethral obstruction, or identify urethral rupture. The catheter can also be used to lavage the bladder to facilitate dissolution of calculi using Walpole solution or a commercially available urinary lavage product (Renacidin, Guardian Laboratories, Hauppauge, N.Y.).[35]

In cases of bladder rupture, the urine should be drained from the abdominal cavity and a surgical procedure should be performed to divert urine to the exterior. If primary repair of the bladder defect is desired, a laparotomy and cystotomy or tube cystostomy can be performed. Primary repair of the bladder defect is not always necessary, however, because spontaneous sealing of the bladder with fibrin or omentum can occur. Daily or continuous abdominal drainage may have to be performed until spontaneous sealing occurs. Tears are more likely to seal spontaneously if they are located on the dorsal aspect of the bladder.

In *bladder marsupialization* the apex of the bladder is exteriorized using a small paramedian incision, and the seromuscular layer of the bladder is circumferentially secured to the abdominal wall. A cystotomy is performed, and the bladder mucosa is secured to the skin, creating a permanent opening for urine drainage from the bladder to the exterior.[36] Advantages of bladder marsupialization include decreased hospitalization time and expense for the owner. However, complications include chronic urine scalding, ascending bacterial infection, stricture formation, reobstruction, and bladder prolapse.

Ureteral calculi may be removed by *ureterotomy*.[37] *Nephrectomy* may be performed in unilateral cases of obstructive nephrolithiasis.[38] If unilateral nephrectomy is under consideration, measurement of BUN, serum creatinine, and USG should be performed, and US and renal biopsy can be used to evaluate the remaining kidney.

POSTOPERATIVE CONSIDERATIONS. Continued assessment of hydration status, urine output, serum creatinine, and serum electrolyte concentrations is indicated after surgery. Postobstruction diuresis may result from tubular damage, accumulation of urea or natriuretic factors, or preoperative fluid therapy. Induction of modest diuresis through fluid therapy after surgery may help to reduce azotemia and accumulation of blood clots and bacteria in the urethra.

Antimicrobial therapy with an antibiotic that achieves high urine concentrations is warranted. Duration of antimicrobial therapy depends on the surgical procedure chosen, residue withholding considerations, legal restrictions on use of certain products, and whether or not UTI exists at surgery. For tube cystostomy, antimicrobial therapy is recommended by some while the tube is in place and for at least 1 week after the tube is removed. A study examining indwelling Foley catheters identified *Aerococcus* and *Enterococcus* most frequently, and 42% of cultures were resistant to two or more antibiotics.[39] Therefore, it is recommended to submit urine samples for culture and sensitivity testing.

Prevention

A preventive approach to urolithiasis begins with a search for risk factors associated with the diet, management, and environment. Whenever possible, ration analysis and mineral analysis of the urolith(s) should be performed to accurately identify causative dietary factors. Consult Box 34.1 for urolith analysis laboratories. If uroliths are not obtained, ration analysis and a thorough dietary history may provide a strong suggestion of the urolith type. Considering the central role of urinary supersaturation in calculogenesis, the ultimate aim of preventive measures should be reduction of urinary concentration of calculogenic mineral ions. The urine should be diluted to such an extent that the calculogenic ions are less prone to precipitate. Dilution of urine is achieved through increased salt and water intake.

DIETARY MANAGEMENT. Prevention of urinary calculi can be difficult because of the conflicting dietary effects of minerals, pH, individual animal susceptibility, and feed availability. General guidelines for prevention of phosphatic calculi require adjustment of the dietary calcium–to–phosphorus ratio to a level of greater than 2 : 1, which can be performed by reducing the amount of grain or other high-phosphorus dietary components and/or increasing calcium in the diet with forages like alfalfa or other legumes. Use of a 0 mEq/kg DCAD diet using ammonium chloride has been shown to help reduce urinary pH to between 6.0 and 6.5 without significantly decreasing

blood pH.[18] Increasing the quantity of long-stem forage in the ration may increase salivary flow and fecal phosphate excretion.

Because restriction of dietary silica intake in ruminants grazing native grasses is not feasible, dietary management is limited to salt (sodium chloride or ammonium chloride) supplementation to increase water consumption and thereby produce a diuretic effect to reduce urinary calculogenic compounds. Loose salt or lick salt is unlikely to be ingested in sufficient quantities to affect water intake. Gradually increasing quantities of sodium chloride or ammonium chloride in creep feed can help reduce silica urolith development in calves and lambs.[13,19] The feeders should be located near a reliable source of palatable water. In one study, reduction of the dietary calcium–to–phosphorus ratio from 2 : 1 to almost 1 : 1 resulted in a trend toward reduced silica calculi formation.[19] Prevention of calcium carbonate uroliths in pet small ruminants can be reduced by feeding or supplementing with grass hay rather than feeding alfalfa alone. Salting the grass hay with increasing concentrations of salt may increase water consumption to help maintain a dilute urine. Use of ammonium chloride can aid in urine acidification and increase water consumption.

Ammonium chloride supplementation fed at a level of 0.5% to 1.5% of ration dry matter was found to reduce urine pH to 6 to 6.5 in a group of goats.[18] Urine pH in this range should increase the solubility of struvite and apatite crystals. However, the pH of the urine is also influenced by the relative concentrations of strong cations (sodium and potassium) and strong anions (chloride and sulfate) of the entire ration, so the efficacy of ammonium chloride in reducing urinary pH may vary among different livestock operations, because the concentration of these cations and anions will vary among rations.[18,40] Long-term or excessive supplementation with ammonium chloride has been reported to result in chronic metabolic acidosis with a corresponding decrease in bone density and excessively low urine pH.[18,40] Ammonium chloride is not palatable, so mixing the salt with a more palatable low-potassium product (e.g., sucrose) is typically necessary. Some animals appear to have a renal physiologic adaptation resulting in gradually increasing urine pH with long-term feeding of ammonium chloride. Owners can monitor for changing urine pH with urine pH strips used on a weekly basis. Pulsed feeding of ammonium chloride can be attempted if the urine pH begins to increase.

WATER MANAGEMENT. Maximizing water intake is an important aspect of urolithiasis prevention, regardless of the urolith type involved. Cleaning water containers should be a regular practice. White water containers allow owners to see contamination of the water with dirt and feed; this may prompt more frequent cleaning. Water palatability may also be improved by providing shade for water containers during the summer and heaters in the fall and winter. Automatic waterers should be checked regularly for proper function. Shallow containers capable of rapid refilling provide higher rates of water turnover, resulting in less stagnation.

In operations involving multiple animals or large pastures, placement of multiple watering sites might allow for more frequent intake. This is especially true for sheep, whose banding instinct usually prevents individuals from traveling alone to distant watering sites.

Urachal Disorders

Stacey R. Byers

Definition and Etiology

Abnormalities of the umbilicus and umbilical remnants, including the urachus, are frequently encountered disease conditions of neonatal calves and, to a lesser extent, in other neonatal ruminant species.[1] Infections of the urachus are often associated with omphalophlebitis, which commonly arises from environmental contamination of the umbilicus at birth. Cloned calves appear to be predisposed to having a patent urachus.[2] The association of umbilical abnormalities with calfhood morbidity and mortality is well known. However, chronic conditions of the urachal remnant are observed in older neonates and mature ruminants, with complications including internal abscessation, adhesions, sepsis, peritonitis, uroperitoneum, cystitis, and intestinal strangulation.[3-6] Urachal fistulas or acquired patent urachus are infrequently observed in ruminants. Chapter 20 provides more information on these disorders.

Clinical Signs and Differential Diagnoses

Calves with internal urachal abscesses, adhesions, and other sequelae are usually older than 4 weeks of age. A history of umbilical infection during the neonatal period may or may not exist, and external umbilical abnormalities may not be present. Clinical signs may be nonspecific and include fever, lethargy, poor body condition, rough hair coat, and poor growth or productivity. Dysuria, pollakiuria, stranguria, and colic may be evident on examination or in the medical history. When an infection extends into the bladder lumen, hematuria and pyuria are expected. Transabdominal palpation of the umbilicus and abdomen in smaller neonates may reveal painful and enlarged umbilical remnants. Complications from associated septicemia (e.g., lameness and joint distention, pneumonia, hypopyon, meningitis) can occur.

If the urachus fails to regress completely, a persistent communication between the bladder apex and the pouchlike urachal remnant occurs. The volume of urine retained in the urachal remnant is variable. Animals with this problem may dribble urine from the urachus during micturition or remain asymptomatic. Urine retention can predispose the animal to UTIs.

Rupture of the infected urachal stalk may result in the acute onset of peritonitis. If the urachal remnant communicates with the bladder lumen, rupture of the urachus results in uroabdomen. Rupture may occur spontaneously or after abdominal trauma or parturition in older animals. A report found a possible inheritance link with abnormal involution in a group of Brown Swiss-Braunvieh cross cattle.[7]

A detailed ultrasonographic examination of the interior of the umbilical remnant and caudoventral abdomen is warranted in cases of suspected urachal or umbilical abnormalities, but adhesions may not be visualized.[7-9] The bladder and other viscera may assume abnormal shape or position as a result of urachal adhesions. The luminal contents of the urachal remnant and bladder may appear flocculent in cases with concurrent cystitis. Uroabdomen is characterized by accumulation of echolucent fluid in the abdominal cavity, with variable amounts of fibrin deposition evident.

Laparoscopic examination can allow a more thorough evaluation of the abdomen and has identified adhesions and focal umbilical artery and urachal enlargements not identified by ultrasonographic examination.[9]

Because of the variable nature of urachal problems, the differential diagnoses will vary according to the organ(s) involved. Urachal adhesions to the intestine or uterus may result in colic, signs of intestinal obstruction, and postpartum peritonitis or uroabdomen. Concurrent signs involving the lower urinary system might indicate the potential for primary ascending infections, such as cystitis or pyelonephritis. In cases of uroabdomen in males, obstructive urolithiasis is an important differential. Urolithiasis, urethritis, or neurologic disease may be included in differential diagnoses of dysuric animals. Nephritis of hematogenous origin or pyelonephritis should be considered in animals showing ill-thrift, colic, kyphosis, or abnormal urine.

VetBooks.ir

VetBooks.ir

Clinical Pathology

Laboratory findings may be variable, but an inflammatory leukogram, hyperfibrinogenemia, and hyperglobulinemia are expected. Urinalysis may be normal or indicative of cystitis if the urinary bladder is involved. Abdominocentesis findings are variable and depend on the presence and extent of peritonitis associated with the urachal lesion. Voluminous blood-tinged abdominal fluid suggests uroperitoneum, and analysis of the fluid and serum creatinine concentration is indicated (see Urolithiasis section earlier).

Pathogenesis

Following bacterial infection of the urachus, the inflammatory response within the abdomen precipitates development of fibrinous adhesions between the urachus and surrounding viscera, including the rumen, intestine, uterus, bladder, or ovaries. Abscesses may form in single or multiple locations in the urachal stalk and, if involving the apex of the urinary bladder, can result in concurrent cystitis. Urachal fibrosis and adhesions may cause mechanical interference of bladder emptying. Infrequently, the urachal abscess perforates, with subsequent peritonitis, sepsis, or uroperitoneum.[3,4] Most urachal infections involve *Trueperella pyogenes*, *E. coli*, *Staphylococcus* spp., or *Streptococcus* spp., but other organisms may be present.[1,5,8,10]

Treatment and Prognosis

For early and uncomplicated or congenital persistent urachal disorders, medical management using chemical cautery and antibiotic therapy has been reported.[1] Chemical cautery of the urachus with sedation and analgesia has been performed using silver nitrate sticks, iodine, or phenol. There is a risk of incomplete resolution or other complications, so animals should be monitored to determine if additional surgical management is warranted.

Surgical management is recommended for complicated cases, infected urachal remnants, where medical management has failed, or when complete evaluation of the abdominal cavity is needed. Ventral midline celiotomy, paramedian celiotomy, or laparoscopy under general anesthesia is recommended to enable complete evaluation of the abdominal cavity.[7,11,12] Complete resolution may require resection of the urachal remnants and the bladder apex if the urachus incorporates or communicates with the bladder. Perioperative and postoperative antibiotic therapy is essential, and appropriate antibiotic selection should be based on culture and sensitivity of the abscess(es) or urine.

Outcomes following surgical management are often satisfactory, but development of adhesions should always be considered a potential risk. A guarded to poor prognosis is warranted for severe peritonitis or extensive adhesions.

Urinary Bladder Eversion and Prolapse

Stacey R. Byers

Definition and Etiology

Urinary bladder eversion and prolapse are uncommon events that occur during or shortly after parturition.[1] With eversion, forceful straining moves the bladder fundus caudally, eventually turning the bladder inside out. The bladder is then forced out of the urethral orifice. Prolapse of the bladder is more frequently associated with dystocia. In this condition a full-thickness tear of the vaginal wall occurs during delivery, allowing the bladder (and possibly other viscera) to be displaced from the abdominal cavity into the vagina.

Clinical Signs and Differential Diagnosis

Females with either eversion or prolapse of the bladder have a smooth, spherical mass within the vagina, usually protruding from the vulva. The female may be alert and ambulatory, but if concurrent hypocalcemia, exhaustion, or peritonitis exists, the animal may be recumbent and depressed. Careful vaginal examination is required to differentiate these two conditions from each other and from vaginal prolapse, vaginal polyps, fat protrusion from a vaginal tear, vaginal neoplasia, fetal membranes, and uterine prolapse.[1] Epidural anesthesia is necessary to prevent straining to reduce fecal contamination while cleaning the perineum and vestibule and to reduce the risk of viscera herniation through the urethra (bladder eversion) or through the vaginal tear (bladder prolapse).

With urinary bladder eversion, the mucosal surface of the bladder is exposed. The ureteral openings may be visible on its dorsal aspect, although these may be occluded and difficult to see if the wall of the bladder is edematous. Vaginal palpation reveals that the protruding tissue originates from the urethral orifice. With time, constriction of the everted bladder by the narrow urethra may cause venous congestion, edema, thrombosis, and eventual necrosis. Palpation and ultrasonographic examination are required for detection of herniation of other viscera through the urethral orifice and into the interior of the everted bladder. Careful fine-needle aspiration of the interior of the eversion has been used to differentiate eversion from prolapse of the bladder. With bladder eversion, aspiration may yield peritoneal fluid, but laceration of herniated bowel is a concern.

In contrast, the serosal surface of the bladder is exposed with urinary bladder prolapse. Careful palpation of the vagina reveals that the bladder protrudes from a full-thickness tear in the floor or lateral wall of the vagina. Other viscera may be present in the vagina, as well. Fine-needle aspiration yields urine from the bladder lumen.

Treatment and Prognosis

Manual reduction of an everted bladder may not be possible if it is edematous or if other viscera have herniated into its interior. The dorsal aspect of the urethra may be incised to widen the route through which the bladder is to be replaced.[1] Viability of the involved structures is of primary concern for prognosis, and laparotomy is required for assessment of the viability of herniated bowel. Bladder paralysis and rupture are potential sequelae to ischemic damage that develops during eversion. Cystitis and pyelonephritis may develop, and antibiotic therapy is warranted if repair is attempted. Animals with chronic conditions may develop hydroureter, hydronephrosis, and renal failure.[2]

A bladder prolapse can be resolved by first passing a flexible catheter into the urethra to remove urine from the bladder. This also confirms the diagnosis and facilitates bladder replacement. After catheterization and removal of urine, the bladder can be replaced into the abdominal cavity, and the vaginal tear can be sutured. Severe contamination of the peritoneal cavity may render attempts at treatment unjustified. Antibiotic therapy is indicated for surgical candidates.

Pelvic Entrapment of the Bladder

Stacey R. Byers

Definition and Etiology

In pelvic entrapment of the bladder, the apex and fundus of the bladder are displaced caudodorsally into the pelvic cavity,

resulting in impaired urine outflow. It has been reported in cattle, sheep, and an alpaca cria. Occurrence has been associated with postpartum straining, perineal hernia, vaginal prolapse, and suspected vaginal irritation or secondary bladder displacement from trauma.[1-3]

Clinical Signs and Differential Diagnoses

Bladder emptying is impaired, and the presence of the bladder in the pelvic inlet induces straining. An affected animal may show tenesmus, pollakiuria, and stranguria. On rectal palpation a soft, fluctuant mass may be detected beside the vagina. Radiography with contrast can be used to demonstrate the pelvic position of the bladder.[1,2] Ultrasonographic examination can be used in larger animals.[3]

Differential diagnoses include proctitis, vaginitis, retained placenta, bladder paralysis, cystitis, and perivaginal abscess. Needle aspiration of the bladder per vaginam has been used to make a definitive diagnosis, although the danger of uterine puncture should be considered.

Treatment and Prognosis

Draining the bladder through catheterization or needle aspiration facilitates replacement of the bladder by manipulation per vaginam. However, fibrinous adhesions between the bladder and vagina may make laparotomy necessary to replace the bladder. Ventral midline laparotomy with replacement and fixation was successfully performed in an alpaca cria.[2]

Enzootic Hematuria

Stacey R. Byers

Definition and Etiology

Enzootic hematuria is a disease of chronic or intermittent hematuria that occurs in a wide variety of ruminants and is most commonly associated with chronic ingestion of bracken fern (*Pteridium* spp.). However, research has identified other fern species (*Pteris* spp., *Cheilanthes sieberi*, *Onchyium contiguum)* associated with enzootic hematuria.[1-3] Enzootic hematuria occurs after ingestion of large quantities of the responsible ferns (approximating the animal's body weight), usually over a period of 1 to 3 months, and is different from acute bracken poisoning. Acute bracken poisoning manifests as acute coagulopathy or fulminant septicemic crisis associated with severe bone marrow suppression (see Chapter 54).

Clinical Signs and Differential Diagnoses

Protracted, possibly intermittent, hematuria is the first clinical sign detected in most animals. Blood clots may be voided and can cause urethral obstruction. Chronic blood loss eventually results in tachycardia, tachypnea, exercise intolerance, pale mucous membranes, and a decline in productivity and body condition. A thickened bladder wall and bladder tumors may be palpated per rectum. Proliferative changes or overt neoplasia of the bladder may cause dysuria, pollakiuria, and, rarely, obstruction of the bladder trigone. Depending on the magnitude and duration of fern ingestion, hematuria may last for months to years before severe debilitation or death occurs.

Examination of serum for evidence of hemolysis and analysis of sediment from a freshly voided urine sample for intact RBCs allow for differentiation of hematuria from the hemoglobinuria found in hemolytic diseases. Icterus, also characteristic of ruminant hemolytic disorders, is not found in cases of enzootic hematuria. Hematuria may be evident in a UTI, but pyuria and bacteriuria are marked, and anemia, if present, is usually mild. Simultaneous involvement of several animals is common with enzootic hematuria. Hematuria may also be evident in cattle affected by malignant catarrhal fever. Protracted, severe hematuria is rare in cases of urolithiasis, and anemia is also not expected.

Ultrasonography or cystoscopy examination of the urinary bladder may help with antemortem diagnosis.[4-6] Diagnosis is often made on necropsy.

Clinical Pathology

Severe, regenerative anemia is often seen with enzootic hematuria. However, evidence of a regenerative response may not be present if bone marrow suppression exists or chronic blood loss induces iron deficiency. The platelet, segmented neutrophil, and lymphocyte counts may be reduced. Clotting profiles show increased antithrombin III and protein S activities.[4] Urinalysis reveals hematuria, proteinuria, and variable pyuria.

Pathophysiology

All parts of the ferns are toxic to ruminants. The ferns contain multiple compounds that have irritant, mutagenic, carcinogenic, and immunosuppressive activities and cause a variety of medical conditions in addition to enzootic hematuria. The carcinogenic compound, ptaquiloside, appears to be the primary compound that leads to the bladder tumors. A synergistic interaction between ptaquiloside and bovine papilloma virus type 2 is thought to induce many of the bladder tumors.[1,3,7,8] Ptaquiloside is also found in the milk and meat of animals grazing the ferns and has been found to increase the risk of esophageal and gastric tumors in humans.[3,9]

Bladder carcinomas from cows with enzootic hematuria have been shown to express both cyclooxygenase-1 (COX-1) and COX-2 at a high level relative to normal controls when evaluated by immunohistochemical methods.[10] The efficacy of COX-2 inhibitor drugs on cancer prevention or treatment in cattle at risk for bladder tumors has yet to be investigated.

Epidemiology

Enzootic hematuria has a worldwide geographic distribution as the plants are found almost everywhere. The ferns are often invasive and opportunistic but do not grow in extreme temperatures or low-humidity conditions.[3] Ruminants are poisoned by grazing the plant or consuming contaminated hay over an extended period of time. Cattle grazing infested pastures may develop hematuria by 2 to 3 years of age. Papillomas of the bladder have occurred as early as 1 year after feeding begins, with invasive carcinomas arising 2 to 6 years later. Within endemic areas, up to 90% of adult cattle may be affected.[11]

Necropsy Findings

Tissue pallor from anemia is often appreciated. The bladder wall is thickened, and the mucosa hemorrhagic and ulcerated. Microscopic examination of the bladder wall reveals capillary engorgement, intramural hemorrhage, and metaplasia of the bladder epithelium. Several types of bladder tumors and mixed-origin neoplasms may be present. Metastasis of epithelial neoplasms to the regional lymph nodes or other organs can occur.[11]

Treatment and Prevention

Treatment of enzootic hematuria is limited to reduction or elimination of the responsible ferns from the diet. Forage improvement may help limit incorporation of the plant into hay. A program of early culling may help prevent low productivity from anemia and neoplasia. Hematuria will cease if bracken feeding is discontinued before the onset of tumor formation.

Urinary Tract Infection

Brandon J. Dominguez

VetBooks.ir

UTI in ruminants typically present as cystitis, ureteritis, and pyelonephritis from ascending infection with *C. renale* or *E. coli*.[1] Other coliform species[2] and close relatives of *C. renale* may be involved with lesser frequency.[3] Less commonly, *Salmonella* spp., *T. pyogenes*, *P. aeruginosa*, *Proteus* spp., *Streptococcus* spp., and *Staphylococcus* spp., among others, have been implicated in renal infections of hematogenous origin (suppurative embolic nephritis).[4-7] In small ruminants, *Corynebacterium pseudotuberculosis* has also been cultured from renal infections.[8]

Clinical Signs

Cystitis is suggested clinically by dysuria and pollakiuria; hematuria and pyuria may not be grossly apparent. Affected animals may dribble urine, tread their feet, swish their tail, or retain an arched stance after voiding. Occasionally, blood, purulent debris, or urinary crystals may be found on the preputial tuft or ventral commissure of the vulva.[1] The bladder may be thickened and painful on rectal palpation, and on cystoscopy, catarrhal, hemorrhagic, fibrinous-purulent, and fibrinous-hemorrhagic lesions may be observed.[9] Generalized signs of malaise are not seen if infection is limited to the bladder.[1]

Acute cases of pyelonephritis often present with a history of sudden reductions in feed intake and milk production. Fever, tachycardia, tachypnea, decreased skin turgor, enophthalmos, ruminal stasis, scleral injection, and occasional episodes of mild colic may be noticed in addition to signs of cystitis.[1] When the left kidney is involved, renal enlargement, pain, and loss of the normal lobulation may be noted on rectal palpation. Affected animals may dribble urine, resulting in phosphate calculi present on the vulvar or preputial hairs. This may be accompanied by wet hair on the perineum and hind legs, progressing to excoriations due to urine scald.

Evaluation of the right kidney in cattle can be accomplished via ultrasound with a 5.0-MHz or lower frequency transducer in the 12th intercostal space and right paralumbar fossa.[10-12] In small or thin cattle, the left kidney may be visible in the left paralumbar fossa on transcutaneous ultrasound. Alternatively, the left kidney can be assessed transrectally with a 5-MHz or higher transducer. In small ruminants and camelids, both kidneys are often visible via transabdominal ultrasound from the right paralumbar fossa. Renal enlargement, abnormal kidney shape, dilated renal calyces, and flocculent echogenic material in the renal pelvis and ureter are suggestive of pyelonephritis.[10-12] The ureters may be palpated per vaginam in cattle, with the examiner using their fingers to detect one or both enlarged, painful ureters adjacent to the ventral vaginal wall.[1]

Chronic pyelonephritis presents with vague signs.[1] Weight loss, muscle wasting, poor growth, anorexia, diarrhea, and reduced milk production may be evident from history. No abnormal behavior or posturing during urination may be noted. Pale mucous membranes (due to anemia) may be noted during physical examination. A loss of lobulation on the left kidney may be evident on rectal palpation in cattle; pain and enlargement may not be noted.[1] Cystic lesions may be noted ultrasonographically in chronic renal disease.[12]

Differential Diagnosis

Mild colic may be a symptom of numerous GI or intraabdominal disorders, and urinalysis findings will be normal. Dysuria may be the result of vaginitis, perivaginal abscess, pelvic entrapment of the bladder, vulvar trauma, or postparturient swelling of the vagina and vulva. Urolithiasis can cause dysuria and hematuria, but males are typically affected, whereas females are predisposed to UTI. On rectal palpation in cattle, bladder distention will be evident in cases of urolithiasis, a finding not expected with UTI. A careful neurologic examination will help determine whether there is underlying bladder paresis or incomplete voiding from neurologic diseases. Hematuria may be due to bleeding from parturition, papillomas in the urinary tract, postparturient hemoglobinuria, or enzootic hematuria. In cases of enzootic hematuria, multiple animals are typically affected and the presence of bracken fern can be demonstrated. In addition, a profound anemia is expected with enzootic hematuria, and if pyuria or bacteriuria is present, it will be mild. Papilloma of the bladder may be ruled out with cystoscopy.

Clinical Pathology

A neutrophilic leukocytosis with hyperfibrinogenemia is expected in cases of pyelonephritis. If the duration of the infection has been several days, hyperglobulinemia will develop. Continued, severe proteinuria, resulting in hypoalbuminemia, can lead to diarrhea because of decreased plasma oncotic pressure. As the chronicity of the disease lengthens, anemia may develop. This may be due in part to the decreased production of erythropoietin in the affected renal tissue and from blood loss through urination.[1] Measurement of serum BUN and creatinine is critical for prognosis in cases of pyelonephritis.[9,13] When azotemia and isosthenuria are combined in cases of pyelonephritis, bilateral kidney involvement is indicated and the prognosis for successful treatment is poor.[1] Prerenal causes should be considered when evaluating the severity of azotemia.

Urinalysis is necessary for definitive diagnosis of UTI. A midstream or endstream caught sample should provide the most accurate results as contaminants in the distal urogenital tract are purged. Concomitant metritis, vaginitis, or prostatitis may contaminate urine with blood, bacteria, and inflammatory cells. Hematuria, proteinuria, and bacteria should be present in the urine of a UTI-afflicted animal. Specific gravity may be in the range of 1.005 to 1.020.[12] A Gram stain of the urine may yield preliminary identification of the causative organism.

Pathophysiology

Initiation of an ascending infection is dependent on the amount and virulence of bacteria introduced into the urinary tract. Urogenital trauma during parturition or obstetric manipulation, abnormal vulvar confirmation, conditions leading to urine retention, and bladder catheterization may provide routes of introduction for pathogens. Impaired bladder emptying due to bladder adhesions, urachal remnant infection, or diseases of the spinal cord may create an environment for the establishment of cystitis and ascending infection. Urethral trauma from catheterization, urolithiasis, breeding, or urogenital papilloma may be adequate to initiate infection.[14] Vesicoureteral reflux due to decreased bladder contractility or ectopic ureters may occur, aiding in the extension of infection up the urinary tract. Ureteral and renal obstruction due to inflammatory debris, hemorrhage, and fibrin deposition may lead to episodic signs of colic. After pyelonephritis is established, necrosis of papillary and tubular epithelium leads to an accumulation of necrotic debris in the renal pelvis, loss of functional nephrons, abscessation, fibrosis, and distortion of the renal shape. Struvite uroliths and other renal calculi may develop when necrotic debris serve as foci of crystal deposition in the alkaline microenvironment created by bacterial urease activity.[4]

C. renale is a large, pleomorphic, nonmotile, gram-positive bacillus.[3] It is grouped with and closely related to two other *Corynebacterium* that may cause pyelonephritis: *C. cystitidis* and

C. pilosum.[5] *C. renale* pyelonephritis has been documented in a sheep[14] and induced experimentally in goats.[15] Evidence suggests that *C. renale* may be maintained in the environment for several weeks.[3] The bacterium may be transmitted by direct vulvar contact between females or by splashing of urine from infected animals. Iatrogenic transmission may occur via contaminated obstetrical instruments or urinary catheters. Males may spread *C. cystitidis* and *C. renale* through sexual contact.[16] *C. renale* adhere to the urinary tract epithelium via pH-mediated pili.[17] Adherence is enhanced in alkaline conditions and reduced in acidic conditions.[18] This pH influence may explain the improvement in clinical signs realized after the feeding of urine-acidifying salts. The organism uses ureolysis and ammonium production to maintain urine alkalinity and promote colonization of the epithelium. A serum antibody response will develop after renal infection. This humoral response is rarely curative, nor does it provide resistance to reinfection.[1]

E. coli, among other coliforms, is frequently implicated in ruminant UTI.[1] The serotype(s) and virulence factors of *E. coli* specifically involved in bovine pyelonephritis are unknown at this time. Because of the ubiquitous nature of this gram-negative coliform, it is thought that infection originates from fecal contamination or a loss of natural defenses in the urogenital tract.

Epidemiology

On-farm prevalence of pyelonephritis in cattle varied from 0.3% to 2.7% in an Israeli study.[13] An Iranian abattoir study found a 13% prevalence of urine infected with pathogenic organisms.[6] Female animals have a greater potential for infection owing to a shorter urethra in addition to potential contamination and trauma during parturition and breeding. A majority of pyelonephritis cases in cows develop within 90 days post calving, which suggests that the postpartum period is a significant risk period in the development of infection.[4] Reproductive tract abnormalities such as pneumovagina, metritis, and poor perineal conformation were identified in 7 out of 15 cows diagnosed with pyelonephritis.[1]

C. renale has typically been regarded as the most common pathogen in bovine pyelonephritis.[2,12] In some studies, *E. coli* has been found as the more prevalent bacteria in pyelonephritis cases.[4,5,19] *C. renale* and *C. pilosum* have been found in healthy cows, whereas *C. cystitidis* is considered the most virulent pathogen in the *C. renale* group.[5] Once established, *C. renale* can be difficult to eradicate on a herd level.

Necropsy Findings

The bladder will have evidence of hemorrhage, ulceration, and fibrin deposition on the epithelial surface, which may extend through the urethra. Polypoid growths may develop with chronic infection. As these resemble tumors, histopathologic examination is necessary for definitive diagnosis.[2] Ureters may be noticeably enlarged on one or both sides and contain purulent debris. Acute to subacute pyelonephritis cases may show gross enlargement of the affected kidney(s). A viscous gray, odorless exudate may be found in the renal pelvis and extend into the medulla and cortex, especially on sagittal section. A Gram stain of the exudate is helpful for differentiation of the cause. Chronic cases of pyelonephritis may have gross distortion of renal size and shape (Fig. 34.19).

Treatment and Prognosis

Aggressive and long-term antibiotics are required for successful treatment of UTI. Diuresis with oral or parenteral fluid therapy is beneficial in facilitating the removal of necrotic debris and bacteria from the urinary tract.[1] Nephrectomy in cases of unilateral pyelonephritis that are unresponsive to medical therapy is an option.[12] Studies have indicated that there is no apparent limitation on growth and production following unilateral nephrectomy if the remaining kidney is normal and healthy.[20]

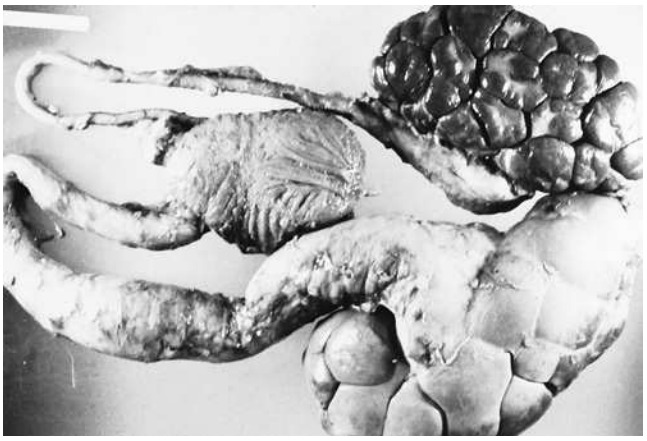

FIG. 34.19 Postmortem specimen of unilateral pyelonephritis and ureteritis in a cow. The affected kidney and ureter are greatly enlarged.

Penicillin is typically the first-choice treatment of *C. renale* and *E. coli* infection. Twice-daily IM administration of procaine penicillin G (22,000 to 44,000 units/kg) or ampicillin trihydrate (11 mg/kg) is effective.[1] Higher serum and urinary concentrations may be attained with IV administration of sodium or potassium penicillin (22,000 to 44,000 IU/kg q6h) or sodium ampicillin (10 to 50 mg/kg q8h). Animals with coliform UTI should be continually monitored for appetite, attitude, pyrexia, and reagent-strip urinalysis. If there is no improvement within 96 hours of treatment, therapy should be modified.[1] Gentamicin (2.2 mg/kg IM bid),[1] trimethoprim-sulfadiazine (15 mg/kg IV once daily),[2] and ceftiofur (3 mg/kg IV bid)[21] have been used to treat refractory coliform UTI (check on whether permitted in the United States). However, the nephrotoxicity of gentamicin is an important consideration,[1] and at present the American Association of Bovine Practitioners has implemented a voluntary ban on aminoglycoside use in cattle due to prolonged withdrawal times. Furthermore, current U.S. regulations limit the use of sulfa antibiotics in lactating dairy cattle to approved formulations only, and ceftiofur use in major food-producing species (cattle, swine, turkeys, chickens) is limited to the label dosage, route, duration, and frequency.[22] Meat and milk withdrawal times must be extended appropriately after prolonged and extralabel dosages of any antibiotic. Urinalysis and urine culture should be assessed 1 week after therapy is discontinued to confirm resolution.

Treatment is more likely to be successful the earlier it is initiated in the course of disease. Case fatality and nonvoluntary cull rates due to pyelonephritis in dairy cattle have been reported between 18%[1] and 47%[4] for treated cases. Recrudescence rates have been reported at 9.4%.[13] Cystitis alone yields a better prognosis than concurrent ureteritis or pyelonephritis, especially if bilateral disease is evident. Cows with marked azotemia noted by a BUN above 100 mg/dL and/or a creatinine above 1.5 mg/dL and pyelonephritis were at much greater risk of culling than nonazotemic cows with pyelonephritis.[13] Recent studies indicate that acute-phase proteins, particularly haptoglobin, serum amyloid A, and α_1-acid glycoprotein, reflect response to treatment and may serve as prognostic indicators.[23]

Prevention and Control

Isolation of diseased animals, particularly with *C. renale*, is recommended to limit the spread of the organism. Cleaning

and disinfection of contaminated areas are advisable. Aseptic technique during urogenital and obstetric procedures can limit iatrogenic transmission. Venereal transmission is difficult to control in herds with natural service and subclinically infected males. Artificial insemination or mass treatment programs could be introduced in herds with increased problems due to UTI.

Amyloidosis

David C. Van Metre

Amyloidosis is caused by extracellular deposition of insoluble, fibrillar protein in tissues.[1] Amyloid arises from various precursor proteins that become abnormally folded. Normally, misfolded proteins are degraded by macrophages in the extracellular space. Amyloid, however, forms beta-pleated sheets that are highly resistant to degradation. Aggregates of amyloid collect in various organs, resulting in dysfunction.

Clinical Signs

Although subclinical deposition of amyloid can occur in a variety of tissues,[2] in cattle, the kidneys are most commonly affected in clinical disease.[3,4] The most common clinical signs of bovine amyloidosis include chronic diarrhea, weight loss, generalized edema, and poor productivity in mature animals.[3-5] Enlargement of the left kidney may be palpated rectally.[5] The enlarged kidney is not painful and maintains its normal lobulation. Because amyloidosis may develop secondary to an underlying inflammatory disease, such as metritis or traumatic reticuloperitonitis, signs of the primary disease process may be superimposed.

Clinical Pathology

Marked proteinuria and hypoalbuminemia are hallmarks of disease.[3-5] Hyperfibrinogenemia, hyperglobulinemia, and an inflammatory leukogram may reflect the underlying inflammatory disease. Renal azotemia may exist. Urinalysis reveals persistent, heavy proteinuria. Importantly, a positive reaction for protein on urine dipstick is expected when the urine is alkaline (as is common in cattle); therefore, more specific tests for protein, such as the sulfosalicylic acid precipitation test, should be used to confirm proteinuria. Polarized light microscopy and electron microscopy have been used to detect amyloid protein in urine sediment.[6] There is no pyuria or hematuria.

Differential Diagnosis

Amyloidosis must be differentiated from other diseases causing chronic diarrhea, hypoproteinemia, weight loss, and poor productivity. Diseases to consider include Johne's disease, copper deficiency, salmonellosis, bovine viral diarrhea, GI parasitism, liver fluke infestation, peritonitis, bovine leukosis virus infection, and glomerulonephritis. Glomerulonephritis is the only other differential diagnosis wherein persistent proteinuria is an expected feature. Renal biopsy can differentiate these two conditions.

Pathophysiology

Light-chain (AL) amyloidosis is a rare disorder associated with immune cell dyscrasias, such as multiple myeloma. In AL amyloidosis, the amyloid forms from abnormally folded immunoglobulin light chain.[1] In contrast, bovine amyloidosis is classified as the reactive (AA) type, which is frequently associated with chronic inflammatory disease in domestic animals and humans.[1-5] Most, but not all, cattle with AA amyloidosis have concurrent inflammatory disease, such as traumatic reticuloperitonitis, pneumonia, mastitis, footrot, or metritis. Serum amyloid A protein (SAA) is an acute-phase protein that is synthesized in the liver and is a precursor of amyloid A (AA) fibril in tissues.[1] SAA concentrations increase in cattle with inflammatory disease.[3] Some of these cattle may subsequently develop amyloid deposits in organs because of abnormal catabolism, misfolding, and deposition of SAA.[1] Once embedded in tissue, smaller AA fibrils may serve as a nidus for further AA accretion and enlargement of the amyloid deposit.[7] Accumulation of amyloid in the glomerulus alters glomerular filtration and enables sustained albuminuria and a gradual loss of plasma oncotic pressure. Diarrhea develops as a result of gut wall edema, fluid loss into the gut lumen from the hypooncotic plasma space, and amyloid deposition in the GI tract.[5]

Necropsy Findings

Renal enlargement with yellow-tan to white discoloration is frequently present. A waxy quality of the renal parenchyma may be appreciated on cut surface of the kidney.[3-5] Generalized edema is apparent. Primary inflammatory disease may be found in other sites. Histologic examination of the kidney reveals amyloid deposition in the glomerulus, interstitium, and tubule lumen.

Prognosis

The prognosis for affected cattle is poor. The resilient nature of the amyloid protein generally results in its persistence in tissues, even if the underlying inflammatory disease is treated. Specific treatment for amyloidosis has not been reported in cattle. The potential for cross-species transmission of amyloidosis is an area of active research.[8]

Amyloidosis in Other Ruminants

AA amyloidosis has also been reported in domestic sheep and goats, as well as a variety of nondomesticated ruminants.[9-11] It appears to be a consequence of chronic suppurative diseases such as pneumonia,[9] caseous lymphadenitis,[10] and in lambs, polyarthritis caused by *Erysipelothrix rhusiopathiae*.[11] As for cattle, amyloid deposition can be detected histologically in multiple tissues of affected animals, with gross and histologic lesions primarily involving the kidneys. The clinical course of AA amyloidosis in small ruminants is poorly described but is speculated to be a protein-losing glomerulopathy, akin to the disease in cattle.[10]

Glomerulonephritis

David C. Van Metre

Glomerulonephritis (GN) is a rare kidney disorder of ruminants that may result from deposition of antigen-antibody complexes and/or complement in the glomerulus, or from binding of antibody to intrinsic or foreign antigens localized to the glomerulus. Glomerular injury occurs subsequent to targeting of glomerular tissues by the immune system. Clinical signs reflect sustained albumin loss in the urine and the resultant loss of plasma oncotic pressure.

Clinical Signs

Cattle with GN may have a history of lethargy, weight loss, mucous membrane pallor, poor productivity, and chronic diarrhea,[1,2] although the course of disease may be acute in

VetBooks.ir

some cases.[3] Generalized edema is often apparent, typically involving the brisket and submandibular space. An enlarged but nonpainful left kidney may be felt on rectal palpation.[2] GN can occur in cattle with liver fluke infestation,[4] metritis,[5] or those acutely[6] or persistently[7,8] infected with bovine viral diarrhea (BVD) virus. As is expected for persistent BVD infection, the appearance of affected cattle can range from unthrifty[7] to clinically normal.[8] GN can also occur without a detectable concurrent disease.[2,3] Further, a heritable proliferative glomerulopathy (defined as hyperplasia of cells within the glomeruli without a marked inflammatory infiltrate) has been described in Gelbvieh calves; clinical signs in affected animals reflect a concurrent peripheral neuropathy that manifests as paraparesis, hind limb ataxia, and recumbency.[9]

In small ruminants, the clinical course of GN is less well described than for cattle, but thin condition, pale mucous membranes, and generalized edema are expected.[10] Subclinical GN has also been detected at necropsy in sheep with caseous lymphadenitis,[11] Maedi-Visna virus infection,[12] and in sheep experimentally implanted with long-term, indwelling vascular catheters.[13] Finnish Landrace lambs may develop GN early in life as a result of a heritable defect in the C3 component of complement.[14] Clinical signs of this disease begin within hours after birth to 3 months of age. Affected lambs may be dull and ataxic and appear blind. Fine muscle tremors, colic, and convulsions may also be seen.

Differential Diagnosis

The differential diagnosis for ruminants with GN is similar to that for amyloidosis (see preceding section).

Clinical Pathology

Heavy proteinuria, mild anemia, hypoalbuminemia, and azotemia have been reported in ruminants with GN.[1-5,7,10] Variable amounts of granular or hyaline casts, red blood cells, and leukocytes may be found in the urine sediment. GN in Finnish Landrace lambs is characterized by uremia, hypoalbuminemia, proteinuria, hypocalcemia, and hyperphosphatemia.[14]

Pathophysiology

In humans and animals, GN may result from a variety of infectious, toxic, or autoimmune disorders, all of which induce eventual immunologic injury to the glomerulus.[15,16] Antibodies may be directed against the host's own antigens or antigens of infectious agents that become "planted" in the vascular endothelium, mesangial cells, or basement membrane. In many cases, circulating immune complexes develop under conditions of sustained antigenemia produced by chronic infections. These immune complexes deposit in the glomeruli and adjacent capillary walls. The ultimate consequences are activation of complement and chemotaxis of leukocytes, both of which result in glomerular injury and increased glomerular permeability.[15,16] Immunohistochemical data suggest involvement of these immune-mediated mechanisms in spontaneous GN,[1-3] as well as GN associated with infection with BVD,[6-8] Maedi-Visna virus,[12] and indwelling vascular catheters.[13] Notably, glomerular lesions may be found in animals with septicemia, as septic emboli may embed in the glomeruli or surrounding capillary beds, resulting in multifocal glomerulitis.[14-16]

Passage of plasma albumin through the damaged glomerulus results in chronic albuminuria, eventually leading to reduced plasma oncotic pressure and generalized edema. Affected animals may develop nephrotic syndrome, characterized by hypoalbuminemia, generalized edema, unrelenting proteinuria, and hypercholesterolemia[1-3,10]; however, because serum cholesterol is not commonly measured in ruminant biochemistry analysis, the frequency of hypercholesterolemia in affected ruminants is unknown.

Treatment and Prognosis

In other species, treatment aimed at removal of the source of antigen in the bloodstream may reduce immune complex deposition and slow or reverse the progression of disease. Treatment of GN in ruminants has not been described. Because most clinically overt cases of GN are advanced at the time of diagnosis in ruminants, the prognosis can be assumed to be poor.

Congenital Defects

David C. Van Metre

Most severe congenital defects of the urinary tract of ruminants manifest at an early age, although occasionally defects remain clinically occult until adulthood and some are incidental findings at necropsy or slaughter. Congenital defects of the urinary system should be considered in the differential diagnoses for a young animal with renal disease or abnormal urination. However, tubular necrosis caused by severe volume depletion, nephrotoxins, and infectious diseases are much more common. If a congenital defect of the urinary tract is identified, a careful examination of other body systems should be performed; 73% of lambs with urogenital defects were found to have one or more defects in other organ systems.[1]

Renal Defects

Common renal defects in cattle include fused kidney, polycystic kidney, unilateral renal agenesis, and renal oxalosis.[2] A single report exists of ectopic fused kidneys and hermaphroditism in a cross-bred calf.[3] In sheep, common defects include renal lobulation, fused kidney, hydronephrosis and hydroureter, polycystic kidney, and unilateral or bilateral renal agenesis.[1,2] Unilateral renal agenesis and polycystic disease involving the liver, pancreas, and kidney have been reported in goats.[2,4] A retroperitoneal, perirenal *pseudocyst* (a fluid sac lacking an epithelial layer) was described in a ram with acute abdominal pain.[5] Pseudocysts typically develop as outpocketings of the renal capsule and can develop as a result of renal trauma, urinary tract obstruction, or vascular or lymphatic anomalies.

Renal oxalosis is a metabolic disease that is suspected to have an inherited basis[6]; a severe form has been reported in Beefmaster calves.[7] Affected calves show weakness, lethargy, and anorexia within days to several weeks of age. Dehydration, diarrhea, and alopecia may develop. Evidence of renal failure is found on serum chemistry analysis. An inherited abnormality of glycine or glyoxalate metabolism may generate high levels of endogenous oxalate, which readily complexes with calcium. Subsequently, calcium oxalate crystals accumulate in the renal tubules, obstructing tubular outflow. Exposure to oxalate-containing plants and ethylene glycol must be ruled out in all cases of renal oxalosis.

Ectopic Ureter

Ectopic ureter is a rare congenital defect in which one or both ureters terminate in an abnormal location. An ectopic ureter may terminate in the urethra, vagina, or cervix or caudal to the bladder trigone in females. In males, the ectopic ureter usually terminates in the urethra, vas deferens, or seminal vesicles. Urinary incontinence is the most common presenting complaint for affected animals.[8] Urine dribbling results in scalding of the perineum and medial surfaces of the hindlimbs in heifers, and scalding in males is usually located on the prepuce

and ventral abdomen. Occasional episodes of normal micturition may be seen. UTI, polycystic kidney(s), and hydronephrosis may exist concurrent to ectopic ureter(s). Diagnosis and treatment of this condition in ruminants are similar to horses (see the previous section in this chapter). The use of affected animals for breeding should be discouraged.

Neoplasia

David C. Van Metre

Other than those associated with ingestion of bracken fern, primary neoplasms of the urinary tract of ruminants are rare. In a North American abbatoir survey, primary tumors of the bladder were detected in 0.05% of more than 21,000 cattle examined, with cases of papillomas, adenomas, and transitional cell carcinomas identified in the sample population.[1] Tumors of the genitalia, typically fibropapillomas and squamous cell carcinomas, may impinge upon urine egress from the urethra. Urinary tract involvement may be seen in occasional cases of lymphosarcoma in ruminants.[3]

Hemolytic Uremic Syndrome

David G. Renter • Charles C. Dodd

Hemolytic uremic syndrome (HUS) is a thrombotic microangiopathy (TM) disorder of multiple etiologies. Although primarily a disease of humans, there are reports of HUS in multiple species including horses and cattle. Clinically, HUS manifests as microangiopathic hemolytic anemia, thrombocytopenia, and, in many cases, renal failure. HUS is characterized morphologically by thrombotic lesions in capillaries and arterioles in tissues including those of the kidney.[1] The presence of schistocytes (fragmented red cells) in peripheral blood is considered an important diagnostic indicator of TM,[1] but an apparent lack of schistocytes in peripheral blood has been reported in both human[2] and equine[3] cases of HUS. Unlike DIC, TM disorders are generally associated with normal coagulation times and normal to slightly elevated fibrin split products.[1] TM disorders can be classified as typical HUS, atypical HUS, and thrombotic thrombocytopenic purpura.[1]

The typical form of HUS in humans is associated with consumption of food or water contaminated with Shiga toxin–producing bacteria, whereas atypical HUS is associated with inherited mutations of complement-regulatory proteins and diverse causes of endothelial injury including antiphospholipid antibodies, complications of pregnancy and contraceptives, vascular renal diseases like systemic sclerosis and malignant hypertension, use of chemotherapeutic and immunosuppressive drugs, and radiation.[1,4,5] Typical HUS is a major cause of ARF in young children and infants, and the majority of the cases occur after intestinal infection with Shiga toxin–producing enterohemorrhagic *E. coli* (EHEC).[1,6] *E. coli* O157:H7 is the most commonly reported serotype of EHEC in human cases of HUS, but many other EHEC serotypes have caused the syndrome.[6] Infection with neuraminidase-producing *Streptococcus pneumoniae* has also been reported to cause typical HUS in humans.[7,8] Although literature on HUS in large animals is limited, case reports on four horses[3,9,10] and two cows[11,12] have demonstrated clinical syndromes and pathologic lesions consistent with HUS in humans.

Clinical Findings

Horses with clinical signs indicative of HUS exhibited fever, lethargy, diarrhea, hematuria, hemoglobinuria, azotemia, oliguria, and ventral edema.[3,9,10] Hematologic findings in three cases included leukocytosis, anemia, and evidence of hemolysis.[9,10] The blood smear of one of the four equine cases of apparent HUS revealed the presence of poikilocytes and schistocytes.[3,9,10] All four horses with evidence suggestive of HUS were euthanatized following unsuccessful treatment with fluid therapy and diuretics.[3,9,10]

In a postparturient mare ultimately diagnosed with HUS, there was initial clinical and laboratory evidence of endotoxemia and endometritis.[3] However, after clinical signs of endotoxemia subsided, stranguria, hematuria, hemoglobinuria, tubular casts, thrombocytopenia, hyperfibrinogenemia, azotemia, and a left shift in the leukogram were noted.[3] Her foal was apparently healthy at birth but subsequently developed progressive CNS signs culminating in refractory seizures.[3] Although a direct causal relationship was not established, *E. coli* O103:H2 was recovered from the GI contents of both the mare and foal, as well as from the mare's uterus. In humans, serotype O103:H2 is one of the more common non-O157 EHECs.[6]

A reported fatal postparturient HUS case in a heifer was characterized by severe, progressive, anuric renal failure, acute hemolytic anemia, and consumptive thrombocytopenia.[12] A 6-year-old cow that had evidence of metritis 1 month after parturition was a suspected HUS case based on clinical and laboratory findings including anemia, hemolysis, thrombocytopenia, azotemia, and hemorrhagic diathesis.[11]

In humans, HUS can present suddenly as generalized hemorrhagic diathesis (especially hematemesis and melena), pallor, severe oligoanuria, hematuria, edema, microangiopathic hemolytic anemia, and, on occasion, seizures or other prominent neurologic changes.[1,12] In prodromal human cases, HUS develops an average of 1 week after the onset of diarrhea.[12] The classic clinical presentation of typical HUS in people includes the triad of ARF, thrombocytopenia, and hemolytic anemia.[1] Treatment in this acute phase of HUS primarily involves supportive care; there is limited evidence for more specific therapies, and some treatments may be detrimental.[4,13-15] At this writing, conflicting data exist in the published literature regarding the efficacy or potential for harm imparted by certain antimicrobials used to treat HUS. For example, in vitro research indicates that fluoroquinolone administration may result in increased Shiga toxin production by certain strains of causative bacteria,[15] so avoiding use of this drug in cases of suspected HUS is likely prudent. New therapeutic strategies, including those aimed at binding or neutralizing Shiga toxins, have shown promising results in animal models for human disease.[15] Supportive therapy that includes fluid and electrolyte replacement, plasma therapy, and dialysis can be critically important in the acute stage of HUS. Approximately one third of those surviving the acute phase are at risk for chronic sequelae.[14] Although diabetes, intestinal strictures, myocardial infarction, and motor, sensory, or intellectual deficits and other sequelae can occur, chronic renal lesions leading to end-stage renal disease are more common.[14]

Pathophysiology and Necropsy Findings

Two processes appear to dominate the pathogenesis of TM and ultimately cause vascular obstruction and vasoconstriction resulting in organ ischemia: (1) endothelial injury and activation, leading to intravascular thrombosis, and (2) platelet aggregation.[1] In humans, endothelial injury appears to be the primary cause of HUS, and HUS is the most common life-threatening complication of hemorrhagic colitis from EHEC infection.[1,6] EHEC produces exotoxins Shiga toxin 1 and Shiga toxin 2, also referred to as *verotoxin 1* and *verotoxin 2*. Shiga toxins are considered a necessary but insufficient cause of typical HUS because other bacterial and host factors are important for disease progression.[6,16] Many serotypes of *E. coli* (as well as *Shigella*

VetBooks.ir

and other Enterobacteriaceae) can carry Shiga toxin genes and are capable of causing disease, yet certain EHEC serotypes (e.g., O157:H7) are more common human pathogens.[6] EHECs are considered noninvasive but attach to the intestinal mucosa and produce characteristic attaching and effacing lesions seen histologically.[1,6,16] Microvascular endothelium is the major target of Shiga toxins, which are released from the bacteria in the intestine and absorbed across the gut epithelium, where they access the systemic circulation and are transported to small vessel endothelial cells.[6,16] The toxins bind to specific glycolipid receptors on the surface of vascular endothelial cells, are internalized by endocytosis, and may injure the cell through inhibition of protein synthesis, stimulation of prothrombotic messages, or induction of apoptosis.[6,16] Exposure of subendothelial collagen followed by activation of the coagulation cascade may result in thrombosis of small vessels in the kidney and other organs. Acute oliguric or anuric renal failure can result from fibrin/platelet thrombi in renal vessels and glomeruli, fibrinoid necrosis of vessel walls, congestion of glomeruli, and tubular ischemia.[1,16]

Cattle feces are considered to be a major source of EHEC, but these bacteria have been isolated from the feces of many other species including other livestock and humans.[16,17] Although EHECs do not generally cause illness in cattle, they do colonize the large intestine.[17] It is generally believed that the lack of specific glycolipid receptors for Shiga toxins is the reason cattle typically do not develop severe colitis or HUS, despite the common presence of EHEC in their gastrointestinal tracts.[17] Humans are generally infected with EHEC via consumption of food and water contaminated by feces. However, the small infectious dose makes direct contact with EHEC-positive animals (e.g., at petting zoos) and person-to-person transmission also a concern.[16,17]

In four of the large animal cases reported with HUS, the inciting cause was unknown and isolation of EHEC or other Shiga toxin–producing organisms was not attempted.[9,10,12] One heifer had a necrotizing endometritis, but during postmortem examination of three horses, no focus of infection was identified.[9,10,12] Renomegaly, renal infarcts, and scattered petechial and ecchymotic hemorrhages within the renal parenchyma were apparent on gross necropsy. Acute tubular necrosis and fibrin thrombi within the glomerular capillaries were evident on histologic examination.[9,10,12]

In another equine case report, an EHEC serotype O103:H2 carrying a Shiga toxin gene was recovered from both the mare and foal, but direct Shiga toxin assays were not performed.[6] While the causal significance of this finding is unclear, the unusual and concurrent disease progression in both animals may suggest a common etiology. Except for lack of evidence of microangiopathic hemolysis on a blood smear, the mare had clinical and postmortem signs consistent with HUS.[6] Significant renal pathology included evidence for plasma protein and hemoglobin in both cortical and medullary tubules, with occasional epithelial necrosis. In addition, renal capillary lumina were apparently obscured by fibrin, and only remnants of glomerular capillary endothelial cell cytoplasm were evident. Evidence of numerous platelets within the glomerular capillaries and their adherence to exposed basement membranes was apparent, as were other pathologic changes.[6] The foal's brain had evidence of widened perivascular spaces, with apparent perivascular plasma protein accumulations in the corpus striatum and thalamus.[6]

Although the etiology is often undetermined in large animal cases of apparent HUS, the clinical signs and pathologic lesions reported are compatible with a diagnosis of HUS. It may be notable that three of six reported cases occurred postpartum. On the basis of HUS reports in large animals, it appears there may be features comparable with the disease syndrome in humans.

Tubular Necrosis

Meredyth L. Jones

Tubular necrosis (TN) is a term referring to intrinsic acute renal failure (ARF) caused by hemodynamic, nephrotoxic, glomerular, or interstitial disorders. Tubular damage may be a primary clinical entity or a secondary effect of another systemic illness. The kidneys receive a large proportion of circulating blood volume, resulting in a high rate of toxin exposure, as well as increased vulnerability to ischemia and reperfusion injury with diseases causing changes in nutrient blood flow. Acute renal failure, characterized by a sudden decrease in glomerular filtration rate, nitrogenous waste accumulation, and loss of the ability to manage sodium, electrolytes, protein, acid-base and water balance, develops over hours to days. Depending on the nature and duration of the primary insult, widespread dysfunction or necrosis of tubular epithelial cells may produce reversible renal injury, ARF, or chronic renal failure (CRF).

Potential causes of TN and ARF are included in Table 34.2.

Clinical Signs

The clinical signs of ARF in ruminants are nonspecific and usually not indicative of overt urinary tract dysfunction. Depending on the inciting cause, anuria, oliguria, or polyuria may exist. Cattle with ARF frequently are presented for evaluation of poor appetite, diarrhea, or epistaxis.[1] Depression, nasal discharge, ileus, melena, and mild free-gas bloat may also be present. If a concurrent septic condition exists, fever, tachycardia, and scleral injection may be present. The saliva may have a strong ammonia smell. Muscular weakness, even recumbency, may result from the acid-base and electrolyte imbalances and intravascular volume depletion that occur with severe, acute TN. Rectal palpation findings are usually unremarkable, although renal enlargement and perirenal edema may be found in occasional cases. If untreated, CRF may ensue, usually producing weight loss in addition to the signs listed. In such cases, a reduction in size of the left kidney may be appreciated on rectal palpation.

Renal (uremic) encephalopathy is a syndrome of brain dysfunction associated with renal disease. It is characterized by signs of intracranial disease, such as altered behavior or sensorium, weakness, motor dysfunction, and convulsions, which may resolve on restoration of normal renal function or improvement of clinical parameters of renal disease. The pathogenesis of renal encephalopathy is complex and incompletely understood, but neurologic function appears to be impaired by alterations in the extracellular fluid content of acids, phosphorus, amino acids, or certain hormones. Alteration in neurotransmitter balance or release within the central nervous system (CNS) may also be involved. Renal encephalopathy appears to be a rare complication of renal failure in ruminants, as reported in two cows and a goat, where the lesions included myelin vacuolation.[2-4]

Differential Diagnosis

Formulation of a differential diagnosis list for a ruminant with TN may be difficult because of the nonspecific nature of clinical signs and variety of primary disease conditions that may predispose an animal to TN. Generic systemic illness differential diagnoses are similar to those of renal origin. Diseases causing signs of acute, severe illness in ruminants include pneumonia, pleuritis, mastitis, metritis, peritonitis, endocarditis, and metabolic derangements.

VetBooks.ir

TABLE 34.2

Differential Diagnoses for Acute Renal Failure in Ruminants

Inorganic Compounds	Organic Compounds	Therapeutics	Endogenous Compounds	Hemodynamic Causes	Infectious Agents	Plants
Arsenic	Cantharidin	Aminoglycosides	Calcium oxalate	Blood loss	Malignant catarrhal fever	Castor bean *(Ricin)*
Bismuth	Carbamate fungicides	Gentamicin, neomycin, amikacin	Hemoglobin	Endotoxic shock	*Coxiella burnetii*	Beets *(Beta)*
Boric acid	Carbon tetrachloride	Amphotericin B	Myoglobin	Disseminated intravascular coagulation	*Leptospira* spp.	Bristle grass *(Setaria)*
Cadmium	Cholecalciferol-based rodenticides	Bacitracin		Renal vein thrombosis	*Mycobacterium* spp.	Cocklebur *(Xanthium)*
Calcium	Diquat	Cephalosporins		Heat-related injury	Rift Valley fever	Crocus *(Colchicum)*
Chromium	Ethylene glycol	Doxycycline			Septicemia	Curlydock *(Rumex)*
Copper	Mycotoxins	Ionophores			-*Mycoplasma agalactiae*	Daisy *(Nolletia)*
Lead	Natural gas condensate	NSAIDs			-*Salmonella enterica*	Greasewood *(Sarcobatus)*
Mercury	Ochratoxin, citrinin, fumonisin	Oxytetracycline			-Others	Halogeton *(Halogeton)*
Molybdenum	Oxalic acid	Polymyxin B				Hybrid sudan or Sudan grass *(Sorghum)*
Phosphorus	Pentachlorophenol	Sulfonamides				Inkweed *(Phytolacca)*
Sodium fluoride	Phenolics	Vitamin C				Jessamine *(Cestrum)*
Uranium	Stillage liquid from ethanol production	Vitamin D, particularly D3				Kleingrass *(Panicum)*
Zinc		Vitamin K3				*Kochia scoparia*

NSAIDs, Nonsteroidal antiinflammatory drugs.

Pathologic Studies

The complete blood count and serum biochemistry can provide important evidence for the presence of renal disease and clues as to its etiology. Inflammatory diseases are common in ruminants, and the leukogram may reflect those primarily affecting the upper urinary tract. Acute inflammation affecting renal tubules may result in neutropenia or a left shift to immature (band) neutrophils. Renal enzymes and electrolytes evaluated in the serum biochemistry are useful indicators of renal function. Blood or serum urea nitrogen (BUN) is interpreted as a measure of glomerular filtration rate (GFR), reflecting function and perfusion of the kidneys. BUN is influenced by the protein level in the diet and the ability of the rumen to recycle urea. Creatinine is produced and eliminated in constant amounts in the body and is not influenced by rumen physiology, making it superior for evaluation of renal perfusion and function in ruminants, although it may be elevated above reference ranges in heavily muscled bulls with adequate renal function. Azotemia may result from prerenal, renal, or postrenal causes, with renal causes indicated by persistent isosthenuria or hyposthenuria in the absence of iatrogenic causes. Overinterpretation of a single, dilute urine sample should be avoided.

Fractional excretion of (FE) electrolytes can further delineate the nature of renal azotemia. Fractional clearance of sodium has been used to help document renal failure in cattle, with values of 0% to 4% described in normal cattle.[5] Age, ration, and metabolic status may affect FE values.[5] When applying this test, it is prudent to compare the patient's FE value for sodium to that of an age-matched herdmate in a similar physiologic state and on a similar ration. The normal values for several urinary diagnostic indices in healthy calves have been reported.[6]

Hyponatremia, hypochloremia, and metabolic alkalosis may also be present with ARF, with variable potassium levels.[1,7] Because the kidney is the primary organ controlling magnesium excretion in ruminants, hypermagnesemia may occur in TN, particularly under conditions of high magnesium intake.[1,8] Hyperphosphatemia results from reduced phosphorus excretion in saliva during anorexia, reduced urinary phosphorus excretion, and tissue hypoxia.[9,10] Hypocalcemia is also common in TN in ruminants because of reduced calcium intake, gastrointestinal stasis, urinary losses, and the competitive effect of hyperphosphatemia.[1] Metabolic acidosis may develop in juvenile ruminants with TN and concurrent diarrhea.[5,10]

A urinalysis should be performed on all animals with suspected renal disease. Proteinuria, hematuria, and granular casts may be found in cases of tubular necrosis.

Table 34.3 lists additional clinical and clinicopathologic criteria that may facilitate diagnosis of TN caused by nephrotoxins.

Pathophysiology

The mechanisms of TN include hemodynamic changes within the kidney, as well as ischemic and toxic damage to tubular cells. Reduced blood flow to the kidneys most often occurs during generalized loss of vascular volume, as seen with marked

VetBooks.ir

TABLE 34.3

Clinical Characteristics of Acute Toxic Nephrosis Caused by Common Nephrotoxins

Nephrotoxin	Clinical Findings[a]
Aminoglycosides	Usually nonoliguric, ototoxicosis possible; hematuria, glucosuria, proteinuria, increased serum trough concentration of drug
Tetracycline	Hematuria, glucosuria, proteinuria; possible hepatocellular enzyme elevation
Ionophores	Diarrhea, dark urine, dyspnea, cardiac dysrhythmias; elevated CK, AST, and indirect bilirubin
Ethylene glycol	Anuria or oliguria, tachypnea, ataxia, weakness; hemolysis, increased anion gap, increased serum osmolality, increased osmolar gap, acidosis, calcium oxalate crystalluria
Oxalate-containing plants, vitamin C	Hindlimb ataxia or paresis, apprehension, salivation; hypocalcemia, calcium oxalate crystalluria, aciduria, increased renal cortical echogenicity on ultrasonogram
Oak, acorns	Hemorrhagic diarrhea, ascites, hydrothorax, subcutaneous and perirenal edema; hyperfibrinogenemia, increased hepatic enzymes
Myoglobin	Muscle stiffness and weakness, dark urine; elevated serum CK and AST, positive reactions for blood and protein on urine chemistry strip, hemolyzed serum not present
Hemoglobin/ methemoglobin	Icteric to pale mucous membranes, tachycardia, tachypnea, red or brown urine; positive blood and protein reactions on urine chemistry strip, anemia, elevated serum total protein, hemolyzed serum (hemoglobin only)
Arsenic	Colic, hemorrhagic diarrhea, ataxia; elevated blood and liver arsenic levels

[a]Many general clinical characteristics of acute tubular necrosis are also present. See Clinical Signs and Clinical Pathology.

AST, Aspartate aminotransferase; *CK*, creatine kinase.

blood loss, septicemia, endotoxemia, or severe dehydration. In ruminants, the most common primary conditions resulting in these changes include mastitis, metritis, enteritis, rumen acidosis, and intestinal accidents. These conditions may also cause infarction of the renal cortex and renal vein thrombosis.[1] Acute, severe renal tubular necrosis has been reported in lambs as heat stress-related injury, similar to ischemic, heat-induced injury in humans.[11] Prolonged, severe ischemia may destroy the tubular basement membrane, thereby preventing tubular epithelial cell regeneration.[12] Rumen acidosis or other conditions resulting in severe rumen distension may additionally result in mechanical obstruction of renal vasculature, impairing renal perfusion.[1]

Bilateral bacterial infection of the kidneys may result in ARF or CRF as a result of destruction of nephrons by bacterial toxins and host inflammatory response. Renal infection may be established by ascending urinary tract infection or via hematogenous infection of the kidneys.

Pigment nephrosis is an endogenous toxicity from the presentation of large amounts of hemoglobin or myoglobin to the kidneys as a result of hemolytic disease or myopathies. These pigments result in renal vasoconstriction and tubular obstruction from protein coagulation.

A variety of toxins may result in significant damage to the kidneys by a variety of mechanisms that result in ARF. The high metabolic demands of renal tubular epithelial cells render them susceptible to toxins that disrupt cellular enzymes. The injury caused by most nephrotoxins is compounded by dehydration, which concentrates the toxin in the tubular filtrate, slows toxin clearance, and if severe, reduces renal perfusion. Because some nephrotoxins are therapeutic agents, it is vital that the veterinarian monitor appetite, body weight, water intake, urine output, routine urine chemistry, serum drug concentration, and serum creatinine concentration during administration of these agents. Young or elderly patients, patients with preexisting renal insufficiency or sepsis, those receiving other potentially nephrotoxic drugs, and patients on prolonged or high-dose therapy with these agents warrant the closest attention.[13] Nonsteroidal antiinflammatory drugs block the effects of prostaglandins, which are important for maintenance of renal blood flow, and may cause medullary crest necrosis when used in pediatric, geriatric, and inadequately hydrated patients or for a prolonged dosing regimen.[14] Some sulfonamide antimicrobials have been associated with deposition of insoluble precipitates in the renal tubules and blocking excretion of creatinine.[15] Aminoglycoside antimicrobials, particularly gentamicin, have cumulative effects on the renal tubules and may cause cell death through mitochondrial oxidation and other mechanisms.[13,16]

Ethylene glycol, the primary ingredient in many antifreeze products, is converted by the liver into nephrotoxic metabolites, mainly glycolic acid. Additionally, calcium oxalate crystals form and are deposited in the renal tubules, causing further compromise.[17] Lethal doses for ethylene glycol are 5 to 10 mL/kg in mature cattle and 2 mL/kg in preruminating calves.[18,19] Insoluble oxalate crystal deposition in the renal tubules is also a common pathologic mechanism for some nephrotoxic plant poisonings including halogeton, greaseweed, pigweed, sorrel, dock, and Russian thistle. Several nephrotoxic plants also exhibit effects on other body systems including the respiratory, gastrointestinal, cardiac, and hepatic systems, with additional symptoms observed. Many of the nephrotoxic plants, particularly those causing oxalate toxicity, are also nitrate accumulators.

Treatment and Prognosis

Treatment of ARF should include binding and removing any offending toxin or source, promoting diuresis through intravenous (IV) fluid administration and diuretic medications, correcting acid-base and electrolyte derangements, and close monitoring for positive or adverse responses to treatment. Rumenotomy, with removal of toxic material, is most beneficial if performed soon (within 24 hours) after the animal has ingested a nephrotoxin. Activated charcoal (2 to 4 g/kg PO) may bind the agent in the gut lumen. The use of magnesium sulfate or other magnesium-containing laxatives should be avoided in such cases because severe hypermagnesemia may result in animals with concurrent compromise of renal function.[8] Drugs that directly target known nephrotoxins, such as heavy metal chelators, may be initiated. Prophylactic diuresis should be instituted as soon as an animal has suspected exposure to a potentially harmful quantity of a nephrotoxin. Delaying treatment until azotemia is present allows for a significant (>75%) loss of nephron function before medical intervention.

The cornerstone of treatment of TN is restoration of adequate renal perfusion and urine production. This is most

VetBooks.ir

effectively achieved through IV administration of isotonic, sodium-containing fluids, with calcium and potassium supplementation as indicated. Normal (0.9%) saline or 0.45% saline + 2.5% dextrose serve as reasonable base fluids. Additional IV potassium can be substituted if indicated after initial therapy, being cautious to remain below the generally recommended toxicity rate of 0.5 mEq/kg/h. Diuresis should continue until the patient is producing sufficient volumes of urine. If cost or facilities make IV fluid therapy impractical, repeated administration of water and electrolytes by orogastric or nasogastric tube is an option. A small-bore tube can be passed through the nasal cavity into the rumen and secured to the animal's halter to allow one person to administer fluids repeatedly without the need for repeated tube passage. Placement of a small rumenostomy also would allow one person to administer fluids repeatedly with relative ease. Administration of IV or oral fluids at 1.5 to 2 times the adult maintenance level of 60 mL/kg/day may be adequate to induce diuresis. The patient should be monitored for chemosis, ventral or peripheral edema, or labored or rapid respiration, which may be indicative of overhydration. Fluid therapy should be continued until azotemia resolves, at which time the patient's voluntary fluid intake can be assessed. Oral supplementation of potassium and calcium salts may be necessary in some cases because it is often not possible to include adequate yet safe levels of these salts to IV fluids in cases of refractory hypokalemia and hypocalcemia, respectively.

Restoration of urine production is necessary in anuric or oliguric animals. If fluid therapy does not promote diuresis, furosemide (1 mg/kg IV or IM) may be administered. Repeated administration (every 1 to 2 hours) may be necessary to induce urine production. With repeated use of furosemide, the patient's serum sodium and potassium concentrations must be monitored. Mannitol (0.25 to 1 g/kg IV bolus) can be used to provide osmotic diuresis.

Vasopressors and inotropes may assist with renal perfusion but must be administered using fluid pumps as constant rate infusions. These have wide and controversial ranges of therapeutic efficacy. Drugs and dosages used anecdotally in ruminants include intravenous dopamine (2 to 5 µg/kg/min), dobutamine (5 to 10 µg/kg/min), and combination norepinephrine (0.4 µg/kg/min) + dobutamine (5 µg/kg/min) based on available information.[20] It should be noted that the use of dopamine alone in cases of ARF may not be as beneficial as once thought and adverse effects have been discovered.[21]

Additional supportive therapy may include broad-spectrum antimicrobials against susceptible infectious agents, plasma transfusion to treat hypoproteinemia, and nutritional support through parenteral nutrition or rumen transfaunation. Anti-inflammatory agents may prove useful but should be used cautiously where renal damage exists and only when the kidneys are being therapeutically well perfused. Urinalysis and FE of electrolytes can be measured in conjunction with serum monitoring parameters during intensively managed cases.

Lesions that occlude tubular blood flow (renal vein thrombosis, DIC) warrant a poor prognosis, whereas renal failure resulting from toxic causes carries a more favorable prognosis with early diagnosis and aggressive therapy. Return of appetite and progressive reduction in BUN and serum creatinine levels are positive prognostic indicators.[7] Prolonged supportive treatment (2 to 3 weeks) may be necessary to allow for regeneration of tubular epithelium in cases of acute TN.

Leptospirosis

Robert J. Callan

Leptospirosis is a complex disease of both animals and humans caused by pathogenic species of *Leptospira*.[1-9] Pathogenic *Leptospira* species persist as chronic infections of the renal tubules of the maintenance host species, often causing little or no disease. Transmission to incidental hosts results from direct contact with urine from an infected maintenance host or through environmental or feed contamination with infected urine. Infection in the incidental host can cause acute disease in multiple organ systems (e.g., kidney, liver, CNS) and result in abortion or reproductive failure. This discussion focuses on *Leptospira* infection and disease of the urogenital system of ruminants.

Leptospira is a diverse genus of motile, gram-negative, obligate aerobic, tightly coiled spirochetes approximately 0.1 to 0.3 µm in diameter and 6 to 20 µm in length.[1,2,5,8,9] The bacteria can survive in the environment for up to 6 months.[2,5,10] *Leptospira* spp. prefer a warm, moist environment with a pH of 7.2 to 8.0. Survival is short under dry conditions or at temperatures below 10° C.[2] *Leptospira* does not survive freezing in the environment.[11]

Before 1989, *Leptospira* was divided into the pathogenic species *L. interrogans* and nonpathogenic saprophytic species *Leptospira biflexa*. The current taxonomy and classification of *Leptospira* use a complex system of both genetic and serologic characteristics.[1,5,9,12] The *Leptospira* species is determined by DNA sequence similarity.[1,5,9] Twenty-two genomospecies have been identified on the basis of DNA sequence heterogeneity (e.g., *Leptospira borgpetersenii*).[9,12] Further classification by serovar is based on antigenic grouping of the lipopolysaccharide (LPS) and other outer surface antigens using the cross-agglutinin adsorption test (CAAT).[12] More than 250 serovars are characterized for pathogenic strains of *Leptospira* (e.g., *L. borgpetersenii* serovar *hardjo*). Serovars may be further divided into serogroups (e.g., *L. borgpetersenii* serovar *hardjo* type hardjobovis). Serogroups represent antigenically related serovars and are determined by the microagglutination test (MAT). There are currently 24 serogroups described for pathogenic strains of *Leptospira*.[12] Because serovars of a given serogroup can be distributed across multiple *Leptospira* species, the serogroup classification does not represent taxonomic relatedness.

Epidemiology

Leptospirosis is predominantly observed under conditions where livestock come in direct or indirect contact with urine from an infected maintenance host (Table 34.4).[1,2,5,10] The prevalence of infection within a maintenance host population tends to be high (30% to 50%); in such populations, infection is often spread between animals by direct contact.[2] Transmission to incidental hosts is generally by contact with the environment, feed, or water that is contaminated with urine from an infected maintenance host. Transmission can also occur from contact with an infected fetus or uterine discharge. Survival of the bacteria in the environment and the incidence of infection in animals are increased in warm, humid climates. The seasonal incidence is higher during the summer or fall in temperate regions and during the rainy season in warm-climate regions.[5] Environmental conditions that contribute to moist surroundings and foot abrasions may contribute to *Leptospira* transmission, particularly in housed dairy cattle.

Cattle are the primary maintenance host reservoir of *L. interrogans* serovar *hardjo* type hardjopragitno and *L. borgpetersenii* serovar *hardjo* type hardjobovis. *L. interrogans* serovar *hardjo* type hardjopragitno is isolated primarily from cattle in the United Kingdom, and *L. borgpetersenii* serovar *hardjo* type hardjobovis is observed worldwide. Sheep and goats may also serve as maintenance hosts for *L. borgpetersenii serovar hardjo* type hardjobovis.[13-15] Cattle can serve as maintenance or incidental hosts for *L. interrogans* serovar *pomona* and *L. interrogans* serovar *grippotyphosa*.

VetBooks.ir

TABLE 34.4

Current Nomenclature, Maintenance Host, and Incidental Hosts for Common *Leptospira* Isolates in Ruminants

Genomospecies	Serovar	Maintenance Host	Incidental Hosts
Leptospira interrogans	*Canicola*	Dogs	Cattle
L. interrogans	*Pomona*	Swine, opossums, skunks, raccoons	Horses, cattle, sheep, goats, dogs
L. interrogans	*Icterohaemorrhagiae*	Rats	Dogs, cattle, swine
L. interrogans	*Bratislava*	Pigs, mice, horses	Dogs, cattle, horses
L. interrogans	*Hardjo type hardjoprajitno*	Cattle	Sheep, goats
Leptospira borgpetersenii	*Hardjo type hardjobovis*	Cattle	Sheep, goats
L. borgpetersenii	*Ballum*	Mice	—
Leptospira kirschneri	*Grippotyphosa*	Raccoons, muskrats, squirrels	Cattle, sheep, horses, dogs

Serovars *hardjo*, *pomona*, and *grippotyphosa* are most often implicated in renal infection of cattle.[16] Although data are scarce, renal disease caused by leptospirosis in small ruminants appears to be uncommon.[11,17] Detection of *Leptospira* spp. from vaginal fluid and semen of sheep and goats has been reported and suggests the possibility of venereal transmission in those species.[13,18] Sheep may serve as subclinical carriers of serovars *hardjo*, *hardjobovis*, and *pomona*.[3,13,19,20] Some serovars of *Leptospira* have zoonotic potential, and humans are always considered an incidental host.[1,2,4,5]

An abattoir study of more than 5000 cattle in the United States identified approximately 2% renal carriers of *L. interrogans*.[16] Serovar *hardjo* was the most common renal isolate, followed by serovars *pomona* and *grippotyphosa*. A study of Texas slaughterhouse cattle detected *Leptospira* spp. in 36% of urine samples by PCR. The seroprevalence for serovars *pomona* and *hardjo* was 22% and 15%, respectively.[21] A national survey showed 49% seroprevalence for *L. interrogans* serovars in cattle, with the highest seroprevalence found in cattle from southeastern, south-central, and Pacific Coast states.[22] Because contact with urine from infected animals is a means of transmission within cattle populations, high stocking density or confinement may increase the rate of infection in a herd.

In general, infection of cattle with the host-adapted serovar *hardjo* rarely results in acute, severe disease. If present, signs of disease are usually mild in acutely infected cattle and may simply present as cases of undifferentiated fever. Persistent, latent urogenital infection usually follows acute infection of host-adapted serovars in cattle, with most overt losses attributable to adverse effects on reproduction.[4,23-25]

Acute, severe renal disease is more characteristic of incidental (also termed *accidental*) infection of cattle, particularly calves, with a non–host-adapted serovar of *Leptospira*. However, exceptions to this generalization do occur because host immunity and virulence of the organism are variable.[3,4]

Clinical Findings

Serovar *hardjo* is host adapted to cattle, and many infections are asymptomatic or result in nonspecific reproductive failure or abortion. *Leptospira* serovar *hardjo* infection of cattle may produce chronic interstitial nephritis of variable severity, but overt renal dysfunction is rarely observed.[26] Chronic infection of the genital tract of cows and bulls is common.[7,27] Protracted shedding of the organism in the urine often occurs, possibly lasting for the life of the animal.[26,27] Infertility, stillbirth, abortion, and birth of weak calves are typical clinical manifestations of infection with serovar *hardjo* in cows.[7,24,28,29] The fetus can be infected in utero, and if it survives the acute infection, it may be born persistently infected.[2] Fever, agalactia, and mastitis may occasionally occur, and the resulting syndrome has been termed the *milk-drop syndrome*[3] or *flabby udder*[4] in lactating cows. The udder is uniformly soft, and the milk may be yellow or red tinged and thick.

In contrast, infection with non–host-adapted serovars can result in severe systemic disease, hemolytic anemia, hepatitis, interstitial nephritis, and tubular nephrosis in calves and less often in adult cattle.[7,26] Meningitis is a rare manifestation.[17] Agalactia and mastitis often occur in lactating cows, and pregnant cows may abort. Urine shedding of non–host-adapted serovars by infected cattle can persist for weeks to months.[4,7,29] Renal lesions result from direct damage to the vascular endothelium during leptospiremia, hypoxia from endothelial damage and hemolysis, tubular epithelial damage from hemoglobin, and interstitial nephritis.[2,5,26] Some *Leptospira* serovars, particularly *pomona*, produce hemolysins that can cause acute intravascular hemolysis and anemia in cattle.

Clinical signs associated with acute infection may include fever, anorexia, lethargy, decreased milk production, petechiation, hemolytic anemia, icterus, and hemoglobinuria. Oliguria may be seen with interstitial nephritis or hemoglobinuric nephrosis. Elevated creatinine concentration caused by prerenal or renal causes may be observed on serum chemistry analysis. Examination of the urine may show proteinuria, pyuria, and cellular or granular casts in cases of nephritis. Hemoglobinemia and hemoglobinuria may be observed in patients with leptospire-induced hemolysis and can occasionally result in hemoglobinuric nephrosis (pigment nephropathy).

Pathophysiology

Contaminated feed and surface water, wildlife, rodents, and domestic animals are potential sources of pathogenic serovars for cattle.[2-5] Leptospires penetrate external mucosal surfaces and scarified or macerated skin. The bacteria multiply locally during an incubation period that can last 2 to 20 days.[2,5] After the incubation phase, the organism enters the bloodstream through the lymphatics or by direct penetration into the blood vessel. Leptospiremia results in dissemination throughout the body and infection of multiple organs. This bacteremic phase lasts 4 to 7 days. Fever and other systemic signs are often present in clinically affected animals. Humoral antibodies can be detected at the end of the bacteremic phase. Opsonizing antibodies are generated and aid in clearing infection from most tissues in the host.

During the convalescent phase, leptospires may become localized in the mammary gland, kidney, or genital tract, where they appear to be protected from the immune response.[2,30] Depending on the virulence of the serovar involved, chronic renal infection may create few histologic changes, mild interstitial nephritis, or diffuse, severe, lymphocytic interstitial nephritis with fibrosis.[17] Nephritis may persist long after the host immune response has cleared the organism. Chronic infection of the kidney or reproductive tract allows for

VetBooks.ir

transmission of the organism in urine, uterine and vaginal secretions, placenta, fetal tissues, and semen.[3,7,27,31] Shedding in the urine may last for weeks to months with non–host-adapted infections. Renal shedding of host-adapted serovars can persist for months to years. The bacteria reside in the lumen of the renal proximal tubules, where they are protected from phagocytes and humoral antibodies. The bacteria do not stimulate a systemic immune response while localized in the proximal tubule lumen, so serum antibody titers can decline and become negative even though the kidney is infected and urinary shedding of bacteria continues.

Multiple potential virulence factors may contribute to leptospirosis.[1,5,8,32] Virulence mechanisms include the toxin effect of lipopolysaccharide, adhesion to cells and extracellular matrix, bacterial motility, hemolysins, and iron sequestration. Leptospiral LPS and outer membrane proteins are believed to contribute to the development of interstitial nephritis. Motility is an important pathogenic mechanism and contributes to invasion and dissemination of the bacteria. As many as 50 genes are related to leptospiral motility.[1] Adherence to cells is in part conferred by fibronectin-binding protein present on the surface of pathogenic strains but not on nonpathogenic strains. Leptospiral immunoglobulin-like protein A, B, and C (LigA, LigB, LigC) may also be involved in attachment and invasion. Additional proteins that may contribute to virulence include hemolysins, sphingomyelinase C, sphingomyelinase H, and hemolysis-associated protein 1 (HAP-1).[1,5,8,32] There appears to be significant redundancy in proteins associated with virulence mechanisms, making it difficult to isolate individual virulence factors using single gene knockout mutations.

Diagnosis

Diagnosis of *Leptospira* spp. infections is challenging due to the imperfect nature of currently available tests.[33] The microscopic agglutination test (MAT) is the most widely used serologic test for the diagnosis of leptospirosis in cattle. The MAT detects antibodies to specific serovars, but cross-reactivity occurs between related serovars, particularly within the same serogroup. Thus, an infection with one strain may result in increased MAT titer to multiple serovars. Serum antibody enzyme-linked immunosorbent assay (ELISA) tests have been developed for research but have not yet been adopted in the routine clinical diagnostic setting for animals.[34-37]

An elevated serum antibody titer is observed after the bacteremic phase and is suggestive of *Leptospira* infection when associated with concurrent clinical signs, but interpretation of a single titer is problematic in vaccinated animals or when endemic exposure is suspected.[7,8,30] A fourfold increase in MAT titer between acute and convalescent serum samples, or conversion from a negative titer to a titer of 100 or greater, supports a diagnosis for both host-adapted and non–host-adapted serovars. However, vaccinated animals may have a diminished serologic response after challenge and renal colonization with *L. borgpetersenii* serovar *hardjo*.[38] Serologic detection of persistent infection with serovar *hardjo* can be difficult because paired serum titers may be increasing, static, decreasing, or undetectable at the time of clinical examination (e.g., at abortion).[7,30] Serology is unsuitable for screening individual animals for carrier status because many animals that are chronically infected and shedding may have negative serologic status.[39,40] Considering the serovar with the highest titer as being the infecting strain is generally recommended. However, serologic antibody titers may not accurately predict the infecting strain.[40,41]

Leptospira shedding in urine and semen can be detected by multiple tests, including urine culture, phase-contrast microscopy, darkfield microscopy, fluorescent antibody (FA), PCR, nucleic acid hybridization, and immunoblot.[8,16,30,31,42-44] Urine cultures are often unrewarding because of the fastidious nature of the organism, and conclusive results may not be obtained for up to 6 months.[8,31] Darkfield microscopy, FA, and PCR assays are typically used by veterinary diagnostic laboratories to identify *Leptospira* species from urine samples. None of these tests will determine the infecting serovar. The sensitivity of detecting *Leptospira* shedding can be improved by performing two tests on a single sample.[31,44] Evaluation of serovar-specific antibody titers from positive animals may aid in identification of the infecting serovar.

Second-voiding urine samples collected after administration of IV furosemide are recommended for urine testing.[11,45] Furosemide is administered at 0.5 to 1.0 mg/kg IV or IM, and the first-voided urine is discarded. A second urine sample is then collected after cleaning the vulva of gross debris. Approximately 10 mL of urine should be collected and stored on ice (not frozen) for transport to the diagnostic laboratory. Urine from 10 to 15 adult animals should be tested when evaluating a herd for endemic *Leptospira* serovar *hardjo* infection.

Biopsy or necropsy samples of renal tissue may be treated with Warthin-Starry or Levaditi silver stains for microscopic examination.[17] Immunoperoxidase staining was shown to be more sensitive for identifying *Leptospira* species in kidney and liver of naturally infected cattle than Levaditi silver stain.[46]

Treatment and Prognosis

Treatment of acute leptospirosis caused by non–host-adapted serovars should focus on eliminating the bacteria, systemic support, and diuresis if renal involvement is observed. In vitro susceptibility has been demonstrated for several antibiotics that could be used in food-producing ruminants, including ampicillin, amoxicillin, penicillin G, erythromycin, tetracycline, tylosin, and tilmicosin.[29,47-49] Daily oxytetracycline (100 mg/mL, 10 mg/kg IV or IM once daily for 5 to 7 days) or long-acting oxytetracycline (20 mg/kg IM or SC every other day for two to four treatments) are considered clinically effective, but controlled clinical studies reporting efficacy in acute leptospirosis have not been reported. Penicillin G procaine (25,000 IU/kg IM twice daily) and sodium ampicillin (20 mg/kg IM twice daily) have been suggested for treatment, but the efficacy of these regimens in cattle remains unproven.[11] In humans, doxycycline (100 mg q12h for 7 days) has been shown to reduce the duration and severity of illness.[5] Consideration of other antibiotics for treating acute leptospirosis should be based on their efficacy in clearing renal infections with host-adapted *L. borgpetersenii* serovar *hardjo* (see later).

IV or oral fluids may be indicated for systemic support. In animals with severe hemolysis, blood transfusion may be considered. Diuresis should be established in animals with hemoglobinuria or evidence of ARF from hemoglobinuric nephrosis or interstitial nephritis. The prognosis for renal disease caused by leptospirosis is influenced by the virulence of the serovar involved, host immunity, and extent of renal lesions. Cases with renal azotemia warrant a guarded prognosis because more than 75% of nephrons are affected in such cases, and chronic interstitial nephritis and fibrosis may occur after treatment of the acute disease.

Several antibiotics have been shown effective in clearing *Leptospira* spp. renal colonization and shedding in cattle. Long-acting oxytetracycline (20 mg/kg IM or SC, two doses 10 days apart) has been recommended to treat chronic leptospiral infections or reduce the risk of introduction of infected animals into a herd.[3] Oxytetracycline (20 mg/kg IM once), ceftiofur sodium (2.2 mg/kg IM q24h for five treatments), ceftiofur crystalline free acid (6.6 mg/kg SC at the base of the ear once), tilmicosin (10 mg/kg SC once), and tulathromycin (2.5 mg/kg SC once) have been shown effective in clearing renal shedding of *L. borgpetersenii* serovar *hardjo* type hardjobovis from experimentally infected cattle.[50,51] The efficacy of these antibiotic

VetBooks.ir

treatments has not been demonstrated in acute infections with other species and serovars of *Leptospira*, but their use could be considered relative to the lack of clinical data showing specific antimicrobial efficacy for treating acute leptospirosis in ruminants and swine.

Prevention

Draining or fencing off standing water may reduce transmission. Maintaining a dry, clean environment may also help reduce exposure and infection. Limiting rodent and wildlife contact with cattle and their feed and water is often difficult to accomplish but reduces the potential for transmission of non–host-adapted leptospires.[7] For host-adapted *Leptospira* serovar *hardjo*, preventing or eliminating the renal carrier state in infected cattle is necessary to reduce transmission.

Vaccination is regarded as an effective means of preventing losses from leptospirosis. Conventional pentavalent (*L. canicola*, *grippotyphosa*, *hardjo*, *icterohaemorrhagiae*, and *pomona*), whole-cell, inactivated leptospiral vaccines are recommended in calves and adult cattle as an aid to prevent clinical disease caused by *Leptospira* spp. However, these conventional pentavalent vaccines may not consistently prevent renal colonization and shedding after challenge with host-adapted *L. borgpetersenii* serovar *hardjo* type hardjobovis.[52,53]

A monovalent *L. borgpetersenii* serovar *hardjo* type hardjobovis vaccine (Spirovac, Pfizer Animal Health, New York, N.Y.) is licensed for preventing *Leptospira* serovar *hardjo* infection, including reproductive and renal tract colonization and urinary shedding for up to 12 months. This vaccine stimulates an immune response characterized by IgG1 and IgG2 agglutinating antibodies, as well as antigen-specific T-cell production of interferon (IFN)-γ.[38,54-56] The strong IFN-γ response is consistent with induction of a type 1 immune response and may be responsible for antibody class switching to IgG2, which is a more potent opsonin than IgG1.[54] A multivalent vaccine containing *L. borgpetersenii* serovar *hardjo* (Vira Shield 6+VL5HB, Novartis Animal Health, Larchwood, Iowa) has also been shown to prevent renal and reproductive system colonization and decrease shedding in cattle.[57]

Because *Leptospira* species are largely extracellular pathogens, the relevant protective immune response appears to be antibody-mediated neutralization and opsonization during leptospiremia.[1,5] There is no indication that cytotoxic immunity is a relevant immune response for protection or resolution of *Leptospira* infection. However, the exact immunologic mechanism responsible for protection from colonization and shedding of *L. borgpetersenii* serovar *hardjo* type hardjobovis in cattle is not fully understood. Although vaccines help prevent colonization and shedding of *Leptospira* serovar *hardjo* from the kidney, they are not effective in resolving current renal infection and elimination of the carrier state. Thus, vaccination at an early age followed by annual boosters is recommended to prevent initial renal colonization. Renal shedding in previously infected animals can be resolved by antibiotic treatment, and vaccination can be used to prevent future colonization. The efficacy of combined antibiotic and vaccination programs in controlling *L. borgpetersenii serovar hardjo* type hardjobovis infection and reproductive losses at the herd level is not fully established. Combination treatment with oxytetracycline and vaccination with a monovalent *L. borgpetersenii serovar hardjo* type hardjobovis vaccine (Spirovac, Pfizer Animal Health, New York, N.Y.) did result in decreased detection of leptospires in urine and kidney samples from dairy cattle.[58] However, one study in beef cattle and one in dairy cattle did not show improvement in herd reproductive performance following similar intervention.[59,60]

Diseases of the Nervous System

ROBERT J. MACKAY and JOHN R. MIDDLETON, *Consulting Editors*
MONICA ALEMAN

Cerebrospinal Fluid

Mary O. Smith • Lisle W. George • John R. Middleton

Cerebrospinal fluid (CSF) is partly derived from and in equilibrium with the extracellular fluid that bathes the brain and spinal cord parenchyma.[1-4] The composition is an indicator of the state of the intrathecal contents. CSF is produced by a combination of ultrafiltration of plasma and active secretion.[5] The sites of CSF production are the choroid plexuses of the lateral, third, and fourth ventricles; the ependymal lining of the ventricular system; the pia arachnoid; and the meningeal blood vessels. The CSF in the ventricular system flows caudally and diffuses out of the lateral apertures in the fourth ventricle. It then circulates around the brain and spinal cord. Circulation of CSF is achieved through regional pressure changes caused by spinal motion and pulsations of blood vessels. CSF is resorbed from both the cranial cavity (75%) and the spinal canal (25%).[6] Some resorption of brain CSF occurs at the arachnoid villi that are near large veins and sinuses, but most resorption occurs at the cribriform plate, into nasal lymphatics.[7,8] Spinal CSF is resorbed into the lymphatic vessels near spinal nerves.

The predominant direction of CSF flow in the spinal canal is cranial to caudal. CSF specimens can be collected from the cisterna magna when the site of interest is the brain, whereas it should be collected from the lumbar subarachnoid space when the lesion is in the spinal cord. In large animals, however, the risks associated with the general anesthesia required for cisterna magna tap are considerable, and so lumbar puncture is usually the most suitable technique for CSF collection in these species, regardless of the site of the lesion.[9,10]

Collection of Cerebrospinal Fluid

Lumbosacral Spinal Tap

For collection of CSF by lumbosacral puncture, the animal is lightly sedated, and the skin of the dorsal midline over the junction of the sixth lumbar (L6) and first sacral (S1) vertebrae is surgically prepared (Fig. 35.1). A variety of standard sedative protocols are suitable; xylazine has been shown to reduce CSF pressure.[11] Correct placement of the spinal needle is more easily achieved when the animal is standing. The proper anatomic site for insertion of the spinal needle is between the dorsal spinous process of L6 cranially and S1 caudally and the two tuber sacrales laterally. The overlying skin forms a depression that can be revealed by palpation, although this may be difficult in well-muscled animals. The correct site for needle placement can also be determined by locating (1) the dorsal midline at the highest point of the quarters or (2) the point where an imaginary line drawn between the caudal aspects of the two tuber coxae intersects the midline.

The skin is anesthetized with 2% lidocaine, and a 1-cm incision is made with a No. 15 scalpel blade. Alternatively, the skin can be punctured with a 14-gauge needle and the needle removed or left in place as a guide through which the spinal needle is passed. In adult horses and cattle, a 6- to 9-inch, 18- to 20-gauge spinal needle is inserted perpendicularly through the incision (or 14-gauge needle) and advanced, usually with the stylet seated, until the tip punctures the lumbosacral cistern. For small ruminants, foals, and calves, a 3.5-inch needle can be used. Use of hypodermic needles for CSF collection is discouraged because they have a cutting surface on the end; such a surface is absent on spinal needles. A "snapping" sensation is sometimes felt as the needle passes through the interarcuate ligament. The patient may reflexively contract the tail, anus, and gluteal muscles. Some patients, particularly horses, may respond with violent motor activity. Therefore a lumbosacral spinal tap performed on a conscious horse should be done only when the animal is restrained in stocks. The average depth of insertion is 17.64 cm (7 inches) in adult horses, 8.26 cm (3.3 inches) in ponies,[10] and approximately 7.5 to 10 cm (3 to 4 inches) in adult cattle.

The spinal needle is advanced gently to the floor of the spinal canal. Passage of the needle through the terminal spinal cord or the cauda equina does not cause subsequent neurologic abnormalities. When the needle is seated in the spinal canal, the stylet is removed, and fluid is allowed to drip from the hub into a sterile tube, or gentle negative pressure can be applied to withdraw spinal fluid into a series of 3-mL syringes. If frank blood is obtained, the tip of the needle is probably in one of the ventral vertebral sinuses. The needle should be withdrawn a few millimeters, and a clean syringe should be attached to the hub. Compression of the jugular vein causes engorgement of the ventral vertebral plexus, which increases CSF pressure in the lumbosacral cistern.

Cisterna Magna Tap

General anesthesia is required for a cisterna magna tap. After the patient has been anesthetized, the dorsal area of the neck overlying the atlanto-occipital joint is surgically prepared. The patient's head is held flexed at a right angle to the neck, with the sagittal plane of the head parallel to the floor or table on which the patient is lying. The head must not be allowed to

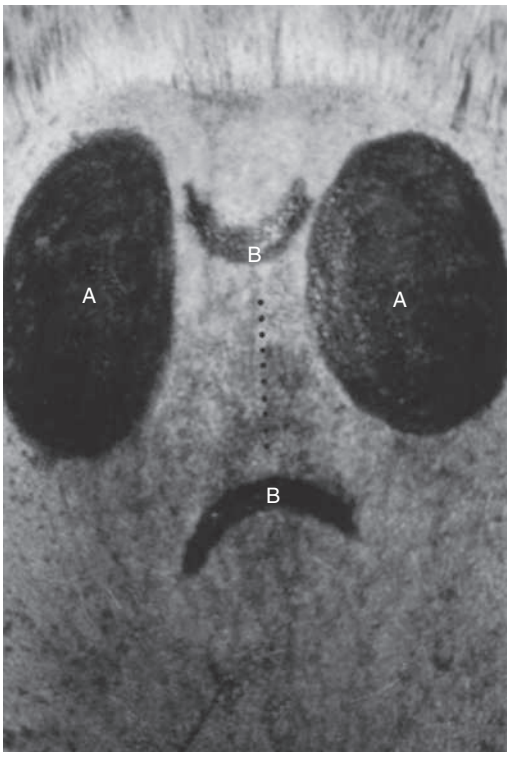

FIG. 35.1 Close-up view of landmarks for a lumbar cistern puncture in a horse. The large dark ovals *(A)* represent the position of the two tubers sacrale. The smaller curved lines *(B)* represent the respective caudal and cranial aspects of the L6 and S1 dorsal spinal processes. The *dotted line* represents the optimum area for placement of a skin stab.

FIG. 35.2 View of the ideal area for a cisterna magna cerebrospinal fluid tap in a cow. The two lines *(a)* represent the wings of the atlas. The large spot in the center *(b)* is the optimum area for needle insertion. Use of anesthesia and restraint is essential to prevent head movement.

move while the needle is inserted. The needle is inserted 1 to 2 cm caudal to a point, usually 6 to 9 cm (2.5 to 3.5 inches) from the poll (Fig. 35.2), that corresponds to the intersection of the dorsal midline, and a line is drawn between the cranial aspects of the wings of the atlas. A 3.5-inch, 18-gauge spinal needle is inserted perpendicular to the skin and aimed toward the nose. The needle is advanced slowly with the stylet seated. After the needle has been advanced a few millimeters, the stylet is removed, and the hub of the needle is examined for CSF flow. The stylet is replaced if it is dry and CSF is not spontaneously dripping from the hub, and the needle is advanced another few millimeters and checked again for CSF flow. Entry of the tip of the needle into the cisterna magna may be accompanied by the sensation of "popping" through a tissue plane or by a sudden decrease in resistance to the advancement of the needle. In other cases, no such sensation is perceived; thus CSF flow must be checked every time the needle is advanced a few millimeters.

In most adult large animals, the needle is seated at approximately 5 to 8.75 cm (2 to 3.5 inches). While the needle is advanced, the heel of the hand should be held firmly against the patient's neck to minimize the possibility of spinal cord injury. The mean depth of insertion is 6.5 cm (2.5 inches) in adult horses[10] and 5 cm (2.25 inches) in adult cattle. In a cisterna magna tap, the needle entry site is close to the cervical spinal cord and brainstem. To minimize the danger of central nervous system (CNS) damage during a cisterna magna tap, the patient should be adequately anesthetized and ventilated because an increase in the partial pressure of carbon dioxide (P_{CO_2}) results in an elevation in intracranial pressure.[12] Removal of fluid from the cisterna magna is contraindicated in a patient with increased intracranial pressure because the brain may herniate through the foramen magnum, which could be fatal. Signs of increased CSF pressure include a moderate to marked decrease in mentation, mydriatic pupils, opisthotonos, extensor rigidity, ventrolateral strabismus, and papilledema.

Ultrasonography can be used as an aid to needle placement for collection of CSF from both the atlanto-occipital cistern and the lumbosacral subarachnoid space.[13,14]

Myelography

Contrast material for myelography is injected into the cisterna magna in large animal patients. Withdrawal of CSF before injecting the contrast medium is unnecessary, as is reinjection of CSF after it has been withdrawn. The turnover of CSF is rapid and under strict homeostatic control; therefore withdrawal of CSF through a spinal tap does not have deleterious effects that necessitate its replacement.[15-17]

Analysis of Cerebrospinal Fluid

The color of the CSF should be noted as it flows from the hub of the spinal needle. Blood can originate from the tapping procedure (iatrogenic hemorrhage) or from a traumatic CNS lesion. Iatrogenic hemorrhage is usually unevenly mixed in the CSF and disappears as the fluid drips from the needle. Fluid collected immediately after placement of the spinal needle tends to be mildly contaminated with blood even when this is not apparent grossly. Subsequent aliquots are usually less contaminated, and so the later aliquots are most suitable for cellular and protein analysis.[18] Blood from CNS hemorrhage is evenly mixed with CSF even after a large amount has been removed. Hemorrhage that occurred days earlier may have a brownish rather than red discoloration. Prior hemorrhage also results in *xanthochromia*, a yellow discoloration of the CSF. Xanthochromia can be observed in the CSF for at least 10 days after the introduction of blood. Xanthochromic samples do not contain bilirubin.

The normal values for CSF are presented in Table 35.1. Cell counts should be determined in a noncentrifuged specimen as soon as the sample is collected, with the use of a hemocytometer. Automated methods for counting cells are not suitable for CSF because the low numbers of cells in CSF in comparison with blood result in erroneous counts. Morphologic examination of cells from CSF is most suitable on cytospin preparations in an appropriately equipped laboratory. Normal CSF from large animals contains fewer than six white blood cells (WBCs) per deciliter; however, WBC counts greater than 40 cells/dL have occasionally been documented in the CSF of normal

TABLE 35.1

Normal Range of Values in Cerebrospinal Fluid for Large Animals[1,4,5]

Component	Unit	Equine	Bovine	Ovine	Caprine
Specific gravity	1.004-1.008	1.004-1.008	NA	NA	NA
Refractive index	1.3343-1.3349	1.3343-1.3349	NA	NA	NA
Protein	mg/dL	5-100	20-40	8-70	24-40
White blood cells (WBCs)	WBCs/dL	0-6	0-3	0-5	0-7
Glucose	mg/dL	30-70	35-70	48-109	45-87

Potassium	mEq/L	2.5-3.5	2.7-3.2	3-3.3	3
Creatine kinase	IU/L	0-8	2-48	NA	NA
Magnesium	mEq/L	NA	1.7-2.7	NA	NA

[a]Cerebrospinal fluid (CSF) sodium level is the same as serum or plasma sodium level when measured with ion-specific electrodes. When other measurements are used, the level of sodium in CSF is usually higher than that in plasma.

NA, Result not available.

horses.[19] Although various "correction factors" have been suggested to correct for the effects of iatrogenic blood contamination, they are inaccurate and should not be used.[18,20]

The refractive index of normal CSF is less than 1.335. The protein concentration of CSF is less than 50 mg/dL in normal adult ruminants and less than 100 mg/dL in normal horses, although reference values vary with the techniques used for protein measurement. Reference values should be established for each laboratory.[21]

Studies of the specific and relative quantities of albumin and immunoglobulins, particularly immunoglobulins G and M (IgG and IgM), have been stimulated by the increasing importance of immunologic testing of CSF for diseases such as equine protozoal encephalomyelitis. Reference values for a number of parameters have been established.[22] The most important of these parameters are *albumin quotient*, a measure of blood-brain barrier permeability,[23] and *IgG index*, a measure of intrathecal production of IgG.[24] The formulae for these parameters are as follows:

$$\text{Albumin quotient} = (\text{CSF albumin}/\text{Serum albumin}) \times 100$$

$$\text{IgG index} = (\text{CSF IgG}/\text{Serum IgG}) \times (\text{Serum albumin}/\text{CSF albumin})$$

Reference values must be established for each species. An elevated albumin quotient indicates blood-brain barrier leakage or contamination of CSF with blood, with possible introduction of immunoglobulins from serum. An elevated IgG index indicates intrathecal production of IgG and may support a diagnosis of infectious disease of the CNS. The usefulness of these parameters is influenced by a number of other variables, including the immunoreactivity of blood.[24] Therefore clinical interpretations must be made with great caution. The composition of protein from the CSF of horses and cattle has been established.[3-5,10]

The concentrations of glucose and protein in the CSF of newborn foals are almost twice those found in the CSF of adults, but they approximate adult normal values by the age of 2 weeks.[25] In contrast, calves between 1 and 2 months have lower protein concentration and higher leukocyte numbers in CSF than do adult cattle.[26]

Neural tissue contains the BB isoenzyme of creatine kinase (CK-BB), which increases after damage to the nerve cells.[27-29] The molecule does not cross the blood-brain barrier, and so CK in the CSF originates from neural tissue. Contamination of CSF with dura or fat, however, falsely elevates the CK concentration. Some have suggested that CK is an accurate marker and a prognostic indicator of CNS disease, but other studies have not supported this conclusion, and measurement of CK, although interesting, has limited clinical utility.[27,29,30]

The normal concentration of glucose in CSF is approximately 80% of that in blood. A decline in the ratio of CSF to serum glucose occurs in animals with bacterial meningitis because of increased use of glucose by inflammatory cells.

Measuring sodium concentration of the CSF may be helpful for diagnosing salt poisoning in cattle. In animals that do not have salt poisoning, the sodium concentration is less than 160 mmol/L; in animals with salt poisoning, the concentration is usually greater than 160 mmol/L.

Electrodiagnostic Testing

Monica Aleman, *Consulting Editor*

Neuroelectrodiagnostic medicine is considered an extension of the neurologic examination and comprises several diagnostic techniques for the evaluation of the various components of the nervous, neuromuscular, and muscular systems.[1] Electrodiagnostic testing might assist in the identification, and determination of localization and severity of lesions in certain challenging cases.[1] Although electrodiagnostics might not provide a definitive diagnosis in every case, it aids in the approach, direction, or support of a clinical diagnosis.[2] Depending on the electrodiagnostic technique performed and patient cooperation, some techniques can be done with the patient under intravenous (IV) sedation or general anesthesia. Examples of techniques that can be performed with the patient under IV sedation include electroencephalography, brainstem auditory evoked response (BAER) testing, visual evoked response (VEP) testing (helpful for the study of central blindness), blink reflex testing, electroretinography (ERG; helpful for the study of blindness due to retinal disease), and electromyography (EMG). Techniques that can be performed with the patient under general anesthesia include sensory and motor nerve conduction studies and repetitive nerve stimulation (RNS).[2-10] It is preferable for single-fiber EMG (SF-EMG) to be done with the patient under general anesthesia for more accurate performance and interpretation of results.[2] However, this technique has been performed in awake horses.

Electroencephalography

Electroencephalography is the recording of spontaneous electrical activity (field potentials) of the cerebral cortex. It is the graphic representation of the voltage difference between two locations within the cerebral cortex plotted over time.

VetBooks.ir

This primarily represents synaptic activity: excitatory post-synaptic potentials (EPSP) and inhibitory post-synaptic potentials (IPSP) in cortical neurons, mainly pyramidal cells. It has been estimated that approximately a minimum of 108 neurons are needed to produce a detectable change in voltage on the electroencephalogram (EEG). However, electrical activity might be modified by deeper structures such as the brainstem, reticular activating system, and thalamus. Thalamic oscillations are transmitted to the cerebral cortex via projection neurons and are thought to be responsible for the slow waves and spindles associated with slow-wave sleep. With regards to electrical activity, ion excitation or inhibition occurs between the intracellular and extracellular spaces when sodium or chloride, respectively, moves intracellularly. The extracellular current is what gives rise to the surface recorded EEG.

Electroencephalography is valuable diagnostic technique for the study of paroxysmal activity (e.g., epileptic discharges), sleep and sleep disorders, alterations in behavior, and detecting abnormal activity such as seizure-like episodes, tremors, and myoclonic activity other than seizures.[11-14] Along with clinical observations, electroencephalography aids in the refinement of epileptic disorders (e.g., localization and classification of paroxysmal discharges within the cerebral cortex).[11] A normal EEG does not rule out the presence of an epileptic disorder; it means only that at the time of recording, abnormal electrical activity was not observed. Alteration in mentation and behavior might be associated with paroxysmal activity, but this is not possible to define unless electroencephalography is performed.[15] The effects of antiseizure medication in the patient can also be evaluated through evaluation of the EEG. Similarly, sleep and sleep disorders can be further investigated and classified on the basis of clinical observations, along with evaluation of the EEG.[16,17] Sleep deprivation is not a sleep disorder; it is simply lack of sleep, whose various causes include sleep disorders.[16,17] Other reports about the use of electroencephalography include the assessment of nociception during surgical procedures and studying the effects of various sedatives and anesthetics on the EEG.[3,18-25] Electroencephalography has also been used in slaughter facilities to monitor brain activity during captive bolt stunning in cattle.[26] The author has used electroencephalography in patient monitoring at the intensive care unit (e.g., for traumatic brain injury, status epilepticus, comatose patients) and euthanasia (i.e., through overdose of intravenous [IV] barbiturates or intrathecal lidocaine during general anesthesia).[27,28] Depth of anesthesia has also been studied with EEG power spectrum analysis in horses.[19,29]

Depending on patient cooperation, goals of the study, and disease process, the EEG can be obtained with the patient in standing sedation or general anesthesia. However, it is recommended that electroencephalography in a horse be performed when the horse is not anesthetized because of the effects of drugs and anesthetics on EEGs.[17] Examples of alterations in the EEG include suppression of electroencephalographic activity by anesthetics, transient paroxysmal discharges, and the lack of observation of all states of vigilance. The major disadvantage of performing electroencephalography in a sedated horse is movement artifacts. However, interpretable recordings are possible. Furthermore, the states of vigilance can be evaluated only in a nonanesthetized animal. States of vigilance in the horse as determined through electroencephalography consist of wakefulness, drowsiness, slow-wave sleep, and rapid eye movement (REM) sleep.[17] Automated quantification of electroencephalographic activity in animals have been used. However, a disadvantage of quantitative electroencephalography is that artifacts might be included in the analysis of data, which results in misleading clinical interpretation.

While the EEG is recorded, electro-oculography, electrocardiography, and respiratory monitoring are concurrently performed to distinguish electrical activity by other structures

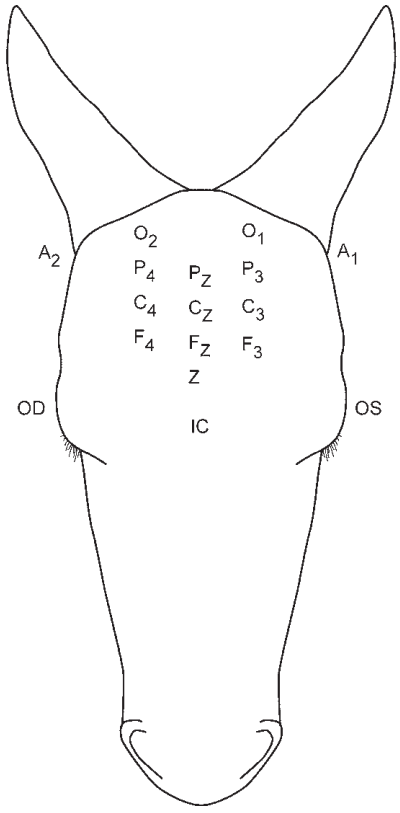

FIG. 35.3 Electrode placement in electroencephalography. *Even numbers* represent the right side; *odd numbers* represent the left side; *A*, aural; *C*, central; *F*, frontal; *FP*, frontopolar; *IC*, intercanthus; *O*, occipital; *OD*, right eye; *OS*, left eye; *P*, parietal; *Z*, ground; subscript *z*, midline. *From Aleman M, Gray LC, Williams DC, et al. Juvenile idiopathic epilepsy in Egyptian Arabian foals: 22 cases (1985-2005).* J Vet Intern Med *2006;20:1443–1449.*

or movement.[17] Furthermore, concurrent performance of electroencephalography, electrocardiography, and respiratory monitoring could be very useful and in some cases diagnostic for the investigation of causes of collapse (e.g., distinguishing syncope from seizures). The author also performs concurrent video recording to further investigate the effects of movement on the EEG in the standing sedated horse.[3,17] Electrode nomenclature and placement are based on a modified human 10-20 system and described in horses previously.[17,30] Two EEG montages have been described in the literature: bipolar and referential.[17] Electrode placement can be rostral to caudal or transverse in a bipolar montage (Fig. 35.3). Needle or surface electrodes are commonly used in veterinary medicine. If surface electrodes are used, the skin in the area of the recording has to be shaved and cleaned for better contact. In contrast, needle electrodes can be placed subcutaneously in the scalp without additional preparation.[17] The author's institution has a protocol for EEG recording, and areas to record include the prefrontal (two electrodes), frontal (three), central (three), parietal (three) and occipital (two) regions (see Fig. 35.3). Concurrently, electro-oculography (two subcutaneous electrodes per eye, one each in the upper and lower eyelids), electromyography (two subcutaneous electrodes in the splenius muscle), and electrocardiography (one subcutaneous electrode in the region of the left-sided heart base and one at the left-sided heart apex) are also performed.[17,30] An additional electrode needs to be placed as the ground (between the two prefrontal electrodes). The author usually records for 30 minutes to 1 hour, except in sleep studies, in which case the electrodes are glued to the scalp and recording lasts several hours.

The recorded frequencies are confined to a relatively low range (0.5 to 50 Hz), most being below 30 Hz. Waveform frequencies are 0 to less than 4 Hz (delta waves), 4 to less than 8 Hz (theta waves), 8 to less than 13 Hz (alpha waves), 13 to less than 30 Hz (beta waves), and 30 Hz or more (gamma waves; Fig. 35.4). Electroencephalography produces a low-voltage signal: The recorded amplitude varies from a few to several hundred microvolts, usually less than 100 μV. In contrast, the electrocardiogram is recorded in millivolts (Fig. 35.5). Epileptic discharges are depicted as distinct paroxysmal EEG waveforms that are strongly associated with seizures. Common types include spikes (<70 ms), sharp waves (70 to 200 ms), and spike-and-wave discharges (>200 ms; Fig. 35.6). These discharges can be observed as single or multiple discharges.

Study of sleep in animals has been based mainly on observation. However, to further understand normal sleep and its

variants, as well as abnormal sleep, EEG recording for several hours a day is important.[16] A few indoor studies in some species (e.g., horses) have allowed the staging of phases of vigilance.[16] However, those stages might not represent natural sleep. In wakefulness, fast electroencephalographic activity is observed; however, the transition from wakefulness to drowsiness is not as defined as in humans. In the transition stage, intermittent rhythmic 4-Hz background activity is observed on the EEG.[17] During this period, horses are usually standing. Variants of sleep can occur during this period. Other normal transient events (sleep spindles and K complexes) have been recorded on EEGs from horses and can be used to identify sleep (equivalent to light sleep in humans).[17] The gradual appearance of high-amplitude delta activity, signifying a deeper plane of sleep (human slow-wave sleep [stages 3 and 4]), is similar between species. In horses, the equivalents to stages 2 to 4 of humans can be collectively referred to as slow-wave sleep. Slow-wave sleep can occur while the horse is standing or recumbent. REM sleep in horses has a pattern similar to that in other species: low voltage and mixed frequencies with episodic fast eye movements and loss of EMG activity.[17] This stage of sleep constitutes approximately 15% of the total sleep time in horses. This stage cannot occur in the standing horse, otherwise the horse would collapse from lack of muscle tone.[16] Horses lie down in lateral recumbency or, if in sternal recumbency, theysupport their heads on the ground or an object.

Auditory Evoked Responses

These consist of the study of early latencies (0 to 10 ms) such as BAER, middle latency (10 to 80 ms), late latency (80 to 250 ms), and long latency (>250 ms).

Brainstem Auditory Evoked Response

BAER testing is performed to evaluate the integrity of the auditory pathway from its peripheral (cochlear nerve) to central (brainstem) components.[31] It is useful in the detection of complete, partial, unilateral or bilateral auditory loss and in the differentiation between conductive and sensorineural auditory loss.[31] In animal species, five distinct waveforms are recognized and represent specific areas in the auditory pathway: the cochlear nerve (wave I), the cochlear nucleus in the medulla (wave II), the olivary nucleus in the medulla (wave III), the lateral lemniscus at the pons (wave IV), and the caudal colliculus in the midbrain (wave V). To better identify the different waveforms, two different derivations have been used in veterinary medicine: vertex to mastoid for large and small animals, vertex to C2 in large animals, and vertex to T1 in small animals.[32,33]

BAER interpretation consists of the evaluation of wave configuration, symmetry (right and left ears), latency, and interval. Clinically relevant amplitude difference includes the ratio of waves V and I (V/I amplitude ratio), whereby a ratio of less than 2 is strongly suggestive of brainstem disease. Reference ranges for the interpretation of BAER have been published for various species and ages.[4,33-35] It is important to note differences in methods such as transducer and derivations (vertex to mastoid versus vertex to C2) used.[33] For example, the use of insert earphones, with stimulus delivery by tubing 25 cm in length, adds an additional 0.9 ms to the recorded latencies of each peak in comparison with headphones with no additional tubing.[4,33] In BAER testing with the horse in standing sedation or general anesthesia, minor latency differences in BAER waves are not significant and therefore not clinically relevant.[4,32,36] Excessive debris or wax can obstruct the conduction of sound during BAER testing, which results in false results of auditory loss.

BAER can vary with age, gender, breed, head size, and skull thickness.Differences in body temperature can also alter BAER.[31] Evolutionary biological differences between prey and predator species also play a role in how early full hearing develops. For instance, neonatal foals are born with fully developed hearing and wave latencies comparable to those of adult horses, whereas in puppies, it might take a few weeks before a BAER study can be performed with reliable results.[33,37] Table 35.2 lists some causes of wave prolongation.

Causes of hearing loss in adult horses include temporohyoid osteoarthropathy (THO), congenital sensorineural deafness in Paint horses, multifocal brain disease, and otitis media/interna.[31-43] Causes of hearing loss in neonatal foals include congenital sensorineural hearing loss, congenital anomalies (skull deformation), sepsis, neonatal encephalopathy, neonatal isoerythrolysis, and prematurity.[44,45] BAER testing can be used for the investigation of brainstem disease (inflammatory, infectious, vascular), traumatic brain injury, and other brain disorders. BAER testing has also been used to confirm brain death during euthanasia.[27,28]

TABLE 35.2

Brainstem Auditory Evoked Responses (BAER): Possible Causes of Wave Prolongation

Prolonged Wave	Possible Causes
I	External ear disease Middle ear disease Cochlear disease Temporohyoid osteoarthropathy Aminoglycosides
I–V Interval	Brainstem disease
I–III Interval	Caudal brainstem disease
III–V Interval	Rostral brainstem disease
V/I Ratio	If <2.5, strongly suggestive of brainstem disease

Electromyography

Electromyography is the study of the electrical activity of the muscle.[38] The distribution of electromyographic abnormalities might aid in the localization of lesions in spinal cord segments (lower motor neurons), nerve plexus, and

Electrodiagnostic Techniques for the Investigation of Neurogenic, Neuromuscular, and Muscle Disorders

Electrodiagnostics	Disorders
Electromyography (EMG)	
Insertion	
Absent	Advanced or end-stage disease of nonmuscle tissue (fat, fibrous)
Prolonged	Denervated muscle, polymyositis
Spontaneous Activity	
Fibrillation potentials (FP)	Neurogenic, neuromuscular, muscle disease
Positive sharp waves (PSW)	Neurogenic, neuromuscular, muscle disease
Complex repetitive discharges (CRD)	Neurogenic: motor neuron disease; muscle: HYPP, others
Myotonic discharges (MD)	Myotonic disorders: myotonia congenita/dystrophica
Nerve Conduction Velocity (NCV)	
Motor	Various causes: lead toxicity, delayed OP toxicity
Sensory	Various causes: most toxic neuropathies
Repetitive Nerve Stimulation (RNS)	
Decremental CMAP	Myasthenia gravis (humans, small animals)
Decreased baseline CMAP	Botulism
Incremental CMAP (amplitude, AUC)	Botulism, hypermagnesemia (facilitation)
Incremental CMAP (amplitude only)	Nonpathologic (pseudofacilitation)
Mixed/multiple patterns	Organophosphate toxicity
Single-Fiber Electromyography (SF-EMG)	
Increased jitter	Junctionopathies

AUC, Area under the curve; *CMAP*, compound muscle action potential; *HYPP*, hyperkalemic periodic paralysis; *OP*, organophosphate poisoning.

Modified from Aleman M. Neurologic or Neuromuscular Disorders in Horses. Modified from: *Vet Clin N Am Equine* 2011;27:481-506.[2]

nerves (Table 35.3).[7,39,40] Quantitative EMG can further assist in classifying disorders as myopathic, neurogenic, or both.[7,8,41-44] EMG usually does not provide a definitive diagnosis, but the findings might support or refute a clinical diagnosis. For example, myotonic discharges are a hallmark feature of myotonic disorders but do not indicate a specific myotonic disorder (e.g., myotonia congenita versus myotonia dystrophica).[45] Other EMG alterations such as complex repetitive discharges are identified in horses with hyperkalemic periodic paralysis.[46] However, these discharges can be observed in other disorders.

Patient preparation for the procedure is better performed in stocks for safety reasons; the restraint provided limits excessive movement. Electromyography can be performed in a standing horse without sedation in some cases. In the author's experience, horses usually react more when distal limb muscles are tested, and sedation may be required. The procedure can also be performed with the patient under general anesthesia. The author prefers performing the study with the patient under IV sedation.

The study in a standing horse can be diagnostic and provides information about the electrical activity of contracting muscle (electromyography during activity) provoked by the examiner (e.g., making the horse move its limbs or neck, bear more weight on one limb) or of voluntary movement, and possible risks of anesthesia are avoided. The study during controlled or sustained voluntary muscle contraction is routinely performed in awake human patients but not possible in veterinary medicine.[47] Depending on the muscles tested and duration of the study, the examiner may use short- or long-acting sedatives (xylazine hydrochloride, 0.3 to 0.4 mg/kg IV, or detomidine hydrochloride, 0.005 to 0.01 mg/kg IV, respectively).[2] It is important that the area of the muscles to be studied is clean because a needle will be inserted into the muscle and redirected multiple times. The area should be cleaned or washed if necessary. If the area appears clean, the author usually wipes the area with alcohol gauzes until no dirt is visible. Risks associated with electromyography are uncommon or rare and might include infection at the needle insertion site and inadvertent probing of a nerve or nerve terminal. Mild local discomfort might be experienced at the insertion site.

Both insertional and spontaneous EMG activity can be recorded. Insertional activity is the activity related to mechanical stimulation of muscle fibers upon insertion of the electrode into the muscle being tested. This activity should not last more than 1 to 2 seconds in normal animals.[39] Insertional activities that are absent, decreased (low amplitude), increased (high amplitude), or prolonged (long duration) are abnormal. Normal spontaneous activity may be found at the end plate or motor unit region.[39] Spontaneous normal activity includes miniature end plate potentials, end plate spikes, and motor unit action potential (MUAP).[38] The morphologic features (phases, peaks, turns), duration, and amplitude of each MUAP are important for determining abnormality and whether it might be myopathic or neurogenic; for example, giant MUAPs are observed in neurogenic disease.[38,48] Spontaneous activity with neuromuscular disease includes fibrillation potentials, positive sharp waves, complex repetitive discharges, myotonic discharges, and neuromyotonic discharges.[7,40,46,49-51] In acute neuropathic disorders, abnormalities might not be evident on the EMG immediately.[39] It might take approximately 2 weeks to detect alterations in the EMG.[47]

Nerve Conduction Velocity Studies

Nerve conduction velocity (NCV) studies are performed to evaluate multiple parameters (e.g., amplitude, latency, velocity) of motor and sensory evoked responses to stimulation of nerves (see Table 35.3).[52] To study motor nerve conduction, a nerve must be stimulated during recording from a muscle innervated by that nerve.[2] To study sensory nerve conduction a mixed nerve must be stimulated during recording from a cutaneous nerve.[52] NCV studies aid in the localization of nerve, neuromuscular junction, and muscle disease. Furthermore, they help distinguish between axonal degeneration and demyelination.[52] NCV studies of the facial, radial, median, ulnar, lateral and medial palmar and plantar, sural, and superficial and deep peroneal nerves have been reported in horses and ponies.[6,53-61] These studies should be performed with the animal under general anesthesia for safety reasons, for patient cooperation, to prevent pain in the patient, and to obtain interpretable recordings. Most toxic neuropathies have symmetric clinical manifestations and are predominantly sensory.[62] Acute lead poisoning can cause motor neuropathy, and chronic lead poisoning can cause both sensory and motor neuropathy.[62]

Repetitive Nerve Stimulation

Repetitive nerve stimulation (RNS) is one of the most useful diagnostic techniques for the study of neuromuscular disease (see Table 35.3).[63] A compound muscle action potential (CMAP) or M wave reflects the number of muscle fibers activated by

a train of stimuli (repetitive stimulation) applied to a single nerve. The test result is considered abnormal if the number muscle fibers activated during repetitive stimulation (usually 10 consecutive stimuli) decreases.[63] This is called a *decremental response* and is observed in cases of myasthenia gravis.[64] The opposite, an incremental response of the M waves in its amplitude and area under the curve (more muscle fibers activated), is observed in cases of botulism.[5]

Single-Fiber Electromyography

This is a selective EMG study for the study of junctionopathies by allowing the measurement of neuromuscular transmission of single end plates (see Table 35.3).[65] The MUAPs from a single motor unit are recorded over a small area with a concentric EMG electrode. Variations in myofiber end plate potential amplitude and firing threshold result in variations in latency of subsequent action potentials during nerve stimulation.[64] This phenomenon, termed *neuromuscular jitter*, is increased in diseases in which neuromuscular transmission is disturbed.[63,64] This technique has been scarcely used in veterinary medicine.[66-68]

Diseases Manifesting Principally With Forebrain Dysfunction or Multiple-Level Brain Dysfunction

Alphaviruses

Robert J. MacKay

The causative agents of eastern, western, and Venezuelan equine encephalomyelitis (EEE, WEE, and VEE) are New World arboviruses belonging to the genus *Alphavirus* of the family Togaviridae.[1] Ross River virus is an Old World alphavirus in Australia that was implicated in more than 100 cases of neurologic disease in horses during an outbreak of arboviral encephalitis in 2011 and previously was suspected of causing a syndrome of lethargy, muscle soreness, and ataxia in horses in Victoria and South Australia.[2,3]

EEE, WEE, and VEE affect all common domestic equid species, including horses, mules, and donkeys. Each of the viruses was first isolated during epizootics in the 1930s.[4-6] Alphaviruses are nonsegmented, single-stranded, positive-sense RNA viruses..[7] Each of the three equine alphaviral encephalitides is among the 13 equine infectious diseases that must be reported to the World Organization for Animal Health (Office International des Epizooties [OIE]). Data on the occurrence of these diseases in the United States are collected by veterinarians, diagnostic laboratories, and state animal health officials and are reported to the National Animal Health Reporting System.

At least three strains of the WEE virus antigenic complex have been identified. Two of these are found in both North and South America, which suggests that circulation of WEE viruses between the New World continents is common.[7,8] There is a distinct North American lineage and three South American lineages of the EEE virus antigenic complex.[7] South American strains are now classified as a distinct species, *Madariaga* virus.[9] In contrast to the situation with the WEE virus, there is no evidence of movement of EEE virus between North and South America.

The VEE antigenic complex contains six subtypes, eight varieties, and seven species, most of which are maintained continuously in enzootic life cycles in northern South America.[7,10] Until the 1990s, when a subtype IE variant caused two outbreaks in Mexico, all equine epizootics had been caused by subtypes IAB and IC.[11]

History

WESTERN EQUINE ENCEPHALOMYELITIS. What was almost certainly the first recorded outbreak of WEE in horses occurred in the Great Plains of the United States in 1912, when at least 35,000 horses died of the disease.[5,12] Epizootics in California and other western states in 1930 to 1932 resulted in the deaths of an estimated 9200 horses and mules (≈50% of those affected).[5,13] In 1938, WEE was recognized in every state west of the Mississippi River and affected more than 184,000 horses in that year alone.[1] WEE virus was also implicated in outbreaks of fatal equine disease in the early 20th century in Canada and Argentina, and epizootics have since been reported in western Canada, Mexico, Central America, and South America.[14] Between 1972 and 1981, an annual average of 267 cases of WEE in horses was reported by the National Veterinary Services Laboratory in Ames, Iowa[14,15]; in 1993, there were 15 cases in 10 states, and since 2005, no case has been reported in the United States. There have been isolated cases of encephalomyelitis in Florida horses associated with the Highlands J virus, an eastern member of the WEE virus complex with epidemiologic characteristics similar to those of EEE virus.[16]

EASTERN EQUINE ENCEPHALOMYELITIS. An outbreak of what was probably EEE was recorded in 1831 in Massachusetts.[17] Approximately 100 horses were affected, and 75 died. Over the subsequent century, there were at least five other outbreaks characteristic of EEE.[18] An epizootic in 1933 involved a least 1000 horses in the coastal regions of the mid-Atlantic states.[4] Epizootics of EEE in North America have since occurred periodically in the coastal areas of the Atlantic, the southeastern United States, and Texas. In the largest recorded outbreak, in 1947 in southern Louisiana and Texas, 14,344 cases of EEE were recorded and resulted in 11,722 deaths (mortality rate of 82%).[19] Focal outbreaks and sporadic cases have also occurred regularly in Michigan and are occasionally reported from other locations in the eastern half of the United States and Canada. A single case of EEE in a stallion in California was reported in 2002.[20] Although the origin of the infection in this horse was not determined with certainty, incompletely activated EEE vaccine was suspected. Despite the availability of effective vaccines since the late 1930s, cases of EEE still occur every year in Florida and other southeastern states. The annual incidence of EEE in horses in the United States since 2003 has ranged from 60 (in 2011) to 712 (in 2003).

Epizootics of a mild form of EEE have been widespread in Central and South America, extending southward from Panama to Argentina.[18] More recently, outbreaks with high rates of mortality have occurred in Brazil.[21] The disease has also caused serious losses in the Caribbean.[17]

VENEZUELAN EQUINE ENCEPHALITIS. The disease in equids was first recognized and described in Venezuela and Colombia in 1938.[6] At intervals of approximately 10 years, there were large subtype IAB or IC epizootics in northern South America that usually involved tens of thousands of horses. Some of these outbreaks may have been caused by incompletely inactivated vaccine. One epizootic in central Colombia during 1962 to 1964 was estimated to have killed 100,000 horses.[22] An outbreak of VEE caused by subtype IAB began in Peru in the winter of 1969, jumped to Central America in June 1969, and then entered Mexico in 1970. The outbreak spread north to the U.S. border in the spring of 1971, and the first case of VEE in a U.S. horse was confirmed on June 30.[23] By the time of the last case on November 7, 1971, more than 1500 horses had died in the southern counties of Texas. No further epizootic activity was reported until 1992, when a series of epizootics of VEE subtype IC began. Subtype IE has been associated with fatal VEE in Mexico, beginning with small outbreaks in 1993 and 1996.[24]

Epidemiology

EASTERN EQUINE ENCEPHALOMYELITIS AND WESTERN EQUINE ENCEPHALOMYELITIS. In North America, the WEE and EEE viruses are maintained between epizootics by low-level cycling between New World passerine birds (i.e., songbirds) and ornithophilic mosquitoes in freshwater, forested swamp habitats.[1] Snakes may also be an overwintering host for North American EEE virus.[25] Infected mosquitoes can be found throughout the year in Florida and other southeastern states. Under favorable environmental conditions, the viruses periodically spread outward from focal reservoirs to infect the general wild bird population, through which they are spread and amplified by rapid bird–mosquito–bird transmission. The mosquito vectors involved in maintenance and amplification of WEE and EEE viruses are usually *Culex tarsalis* and *Culiseta melanura*, respectively. Many avian species, including migratory passerine birds (e.g., starlings and northern cardinals) and wading birds, become infected and develop high-order viremia and high serum titers of EEE virus or WEE virus but usually do not become ill. Among some introduced species, including pigeons, house sparrows, Chukar partridges, and Chinese pheasants, infection with EEE virus may cause high rates of morbidity and mortality.

Cases of encephalitis usually begin in susceptible horses 2 to 3 weeks after the virus spreads into birds. Human cases may occur several weeks later. *C. tarsalis* transfers WEE virus from bird to horse (and human). Although *C. melanura* may also function in some locations as a bridge vector for EEE virus, mosquitoes of a variety of other species usually transfer the virus from bird to horse.[7,18] Viremia in horses is low titer, so mosquitoes feeding on horses with either EEE or WEE virus are unlikely to be infected further, and horses are considered "dead-end" hosts. Both EEE and WEE viruses have been associated with neurologic disease in calves, and EEE virus has caused fatal infections in New World camelids, deer, ratite birds, cats, dogs, mice, foxes, sheep, and pigs.[7,26-28]

Epizootics of EEE and WEE usually last 1 to 3 months and occur in summer and early fall when warmth and humidity favor breeding, longevity, and mobility of mosquito populations.[29] Outbreaks in Massachusetts and Michigan probably occurred during the second consecutive year in which rainfall exceeded the annual mean by more than 20 cm; however, unusually high temperatures did not appear to be a risk factor.[29,30] The month in which disease onset peaks varies from June in Florida to August or September in northern and western states.[5,26,31,32] In Florida and some other southeastern states, isolated cases of EEE can occur at any time of year.[31] Standing surface water for mosquito larval development, bush cover for wild hosts, and the immune status of the various hosts also affect the timing and magnitude of equine epizootics.

Many of these physical factors are significantly affected by the cultivation, clearing, and irrigation of land and by drainage of swamps. The proximity and size of plantations of trees were risk factors for EEE for horses in Florida.[33] The equine epizootic usually declines with the onset of cool or dry weather unsuitable for mosquito or bird activity, as well as with the depletion of susceptible equine hosts by death or development of immunity among survivors.

The epidemiologic features of EEE and WEE viruses in South America are poorly understood. Small mammals play a greater role in sylvatic cycles of viral transmission in South America than in North America. *Culex (Melanoconion)* subspecies and *Aedes albifasciatus* appear to be involved in transmission of EEE virus and WEE virus, respectively.[8,34]

VENEZUELAN EQUINE ENCEPHALOMYELITIS. Enzootic VEE viruses are maintained by cycling between mosquitoes and small rodents. The Everglades virus, a subtype II found in the Everglades region of Florida, is of this type, cycling between *Culex (Melanoconion)* subspecies mosquitoes and wild rodents.[10] The epizootic varieties IAB and IC have probably arisen on at least four separate occasions by mutation of enzootic subtype ID strains.[11,35] Because of the high-order viremia that develops in infected animals, the defining characteristic of epizootic VEE virus varieties is that equids serve as amplification hosts. Domestic rabbits, goats, dogs, and sheep also suffer fatal disease during VEE outbreaks.[10] There does not appear to be any single "epizootic" vector mosquito species; during outbreaks, the virus may be isolated from mosquitoes of many different species.[10] Epizootics terminate when susceptible horses are no longer available. The leapfrog-type spread characteristic of VEE is usually attributed to transport of horses incubating the virus. Movement of infected bats may also contribute to discontinuous spread of virus. In contrast to the situation with WEE and EEE viruses, birds do not have an important role in amplification and spread of epizootic VEE virus. It is not yet clear whether neurovirulent subtype IE virus is amplified in horses. Evidence from experimental infections suggests that viral titers in blood of infected horses may be insufficient to infect feeding mosquitoes.[36] The interepizootic reservoir of epizootic varieties, if any, is not known.

Clinical Findings

Clinical signs of infection with each of the viruses are similar, although signs of EEE are typically more severe and progress more rapidly than those of VEE and WEE.[4,5,19,20,29,37,38] Infected horses respond in any or even all of the following ways after experimental infections:

1. Inapparent infection with a very-low-grade viremia and fever approximately 2 days after inoculation. This manifestation corresponds to the initial viremia after viral proliferation in regional lymph nodes and probably occurs commonly during outbreaks without progression to subsequent stages.
2. Generalized febrile illness (up to 41.7° C), with anorexia, depression, tachycardia, and diarrhea. This stage is associated with viral proliferation in various body organs after spread from regional lymph nodes.
3. Clinical encephalomyelitis, which is the classic form of the disease.[39]

Young horses (especially yearlings) are most susceptible: Approximately 90% of 95 horses with EEE admitted to the University of Florida (UF) College of Veterinary Medicine Large Animal Hospital were younger than 5 years of age. The onset of neurologic signs, associated with the second febrile crisis, typically occurs approximately 5 days after infection (range 2 days to 2 weeks), and most deaths occur 2 to 3 days later.[38,39] Almost all horses with EEE are febrile at the onset of neurologic signs (mean of 40.3° C in horses admitted to the UF Large Animal Hospital), although the temperature declines thereafter. The onset of severe neurologic signs is peracute to acute, and progression is rapid. Horses may not be found to be affected until they are recumbent and comatose or dead. If they are observed while alive, initial CNS signs are quite variable and referable to diffuse or multifocal forebrain disease; evidence of brainstem and spinal cord involvement quickly becomes obvious as the illness progresses (Fig. 35.7). Obtundation is the most common initial clinical sign, although owners also report suspected colic as part of the initial presentation.

Affected horses often stand apart from pasturemates, have no interest in food, or fail to respond to an owner's call. Further signs of dementia may follow, including head pressing, odontoprisis, hyperesthesia, irritability, aggression (rarely), leaning against a wall or fence, or compulsive walking, often in a circle (especially around the inside of a stall or small paddock). Several observers have noted a "peculiar looseness of the lips" as a characteristic early sign.[5,40] Blindness and lack of a menace

FIG. 35.7 Eastern equine encephalomyelitis in an 18-month-old Paint filly. At presentation, the filly was febrile (39.9° C [103.8° F]), stuporous, and cortically blind and had a marked head tilt and body lean to the left, indicative of asymmetric central vestibular dysfunction. Vaccination history was unknown. With nursing care, this filly completely recovered over several weeks.

response may also be noted at this stage. Signs of cranial nerve disease, including abnormal pupillary light reflexes, head tilt, nystagmus, tight circling, facial and tongue paralysis, and inability to swallow often develop as the disease advances. Abnormal signs usually manifest asymmetrically, at least initially. Ataxia and paresis of the trunk and limbs cause gait to become progressively unsteadier. Tremors occur in the antigravity muscles of the limbs. Once recumbent, affected horses seldom regain their footing and are often noted to make galloping or swimming movements in lateral recumbency.[5] Seizures occur in approximately one third of horses with EEE and may happen at any stage. Mucopurulent nasal and ocular discharges and abrasions/lacerations of the face and limbs are the most common nonneurologic findings; the latter occurs secondary to trauma from falling, seizures, or running into objects.

Mortality rates are 75% to 95% for EEE, 19% to 50% for WEE, and 19% to 83% for VEE.[5,7,19,34,41] Vaccination within the preceding year was reported to be associated with lower risk of death in horses with EEE.[29,31] Death is usually preceded by a period of recumbency during which the horse may be semicomatose and convulsing. Surviving horses gradually recover over a period of weeks. Many horses with WEE apparently recover completely, but it is estimated that two thirds of horses that survive EEE have residual signs of CNS damage, such as central blindness, dullness, and diminished learning capacity or signs of cranial nerve dysfunction such as facial paralysis and head tilt.[18] Such horses are often referred to as "dummies."

Laboratory Findings Abnormalities on hemograms and in plasma chemistry panels of horses with alphaviral encephalomyelitis are minor and nonspecific. Horses with EEE may have abnormal WBC counts and high fibrinogen concentration. In 73 horses with EEE admitted to the UF Large Animal Hospital, the following hematologic abnormalities were noted: leukocytosis (56%), neutrophilia (60%), hyperfibrinogenemia (57%), monocytosis (36%), lymphopenia (13%), leukopenia (7%), neutropenia (4%), and lymphocytosis (3%). Mild to moderate elevations in plasma enzyme activities of affected horses either reflect direct organ damage or are secondary to anorexia, fever, stress, recumbency, and seizures. Hyperammonemia is found in some horses with EEE; its significance in horses is unknown but may reflect intestinal or hepatic injury by EEE virus.

The results of CSF analysis for horses with EEE are quite distinctive. More than 95% of horses with EEE admitted to the UF Large Animal Hospital had abnormal CSF cytologic findings. Among patients at the UF Large Animal Hospital, 88% of samples had high protein concentrations (mean of all samples, 139 mg/dL; range, 38 to 526 mg/dL; normal is <60 mg/dL). Nucleated cell counts (normal range, 0 to 6/μL) were high in 87% of samples (mean, 248/μL; range, 0 to 3100/μL); pleocytosis is characterized by high neutrophil concentrations (mean, 46%; range, 0% to 97%). Neutrophils are typically nondegenerate. Protein concentrations and nucleated cell counts are typically higher in samples obtained from the atlantooccipital site than they are in samples from lumbosacral taps. In the WEE outbreaks of 1930 to 1932, CSF nucleated cell counts were typically 12 to 30/μL, and most cells were lymphocytes.[13]

Diagnosis A clinical diagnosis is usually presumptive, especially in areas where these diseases are prevalent during the mosquito season. The finding in a CSF sample of moderate neutrophilic or lymphocytic pleocytosis further supports a diagnosis of alphaviral encephalomyelitis. Hemagglutination-inhibition, complement fixation, fluorescent antibody, and virus neutralization tests have traditionally been used for serologic diagnosis.[18] IgM antibody capture–ELISA is the method of choice for use in horses with viral encephalomyelitis because titers of greater than 1:400 can distinguish vaccination-induced (IgG only) from viral infection–induced (IgM and IgG) antibody responses.[36,42] These assays are available at many state diagnostic laboratories and also at the National Veterinary Services Laboratories (NVSL) in Ames, Iowa. In surviving horses, demonstration of a fourfold or greater rise in hemagglutination-inhibition or plaque-reduction neutralizing titer between acute and convalescent samples provides additional diagnostic support. Positive results of these tests could simply reflect *subclinical* infection with either virus. Virus can be isolated from fresh or frozen (with low efficiency) cultured brain tissue or mice and can be detected in histologic sections with immunohistochemistry or polymerase chain reaction (PCR) techniques.[43]

Differential diagnoses include hepatoencephalopathy; gastrointestinal (GI) hyperammonemia; heavy metal or other toxicosis; rabies; other viral encephalomyelitis (West Nile encephalitis, Borna disease, equine herpesvirus myeloencephalopathy, Aujeszky disease, louping ill); equine protozoal myeloencephalitis (EPM); trypanosomal (South America), verminous, or bacterial meningoencephalomyelitis; space-occupying lesion within the calvaria (e.g., cholesterol granuloma, neoplasia, brain abscess); brain infarction; brain trauma; and leukoencephalomalacia.

Treatment Treatment is largely supportive and, in the case of EEE, usually ineffective. Any adult horse with presumptive EEE that is unable to stand should be euthanized. Such horses should not be subjected to slinging. Hyperthermia is known to exacerbate brain injury and must be treated vigorously with cold water or alcohol baths until rectal temperature is less than 102° F. Convulsions can be controlled with diazepam, xylazine, or barbiturates (pentobarbital or phenobarbital).

In addition to receiving excellent general nursing care, all affected horses should be treated for brain edema and inflammation, although only horses with a predominance of forebrain signs are likely to respond. Drugs used for this

purpose include dimethyl sulfoxide (DMSO), 1 g/kg as a 10% solution intravenously (IV) or intragastrically; flunixin meglumine (or equivalent nonsteroidal antiinflammatory drug [NSAID]) 1.1 mg/kg q12h for 3 days IV, or orally (PO); dexamethasone (or equivalent corticosteroid), 0.05 to 0.1 mg/kg daily for 3 days IM or IV and then tapered; and mannitol (0.25 to 1 g/kg as a 20% solution IV) or hypertonic saline (e.g., 7.2% saline 2 mL/kg 4 to 6 times IV during the first day). Anecdotal evidence suggests that a lengthy course of dexamethasone is an important determinant of neurologic recovery in surviving cases. Treatment should be titrated to minimize neurologic signs but generally must be tapered over several weeks. Complete recovery, if it occurs, may take several months.

Treatment with serum from horses hyperimmunized against WEE virus was thought to reduce mortality rates modestly during the outbreak in 1930 to 1932; however, these claims were not tested scientifically.[5] Furthermore, administration of large quantities of hyperimmune serum to experimentally infected horses by investigators at Lederle Laboratories was reported to have no beneficial effect.[44]

Adjuvant antiviral therapy with interferon α or β has salutary effects in some experimental models of alphaviral encephalitis and could be tried in valuable horses.[45] A reasonable protocol is described in the section on West Nile encephalitis.

Public Health Significance All three viruses infect humans, causing subclinical, febrile, or neurologic disease.[7] Since 1964, 640 cases of human WEE have been reported in the United States, with annual average of 27 cases in the period up to 1987. Since 1988, however, only five cases of WEE have been reported. In contrast, the 268 cases of EEE in humans reported in the United States since 1964 have occurred at a fairly steady rate of 6 cases per year. Epidemics of VEE are closely associated with equine epizootics; thus during the 1962 to 1964 epizootic in central Colombia, which killed approximately 100,000 horses, 200,000 humans were infected, of whom 1000 (0.5%) died. The enzootic Everglades subtype II strain, which is nonpathogenic for horses, has caused human encephalitis in Florida. No cases of human disease were recorded during the VEE subtype IE equine epizootics in Mexico in 1993 and 1996, but South American strains of EEE virus have been reported to cause encephalitis in humans. Rates of short-term mortality from EEE, WEE, and VEE in humans are 74%, 4%, and less than 1%, respectively. Most human survivors of EEE suffer long-term neurologic impairment.

Postmortem Findings Most organs exhibit congestion, and the brain and spinal cord have a slate-gray discoloration, often with petechial hemorrhage, obvious especially on sections of formalin-fixed tissue.[43,46,47] Brain swelling and evidence of occipital subtentorial herniation are common, with brainstem compression. Histologic study reveals evidence of acute to subacute and multifocal to diffuse meningoencephalomyelitis. Gray matter is predominantly involved, with diffuse neuronal degeneration, gliosis, perivascular and neuroparenchymal infiltrates, and meningitis. Neutrophils or, on occasion, eosinophils are prominent in acute EEE, whereas lymphocytes predominate in older lesions.[46] Treatment with corticosteroids may suppress the inflammatory cell infiltrates, which then appear mild.

Bronchopneumonia is found in approximately 20% of fatal cases of EEE, probably secondary to pharyngeal paresis and aspiration of particulate material. Up to 10% of horses with EEE have histologic evidence of myocardial necrosis, probably a sign of brain–heart syndrome.[47]

Because high infection rates in humans have been documented after exposure to aerosols from infected laboratory animals or as a result of laboratory accidents (or possibly exposure to equine carcasses), necropsies of horses with suspected VEE should be performed only by personnel who possess demonstrable immunity in the form of neutralizing antibody.[48] All laboratory manipulations must be carried out within certified biological safety cabinets in accordance with physical containment level 3 procedures.

Control Active immunization through use of formalinized vaccines began in 1934 and is still the only commercial method of immunization of horses against EEE and WEE viruses. These inactivated vaccines are also used routinely to protect ratites from EEE and WEE and South American camelids from EEE.[49] The attenuated tissue culture–origin vaccine, TC-83, derived from a Trinidad VEE virus isolate, which was originally developed to protect military personnel, provides durable immunity against VEE virus and was effective in minimizing the incursion of VEE into the United States in 1971[23] and in limiting the 1993 and 1996 outbreaks in Mexico. Although TC-83 is no longer licensed for use in horses in the United States, a formalin-inactivated vaccine containing the TC-83 vaccine strain is available and is often included with EEE virus and WEE virus in trivalent products.[50] For any of the formalin-inactivated alphavirus vaccines, adult horses should be given an initial two inoculations 4 to 6 weeks apart at least a month before the anticipated risk period or before the onset of vector mosquito activity and then revaccinated at intervals when the risk is likely to be higher. Vaccination should begin in January or February in Florida and in May or June in parts of Canada and the northern United States. Clinical evidence suggests that vaccination against EEE virus or WEE virus provides less than 6 months of protection, and so revaccination at least once during the mosquito season is necessary in areas with warm climates and long mosquito seasons. Vaccinated mares should receive a booster dose 4 to 6 weeks before foaling to provide colostral antibody for newborn foals.

Foals should be given an initial inoculation at 4 to 6 months (if the dam has been vaccinated) or 3 to 4 months (if either the dam is unvaccinated or the vaccination history is unknown) and then a second inoculation 4 to 6 weeks later and a booster at 10 to 12 months of age. The American Association of Equine Practitioners (AAEP) recommends that foals of vaccinated dams in high-risk areas be given a primary series of four doses beginning at 2 to 3 months of age. Two additional inoculations are then given at approximately 4-week intervals and a booster at 10 to 12 months of age, before the onset of mosquito season.

Routine surveillance of the virus pool by serum antibody testing of sentinel chickens and virus detection in trapped mosquitoes by health authorities often reveals early warning of an impending outbreak and allows time for vaccination of susceptible horses. General mosquito control (removal of standing water, spraying by local authorities) will reduce risk of EEE and VEE in horses.[29] Because of the role of horses in amplification and transmission of VEE virus, quarantine of infected and exposed horses with area-wide and international restrictions on horse movement is an integral part of the management of VEE epizootics.[51]

Miscellaneous and Foreign Emerging Viruses Causing Neurologic Signs

Robert J. MacKay

Since the encroachment of West Nile virus (WNV) in 1999 into North America, the potential for emerging foreign disease with widespread effect has been realized. Given the opportunity, many other viral infections could become established in previously unaffected countries as a result of the globalization of the horse industries and effects of global climate change.

VetBooks.ir

Getah/Ross River Viruses

The Semliki Forest complex of the Togaviridae is widespread throughout its geographic range, either in the Orient (Getah virus) or South Pacific (Ross River virus). Although closely related, these viruses have little geographic overlap. Like the North American alphaviruses, these viruses are transmitted by mosquitoes. The reservoir for Getah virus is not known, although swine appear important in its transmission to mosquitoes.[1] Important reservoirs for Ross River virus are marsupials.[2] Getah virus infection may be transmitted by horses, but this is unlikely to occur with Ross River virus. Seroprevalence in horses varies from less than 10% to more than 90%.[3-5] Ross River virus infection is endemic in horses and widespread; seroprevalence among Australian horses ranges from 50% to 80%.[6,7]

Clinical signs of Getah virus infection include fever, edema of the limbs, and urticaria over a course of 7 to 10 days.[3,5] Horses infected with Ross River virus may develop fever, lameness, swollen joints, inappetence, generalized stiffness, and even colic.[8] Of the horses in which viral encephalitis cases were diagnosed during the 2011 Australian outbreak, more than 100 were seropositive for Ross River virus; however, detailed description of these cases has not yet been published.[7] Getah virus and Ross River virus infections are diagnosed serologically or by reverse transcription polymerase chain reaction (RT-PCR) testing of blood samples. Treatment is supportive. A vaccine for Getah virus is available in Japan. An inactivated vaccine against Ross River virus for humans is being tested in Australia, but no equine vaccine is available.[9]

Borna Disease

Classical Borna disease is a viral encephalitis principally of horses and sheep that was first recognized in southwestern Germany in the eighteenth century but is associated with the village of Borna in the Kingdom of Saxony, where the disease emerged in the late nineteenth century. It is estimated that approximately 16,000 horses in Saxony died of this disease annually from 1896 to 1940.[10] These numbers declined rapidly in the 1960s in parallel with declining horse numbers, and only 1216 horses died of classical Borna disease in Saxony from 1958 to 1991.[10] Outbreaks of classical Borna disease have been restricted to central Europe in the upper Rhine valley in Switzerland, Austria, and Liechtenstein. Borna disease virus–associated encephalitis has also been reported in humans, cattle, an alpaca, deer, zoo herbivores, cats, rabbits, and dogs.[11] Since the 1990s, evidence of Borna disease virus infection—including antibodies, antigen, RNA, or the virus itself—has been reported in many countries and in numerous mammalian species, including humans. There is serologic evidence of Borna disease virus infection in horses in the United States.[12,13] Some of these reports are questionable because of problems with contamination of samples by laboratory Borna disease virus strains and poorly validated immunoassays; however, there have been enough well-documented infections to confirm that Borna disease virus or Borna disease virus–like viruses are widespread.[14] It is possible that Borna disease virus is involved in several human neuropsychiatric diseases, but evidence is lacking.

Borna disease virus 1 (BoDV-1), the etiologic agent of classical Borna disease, is a nonsegmented, negative-sense, single-stranded RNA virus of the order Mononegavirales, family Bornaviridae. For many years BoDV-1 was the only known member of Bornaviridae, but since 2005, at least five additional species have been identified, and endogenized BoDV-1 sequences are common in the genomes of mammals.[11] The significance of this last intriguing finding is unknown.

Most outbreaks in horses and sheep occur during the spring and early summer. Although horse-to-horse transmission is theoretically possible, it is unimportant in the evolution of an outbreak.[14] The virus is probably maintained in small mammals with geographic ranges approximating the endemic Borna disease area. The bicolored white-toothed shrew is an important reservoir host in endemic areas.[15] BoDV-1 is shed through nasal and lacrimal secretions and in the urine of infected animals.[14,16] BoDV-1 is resistant to drying and other adverse environmental conditions. It is assumed that BoDV-1 enters the horse though intranasal infection and migrates to the brain transaxonally.[17] Direct replication occurs in neurons and glial cells, with centrifugal spread to peripheral nerves and retina. BoDV-1 infection of the retina may contribute to the blindness that characterizes acute Borna disease in horses.[18] Subclinical BoDV-1 infection is common; in endemic areas, seroprevalence among horses ranges from 10% to 20%, and it is as high as 50% among stablemates of horses with Borna disease. In subclinically infected horses and in horses that recover from Borna disease, the virus becomes quiescent and largely undetected by the immune system.

The clinical signs of Borna disease in large animals are similar to those of the other equine encephalitides. The incubation period is 4 weeks to 3 months. There is a predominance of forebrain signs initially, followed by signs of brainstem and spinal cord involvement. In moderate to severe cases, horse die 1 to 4 weeks after onset of signs. In mild cases, horses can recover, but abnormalities and exacerbations commonly persist. The prodrome is characterized by fever, inappetence, colic, and vague behavioral changes. The onset of neurologic signs is marked by changes in mentation with alternating hyperresponsiveness and stupor; compulsive walking, often in circles; odontoprisis; and aggression. Other signs of brain disease include trismus, pupil constriction, nystagmus, head tilt, and blindness. With progression, ataxia and weakness of the limbs and trunk occur, and areas of cutaneous desensitization or hyperesthesia develop. Collapse into recumbency and seizures constitutes the final stage. The mortality rates are approximately 80% among affected horses and 50% among affected sheep. Up to 10% of affected horses develop a chronic relapsing form of the disease and may become persistently infected carriers.

For antemortem diagnosis, antibodies to the agent may be found in the serum and CSF of most infected animals by ELISA, indirect fluorescent antibody test (IFAT), and Western blot.[15] CSF analysis often reveals mononuclear pleocytosis and high protein concentration. RT-PCR techniques have demonstrated virus in the CSF and peripheral mononuclear cells.[19] The criteria for diagnosis in a horse with neurologic abnormalities include positivity for BoDV-1 antibodies in serum or CSF and characteristic histopathologic changes.

Pathologic abnormalities resemble those of a viral encephalomyelitis, and the diagnosis is confirmed by immunohistochemistry, virus isolation, and detection of viral nucleic acids.[14,15,20-24] The characteristic microscopic lesion of Borna disease is Joest-Degen inclusion bodies in the neuronal nucleus, but these are not always observed. Virus is detectable easily with monoclonal or polyclonal antibody tests. Histopathologic changes are those of a typical polioencephalomyelitis, with a particular loss of neurons in the hippocampus. The gray matter of the olfactory bulb, basal cortex, caudate nucleus, thalamus, hippocampus, and medulla oblongata is involved.

No antiviral agents are available for the treatment of BoDV-1 infection, and use of amantadine sulfate (developed for treatment of influenza infection) is controversial but common.[25,26] Likewise, vaccination as a protective strategy is controversial. It is widely assumed that a modified live vaccine would offer more protection; however, the live vaccine available until the early 1990s in East Germany was removed from the market because of questionable efficacy.

Henipavirus

Hendra virus (HeV) is one of two *Henipavirus* species. HeV infection of horses was first recognized in 1994 during simultaneous

VetBooks.ir

outbreaks of severe respiratory disease in Queensland, Australia: one in the Hendra suburb of Brisbane and the other near the town of Mackay. Of 22 affected horses, 14 died, and each outbreak was associated with transmission to humans, one of whom died.[27] As of 2015, there had been almost 50 outbreaks of HeV infection in horses, all but one in coastal Queensland and New South Wales. Five outbreaks also involved seven human cases, of which four were fatal. Although horses in the original outbreaks showed signs of fulminant febrile respiratory disease, neurologic signs dominated the clinical presentation in five horses in an unusual outbreak at an equine referral practice in the Redlands suburb of Brisbane in 2008. The illness was characterized by severe obtundation, dementia, head tilt, and progressive ataxia. More recently, the respiratory syndrome has been the typical presentation of horses with HeV infection; neurologic signs are observed only occasionally.

HeV replicates initially in the respiratory epithelium before spreading hematogenously to multiple organs, including the CNS, to cause widespread vasculitis, endothelial syncytia, vascular thrombosis and hemorrhage, and cellular necrosis.

Nipah virus (NiV), the other species of *Henipavirus*, emerged as the cause of porcine respiratory and encephalitis syndrome in Malaya in 1998.[28-30] Signs were predominantly respiratory, and most affected pigs recovered. NiV also caused severe febrile encephalitic illness among workers in contact with infected pigs; of 265 affected people, 105 died. NiV or Nipah-like virus has also been implicated in an outbreak of fatal encephalitis in a group of horses in the Philippines.[31] Deaths also occurred in humans, dogs, and cats that consumed meat from the dead animals.

HeV and NiV are closely related viruses; the genus, *Henipavirus*, belongs to the family Paramyxoviridae. They are enveloped, single-stranded, negative-sense RNA viruses. The henipaviruses are highly pathogenic for a wide range of mammals, including horses, pigs, and humans. The natural reservoirs throughout the geographic range (Northern Australia, Malaysia, and Bangladesh) are fruit bats from the genus *Pteropus* (also known as *flying foxes*).[32] In each spillover event, the virus is probably transmitted to horses through contact with the urine or reproductive fluids of infected bats. During the incubation period in horses, HeV is infectious to other horses and to humans for at least 48 hours before the onset of clinical signs, and at least two outbreaks in stables were caused by introduction of horses that were incubating the virus before manifesting the disease. Virus is secreted in all body fluids and feces of infected horses, and appropriate precautions must be taken to prevent transmission to other horses and humans.

The disease is diagnosed both serologically by ELISA or neutralization test and by detection of RNA by RT-PCR in blood, other body fluids, or tissues taken at necropsy.[30,33]

Infected horses are euthanized as a matter of public health. Ribavirin has been used with partial success to treat NiV and HeV infections of humans, and a monoclonal antibody (m102.4) has been shown to be protective in experimental animals if given before clinical signs are manifested and has been used in several exposed humans.[34] An HeV subunit vaccine (HeV-sG) has been tested successfully in multiple species, including horses, against both HeV and NiV challenge and was launched commercially in Australia in 2013 for vaccination of horses in endemic areas (EquiVac HeV, Pfizer Animal Health).[34]

Bunyaviridae

The Bunyaviridae are mostly arboviruses and are found worldwide. These viruses are usually maintained in mosquito–vertebrate host–mosquito cycles, whereby midges act as the arthropod hosts for a few viruses.[35] Twelve serotypes, known collectively as the *California serogroup*, have been isolated in North America, South America, Africa, Europe, and Asia. In rare cases, these viruses can cause acute encephalitis in horses. Snowshoe hare, Main Drain, and Bunyamwera viruses have been associated with encephalitis in horses,[36-38] and serologic evidence of subclinical infections with Jamestown Canyon virus and Cache Valley virus have been found in horses in the United States.[39,40] Clinical signs in a horse from which Main Drain virus was isolated included ataxia, weakness, stiff neck, head pressing, dysphagia, tachycardia, and fever.[37]

Equine Encephalosis

Equine encephalosis is an arthropod-borne viral infection, affecting all species of equids, and is characterized usually by mild or subclinical infection but occasionally by severe clinical disease.[41] The causal agent, equine encephalosis virus (EEV), is transmitted through the bites of certain *Culicoides* spp. biting midges. EEV is an orbivirus, as are African horse sickness virus and bluetongue virus. All equids (horses, donkeys, zebras) are susceptible to EEV, although donkeys and zebras are thought to be resistant to the clinical disease. The infection is endemic in southern Africa, where seven EEV serotypes have been identified.[42] An outbreak of febrile disease due to EEV in Israel in 2008 and 2009 involved 60 horses, and serologic evidence of the infection has since been found in several other areas outside southern Africa.[43,44]

The virus was originally named for isolation from a horse with typical signs of encephalitis, including mild to severe ataxia, reluctance to walk, stiffness, dementia, and seizures.[41] In its current forms, infections are either subclinical or associated with an influenza-like syndrome of fever, edema, tachycardia, tachypnea, and congested mucosae. An African horse sickness–like syndrome of respiratory distress and cardiac failure has been described, and pregnant horses may abort. A competitive ELISA for detection of group-specific antibody to EEV has been described for use in diagnosis.[45] There is no recognized treatment for EEV infection or method of prevention.

West Nile and Other Flavivirus Encephalitis

Robert J. MacKay

The causative agent of West Nile encephalitis (WNE) is a small, positive-sense, single-stranded, enveloped RNA virus,[1] West Nile virus (WNV), which is a member of the Japanese B encephalitis antigenic complex of neuroinvasive arboviruses within the genus *Flavivirus*, family Togaviridae.[1] In addition to WNE virus, Kunjin, Japanese B encephalitis, and Murray Valley encephalitis viruses are members of the Japanese B encephalitis antigenic complex that have caused encephalomyelitis in horses outside the United States. WNV has seven genetic lineages; two of these, lineages 1 and 2, have caused neuroinvasive equine (and human) infections.[2] Outbreaks of neuroinvasive disease in horses and humans have traditionally been associated with lineage 1 isolates that circulate among the Mediterranean basin, West African, and northern European countries. A virus of this lineage is responsible for the North American epizootic. Lineage 2 isolates are widespread in sub-Saharan Africa and commonly have infected horses without apparent clinical effect. Since 2005, the number of cases has been increasing, and several outbreaks of neurovirulent equine and human disease have been caused by lineage 2 WNV in Africa and Europe.[2,3]

The Kunjin virus is a lineage 1 WNE virus that traditionally has caused mostly subclinical or febrile nonneurologic disease in horses and humans in northwestern Australia and Papua New Guinea. A neurovirulent strain of Kunjin virus emerged in New South Wales in Australia in the late summer and fall of 2011 and caused encephalitis in at least 1000 horses in southeastern Australian states, with mortality rates of 10% to 15%.[4,5] This unprecedented epizootic of Kunjin encephalitis (and also of encephalitis due to the arboviruses Ross River virus and Murray Valley encephalitis virus) followed unusually heavy

VetBooks.ir

spring rainfalls in southeastern Australia.[4] There is evidence that the 2011 outbreak probably resulted from a complex interplay among novel genetic virulence determinants and unusual ecologic and epidemiologic conditions.[5] Since the Murray Valley encephalitis epizootic in 1974, cases had been reported only sporadically.[6] Japanese B encephalitis virus is endemic in east Asia and southeast Asia and has made incursions into the northern tip of Australia.[7] It is maintained in cycles among porcine and avian reservoirs through mosquito hosts. Humans and horses are dead-end hosts. Cases of encephalitis in horses occur sporadically throughout the virus's range, and effective vaccines are available. Although the geographic ranges of WNV and Japanese B encephalitis overlap minimally, diagnostic serologic testing may yield confusing results in areas where both diseases (and vaccinations) do occur. Louping ill, Powassan, and tick-borne encepahlitis viruses are tick-borne flaviviruses that have the potential to cause encephalitis in horses.[1]

History and Distribution WNV was originally isolated from the blood of a febrile woman in the West Nile region of Uganda in 1937. Cases of WNE in humans were first recorded in Israel in the 1950s, and cases in horses were recorded in Egypt and France between 1960 and 1965.[8,9] Since 1996, cases have been sporadic, and outbreaks of equine WNE have been small and localized in numerous countries in the Mediterranean basin and northern Europe. These incursions of lineage 1 and, more recently, lineage 2 WNV continue to expand in number and geographic range.[10] It is now clear that WNV has become enzootic in several locations in Europe.

In August 1999, the first case of WNE in humans was reported in Queens, New York. Characterization of the virus from this outbreak showed it was highly homologous with Israel 1998 (Is98), a strain of WNV that had originally been isolated from a goose.[11] Ultimately, 62 cases occurred in humans in 1999, with 7 mortalities. From August to October 1999, 25 horses on Long Island were diagnosed with WNE; 9 of these horses died.[12] Deaths occurred in numerous native bird species, particularly in corvids (crows, ravens, jays) and in exotic species housed at the Bronx zoo. In 2001 the disease became a national epizootic; cases occurred for the first time in Florida, Kentucky, Louisiana, Georgia, Alabama, Illinois, Indiana, Mississippi, New Hampshire, North Carolina, Tennessee, and Virginia.[13] There were 738 cases reported nationally, of which 33.2% died or were euthanized. Despite the availability of an effective vaccine from August 2001 onward, there was a dramatic westward spread of WNE in 2002, with 15,257 horses affected in 40 states. The national incidence of the disease in horses declined in 2003 to 5181 cases in 44 states. By 2006, equine cases had been reported from all 48 contiguous states. Total annual cases dropped below 1000 in 2007, and only 79 were reported in 2011. In 2012 there was an upswing in WNE in all parts of the country with a total of 627 cases, of which 120 were in Texas. This upswing was attributed to unusual climatic conditions and not to the emergence of a more virulent strain of WNV. From 2013 to 2016, equine WNE cases in the United States averaged 280 annually.

Equine or human WNE or both have been reported in multiple Canadian provinces, and there is serologic evidence of WNV in the Caribbean and Latin America.[1]

Natural History WNV cycles between ornithophilic mosquito vectors and avian reservoir hosts. In temperate climates, the virus overwinters by long-term infection of hibernating vector mosquitoes, followed by vertical (transovarial) transmission and possibly by latent infection of avian hosts.[14] *Culex* spp. are the most important vectors for the North American epizootic in birds. Different species transmit the virus in different parts of the country. Major vector species include *Culex pipiens* in the northeast and central United States, *C. tarsalis* from the far western United States to the panhandle of Texas, and *Culex quinquefasciatus* in the southeastern United States from Texas to Florida. Although birds of more than 300 species have been reported to be WNV-positive, passerine (true perching bird) and charadriiform (shorebird) species are considered the most competent reservoir hosts for WNV in the United States. Corvid species such as crows and blue jays are efficient hosts, but their mortality rates were high during the North American epizootic. The house sparrow (an Old World passerine species) also develops high-titer viremia after WNV infection but is relatively resistant to the adverse effects of the virus. Various domestic mammals, including sheep, alpacas, and dogs, suffered fatal WNE during the North American epizootic.[1,15] Horses, humans, and other mammals are "dead-end" hosts and do not amplify the virus in quantities sufficient to infect mosquitoes. In contrast, alligators exhibit high-titer viremia and may be important reservoirs for infection in the southeastern states.

"Bridge vector" species of mosquito transmit the virus from birds to mammals, including horses. The mosquito species important for bird–horse transmission are not known with certainty but may include members of *C. pipiens* complex, *C. tarsalis*, and *Culex salinarus*.

The occurrence of WNE reflects vector mosquito activity, which is seasonal in temperate zones and year-round in tropical and subtropical regions. Significant viral activity begins in July, and the incidence peaks in September and October. The epizootic usually declines rapidly after the first frost.

Clinical Signs Experimental infections in horses result in viremia 3 to 5 days after viral inoculation into the CSF, and clinical signs begin at 7 to 10 days.[14] Experience during clinical outbreaks indicates a similar 1- to 2-week incubation period before signs of WNE are manifested.

Clinical signs have been extremely varied; however, surveys of cases published across the United States and from Europe have revealed some consistent combinations of signs.[8,12,16-20] Approximately 25% of affected horses have had mild to moderate fever at the time of initial examination, although it is likely that most were febrile before examination. Consensus neurologic signs in 726 cases from the northeastern United States, Florida, Indiana, Nebraska, and Colorado[8,12,16-20] have included limb ataxia (71%), limb weakness (58%), muzzle twitching (45%), obtundation (43%), recumbency (31%), lip droop (22%), hyperresponsiveness/hyperesthesia (18%), odontoprisis (12%), dog-sitting posture (10%), thoracic limb collapse (7%), compulsive walking (7%), muscle atrophy (6%), seizure (4%), blindness (4%), circling (4%), and head pressing (3%). Clinical signs reflect the reported predominance of lesions in the gray matter of the hindbrain and spinal cord of horses with WNE, with lesser involvement of the rostral brainstem and forebrain.[21]

The observation of coarse twitching of the muzzle (and, to a lesser extent, the eyelids) is a particularly distinctive finding in acute cases of WNE. Less frequent are fine fasciculations of the cutaneous muscles of the torso and neck. Horses acutely affected may be frantic, fearful, and hyperresponsive to stimuli. This stage is transient (usually <1 day in duration) and typically is the only behavioral change observed. Mild obtundation is common at initial presentation and progresses to stupor with narcoleptic episodes in horses with severe midbrain or hindbrain involvement. In addition, such horses often have facial or tongue paralysis, or both, or vestibular signs of head tilt and body lean. Ataxia and weakness of the trunk and limbs occur with or without signs of brain disease and may manifest asymmetrically. Such manifestations are clinically indistinguishable from those of horses with EPM. Because of the predilection of WNV for gray matter in thoracic spinal cord segments, horses may present with the unusual combination of acute-onset

VetBooks.ir

FIG. 35.8 West Nile encephalomyelitis in a 3-year-old Thoroughbred gelding with involvement of the gray matter of the spinal cord supplying the thoracic limbs. During the first 5 days after onset, the gelding's thoracic limbs frequently buckled, and he collapsed into this position for several minutes before regaining his feet. Pelvic limb strength was normal.

bilateral thoracic limb weakness/collapse and normal pelvic limb strength (Fig. 35.8). Severely affected horses are often unable to roll from lateral to sternal recumbency and tend to lie quietly without much voluntary activity. Comparable presentations in human patients with paralytic forms of WNE are described as "polio-like."[22] With time, muscles of the thoracic girdle can become severely atrophied, and such horses are rendered permanently unable to move from lateral to sternal recumbency even though they may be able to walk once assisted to stand. The convalescent stage of WNE is described later in the Treatment section.

Published mortality rates during the U.S. epizootic ranged from 22% to 44%. Among 2326 reported cases from across the United States, including national statistics for the years 1999 to 2001, the overall mortality rate was 31%. Surprisingly, death rates were relatively high (43%) among the 1050 cases reported from California during 2004 to 2006. A history of no or incomplete vaccination, persistent recumbency or difficulty standing, paresis of pelvic limbs, and facial or tongue paralysis was associated with poor outcome, and mortality rose with increasing age after the age of 5 years.[17,18,20] In one study, affected females were 2.9 times more likely to die than were affected males.[18]

Laboratory Findings

Abnormalities found in hemograms and serum/plasma chemistry results are usually mild and nonspecific. Of 46 horses with acute WNE admitted to the UF Large Animal Hospital, the most common abnormalities were lymphopenia (23%), hyperbilirubinemia (72%), and high plasma creatinine concentration (8%).[17] Hypokalemia, hyponatremia, and hypochloremia were also common, as were high muscle enzyme activities secondary to trauma and prolonged recumbency.

Most affected horses have CSF pleocytosis. Of 30 samples collected in the UF Large Animal Hospital series, 22 (73%) had abnormally high nucleated cell counts or protein concentrations.[23] Mild xanthochromia was also common. Mononuclear pleocytosis was found in 16 samples (53%), and high protein concentrations with normal nucleated cell counts were found in the other 6. Nucleated cell counts in abnormal samples ranged from 0 to 882 cells/μL (median, 14 cells/μL), and protein concentrations ranged from 64 to 316 mg/dL (median, 100 mg/dL). Cells were predominantly lymphocytes or macrophages with occasional neutrophils. Of 14 samples exhibiting pleocytosis (nucleated cell count, >6 cells/μL) without significant red blood cell (RBC) contamination, neutrophil proportions ranged from 0% to 8% (median, 2.5%; H. L. Wamsley, personal communication, 2007). Of interest is that nucleated cell counts and protein concentrations were significantly higher in lumbosacral samples than in atlantooccipital samples.[23] The CSF findings have not been strongly correlated with the severity of the clinical presentation.

Diagnosis

A presumptive diagnosis is often based on clinical signs, especially in areas where the disease or virus is currently active and the horse has not been vaccinated against WNV within the previous 12 months. Diagnostic confidence is increased by the observation of muzzle twitching. The finding in a CSF sample of mild to moderate mononuclear pleocytosis with low numbers of neutrophils further supports a diagnosis of WNE. In a horse with signs of encephalomyelitis, presumptive diagnosis requires a positive result of a serum IgM antibody capture–ELISA and negative or unsupportive results of tests for other possible diagnoses, including alphaviral encephalitis, equine herpesvirus myeloencephalopathy, EPM, and hepatoencephalopathy. Single-point assays of anti-WNV IgG, such as the plaque-reduction neutralization test, are not particularly useful because titers can be affected by prior vaccination; however, demonstration of a fourfold or greater rise in titer between acute and convalescent samples supports the diagnosis in unvaccinated horses. It must be emphasized that serum antibody tests are diagnostic only of WNV infection, not WNE per se. For every case of WNE, approximately nine horses have nonneurologic or subclinical WNV infections.[14] The finding of WNV-specific IgM in CSF increases the specificity for WNE.

At necropsy, PCR (nested or quantitative), immunohistochemical, and viral isolation methods are used to demonstrate the presence of viral components in the CNS,[14] although immunohistochemistry tests are much less sensitive for WNV than for EEE.

Differential diagnoses for WNE in horses include alphaviral encephalomyelitis (EEE, WEE), rabies, verminous or bacterial meningoencephalomyelitis, EPM, brain or spinal cord trauma, cervical stenotic vertebral myelopathy, hepatic encephalopathy, or compressive mass in the calvaria or vertebral canal.

Treatment

No antiviral treatment for horses with WNE is readily available. Type I interferons (i.e., interferon α or β) or interferon inducers stimulate nonselective cellular resistance to viral infection and are used for prevention or treatment of viral diseases. The limited data so far reported for the use of interferon in humans with WNE do not suggest any positive effect on outcome, although some anecdotal evidence supports this approach in horses. A reasonable dosage is 3×10^6 to 15×10^6 international units (IU) of interferon $\beta_{1\alpha}$ IM or IV (Avonex [Biogen, Cambridge, Mass.], 30 μg) three times weekly. The concept of therapy with WNV-specific globulin is supported by findings in a guinea pig model of WNE, although no controlled studies of its use in horses have been reported. In a limited series of cases, horses given a hyperimmune globulin product showed a trend for less recumbency, but the product had no significant effect on severity of clinical signs or mortality.[14] Several commercial products of this type are available for horses in the United States. These products are given slowly IV according to label instructions.

Supportive care is of paramount importance. Secure footing, deep dry bedding, protective covering of distal limbs and bony prominences, climate control, and provision of ample food and water are important in all cases. Recumbent horses must be repositioned from one side to the other regularly, and decubital injuries must be addressed. Early and systematic use of slinging is helpful in some otherwise recumbent horses. The Anderson sling, which transfers some of the horse's weight onto the upper limbs, is probably more effective in horses with

VetBooks.ir

WNE than are slings that rely entirely on torso support. In one series of 12 horses with prolonged recumbency that were treated by slinging, 2 were able to stand unassisted after slinging was used to help them rise, and 2 were able to stand after slinging was discontinued.[18] In horses that have long-term difficulty in rising to the standing position, semipermanent mobile slinging systems have been devised and marketed. These slings are stocklike frames that have wheels on each corner and webbing that rides under and supports the horse's torso.

NSAIDS and other antiinflammatory drugs are typically used empirically in horses with WNE to control local pain, inflammation, and fever. Drugs commonly used for this purpose are flunixin, 1.1 mg/kg IV or PO (bid in U.S., sid in Europe); DMSO, 0.25 to 1 g/kg in a 10% solution IV or intragastrically bid; vitamin E, 20 IU/kg PO q24h; and pentoxifylline, 10 mg/kg PO bid. The use of corticosteroids is controversial. Because recrudescence of WNV infection and clinical relapse in recovering immunosuppressed horses are at least theoretical concerns, corticosteroids should be used only in horses that are recumbent or in imminent danger of becoming so. A typical dosage regimen is dexamethasone, 0.05 to 0.1 mg/kg IV or 0.1 to 0.2 mg/kg PO, once or twice daily for 1 to 3 days. Affected horses are often treated for presumptive EPM with antiprotozoal drugs (e.g., ponazuril, 5 mg/kg PO q24h) until IgM antibody capture–ELISA results become available.

Recovery, when it occurs, takes from 1 day to several months (mean, 22.3 days for 271 horses recovered from WNE in Nebraska and Colorado[18] and 10.7 days for 569 horses in North Dakota[20]) and is not always complete. Of 125 predominantly pleasure horses in Minnesota that survived WNE, 22 (17.6%) were classified by their owners as incompletely recovered 6 months after diagnosis.[24] Gait abnormalities, behavioral changes, muscle atrophy, and lethargy were among the residual abnormalities reported by the horses' owners. An additional 29 horses (23.2%) were considered fully recovered with residual deficits. A surprisingly high 9% of horses suffered some form of relapse of clinical signs 2 weeks to 5 months after diagnosis.

Necropsy Findings Gross abnormalities of the CNS in horses with WNE are limited to meningeal congestion and hemorrhagic foci in the brain and spinal cord. Histologic study reveals mild to severe multifocal lymphocytic polioencephalomyelitis with a predilection for the ventral and lateral horns of the thoracolumbar spinal cord. The brain exhibits lymphocytic perivascular cuffing and microgliosis in the medulla oblongata and pons and, to a lesser extent, in the basal nuclei, thalamus, and mesencephalon. In severe cases, there is evidence of neuronal degeneration characterized by central chromatolysis, cytoplasmic swelling, or cell shrinkage. The cerebral and cerebellar cortices usually are relatively free of lesions.

Control General mosquito control is important at the individual operation level. Local authorities may undertake area-wide mosquito abatement when sentinel chicken serologic tests or viral isolations from wild birds suggest high local WNV activity.

A killed whole virus vaccine has been available since August 1, 2001, and has had full U.S. Food and Drug Administration approval since 2003. This vaccine is effective beginning approximately 2 weeks after the second dose of the initial series, but antibody levels drop substantially by 4 months after vaccination. Two additional vaccine types became available afterwards: a recombinant subunit vaccine in a pigeon poxvirus vector and a live chimera virus vaccine based on an attenuated yellow fever virus backbone. WNV vaccines are available in combinations with alphaviral encephalitis and tetanus vaccines, although there is evidence that simultaneous multiple vaccines can diminish the antibody response to WNV vaccination.[25] The live chimera vaccine was withdrawn in 2010 for safety reasons, and an inactivated version is now offered. For all products, the primary series or booster vaccination is completed at least 1 month before anticipated WNV activity, and boosters are given once or more annually, depending on the length of the vector season. Various challenge models have been used for each of these vaccines (except the killed version of the chimera vaccine) to demonstrate early protection against encephalitis and continuing protection against infection 12 months after a primary vaccination series. Foals of vaccinated mares should begin vaccination at 4 to 6 months of age and should have been given three inoculations by 12 months of age. Boosters should be given at least annually and more often in high-risk areas. Vaccine failures are more common in old horses. A DNA vaccine against WNV was approved by the U.S. Department of Agriculture in July 2005 but has since been discontinued.

Trauma to the Brain and Cranial Nerves

Robert J. MacKay

Because of their flighty temperaments, fast gaits, and relatively thin calvaria, horses suffer head trauma more often than do other livestock and have a higher rate of neurologic sequelae of such trauma (i.e., traumatic brain injury). Head injuries to horses occur from blows to the frontal-parietal area from running into stationary objects or being kicked by other horses, as well as from impact to the occipital protuberance (poll) or temporal areas after flipping over backward during handling or restraint accidents.[1] Specific cranial nerves may also be injured on the outside of the skull by focal trauma. In the special case of THO, fractures of the petrosal bone can occur suddenly without any external trauma. THO is covered in a separate section. Penetration by missiles, most often bullets, is also a cause of neurotrauma in horses. Missile head injury is not be covered in this section, but a review of the subject is available elsewhere.[2]

Frontal/Parietal Trauma

Blows to the front of the head over the dome of the calvaria directly injure the cerebral cortex adjacent to the point of impact.[3] Brain injuries are most severe when the overlying bone is fractured and pushed inward or if hemorrhage occurs around or within the brain. Because of the violent distortions and movements of the cerebral hemispheres in relation to the impact, additional cortical injuries may occur diametrically opposite the point of collision (contrecoup) and caudally adjacent to the tentorium cerebelli. With the development of the secondary phase of cerebral injury and edema, the enlarging cerebral hemispheres herniate under the falx cerebri (asymmetric injury) or tentorium cerebelli, or both, to compress other parts of the brain. Horses may recover from the acute effects of calvarial fracture only to suffer recurrent seizures later. Horses that collide at speed with fixed objects are at risk for both head trauma and spinal cord injury.[4]

Impact to the Poll and Temporal Areas

When a horse flips over backward, the point of contact is either the poll or the side of the skull.[5-14] Of 34 horses with neurologic signs due to head trauma, 15 were injured by flipping over backwards.[15] Nine of these horses were younger than 1 year. The force of impact is absorbed by the poll, the zygomatic arch, or both and transmitted around the skull to the petrosal bones. Presumably because of the asymmetry of impact, only one side is usually injured. This may be either the upper or lower (i.e., impacted) side. There is hemorrhage into the middle and inner ear with or without fracture through the petrosal bone. The vestibulocochlear end organs in the inner ear are vulnerable to injury by both hemorrhage and the lacerating

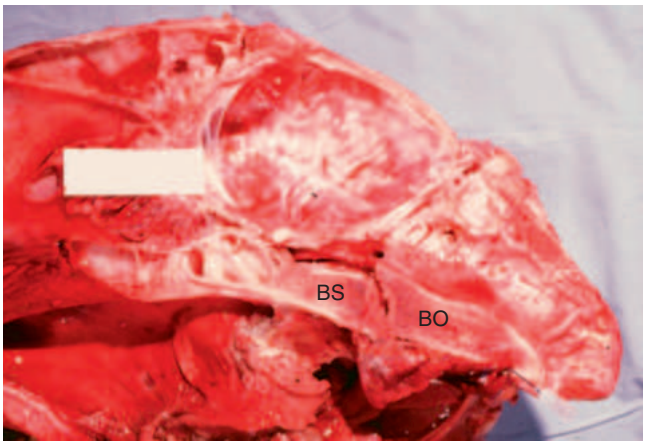

FIG. 35.9 Sagittal section of the skull of a 2-year-old colt that flipped backward during handling and suffered multiple skull fractures. Note separation/fracture in the region of the synchondrosis between the basioccipital *(BO)* and basisphenoid *(BS)* bones and hemorrhage in the region of the attachment of rectus capitis ventralis major.

effects of fracture. In the latter case, the facial nerve may be damaged as it courses through the facial canal within the petrosal bone. When the point of impact is centered on the poll, the basilar bones under the brainstem are subject to fracture and separation (Fig. 35.9). The basioccipital and basisphenoidal bones are pulled apart at their synchondrosis connection, at least in part by the strong distracting force of the rectus capitis ventralis muscles. Fragments of bone from the basisphenoid may be displaced ventrally and caudally by muscular attachments.[14] Because the synchondrosis is beneath the midbrain and flanked on each side by the foramina lacera and guttural pouches, basilar fractures are clinically serious. There may be life-threatening arterial hemorrhage between or into the guttural pouches; injury to cranial nerves IX (glossopharyngeal), X (vagus), XI (accessory), and the mandibular branch of V (trigeminal) as they pass through the foramen lacerum; direct laceration and contusion of the midbrain and adjacent parts of the brainstem; or a combination of these. Because the connection between the basilar bones ossifies and fuses by 2 to 5 years of age, this type of injury is probably more likely to occur in young horses. In the most serious cases, fracture lines extend laterally and dorsally through the squamous temporal and occipital bones or rostrally through the sphenoidal bones (see next section).

Other Cranial Nerve Injuries

The optic nerve of one or both eyes can be stretched and damaged within the optic canals by the violent to-and-fro gyrations of the brain after impact to the head[12,16] and by fractures through the optic canals. Sphenoidal bone fractures also may involve cranial nerves III (oculomotor), IV (trochlear), and VI (abducens) or the ophthalmic and maxillary branches of cranial nerve V as they pass to the orbital foramen and foramen rotundum. Injury to the facial nerve proximal to the vertical ramus of the mandible causes full facial paresis. Proximal facial nerve trauma is usually caused by fractures of the petrosal bone, vertical ramus of the mandible, or stylohyoid bone or by fracture of the paracondylar process related to pulling back in a tied horse.[17] Distal facial nerve damage is usually due to direct injury from a blow, lateral recumbency, or strangulation by a tight-fitting halter. Cattle whose heads are clamped in the head-catch on stanchions may present with "stanchion head" or ptosis and drooping ears caused by bilateral neurapraxia of the auriculopalpebral branches of the facial nerves. The nerve or its branches are often damaged as they cross the mandible or zygomatic arch. Facial paresis after recumbency during general anesthesia is common and usually involves only the nose, lips, or both. When a horse pitches headfirst into the ground while traveling at speed, it is possible for components of a fractured atlas to be driven rostrally around the occipital condyles, where they may traumatize cranial nerve XII (hypoglossal) as it exits the hypoglossal foramen.

Skull fractures occur in cattle from blows to the top of the calvaria.[18] Most skull fractures are located in the center of the frontal bones, where the internal and external plates of the frontal sinus are fused into a single-layer dorsal wall of the cranial vault. This position can be located on the skull as the imaginary cross formed by intersecting lines drawn between the medial canthus of the eye and the horn of the opposite side. Injuries in this area compress the frontal and parietal lobes of the cerebral cortex. The pressure changes result in loss of sensorium, sensory deficits, blindness contralaterally, or convulsions.

In young goats and horned sheep younger than 4 to 6 months of age, the calvaria can be inadvertently opened by removal of excessive bone during disbudding or dehorning. In goats, cerebrocortical burns can occur from overapplication of a hot iron or caustic dehorning paste. Cortical necrosis caused by bacterial infections after dehorning of calves has also been described.

Clinical Signs

Epistaxis is common after a blow to the head of severity sufficient to cause neurologic signs.[5,9] After frontal/parietal or poll trauma, blood may flow from either or both nostrils and is typically dark (venous) and of low to moderate volume. With poll trauma, epistaxis may be bilateral, copious, and occasionally bright red, and may also issue from the mouth.[14] In such cases, the hemorrhage is from one (usually) or both guttural pouches and originates from adjacent veins or arteries.[19] If the tympanum is perforated, blood may flow in addition from the external ear. Profuse hemorrhage into the retropharyngeal area may cause obvious swelling behind the vertical ramus of the mandible and inspiratory dyspnea, which can be life-threatening. Respiratory distress may also be associated with a poorly understood syndrome of noncardiogenic pulmonary edema that is reported to occur after serious head injury. Head trauma in humans is often complicated by systemic arterial hypotension. The cause is not completely understood but may be explained in part by *brain–heart syndrome*, in which myocardial damage is inflicted by the reflex actions of sympathetic nerves.

Immediately after impact to the frontal/parietal area, there is often a period of apparent concussion that may last minutes to hours. The most severely affected animals transiently lose all reflexes and are sometimes thought to be dead. Even after recovery of consciousness, such horses are typically obtunded for up to several hours. Altered behavior (i.e., dementia) is another characteristic of forebrain injury: A suckling foal may lose affinity for its dam; the horse may fail to respond to training cues; and the horse may exhibit yawning, head pressing, compulsive walking (often in circles around the inside of an enclosure, usually toward the side of the injury), or, in rare cases, hyperexcitability or aggression. Because of damage to the visual centers in the occipital cortex, vision and the *menace response* may be impaired in the eye contralateral to the lesion; however, pupillary light reflexes are usually intact. Injury to the somesthetic centers of the parietal cortex interferes with awareness of (and thus response to) touch on the opposite side of the head in a manner analogous to the way in which trauma can cause cortical blindness and an abnormal menace response. This perception of touch is best evaluated by comparing the horse's reactions to tapping the nasal septal mucosa on either side. Seizures, which occurred in 7 of 34 cases of head trauma in one equine series,[15] are likely to be generalized, with loss

VetBooks.ir

of consciousness and uncontrolled autonomic activity (e.g., salivation, urination, defecation, pupillary dilatation, chewing movements) and abnormal motor function (e.g., muscular rigidity, followed by running and paddling movements of the limbs). In comatose horses with cerebral injury, the breathing pattern may be irregular, with periods of either Cheyne-Stokes breathing or hyperventilation.

Midbrain injury is a relatively uncommon but serious complication of head trauma of any type. It may occur immediately after the injury or be secondary to subtentorial herniation of forebrain components, rostral herniation of the cerebellum, or intraparenchymal bleeding. Because of involvement of the ascending reticular activating system, affected horses are usually obtunded and may be comatose. Weakness of limbs is observed bilaterally or on the side opposite an asymmetric midbrain lesion. In recumbent horses with severe midbrain injury, the neck, back, and limbs may be rigidly extended in a decorticate posture. If the nucleus of cranial nerve III (oculomotor) is involved, the horse exhibits strabismus and a dilated, unresponsive pupil. With severe diffuse injury, bilateral pupillary miosis may occur initially, followed by gradual progression to fixed, dilated pupils. Vision is normal unless there is involvement of other parts of the brain.

Vestibular dysfunction is common in horses after poll trauma or THO. Clinical signs may arise because of injury centrally or, more commonly, because of involvement of the vestibular apparatus or vestibulocochlear nerve (cranial nerve VIII). Peripheral vestibular disease is characterized by head tilt, neck turn, body lean, and staggering in tight incomplete circles, all toward the side of the lesion. These signs can be revealed or exacerbated by blindfolding. With acute severe vestibular dysfunction secondary to THO, recumbency may occur suddenly, with flailing and thrashing movements. These signs of vestibular disease can easily be mistaken for seizures. The ipsilateral eye is usually rotated ventrally and laterally, especially when the horse's nose is elevated, and horizontal or rotatory nystagmus may occur, with the fast phase away from the side of the lesion. Facial paralysis is attributable to damage to cranial nerve VII as it passes close to the middle/inner ear. With central vestibular disease, signs are similar to those observed when the injury is peripheral; however, additional signs suggestive of brainstem damage may also be present, including spontaneous vertical nystagmus, signs of other cranial nerve dysfunctions, obtundation, and limb ataxia and weakness. In horses, central lesions quite commonly result in a *paradoxical vestibular syndrome* in which the lesion (usually in the caudal cerebellar peduncle or the flocculonodular lobe of the cerebellum) is located on the side opposite that expected from the clinical signs. An important clue to the presence of this syndrome is the finding of other signs of cranial nerve dysfunction (e.g., facial paralysis) on the side opposite the direction of circling.

In horses with traumatic damage to the pons and medulla of the hindbrain, there is evidence of dysfunction of multiple cranial nerves in association with obtundation and limb ataxia/weakness. An affected horse may exhibit reduced jaw tone or deviation of the jaw (cranial nerveV [motor]), reduced facial sensation (V [sensory]), facial paralysis (VII), vestibular signs (VIII), dysphagia and respiratory stridor (IX and X), or tongue paralysis (XII). The gait may appear hypometric (spastic), like that in horses with compression of the cervical spinal cord. With severe hindbrain lesions, rapid deep breathing or other abnormal respiratory patterns can be observed.

Signs of cerebellar injury are rare and are usually a result of poll trauma. Coarse head tremors are the most consistent sign; these are especially obvious during attempts to eat or suckle (intention tremor). Horses with cerebellar injury typically have a broad-based swaying stance, and limb movements may be hypermetric or spastic, clumsy, faltering, and jerky. Infrequent signs of cerebellar trauma include absence of the menace response with normal vision and paradoxical vestibular syndrome (see earlier description).

With traumatic optic neuropathy (usually after poll trauma), vision and pupillary light reflexes are impaired or absent and pupils are dilated immediately after the injury. Because the secondary phase of nerve injury continues for many hours after the initial trauma, visual function may progressively deteriorate during at least the first 24 hours after trauma. The signs of facial nerve injury depend on the site of damage. Evidence of complete unilateral facial paralysis includes deviation of the nose toward the normal side, reduced flaring of the ipsilateral nostril during inspiration, and ipsilateral drooping of the lip, eyelid, and ear. Reflexes involving cranial nerve VII, such as the lip, eyelid, and ear reflexes, and the menace response are reduced or absent. Inability to close the eyelid causes minimal corneal problems in a horse with normal mentation unless there is also damage to the secretomotor fibers of the facial nerve along its greater petrosal branch or proximal to the geniculate ganglion, in which case interference with lacrimation causes corneal drying (keratitis sicca). Typically, a deep horizontal corneal ulcer develops within hours of the injury. The tongue protrudes out of the paralyzed side of the mouth, which is often misinterpreted as a problem with lingual function. Buccinator (cheek) paralysis causes a form of dysphagia, evidenced by dropping of and accumulation of feed between the teeth and cheeks (quidding). The peripheral parts of other cranial nerves are infrequently damaged with head trauma. The key to distinguishing central from peripheral causes of neurologic deficits is that the former usually involve multiple cranial nerves and are accompanied by obtundation, ataxia, and weakness, which are not found with peripheral lesions.

Pathophysiology Impact to the brain causes immediate damage to intracranial vasculature, neuronal cell bodies, axons, and glia.[2,20,21] Neuronal depolarization initiated at the site of impact may spread centrifugally throughout the cortex and cause the transient coma characteristic of severe concussion. In axons, a dramatic rise in intracellular calcium concentration activates processes that cause interruption of axoplasmic flow and result over hours to days in death of the distal axon. Diffuse axonal injury is thought to account for many of the permanent neurologic sequelae of head trauma. These early events constitute *primary brain injury*. Subsequent damage occurring during the response phase is termed *secondary injury*.

The surface and parenchyma of the brain may be lacerated by fracture fragments pushed inward from the calvaria. Significant bleeding at any site compresses the brain against the skull, thereby raising intracranial pressure (ICP). Extravasated blood also elicits inflammatory responses in glial and other cells, initiating many of the autodestructive cascades that characterize the secondary phase of traumatic brain injury. Bleeding, ischemia, and mechanical damage to tissues result in liberation and production of vasoactive and other mediators.[20,22] The production and action of damaging mediators is much affected by brain temperature: Adverse effects are muted in the presence of hypothermia and are exacerbated by increased temperature.

Hemorrhage, increased permeability of damaged vasculature, and inflammatory edema all increase extravascular volume at the expense of brain volume. Exuberant swelling of the relatively mobile cerebral hemispheres may force portions under the falx cerebri (if asymmetric) or tentorium cerebelli.[20,21] In extreme cases, the pressure of subtentorial herniation in turn pushes the caudal cerebellum through the foramen magnum. The effects of reduced systemic blood pressure and increased ICP combine to choke off oxygen and glucose supply to cells and prevent removal of cellular metabolites such as lactic acid.[22] The consequent tissue hypoxia is more severe if blood oxygen

content is also reduced, as may occur after traumatic blood loss that results in anemia or hypoxemia.

In the hypoxic environment of the traumatized brain, neuronal adenosine triphosphate (ATP) is depleted rapidly, and energy-dependent homeostatic systems of membranes collapse.[22] Calcium and sodium ions flow into cells in response to changes in membrane ion channel function associated with energy depletion, damage by reactive oxygen species, and the actions of glutamate/aspartate. Brain damage that occurs during the primary traumatic event is irreversible; however, there is a window of minutes to days in which equally important secondary injuries theoretically can be prevented or treated.

Diagnosis Changes in routine hemograms and chemistry profiles are nonspecific. Collection of CSF from the atlantooccipital cistern is generally contraindicated in head trauma because of concern about inducing cerebellar herniation, but CSF can be collected via the lumbosacral space. Characteristic changes include xanthochromia, high RBC count, and high protein levels with normal nucleated cell counts.

Conventional diagnostic radiography is the best and most practical method for initial evaluation of skull trauma; on radiographs, however, the extent of bony and soft tissue abnormality is significantly underrepresented. Because the brain is not visible in plain radiographs, degrees of brain injury must be inferred from secondary changes in the skull. Fractures are visible as radiolucent lines within the calvaria; however, such lines may be characteristic of normal suture lines. A step defect is visible when the fracture fragments are misaligned. Lateral views are most useful for detecting parietal/frontal and basilar fractures and for finding bone fragments originating from the basisphenoid or nuchal crest. On dorsoventral images, a thickened stylohyoid or radiodense osseous bulla is most easily appreciated. Increased opacity of the affected bulla may reflect hemorrhage into the middle ear in association with petrosal bone injury, or it may reflect reactive thickening of the ventral bulla wall in cases of THO. Intracranial or spinal intrathecal gas shadows may be visiable if a communication exists between the subarachnoid space and the skin surface, nasal cavity, paranasal sinuses, or middle ear. Bleeding into the paranasal sinuses, guttural pouches, or retropharyngeal area may be radiographically evident. In cases of frontal/parietal impact, it is also prudent to obtain radiographs of the cervical spine so as to detect fractures/dislocations caused by the axial compressive force of the original impact.

On computed tomography (CT), characteristics of brain trauma include change in ventricular size, shape, or position; deviation of the falx cerebri (falx shift); and focal change in brain opacity.[23] Extrdural, subdural, and subarachnoid hemorrhages may each be appreciated as discrete lines between the cortical surface and skull. Administration of iodinated contrast medium intravenously causes focal enhancement of areas of brain injury or hemorrhage. CT is particularly useful for identifying fractures of the bones that surround the caudal fossa; such fractures are often not well depicted by conventional radiography.[24] They include fractures of the petrosal bone, basilar and sphenoid bones, occipital condyles, and squamous temporal bone.[16] Blood in the middle ears, paranasal sinuses, guttural pouches, or retropharyngeal tissues and changes associated with THO are also easily observed. The principal disadvantage of CT in North America, apart from high cost and limited availability of necessary equipment, is the need for general anesthesia. In Europe, and increasingly in North America, CT of the skull can be performed in standing, unanethsetized animals.

The main advantages of magnetic resonance imaging (MRI) over CT include lack of beam-hardening artifacts, ability to acquire images in any plane, and higher sensitivity for detection of early infarcts and edema. CT is more sensitive than MRI for detection of bony abnormalities, acute brain hemorrhage, and intracranial gas. The brain is not accessible to ultrasound imaging; however, the technique is sometimes useful for assessing fractures of the skull.

Clinical findings and historical information may form the sole bases for diagnosis in many cases.

Treatment Relevant treatments for brain injury can be classified in two levels according to evidence-based support for their use. All applicable level 1 treatments should be used in every case of clinically apparent brain injury, whereas level 2 treatments are less clearly indicated and can be considered optional.

LEVEL 1

Treat Other Injuries or Diseases. The normal principles of critical care medicine apply to the brain-injured patient: Establish an airway, obtain vascular access, clean and dress wounds, stanch the bleeding, sedate the horse if necessary, and move the horse to a cool, well-padded area. If necessary, a padded helmet can be used to minimize additional head trauma. A regimen of broad-spectrum antibiotics should be begun if the horse has an open wound or fracture.

Treat Hyperthermia. Hyperthermia after head trauma results from either a resetting of the hypothalamic temperature set point (fever) or excessive heat production in horses with normal set points. High brain temperature accelerates all of the destructive forces unleashed during the secondary phase of brain injury, and so it must be detected and treated vigorously. Rectal temperature should be checked frequently, and efforts at cooling should begin when the rectal temperature exceeds 38° C (101° F). In brief, ambient temperature can be reduced, the hair can be clipped, ice water or isopropyl alcohol can be repeatedly applied to and removed from the skin (including the head), and overhead or box fans can be placed close by. Antipyretic medication (e.g., flunixin meglumine, 1.1 mg/kg IV bid or sid) is particularly useful when the horse has a fever but should be tried in all cases of hyperthermia. NSAIDs have the additional advantages of analgesic and antiinflammatory action.

Prevent or Treat Hypotension. Blood pressure must be normal or close to normal to sustain adequate cerebral perfusion. The old notion that patients with head trauma should be "kept a little dry" is no longer viable. Blood pressure should be monitored frequently, and heart base–adjusted systolic blood pressure should be maintained above 110 mm Hg.[25] Blood volume should be maintained or expanded by IV infusion of isotonic (Normosol-R; Plasma-Lyte A; lactated Ringers solution) or hypertonic (hypersaline) crystalloid or colloid (plasma, hetastarch) solutions. Plasma may have additional useful effects, including antioxidant and protease-inhibiting activities. In the case of significant blood loss, cross-matched whole blood is the fluid of choice. If volume resuscitation alone is inadequate to restore normal pressure, pressor/inotropic drugs may be used (e.g., dopamine, dobutamine, norepinephrine).[25] The effects of these drugs on cerebral vascular tone, however, are difficult to predict.

Optimize Oxygen Content of Blood. Oxygen is carried in blood either bound to hemoglobin (predominantly) or as free gas. Thus it is important that both hemoglobin concentration and partial pressure of arterial oxygen (PaO_2) are at least in the normal range. Hypoxemia (arterial oxygen saturation, <94% in this setting)[25] should be treated by establishing airway patency, treating underlying pulmonary disease (e.g., head trauma–associated noncardiogenic pulmonary edema), and beginning nasal or tracheal insufflation with oxygen. Foals may be intubated and manually or mechanically ventilated. At several equine hospitals, there are hyperbaric oxygen chambers that theoretically could be used to dramatically increase blood oxygen content in horses with brain injury; however, the efficacy

VetBooks.ir

and safety of this approach have not been established. Hemoglobin concentration must be kept above at least 7 g/dL (packed cell volume of 21%) and probably above 11 g/dL. Anemia can be treated with whole blood (preferable in the case of blood loss anemia) or packed RBCs.

Ensure Adequate Pulmonary Ventilation. High P_{CO_2} has the potential to exacerbate CNS acidosis and cerebral edema. In foals, hypercapnia can be addressed by mechanical ventilation of the lungs. In all horses with head trauma, pulmonary ventilation must be optimized by ensuring a patent airway and treating lung disease. For example, acute pulmonary edema may be treated with furosemide (0.5 to 1 mg/kg IV q8h or continuous rate infusion). Ventilation-induced hypocapnia has been advocated as a way to lower ICP[26]; however, low P_{CO_2} may cause reflex cerebral vasoconstriction and probably should not be used in foals with brain injury.

Control Pain. Alleviating pain in brain-injured horses not only is humane but also may reduce ICP.[27] An NSAID (e.g., flunixin meglumine, 1.1 mg/kg IV or PO bid) or opioid (e.g., morphine, 0.1 to 0.3 mg/kg IV or IM qid) can be used for this purpose. Useful analgesic effects have also been achieved with constant-rate infusion of butorphanol or lidocaine.

Regulate Blood Glucose and Maintain Nutrition. Experimental studies have shown that at least 140% of maintenance energy is expended by animals with severe brain injury.[28] Even during the first 24 hours after injury, nutrition (enteral or parenteral) probably should be provided to anorexic horses with head trauma. Blood glucose concentration ought to be kept greater than 80 mg/dL in order to provide adequate substrate for brain cells and less than 180 mg/dL so as to prevent hyperglycemia-induced exacerbation of CNS acidosis and apoptosis of brain cells. Dextrose and regular insulin can be infused IV as needed to maintain normal blood glucose concentration.

Prevent or Treat Brain Swelling. If possible, the neck should be free of constrictive wraps and only one jugular vein should be punctured or catheterized in order to prevent obstruction of venous flow from the head. Likewise, any recumbent horse should have its head elevated at least 10 degrees in order to facilitate blood flow. If the horse is significantly depressed (i.e., at least stuporous) or has signs of worsening brain function, a hyperosmolar infusion should be given to try to reduce the extravascular volume of the brain. The solution of choice is hypertonic saline (e.g., 1232 mmol Na/L), which is given as a continuous IV infusion of 1 mL (1.2 mmol)/kg/h for 6 hours and then 0.2 mL/kg for another 12 hours. Alternatively, boluses of 2 mL/kg can be given q4h in five infusions. Further treatment with hypertonic saline should be based on reassessment of clinical signs and plasma sodium concentration (keep <150 mmol/L). Hypertonic saline has additional salutary actions, including plasma volume expansion, antiinflammatory effect, and reduction of microvascular permeability. Mannitol (20% solution) can also be used for this purpose as a series of bolus infusions of 0.25 to 1 g/kg q4-6h. Craniectomy is not used yet for this purpose in horses, although the necessary surgical approaches have been described.[29]

Treat Seizures. There is no justification for prophylactic anticonvulsant medication. Seizures should, however, be treated vigorously when they occur. They may be treated with diazepam, phenobarbital or pentobarbital. Once a horse has a seizure for the first time, anticonvulsant medication (usually phenobarbital) should be continued for at least a week. If delirious thrashing or recurrent seizures remain a problem, the horse can be immobilized by continuous infusion of propofol or pentobarbital for up to 24 hours.

Perform Emergency Skull Surgery. After the patient is initially stabilized and general anesthesia induced, techniques described in standard texts may be used to carefully elevate and reduce depressed fractures of the frontal/parietal area that impinge on the cerebral cortex.[30-32] No surgical approach to basilar fractures has been described for the horse; such an approach would be extremely difficult and risky.

LEVEL 2. Such treatments are supported by either strong anecdotal data from equine practice or convincing experimental data in other species. However, they do not meet the standard of evidence-based medicine.

Treat With Antioxidants. Oxidant damage is known to be an important part of the secondary phase of brain injury, but clinical evidence supporting the therapeutic use of antioxidants is scant. DMSO is widely used by equine practitioners for treatment of CNS trauma and other disorders. The potential advantages of this drug's antioxidant and diuretic actions are obvious; however, there is virtually no evidence of effectiveness in the setting of brain injury. Common use suggests a protocol of 1 g/kg as a 10% solution in isotonic solution, given IV or by nasogastric tube q12h. Vitamin E (α-tocopherol; 50 IU/kg PO daily), vitamin C (ascorbic acid, 20 mg/kg PO daily), mannitol (see earlier), and allopurinol (5 mg/kg PO q12h) are all antioxidant therapies that can be used in the horse and can be rationalized as part of the overall approach to brain trauma.

Give Conventional Doses of Corticosteroids. High-dose steroids are harmful to humans with brain trauma[33] and should not be used in horses. Traditional antiinflammatory doses of dexamethasone (0.05 to 0.1 mg/kg IV or 0.1 to 0.2 mg/kg PO q12-24h) or prednisolone (1 to 4 mg/kg PO bid) probably inhibit production and action of injurious mediators in the brain and may be of some value.

Give Magnesium Sulfate. Magnesium sulfate has the potential to inhibit several aspects of the secondary injury cascade, including glutamate release, activity of the *N*-methyl-D-aspartate and calcium channels, and lipid peroxidation.[34] In view of these findings and its demonstrated safety in horses, it seems reasonable to give a single 50-mg/kg IV infusion of $MgSO_4$. This dose (25 g in a 500-kg horse) can be conveniently administered with the first 5 to 10 L of IV fluids.

Prognosis In one series, horses that had basilar fractures were 7.5 times more likely to die than were those that did not have such fractures.[15] Nevertheless, one horse with a basilar fracture returned to racing, and of 34 horses with basilar fractures, 21 survived to discharge. Most surviving horses recover completely, although residual vestibular and facial nerve signs sometimes remain.

Facial nerve dysfunction due to neurapraxia usually resolves over days to weeks. If morbid axonal injury (axonotmesis) has occurred, the facial nerve may regrow via axonal sprouting along existing nerve sheaths. Regrowth of nerves occurs at a rate of approximately 1 cm per week, and reinnervation may continue for at least a year.

Traumatic Optic Nerve Blindness of Horses

Robert J. MacKay

Severe blunt trauma to the skull in horses may result in a rapid caudal displacement of the brain and avulsion or stretching of the peripheral optic nerves within the bony optic canals. Typical settings for such injuries are blows to the poll from flipping over backward and trauma to the frontal-parietal area from running into stationary objects such as posts or trees. The clinical signs include sudden blindness, loss of pupillary reflexes, and pupillary dilation. Ophthalmoscopic changes in the retina occur after 2 to 4 weeks and include pallor of the optic disk, reduction in the number and caliber of the retinal vessels, and linear peripapillary pigment disruptions (Fig. 35.10). The condition can be partial or complete, asymmetric or symmetric, and generally does not respond to treatment.[1-3] Because

VetBooks.ir

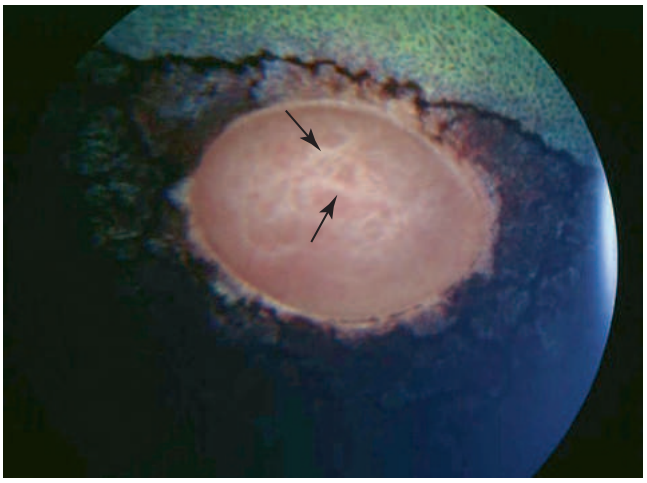

FIG. 35.10 Fundus of 4-month-old Thoroughbred colt that was blind as a result of severe bilateral nerve injury that occurred as a result of poll trauma 2 months earlier. Note absence of fundic blood vessels and exposure of the lattice-like lamina cribrosa *(arrows)*, which indicates demyelination.

traumatic optic nerve injury probably progresses for many hours after the initial injury, robust antiinflammatory treatment during the first 3 days after injury is a rational action. Treatment should include an NSAID such as flunixin meglumine at a dosage of 1.1 mg/kg IV or PO q12-24h and a corticosteroid such as dexamethasone, 0.05 to 1 mg/kg IV or IM sid or bid. The iron chelator deferroxamine has been described as treatment for traumatic optic neuropathy.[3]

Thiamine Deficiency of Horses

Mary O. Smith

Horses may develop thiamine deficiency when fed diets that contain thiaminases. Potential sources of thiaminases are bracken fern *(Pteridium aquilinum)*, horsetails *(Equisetum arvense)*, and toxic doses of amprolium (e.g., 400 to 800 mg/kg/day). The clinical signs of thiamine deficiency are ataxia, conscious proprioceptive deficits, heart block, bradycardia, blindness, weight loss, dysuria, hypothermia of the extremities, and periodic muscular fasciculations. In affected horses, convulsions are a terminal development. Electrolyte changes include hyperkalemia, hyperphosphatemia, hyperglycemia, and decreased glucose tolerance. Parenteral thiamine is an effective treatment.[1,2]

Equine Leukoencephalomalacia

Robert J. MacKay

Equine leukoencephalomalacia (ELEM) is a fatal CNS intoxication of horses caused by ingestion of fumonisin toxins on corn or corn by-products.[1-3] Fumonisin toxins (B_1, B_2, and B_3), produced by the fungi *Fusarium verticillioides* and *Fusarium proliferatum* (previously known together as *Fusarium moniliforme*), interfere with sphingolipid metabolism, disrupting endothelial cell walls and basement membranes.[4] Although all three are toxic, B_1 is the most common and most thoroughly studied. See Chapter 54 for more details.

Clinical Signs The onset of ELEM is usually sudden. In previously healthy animals, the first indication may be death, but most affected horses show abnormal neurologic signs for hours to days before death.[5,6] These include obtundation to the point of stupor and dementia manifested as compulsive walking in large circles, head pressing, and hyperesthesia. Blindness and lack of menace response, as well as reduced reaction to touch around the face, may be present. Movements of the muzzle, lips, and tongue may be weak and ineffectual. Signs are typically asymmetric. Muscle fasciculations occur over the neck and withers and in antigravity muscles, and limb ataxia and weakness are prominent in the terminal phase. Seizures are common after affected horses become recumbent, and many affected horses die while convulsing. The few horses that survive ELEM usually have permanent neurologic dysfunction. Hepatic involvement occurs in many cases, as evidenced by high serum levels of liver enzymes, although hepatic failure is uncommon.[4,7] Signs of liver disease include icterus, petechiation on mucous membranes, and swelling of the muzzle or lips. Fatal outbreaks of liver disease without brain involvement have been reported.[4] Cardiovascular abnormalities are also described in horses with experimental ELEM and include decreases in cardiac contractility, heart rate, and arterial pulse pressure and increases in systemic vascular resistance.[8]

Fumonisin toxins cause a variety of clinical syndromes in other species, including pulmonary edema in swine, but horses appear to be the most susceptible domestic animal species and can show signs when exposed to toxin concentrations as low as 5 to 10 ppm.[4] Regulatory guidance issued by the U.S. Food and Drug Administration calls for fumonisin (B_1, B_2, and B_3) concentrations of no more than 5 ppm in horse feeds.

Clinical Pathology and Diagnosis No findings on routine bloodwork are unique to ELEM. Serum levels of liver enzymes (i.e., aspartate transaminase, γ-glutamyltransferase, and sorbitol dehydrogenase) and bilirubin are often high. Anemia, leukocytosis, and leukopenia all have been reported, but none is a consistent finding. Markedly high protein concentration (i.e., >100 mg/dL) with normal nucleated cell count is a typical CSF finding in affected horses.[9] High serum sphinganine level, sphingosine level, and sphinganine-to-sphingosine ratio suggest acute fumonisin toxicosis,[8] but the assays for these substances are available only at research laboratories. In practice, antemortem diagnosis relies on recognition and demonstration of fumonisin (B_1, B_2, and B_3) concentrations greater than 10 ppm in feed. Fumonisin assays are widely available through diagnostic laboratories, and turnaround should be rapid.

Differential diagnoses include traumatic brain injury, the arboviral encephalitides, hepatic encephalopathy, EPM, and botulism.

Epidemiology Leukoencephalomalacia occurs worldwide. Corn becomes contaminated during growth rather than in storage, and climatic factors that stress the plants, such as drought followed by high rainfall, increase the likelihood of mold development. The fungus is introduced into the growing corn by insects such as the western flower thrip, which enters the ear and damages the kernel as it feeds.[10] Cereal grains and baled hay similarly may be contaminated.[11] Most cases of related equine disease occur during the winter and early spring.[1] Repeated exposure to the toxin, rather than a single large dose, seems to be associated with the development of clinical signs.[12] Experimental studies with infected corn demonstrated an onset of clinical signs on the ninth day after the beginning of the feeding period, but the reported delay between exposure and signs in outbreaks has ranged between 4 and 180 days. Older animals develop clinical signs of ELEM more rapidly than do younger animals and thus appear to be more susceptible to the effects of the mycotoxin.

The rates of disease in exposed horses vary widely, from 14% to 100% in some reports; the rate of lethality is close to 100%.

Pathology The major pathologic features in the CNS result from the vascular damage caused by fumonisin toxins,

VetBooks.ir

including liquefactive necrosis and degeneration or malacia of the white matter of one or both cerebral hemispheres.[5,13] The lesions may vary from grossly inapparent in peracute cases to complete subcortical cerebral necrosis. Flattening of the cortical gyri, enlargement of the cerebral cortex, vascular congestion, cortical softening, yellowish discoloration of the white matter, hemorrhage, and cavitation of the cerebral cortex may be present.[1] A gelatinous fluid can be observed in many of the cavitary lesions. Hemorrhage in the CNS has also been reported. Lesions in the visceral organs, including hepatic congestion, centrilobular hepatic necrosis, hemorrhagic enteritis, and cystitis, are found in some affected horses. The relationship between these lesions in the CNS and those in the liver, urinary bladder, and GI tract is unknown.

Treatment Specific treatment is not available, and early euthanasia is usually the most humane option. Because of cerebral edema, it is rational to administer IV antiedema drugs, including corticosteroids (e.g., dexamethasone 0.1 mg/kg daily), DMSO (1 g/kg as a 10% solution), hypertonic saline (4 mL/kg of 7.2% NaCl every 4 hours), or mannitol (1 g/kg as a 20% solution). Nonsteroidal antiinflammatory drugs (e.g., flunixin meglumine 1.1 mg/kg PO or IV bid), once or twice daily antioxidants (DMSO, α-tocopherol, 20 IU/kg PO), ascorbic acid (25 mg/kg in IV fluids), and thiamine (5 mg/kg, slowly IV) can all be tried to limit secondary brain injury, but none of these treatments is likely to be effective.

Intracarotid Drug Injection

Robert J. MacKay • Mary O. Smith

Intracarotid drug injection is common in horses because the jugular vein and the common carotid artery are closely apposed in the caudal third of the neck. The condition is rare in cattle because the omohyoid muscle lies between the carotid artery and the jugular vein in the posterior part of the neck.[1] Hypertonic or caustic drugs (including phenothiazine tranquilizers, chloramphenicol, chloral hydrate, barbiturate anesthetics, phenylbutazone, calcium gluconate, and sodium iodide) cause cortical necrosis when injected into the carotid artery.[2-5]

The common carotid artery provides blood supply to the circle of Willis via the internal carotid artery and thence to the thalamus and rostral and middle cerebrum. The internal carotid artery also provides arterial supply to the eyeball via the ophthalmic artery. In contrast, the blood supply to the caudal cerebrum, midbrain, pons, medulla, cerebellum, and inner ear is via the vertebrobasilar arteries and originates in the vertebral branches of the subclavian arteries. Thus the carotid artery injectate travels principally to the ipsilateral thalamus, cerebrum, and eye but relatively spares the rest of the brain. The effect of the arrival in the forebrain of a bolus of irritant material is akin to a cerebral stroke of variable severity. Intense vasospasm occurs, as does physical endothelial damage with endothelial swelling, increased vascular permeability, mural necrosis, hemorrhage, intercellular edema, and thrombosis. As a result of ischemia, glucose, oxygen, and energy starvation occur, progressing to calcium ion influx, anaerobic metabolism, and eventually loss of function and accumulation of excitotoxic amino acids, free radicals, and eicosanoids. At necropsy, ipsilateral brain swelling and hemorrhage are grossly evident.

When the drug is injected into the carotid artery, the animal recoils backward and falls over. Some horses strike or rear violently or run wildly, often in circles toward the injected side, without regard to obstacles. After falling, many horses convulse violently, whereas others become comatose without showing excessive motor activity. Some severely affected animals die after a variable period, but others regain their footing and recover completely. Milder and residual neurologic signs include contralateral (thalamic) or ipsilateral (retinal) blindness (or both), contralateral facial hypalgesia, circling (toward the side of the injection), and contralateral conscious proprioceptive deficit.

If it can be done safely, convulsing horses should be given IV anticonvulsant medications (diazepam, 0.1 to 0.4 mg/kg; pentobarbital, 2 to 10 mg/kg; or xylazine, 0.2 to 1.1 mg/kg), which can be repeated as needed to control seizures. If possible, horses should be placed in a padded stall and treated with antiinflammatories, including dexamethasone (0.05 to 1 mg/kg IV or IM sid), flunixin (1.1 mg/kg PO or IV bid) or equivalent, and DMSO (1 g/kg IV as a 10% solution bid). The use of hypertonic antiedema drugs in this setting is controversial because of the possibility of active bleeding in the CNS and loss of the blood-brain barrier.

Intracarotid injection of drugs is best prevented by the use of large-bore needles or catheters for intravenous injections. In the horse, venipunctures should be performed in the anterior one third of the jugular furrow because the artery and vein are separated by the omohyoid muscle in this area. The inexperienced phlebotomist may prefer to place the needle into the vessel without a syringe attached to confirm that the blood is dark and drips from the hub, which indicates proper placement into the jugular vein. Conversely, intracarotid placement of the needle results in forceful, often pulsatile ejection of bright red arterial blood from the hub.

Brain Tumors

Mary O. Smith • Lisle W. George

Nervous system tumors of ruminants include medulloblastoma, ependymoblastoma, neurofibrosarcoma, angioblastoma, meningioma, meningeal hemangioma, neurofibroma, schwannoma, choroid plexus papilloma, pituitary adenocarcinoma, primitive neurectodermal tumor, and reticulosis.[1-5] CNS tumors of horses include pituitary adenomas, microgliomas, medulloepithelioma, choroid plexus papilloma, ependymoma, neurofibroma, meningioma, meningeal carcinoma, and reticulosis.[1,6-10] Secondary tumors that invade the CNS include melanoma, lymphosarcoma, adenocarcinoma, squamous cell carcinoma, hemangiosarcoma, and osteoma.[1,10-15] Of these, lymphosarcoma is most common.[16,17] Metastatic invasion to the CNS occurs either by vascular routes or by extension along the peripheral nerve rootlets.[18] Local extension from adjacent tissue, such as the paranasal sinuses, can also occur.[11]

Clinical signs of brain tumors vary with the location and include abnormalities of gait (ataxia, paresis, hypometria/hypermetria); seizures; altered mentation (especially dullness); facial paresis or paralysis; facial anesthesia or analgesia; dysphagia; head tilt; strabismus; nystagmus; and loss of the menace reflex.[11,18-20] Migration of facial tumors (squamous cell carcinomas) into the cranial vault through the cranial nerve foramina may also result in facial swelling, exophthalmos, Horner syndrome, or asymmetric airflow through the nares.[17] Pituitary adenomas of aged horses (see Chapter 41) rarely cause neurologic disease, but they secrete melanocyte-stimulating hormone, which stimulates the adrenal cortex and causes Cushing disease. Some tumors are discovered incidentally at necropsy.

Antemortem diagnostic tests include radiographs of the skull (for tumors that spread locally and some metastatic tumors), and electroencephalography to elucidate brain dysfunction.[11] Where available, CT or MRI can greatly facilitate diagnosis, but limited availability and considerations of cost restrict their use in most cases.[18,20-22]

Treatment of brain tumors in horses and livestock is generally not feasible because of limitations of cost, nursing care challenges after craniotomy, lack of access to radiation therapy for large animals, and considerations of safety for personnel who

handle animals with significant neurologic deficits. Palliative treatment such as corticosteroids may reduce clinical signs temporarily in some animals. Euthanasia is the choice for most large animals with brain tumors.

Cholinesteric Granuloma Encephalopathy

Robert J. MacKay • Mary O. Smith

Cholinesteric granulomas (CGs) develop in association with the choroid plexuses of the fourth ventricles and lateral ventricles. Up to 20% of older horses have CGs in one or both lateral ventricles, usually without adverse effect.[1] CGs are thought to develop as a chronic inflammatory reaction to cholesterol released from extravasated degenerating RBCs within the choroid plexus. Syndromes of neurologic dysfunction in association with CGs have been described in horses aged 7 to 23 years.[2-5] The onset of signs is ascribed to combinations of attenuation and edema of cerebral tissue overlying a large CG, hydrocephalus secondary to obstruction by a CG of CSF efflux from the lateral ventricle through the foramen of Monro, and ependymitis/meningitis in response to proinflammatory substances released from CG.[2-5] Some affected horses have a history of months to years of intermittent neurologic episodes, presumably related to waxing and waning hydrocephalus, intermittent inflammation, or both.

Signs can develop insidiously or appear suddenly and are usually referable to forebrain dysfunction.[2,4] Affected horses may exhibit dementia, manifested as irritability, aggression, yawning, head pressing, compulsive walking, drifting to one side when walking, circling, abnormal body posture, loss of learned skills, syncope-like attacks, seizures, blindness and lack of menace response with normal pupillary light reflexes, and reduced response to tactile stimulation of the face.[2-5] With presumed CG-associated cerebral edema, signs suggestive of brainstem compression also have been described, including stupor, limb weakness and ataxia, anisocoria, head tilt, stiffness in gait, and facial paresis. Signs are typically asymmetric or unilateral, reflecting asymmetric involvement of the lateral ventricles.

CG should be suspected in any mature horse showing signs referable to waxing and waning forebrain dysfunction. Results of CSF analysis may be normal, may show high protein concentration with normal cell count, or may show mild pleocytosis notable for the presence of nondegenerate neutrophils. The diagnosis is strongly supported by advanced imaging. CT in the standing[5] or anesthetized horse[2,3] is the diagnostic method of choice, but MRI has also been used.[4] The finding on CT of heterodense, hyperattenuating, poorly contrast-enhancing masses in the lateral ventricles is tantamount to the diagnosis of CG. A technique for CG biopsy has been described and can be used to exclude the possibility of other choroid plexus tumors, including papillomas and ependymomas.[3] At necropsy of clinically affected horses, CGs are found as brownish ellipsoid masses at least 3 cm in diameter attached to the choroid plexuses of one or both lateral ventricles. Histologically, these masses contain abundant cholesterol crystals interspersed with empty clefts, hemosiderin, and heavy infiltrations of macrophages and giant cells.

Traditionally, CGs in horses have been considered terminal and untreatable. It is clear, however, that all of the components of the pathophysiology of CG encephalopathy—namely, enlarging granulomas, hydrocephalus, and ependymal inflammation—are potentially treatable with antiinflammatory drugs. In horses with CG encephalopathy, antiinflammatory drugs, including dexamethasone, prednisolone, and phenylbutazone, have induced clinical remissions lasting from months to indefinitely. A reasonable treatment protocol includes seizure control as needed and induction of remission from clinical signs with dexamethasone (0.05 mg/kg IV or 0.1 mg/kg PO, once daily for 7 to 14 days), followed, if successful, by prednisolone (1 mg/kg PO bid), to be given indefinitely except for intermittent trials designed to test the effect of tapering the dose. Hyperosmolar IV solutions (mannitol, 0.5 to 2.0 g/kg as a 20% solution; 7.2% saline, 2 to 4 mL/kg) can be given in the acute phase to address cerebral edema and repeated as needed every 4 to 6 hours for the first 24 hours. More aggressive interventions, including direct drainage of CSF from enlarged lateral ventricles and surgical removal of CG by techniques adapted from human brain surgery, are also possible but have not been described. The prognosis for short- to medium-term (i.e., up to a year) maintenance of remission from clinical signs of CG encephalopathy is considered fair.

Epilepsy

Robert J. MacKay

According to guidelines put forth in 2015 by the International Veterinary Epilepsy Task Force, epilepsy is defined as a *disease of the brain* characterized by a persistent predisposition to generate epileptic seizures.[1] In practice, this usually means at least two unprovoked epileptic seizures more than 30 days apart. A systemic condition or chemical/drug may cause a normal brain to generate *reactive* seizures; however, these are not classified as epilepsy. Epilepsy may be idiopathic or structural. *Idiopathic* epilepsy connotes either genetic predisposition (known or suspected) or epilepsy of unknown cause in which there is no indication of a structural cause. Genetic epilepsies are rare in large animals, but a few heritable epilepsy syndromes have been described in horses, such as juvenile idiopathic epilepsy of Arabian foals of Egyptian lineage,[2] Arabian lavender foal syndrome,[3] and suspected familial epilepsy in cattle of various breeds.[4,5] *Structural* epilepsy occurs as a result of known or suspected intracranial/cerebral disorders, including vascular, inflammatory/infectious, traumatic, anomalous/developmental, neoplastic, or degenerative diseases. Polioencephalomalacia is the most commonly reported diagnosis in ruminants with seizures caused by structural brain disease: In one report, 14 of 19 sheep and goats and 8 of 13 cattle with structural-origin seizures had polioencephalomalacia.[6,7] In 42 horses older than 3 weeks with structural-origin seizures, the causes listed were skull fractures, cerebral hemorrhage, cerebral edema, neoplasia, cholesterinic granuloma, vasculitis, meningoencephalitis, abscesses, intracranial vascular events, leukoencephalomalacia, congenital abnormalities, and EPM.[8]

Epileptic seizures result from abnormal, synchronous, electrical discharges in the neurons of the forebrain that spread to the somatic and visceral motor areas to initiate spontaneous, paroxysmal, involuntary movements that may begin and end spontaneously.[1] Each seizure (ictus) may be *generalized*, involving neural networks of both cerebral hemispheres and resulting in generalized bilateral motor activity over the whole body, or *focal*, involving one side of the forebrain and lateralized motor signs or sensations. Generalized seizures usually begin with tonic muscle contractions of the muscles of the neck and limbs but progress to rhythmic clonic limb thrashing, often accompanied by abnormal eye positions and movements. Affected animals often fall and display various autonomic signs, such as salivation, urination, and defecation. The oroalimentary form of generalized seizures occurs particularly in neonatal foals and is characterized by lip smacking, lip pursing, chewing, licking, odontoprisis, or swallowing.[1] Focal seizures begin as involuntary tonic or clonic contractions of groups of facial, jaw, or body muscles. These signs may stop spontaneously without progression, but more typically they spread from the initial focus to involve the whole body. In rare cases, seizures may be preceded by a prodrome of up to several hours' duration,

VetBooks.ir

usually characterized by signs of restlessness or disorientation, and are usually followed by a period of stupor, restlessness, and central blindness that is usually short-lived but can last several days in foals.

In large animals, the best characterized genetic epilepsy syndrome is *juvenile idiopathic epilepsy* in Arabian horses of Egyptian lineage.[2] Seizures usually begin in affected foals by 2 months of age (range, 2 days to 6 months), but onset as late as 18 months has been described. Seizures are usually symmetric and generalized, often with no prodrome. After a brief period of whole-body myotonus and collapse into lateral recumbency, the animal exhibits clonic ("galloping") limb movements, opisthotonos, sweating, retracted lips, and staring, unblinking eyes. Each seizure can last up to 5 minutes but typically is less than a minute. Postictal signs are usually profound and persistent and are often the first abnormality detected by the owner: obtundation, cortical blindness, loss of maternal bond and interest in suckling, and other variable behavioral signs. Blindness, the last sign to resolve, typically lasts several days (range, hours to 2 weeks). Injuries, especially to the skull, may occur during seizures or as a result of collisions during the period of blindness. Juvenile idiopathic epilepsy responds well to anticonvulsant therapy and does not usually recur (see Treatment section). Untreated foals also may grow out of the condition by a year of age but are subject to cumulative seizure-associated injury, and there are anecdotal reports of permanent behavioral abnormalities in untreated horses.

A diagnosis of epilepsy is supported by the finding of epileptiform discharges on interictal EEG, although this test does not appear to be highly sensitive.[9] Epileptiform discharges were identified on EEG of only 9 of 13 foals with juvenile idiopathic epilepsy.[2] Artifacts induced by patient movement or sedative drugs limit the usefulness of traditional electroencephalography in large animals. Ambulatory electroencephalographic recording, as is routinely used in human neurology, may be a more sensitive and reliable method for investigating suspected seizures in large animal patients.[9]

Specific protocols for antiepileptic drugs have not been established for most large animal species. However, most seizures are controlled in the acute phase with diazepam (0.05 to 0.2 mg/kg IV) and over the long term with oral or IV phenobarbital. A simple approach to treatment of epileptic horses has been described and can be followed in other species[10]: oral phenobarbital, 5 mg/kg twice daily, begun without a loading dose. Treatment at this dosage is continued for at least 2 weeks. If signs are insufficiently controlled, the dosage is increased by 1 mg/kg and continued for another 2 weeks. This cycle of incremental dosage increase is continued until adequate control is achieved or side effects prevent further increase. Potassium bromide (90 mg/kg once daily PO, which may be preceded by an optional loading course of 120 mg/kg/day for 1 week) can be added to phenobarbital in these cases to provide additional anticonvulsant effect.

The therapeutic trough concentration of phenobarbital is 15 to 40 µg/mL. After 6 months of seizure-free therapy, the dosage of phenobarbital can be tapered over several weeks. If the horse remains free of seizures for 6 months after anticonvulsants have been discontinued, the horse is considered by some authorities to be no longer epileptic; however, it is prudent to continue to advise owners that such horses should never be ridden or used for sporting purposes. Foals with juvenile idiopathic epilepsy are usually treated for 3 months with phenobarbital, which is then tapered. Basic pharmacokinetic studies have been used to rationalize antiepileptic dosages of phenytoin (10 to 15 mg/kg PO once daily) and levetiracetam (32 mg/kg), although these drugs have not been field tested for efficacy.[11] All ruminants experiencing seizures should also immediately be treated with thiamine (10 to 20 mg/kg IV, IM, or subcutaneously [SC]).

Narcolepsy-Cataplexy

Robert J. MacKay

Definition and Etiology Narcolepsy is a spectrum of CNS disorders characterized by episodes of excessive sleepiness or muscular weakness, or both, and REM-onset sleep. The disorder actually comprises two separate pathologic phenomena: *narcolepsy*, a tendency for abrupt transitions from wakefulness into non-REM sleep, and *cataplexy*, the pathologic intrusion of REM sleep into wakefulness or at the onset of sleep.[1] Attacks of narcolepsy and cataplexy are considered a paradoxic form of sleep because the EEG is characteristic of an alert, awake animal, but the REM is characteristic of deep sleep.

Sleep–wakefulness regulation is normally achieved through reciprocal interplay of consciousness-arousing and consciousness-depressing regions of the brain.[1] Included in the arousal system are cholinergic and monoaminergic (histaminergic, serotonergic, dopaminergic, and noradrenergic) neurons located in the caudal hypothalamus/brainstem regions that diffusely project to the forebrain to upregulate cortical function. Conversely, gamma-aminobutyric acid (GABA)–ergic neurons of the rostral hypothalamus play a critical role in sleep by inhibiting neurons of the arousal system. Two closely related neuropeptides, *orexins A* and *B* (also known as *hypocretins 1* and *2*), produced exclusively by neurons in the lateral hypothalamus, are neurotransmitters critically involved in the neuronal circuitry regulating sleep and wakefulness states. Via numerous afferent connections, orexin-positive neurons sense the body's external and internal environments and regulate wakefulness accordingly, mostly by stimulating consciousness-arousing monoaminergic neurons. Multiple lines of evidence suggest that sporadic narcolepsy in humans is caused by a dysfunctional orexin system, usually as a result of degeneration of orexin neurons. Some familial cases are associated with nonfunctional orexin receptors. With removal of orexin neuronal function, monoaminergic and GABA-ergic neurons set up a poorly regulated mutually inhibitory circuit, which results in unwanted and abrupt transitions between wakefulness and sleep recognizable clinically as narcolepsy and cataplexy.[1]

Narcolepsy has been reported in numerous horse and pony breeds, a Suffolk lamb, Spanish fighting bulls, a Guernsey bull, and a Brahman bull.[2-11] Most cases appear to be sporadic, but early-onset, probably familial occurrence has been reported in American Miniature Horse, Lipizzaner, Suffolk, Shetland pony, and Fell pony foals[2,12] and has been observed by the author in a family of Morgan horses. The collapse syndrome associated with squeezing neonatal foals traditionally has been viewed as a transient form of cataplexy; however, one study demonstrated that the associated EEG patterns were slow waves consistent with abrupt transition to non-REM sleep and thus were more characteristic of narcolepsy than of cataplexy.[13]

Clinical Signs The clinical signs of narcolepsy include staggering, lowered head and neck, buckling of the thoracic limbs, kneeling posture, flaccidity of the lips, closure of the eyes, loss of the menace reflex, stertorous breathing, and ataxia. During severe narcoleptic attacks (narcolepsy–cataplexy), the animal collapses into lateral recumbency and appears comatose. Only rarely is REM sleep observed after collapse. The sensorium returns to normal after seconds to minutes. In the periods between attacks, the animal appears normal, although repeated attacks result in trauma to the dorsal aspects of the fetlocks and the knees and to the face.[12,14] Cataplexy, which may occur with or without narcolepsy, is a sudden episode of paralysis of the voluntary muscles, often induced by strong emotions (usually positive) in the patient and can range from atonic, areflexic paralysis of all skeletal muscles, except those of the diaphragm and eyes, to slight transient buckling of the limbs without

collapse into recumbency. Episodes of cataplexy last seconds to minutes.

Environmental factors that can stimulate cataplectic attacks include active restraint, suckling, feeding, changing of the stall environment, grooming, or cross-tie–related activities of horses such as saddling, removal of tack, and washing. Despite this association, narcolepsy in adult horses usually occurs while horses are in stalls or at pasture without any obvious prior stimulation.[14] Most cases of narcolepsy in humans are associated with cataplexy, but sleep attacks without cataplexy and cataplexy without sleep attacks also occur. Mild cataplexy and attacks of excessive sleepiness can be difficult to distinguish in adult large animals in that both may cause blank facial expression, hanging of the head and neck, and buckling of the limbs with or without collapse into recumbency.[14] Sudden arousal associated with the stimulation of collapse and ground impact also could terminate either type of episode. In view of diagnostic ambiguities based on observations of mild sleep attacks, cataplexy that persists after collapse is the most frequently recognized manifestation of sleep disorders in large animals.

Signs are generally stable and lifelong. The cataplexy component of juvenile cases usually improves as the animal gets older but rarely resolves completely.

Diagnosis Strict electroencephalographic criteria, including the early onset of waveforms typical of REM sleep at the beginning instead of in the middle of a sleep cycle, are in place for confirming the diagnosis and for distinguishing narcolepsy from narcolepsy without cataplexy. The electroencephalographic changes of narcolepsy and cataplexy have been reported in a Brahman bull.[3] In horses, electroencephalographic waveforms may be normal or may reveal fast waves typical of REM activity.[14] Orexin concentrations in CSF are typically low in humans and dogs with sporadic or familial narcolepsy but normal in familial forms associated with mutations in the genes for orexin receptors.[15,16] In CSF samples from a narcoleptic Icelandic foal and three related narcoleptic Lipizzaner fillies, immunoreactive orexin concentrations were comparable with those from normal horses.[2,17] It is important to evaluate this diagnostic finding in both juvenile and adult-onset forms of the disease in large animals.

Cataplexy can be induced by IV administration of the centrally acting cholinesterase inhibitor physostigmine salicylate (0.05 to 0.1 mg/kg),[4] but attacks cannot be evoked in all animals. In one series of 3 narcoleptic horses challenged, 2 responded positively to the challenge[2]; in another report, only 1 of 10 affected horses had a positive response.[9] Signs of cataplexy can be reversed for at least 24 hours by one dose of atropine sulfate (0.02 to 0.1 mg/kg IV).[9,17] Diagnostic drugs must be administered with caution because of the possibility of inducing colic, especially in horses.

Syncope and seizures are included in the differential diagnosis of narcolepsy. In general, syncope is characterized by acute collapse without warning and, unlike narcolepsy, is not preceded by a gradual lowering of the head and drowsiness. Increased focal or generalized tonic–clonic muscle activity and postictal depression are typical with seizures but not with narcolepsy. In addition, excessive sleepiness can be observed in horses that have an underlying painful physical condition, environment, or social position that prevents them from lying down to sleep.[18] Therefore a complete history and thorough physical examination are essential.

Treatment and Prevention The tricyclic antidepressant imipramine (0.5 to 1 mg/kg PO bid to qid) can be used to treat cataplexy but is ineffective in treatment of the sleepiness component of narcolepsy. This drug must be administered with caution, and oral dosages in horses should not exceed 2 mg/kg.[6] Results of oral imipramine therapy are inconsistent; duration of effect is approximately 5 hours. Anecdotal reports indicate that tyrosine has been of benefit in some, but not all, narcoleptic horses. Its presumed mode of action is to increase dopamine neurotransmitter concentrations.[14]

Selective serotonin reuptake inhibitors are also used in humans for treatment of cataplexy but have not been evaluated in large animals for this purpose.[19] Sodium oxybate (the sodium salt of gamma hydroxybutyrate) is widely used as a wakefulness-promoting drug in narcoleptic humans and may apply to the treatment of veterinary patients.[19]

Headshaking in Horses

Robert J. MacKay

Headshaking renders an otherwise normal horse unsuitable for riding or driving. There is no obvious predilection for age, breed, or gender. In the United Kingdom, owner-reported prevalence of headshaking of horses in 2017 was 4.2%.[1] Surveys have usually demonstrated that more than 50% of headshakers are geldings, and mean ages reported in published series are 7.3 to 12.8 years (range, 1 to 28 years).[2,3] Headshaking develops mostly in horses used for pleasure riding, dressage, or show jumping, but horses of any breed or discipline can be affected.[4,5] Signs of headshaking usually first occur while the horse is being ridden or driven (i.e., with the horse in a bit and bridle) and become more pronounced over time, both in severity and duration.[2] The condition usually renders a horse unsafe or at least unsatisfactory for riding and in severe cases may cause inhumane suffering to the affected horse. Once established, the condition occurs during any form of exercise, and approximately 60% of affected horses eventually also exhibit headshaking at rest.[2,4] Additional trigger factors that exacerbate or provoke headshaking have been identified: bright light, sun, heat, cold, stress, wind or rain, eating hay, extreme neck flexion, riding on narrow roads, hearing people's voices, and riding near trees or water.[6,7] On average, approximately half of cases from multiple series are either partially or completely seasonal; signs begin suddenly or get worse in spring and end or become milder in the late summer or fall.[2,6,8] A few cases begin in the fall and end in late winter. Signs may stop for weeks, only to recur for no apparent reason.

Headshaking is classified as either *symptomatic* or *idiopathic*. Symptomatic headshaking has an identifiable physical cause that, if removed, permanently resolves the problem. Idiopathic cases either have no discernable basis or continue after removal of a putative cause. Reported or postulated symptomatic causes have included skull lesions, allergic rhinitis, vasomotor rhinitis, otitis externa or media/interna, *Trombicula autumnalis* (harvest mite) infection, fungal sinusitis, THO, temporomandibular degenerative joint disease, mites or ticks in the external ear canals, guttural pouch mycosis, *Onchocerca* dermatitis, dental problems, sinus surgery, cervical arthritis, and ocular lesions, such as cystic corpora nigricans, "floaters" in the anterior chamber, allergic conjunctivitis, and blocked lacrimal ducts.[9-12] Because horses are normally programmed for headshaking as, for example, for fly avoidance,[13] almost any unpleasant condition around the head (or possibly elsewhere on the body) seems to have the potential to amplify the behavior to abnormal levels. Despite the seemingly impressive (and incomplete) number of potential causes just listed, no physical basis for headshaking was found in 89 of a series of 100 reported cases.[2] Headshaking does not appear to be associated with latent equine herpesvirus 1 infection.[14]

Headshaking may be defined as involuntary sudden violent repetitive movements of the head, either dorsally and ventrally in the median plane (most common), horizontally, and/or in a rotatory manner. Other signs, particularly in horses with idiopathic headshaking, have included snorting, sneezing,

VetBooks.ir

snoring breath sounds, rubbing the face on stationary objects, keeping the head low while trotting or even rubbing the nose along the ground, acting as if a bee has flown up the nose, excessive nasal and lacrimal discharge, hyperesthesia/hyperresponsiveness around the face, anxiety and agitation, hopping off the ground in one or both thoracic limbs, head pressing, shade seeking, muscle fasciculations, sweating, and striking at the nose. Many of these signs seem directed by the horse toward noxious sensations coming from the nose or face. In one study, anesthesia of the infraorbital nerves at the infraorbital foramina prevented headshaking in 3 of 19 horses,[15] whereas in another, 24 of 27 horses stopped headshaking when the caudal nasal nerves were blocked.[16] The latter technique probably blocks the maxillary nerve in addition to branches such as the caudal nasal nerve and infraorbital nerve.[17] These results indicate that idiopathic headshaking is triggered in the caudal parts of the nasal passages in most horses.

Sensory nerve conduction studies have been used to show that the threshold for activation of the infraorbital nerve of headshakers is lower than that for normal horses.[7] Idiopathic headshaking that can be relieved by sensory nerve blocks is termed *trigeminal-mediated headshaking*. Some cases of headshaking are almost entirely induced by bright light and appear to represent summation of stimuli arriving via both the optic and trigeminal nerves.[3] It is not yet known how these clear-cut cases of *photic* headshaking are related to the much more numerous cases in which light is not directly involved or is only a weak trigger. It may be that photoperiod (i.e., the proportion of the day that is light) is more important than light intensity in such horses and may explain the role of season in many cases.[3] Whatever the inciting cause, idiopathic headshaking appears to be a nasal/facial pain syndrome associated with hyperexcitability of trigeminal pain pathways.[7] In humans, trigeminal neuralgia is often caused by vascular impingement on the trigeminal ganglion or nerve root adjacent to the brainstem. Trigeminal nerve root demyelination, a characteristic finding in humans with trigeminal neuralgia, has not been found in headshakers.[18]

Horses with headshaking should undergo a complete physical examination; ophthalmic, otoscopic, neurologic, and dental examinations; endoscopic examination of nasal passages, pharynx, and guttural pouches; radiography of the skull; and a complete blood cell count and chemistry panel. When available, CT is the preferred imaging technique. No abnormalities are usually noted in these examinations.

Treatment

PHYSICAL. Mild cases of headshaking that occur during exercise can often be partially suppressed by the use of muzzle nets or devices that dangle over the face and nostrils. Approximately 30% of horses managed with muzzle nets showed at least 70% improvement, although the durability of any salutary effect has not been established.[19] There was no difference between the effectiveness of full face nets and that of nasal nets. A number of organizations and jurisdictions now allow horses to be shown wearing a muzzle net. A few horses respond to a heavy hair net or a dangling device that makes contact with the nose area or upper forehead. This type of contact may prevent the nerve from firing, in a manner similar to blocking a sneeze by placing a finger under the nose and applying pressure.[20] Facemasks and contact lenses that substantially reduce ambient light are available and are very effective in preventing photic headshaking.[3] Some researchers have argued that bitless bridles may be helpful if the action of the bit triggers headshaking.[21] These devices have been used widely.[6]

SURGICAL. Surgical approaches to headshaking are controversial because considerable morbidity and even severe suffering are frequent side effects of the procedures.[6] Notwithstanding these problems, surgery does appear to achieve a permanent cure in some horses.[15-17,22] The objective of surgery is interruption of pain pathways in the trigeminal nerve or its branches. Two approaches have been used: infraorbital neurectomy and caudal infraorbital nerve compression. In the first procedure, a 2-cm section of nerve is removed just rostral to the infraorbital foramen.[15,22] To effect nerve compression, up to eight platinum embolization coils are introduced via the infraorbital foramen and packed around the infraorbital nerve within the caudal aspect of the infraorbital canal.[16,17] Five of 26 horses (19%)[15,22] and 26 of 57 (46%)[16] horses had long-term elimination of headshaking after infraorbital neurectomy and caudal compression, respectively. Temporary remission of headshaking was achieved in other horses but was followed by relapse weeks to months after surgery. Further long-term remissions were achieved when the procedure was repeated in some of the horses that suffered relapse.[16,22] Exacerbation of headshaking and self-inflicted trauma around the muzzle and lips were problems in most horses after these procedures. These complications typically resolved within weeks but were persistent in some; four of these horses were euthanized because of the severity of signs. The results of nerve blocks was not completely predictive of response to surgeries; however, two of three horses that responded to infraorbital blocks achieved complete remission with infraorbital neurectomy.[15] Tracheostomy has been shown to be effective as a salvage procedure, presumably by bypassing the passage of air through the nasal passages.[6]

MEDICAL. It is unlikely that complete and permanent remission can be achieved medically. Cyproheptadine, 0.3 mg/kg PO twice daily, has been used with some success for photic headshaking[3] and with limited success in other cases of idiopathic headshaking.[4,15,23] Mild lethargy and colic are occasional side effects. Headshaking can be suppressed for variable periods by the potent analgesic antiseizure drugs carbamazepine and gabapentin, but effects are often not complete, and signs return within several weeks after treatment begins.[6,24] Cyproheptadine may potentiate the analgesic actions of carbamazepine. In one horse, persistent 95% remission was obtained by the CT-guided injection of glycerol into the trigeminal ganglia.[25] Individual horses are reported to have responded to corticosteroids or antihistamines, which perhaps indicates a role for allergic rhinitis in those few cases, but intermittent treatment with high-dose dexamethasone or NSAIDs is ineffective.[2,15,26] Melatonin is advocated as a way to suppress the neurologic responses to increasing photoperiod (i.e., seasonal effect), so it should be started before the anticipated seasonal onset of headshaking.[3] This has reportedly been effective in a few cases. Various other supplements and traditional or alternative products have anecdotal or conceptual support with (as yet) no evidence. Most of them are inexpensive and nontoxic at recommended doses. There are protocols for chiropractic therapy and acupuncture for headshaking. These have not been successful in the author's experience.

ELECTRICAL NERVE STIMULATION. Percutaneous electrical nerve stimulation (PENS) of the infraorbital nerves is a promising technique for the management of trigeminal-mediated headshaking. Nerves are stimulated by subcutaneously positioned portable PENS probes.[27] After three treatments with a neurostimulation device, five of seven horses had durable positive responses, returning to work at the same level as before the onset of headshaking. Median remission time was 15.5 weeks (range, 0 to 24 weeks). PENS treatments need to be repeated when clinical signs return. The procedure has now been used in more than 130 horses, of which approximately 50% have returned to their previous level of activity.[28] The logical next step would be the development of programmable

implantable nerve stimulators that could conveniently be used for long-term control of trigeminal-mediated headshaking.

Small Ruminant Lentivirus Infections

Mary O. Smith • Lisle W. George • John R. Middleton

Maedi-visna virus and caprine arthritis–encephalitis (CAE) virus are retroviruses in the subfamily Lentivirinae that constitute a single virus group, termed the *small ruminant lentiviruses*, which can cross between small ruminant species.[1-3] These agents are enveloped RNA viruses.[4]

Definition and Etiology

Maedi-Visna Virus Infection (Ovine Progressive Pneumonia Virus Infection; Zwoegerziekte)

Maedi-visna virus causes a chronic disease of sheep.[1-4] Visna virus, which affects the brain, is closely related to the many lentiviruses that cause immunodeficiency and neurologic disease in other species; these viruses include equine arteritis virus, CAE virus, and simian, feline, and human immunodeficiency viruses.[5] The respiratory aspects of the viral infection (maedi virus) are discussed in Chapter 31.

Epidemiology Maedi-visna virus is spread through ingestion of infected milk by neonates, through in utero transmission, and horizontally within a herd.

Pathogenesis After exposure to the virus, sheep develop an asymptomatic infection for as long as 6 weeks. Replication of the virus occurs in circulating cells during this stage of the infection.[6] Once the disease has been recognized, affected sheep should be slaughtered. Control measures are discussed in Chapter 31.

The lesions of maedi-visna virus infection are partly induced by the host's inflammatory response. Experimental immunosuppression of infected sheep ameliorates the severity of the clinical signs and reduces the CNS lesions without altering the amount of viral shedding.[7,8] The maedi-visna virus is in itself immunosuppressive, and infections may lead to a variety of secondary bacterial infections.[9] Chronic viremia is typical.

Clinical Signs Neurologic disease caused by maedi-visna virus is relatively rare. Adult sheep and lambs as young as 4 months of age can be affected.[10] Nervous system signs may be characteristic of a diffuse encephalitis and include ataxia, twitching of the facial muscles, conscious proprioceptive deficits, circling, and blindness; gait along a straight path is normal, but the animal staggers or stumbles when turned or when forced to perform a complex maneuver. Coma, convulsions, and hyperexcitability may occur in the terminal stages. Other sheep have gradually progressive limb weakness and ataxia, often worse in the rear limbs; neurologic dysfunction localized to the spinal cord may be the sole clinical manifestation of maedi-visna virus infection.[11] Some sheep merely show emaciation without neurologic signs. Others may show nonsuppurative, progressive arthritis of one or more joints or symmetric enlargement of the mammary gland. The time between the onset of clinical signs and death is highly variable but can be as long as 2 years. The presence of antibody in the serum is considered evidence of active infection.[12,13]

Clinical Pathology The CSF of affected animals is characterized by pleocytosis, with the cell counts ranging from 1012/dL to 1478/dL in animals infected for 1 month and 4 years, respectively.[14] The protein concentrations of CSF can range from 50 to 100 mg/dL for 30 days after infection. Antiviral antibody and virus can be detected in CSF specimens.

Pathology Gross lesions of visna infection are rare when inflammation and malacia are extensive. In such cases, areas of yellowish tan discoloration are present in white matter.[15] The microscopic lesions of visna are predominantly those of a diffuse, nonsuppurative, perivascular inflammation throughout the neuraxis; white matter is affected more severely than gray matter. Lesions include demyelination, gliosis, lymphocytic choriomeningitis, and focal necrotic areas that are infiltrated by macrophages.[16,17]

Diagnosis The diagnosis of visna infection starts with recognition of the clinical neurologic disease in groups of animals in which the pulmonary, joint, or mammary form of the disease is also present. Agar gel immunodiffusion (AGID) testing has been superseded by more accurate ELISA and PCR tests.[18] The diagnosis and epidemiologic features of maedi-visna virus infection are discussed in detail in Chapter 31.

Treatment and Control No effective treatment for maedi-visna virus infection is available. Prevention is based on herd hygiene and culling of affected animals, as described in Chapter 31.

Definition and Etiology

Caprine Arthritis-Encephalitis Virus Infection (Infectious Leukoencephalomyelitis)

CAE is caused by a small ruminant lentivirus that is closely related to the virus that causes maedi-visna virus infection in sheep.[1]

Epidemiology The disease is distributed worldwide but tends to be more common in regions with intensive goat-rearing operations.

Pathogenesis When inoculated into goats, the virus causes a chronic infection characterized by demyelinating encephalomyelitis, arthritis, and interstitial pneumonia. The pathologic changes resemble those of an autoimmune process and are probably caused by interactions among the host's immunologic responses, denatured myelin, and the virus.[2]

Clinical Signs The systemic manifestations of the disease are thoroughly discussed in Chapter 38. The leukoencephalomyelitis form of CAE occurs predominantly in goats younger than 1 year of age; occasional cases occur in older goats.[3] The clinical signs of leukoencephalomyelitis are highly variable but typically involve the spinal cord. Signs include progressive ataxia, paraparesis, paraplegia, tetraparesis, tetraplegia, hemiparesis, and hemiplegia. Goats with lesions in the cervical spinal cord (L1 to L4 levels) are recumbent and unable to raise their heads from the ground. They may show resistance to passive neck flexion. Spinal reflexes range from hypertonia and hyperreflexia to hypotonia and hyporeflexia. Intracranial signs may also develop; these include head tilt, nystagmus, tremors, torticollis, salivation, depression, coma, and opisthotonos.[4-10] Vision and pupillary light reflexes may be diminished. The neurologic deficits may be either symmetric or asymmetric. This diversity of signs is related to the variable location of lesions in the CNS.

Other signs that may be associated with CAE infection include fever (although the occurrence of this, too, is highly variable), enlarged joints, mammary gland enlargement (usually symmetric), vague and shifting leg lameness, weight loss, and tachypnea without significant auscultatory abnormalities.

The major differential diagnostic considerations for the neurologic form of CAE include head or spinal trauma, listeriosis, cerebrospinal nematodiasis (verminous meningoencephalomyelitis caused by *Parelaphostrongylus tenuis*, the meningeal worm of the white-tailed deer), and multisystemic infections with

VetBooks.ir

Mycoplasma spp. The CAE virus causes neurologic lesions in numerous regions of the CNS, whereas the lesions of listeriosis are generally restricted to the brainstem. Mycoplasmal infections typically affect kids 1 to 6 months of age, and affected animals are systemically ill and often display septic polyarthritis and polyserositis. *Mycoplasma* infections of goats are described further in Chapter 38. Verminous meningoencephalomyelitis and CAE virus can be presumptively distinguished by serologic or PCR testing for CAE virus and CSF analysis, season, and geographic distribution of the white-tailed deer host for meningeal worm. However, the neurologic forms of these diseases cannot be definitively diagnosed by these means.

Clinical Pathology The results of hematologic and blood chemistry analyses are generally normal; however, in one study of affected goats, total plasma protein levels were increased and hypergammaglobulinemia was common.[4] The changes in the CSF are characteristic of a chronic granulomatous inflammation. Specific changes include an increased protein concentration and pleocytosis.[11] Cell counts in the CSF of affected goats range from 5/dL to 1800/dL, and the protein concentration ranges from 0 to 700 mg/dL.[3]

Pathology Gross pathologic changes in the CNS of naturally infected goats include cloudiness of the meninges and tan discoloration of the white matter.[3] Microscopic changes include disseminated perivascular accumulations of mononuclear cells, demyelination originating in the subependymal region, astrocytosis, and mononuclear leptomeningitis.[2,4,8,12,13] Spinal cord lesions are most frequently observed in the thoracolumbar segments.[3]

Diagnosis Previously, an AGID test was used for the diagnosis of CAE, but this has been superseded by ELISA and PCR tests.[12,14] The virus may also be cultured from infected tissue.[15]

Treatment and Control No treatment is available for goats with leukoencephalomyelitis. Control measures are discussed in Chapter 38.

Border Disease (Hairy Shaker Lambs; Hypomyelogenesis Congenita)

Definition and Etiology Border disease is a congenital infection of sheep and goats caused by a noncytopathic togavirus (genus *Pestivirus*).[1] The border disease agent is antigenically similar to the viruses that cause bovine viral diarrhea (BVD) and hog cholera (classical swine fever). Once introduced into a flock, the border disease virus causes abortion, infertility, and deformities in lambs. In a naive ewe, viral infection during pregnancy results in a variety of complications, including early embryonic death, abortion, and stillbirth, and lambs that survive are small and malformed. It is important to note that lambs infected in utero become immunotolerant and remain viremic for life, similar to calves persistently infected with BVD virus.[2] Adult sheep that become infected with the border disease virus develop an inapparent, short-lived viremia and become immune to reinfection.

Epidemiology Border disease is transmitted both vertically and horizontally.[3,4] As with BVD in cattle, the major reservoir in infected herds is the congenitally infected, seronegative animal that shows no symptoms.[2,5] Such animals may shed the virus through the placenta, infected offspring, saliva, respiratory secretions, urine, or feces.[3,6] In one seroepidemiologic study of infected ewes in the western United States, lambs were more often seropositive than were ewes.[2] A large percentage of the seropositive lambs were born to seronegative ewes, which indicated the presence of a large amount of virus cycling from carriers that have no symptoms. Strain-related differences in viral pathogenicity appear to exist.[7]

Pathogenesis Hypomyelination is probably caused by a combination of virus-induced degeneration of the oligodendroglial cells (dysmyelinogenesis), persistent viral infection, and diminished secretion of the thyroid hormones.[8] The diminished production of thyroid hormones is thought to be related to direct inhibition of the thyroid gland, because the pituitary activity of affected lambs appears to be normal. In lambs infected in utero, white and gray matter is decreased in the spinal cord as a result of the decreased myelin content.[9] Depressed blastogenic activity of lymphocytes, a decrease in T-helper cell function, and an increase in T-suppressor cell function have been demonstrated in affected lambs between 4 and 7 months of age and indicate viral immunosuppression.[3,10,11] Such lambs may succumb to common diseases such as parasitism, diarrhea, and bronchopneumonia.

Clinical Signs The severity of clinical signs in affected lambs varies. Changes are most marked in newborn lambs infected in early gestation (before 50 days). The CNS, skin, and skeleton are the most seriously affected. The hairs of congenitally affected lambs are coarse, straight, and elongated and stand out from the body like a halo.[12] The coat is abnormally pigmented and may have a dark-gray appearance or hyperpigmented spots that are especially prominent over the top of the neck.[13] Animals that survive shed the abnormal hairs at 9 to 12 weeks of age and replace them with normal hair fibers. Affected lambs also have a short, thickened body, shortened legs, smaller orbital size, and doming of the frontal bone.[14,15]

Arthrogryposis occasionally occurs. Some infected lambs show neurologic symptoms such as ataxia and uncontrollable tremors; the latter sign, combined with the characteristic hair coat, accounts for the common term "hairy shakers." The tremors are coarse, involve the trunk and head, and disappear when the animal is asleep.[16,17] Affected lambs are often alert and appetent but initially need assistance to stand and nurse. Some animals walk normally but hop on the rear limbs when forced to run. The CNS signs usually disappear by 20 weeks of age, but the animals appear stunted. Affected animals have far lesser viability than do uninfected herdmates and may die unexpectedly. Aside from neonatal death losses, economic burdens imposed by the viral infection include low birth weights, diminished weaning weights, lowered carcass quality, and infertility.[15,18]

Abortions occurred 9 to 106 days after inoculation in 30% of experimentally infected sheep.[6,13,14] In field outbreaks, the average gestational age of the aborted fetus is 63 days. Teratogenic effects are most often observed when lambs are infected at 50 to 90 days of gestation.[19] Fetal mummification occasionally occurs.

The border disease virus is also pathogenic in goats.[20] As in sheep, inoculation of pregnant does results in fetal mummification and abortion. The spinal cords of infected kids are hypomyelinated, but the haircoat is normal.

The border disease virus has low pathogenicity in cattle. Abortions can be induced in cows inoculated with the virus at approximately 50 days of gestation, and affected calves have cerebral cavitations.[21] When cattle comingle with infected sheep, cattle can be naturally infected.[22]

Pathology The macroscopic changes associated with border disease virus infection are hydranencephaly, porencephaly, microcephaly, cerebellar hypoplasia, abnormal curvature of the ribs, brachygnathia, doming of the frontal bones of the skull, narrowing of the distance between the orbits, a decrease

in orbital size, shortening of the crown-to-rump and diaphyseal lengths, retention of secondary hair fibers, and abnormal skin pigmentation.

Microscopic changes in lambs with congenital infection include hypomyelinogenesis and hypercellularity of the white matter with abnormal-appearing glial cells.[16,17,19] The CNS shows dysmyelinogenesis, secondary demyelination, and periarteritis. Viral antigen can be demonstrated in CNS arterioles.[23]

Diagnosis Identification of the viral antigens in tissues with fluorescent antibody tests is the most accurate method of diagnosing border disease. Tissues that most consistently contain viral antigens are those of the abomasum, pancreas, kidneys, thyroid, and testicles.[24,25] Serodiagnostic methods such as serum neutralization, AGID, and complement fixation tests have been developed.[26] In most cases, the BVD virus has been used as the indicator antigen. Serodiagnosis of infected lambs is difficult because the lambs tend to be immunotolerant and therefore do not develop strong serologic responses. The presence of viral antibodies in the CSF suggests border disease virus infection.

The differential diagnosis for border disease virus infections in sheep and goats includes other causes of infectious abortion, copper deficiency (swayback), and other viral diseases that may result in hydranencephaly, such as those caused by the Cache Valley, bluetongue, and Schmallenberg viruses.

Treatment and Control There are no specific treatments. Control measures are centered on disease monitoring and biosecurity. In herd situations, virus isolation from whole blood or examination of skin biopsy samples by fluorescent antibody tests can help identify carriers.[24] Serologic testing is not a reliable indicator of infection because congenitally, persistently infected animals may be immunotolerant of the virus. Noninfected pregnant sheep should be separated from other members of the flock for the first 60 days of gestation to ensure that in utero infections do not occur.

Encephalitic Bovine Herpesvirus Infection

Definition and Etiology Two herpesviruses, bovine herpesvirus type 1 (BoHV-1) and type 5 (BoHV-5), have in rare cases been associated with encephalitis in cattle.[1-4] BoHV-1 infection typically results in infectious bovine rhinotracheitis (IBR), an acute upper respiratory tract disease characterized by fibrinonecrotic white plaques of the nasal, pharyngeal, and tracheal mucosa and by abortions (see Chapter 31). Other clinical conditions associated with bovine herpesvirus infections include epizootic conjunctivitis (Chapter 39) and infectious balanoposthitis or vulvovaginitis (Chapter 43).

Epidemiology Bovine herpesviruses cause disease in cattle worldwide. Epidemiologic factors that appear to favor dissemination of herpesviruses among cattle include a high stocking rate, repeated introduction of animals from diverse backgrounds, and mass weaning of calves at a time when the passively acquired anti-IBR antibodies are waning.[2] BoHV-1 may survive in the environment for up to a month; cooler ambient temperatures and higher humidity promote virus survival.[5] Calves younger than 6 weeks are most susceptible, but infection and resultant neurologic disease also have been described in adult cattle.[1,3,4,6-9] Animals that survive the disease become persistently infected; virus survives in the nasal and tracheal mucosa and the trigeminal ganglion.[9] Reactivation and virus shedding may occur during periods of stress.[4,5,9] Although clinical disease caused by reactivation of latent virus is usually mild and may go unnoticed, shedding of virus during such episodes can cause infection of in-contact animals. The viruses replicate in the nasal and pharyngeal mucosa. Brain involvement results from centripetal spread along the sensory neurons of the trigeminal and olfactory nerves.[9]

Pathogenesis Encephalitic IBR infections cause a nonsuppurative meningoencephalitis that is widely distributed in the gray matter of the brain, primarily in the cerebrum and thalamus. The virus can usually be isolated from affected calves.[10] Signs of respiratory disease may precede or occur coincidentally with neurologic disease.[10]

Clinical Signs The clinical signs of encephalitis include depression, mild nasal and ocular discharge, conscious proprioceptive deficits, head pressing, aimless circling, bellowing, salivation, bruxism, paralysis of the tongue, head tilt, nystagmus, convulsions, blindness, coma, and death.[2,3] Seizure activity is characterized by a tonic-clonic convulsion with violent spasms or tremors of the head, with all four legs flexed and the head in opisthotonos. Rectal temperatures of 41° C and 42° C (108° F) have been reported.[6] Encephalitic herpesvirus infection is frequently fatal, although asymptomatic cases have been induced experimentally.[10] In experimental infection, signs develop 1 to 2 weeks after infection.

Clinical Pathology and Pathology Mononuclear pleocytosis is found on analysis of CSF.[10] Extensive lymphocytic meningoencephalitis is evident on histologic examination. Intranuclear inclusion bodies are rarely observed in bovine herpesvirus encephalitis. Encephalitis may be evident on histopathologic examination of fetuses from cows that abort as a result of BoHV-1.[11]

Diagnosis Accompanying respiratory disease raises the index of suspicion for herpesvirus encephalitis in animals with neurologic clinical signs. A rising serum titer of neutralizing antibody in surviving animals can be used to confirm infection, although this does not distinguish between BoHV-1 and BoHV-5. Specific diagnosis is usually made at necropsy through a number of modalities, including virus isolation, immunohistochemistry, and PCR.[12-14] Many of these tests do not distinguish between BoHV-1 and BoHV-5; more specific PCR tests can differentiate between these two virus types.[15]

Differential diagnoses for encephalitic herpesvirus infections in cattle include almost all encephalitic, encephalopathic, and neurotoxic diseases of cattle, including rabies, polioencephalomalacia, salt poisoning, and lead toxicity.

Treatment and Control No specific therapy exists for the encephalitic form of BoHV-1 infection. Treatment is palliative and supportive and should include oral or intravenous fluid support, NSAIDs, antibiotics in animals with secondary bacterial pneumonia, and nursing care. Benzodiazepines or phenobarbital may be used for seizure control when necessary (Table 35.4). Animals with severe clinical signs may be euthanized for humane reasons.

Vaccines that protect against BoHV-1 have traditionally been considered potentially useful in the prevention of BoHV-5 infection because of the close antigenic relationship between the two viruses.[7,16] However, more recent trials have shown that certain BoHV-1 vaccines may not confer protection on cattle challenged with BoHV-5.[17,18]

In some European countries, eradication programs that employ testing and culling of infected animals have been successful in eliminating BoHV-1. Bovine herpesviruses can be spread through fomites and by aerosol transmission for up to 4 miles (6.4 km).[5] Strict biosecurity procedures are therefore essential for developing and maintaining virus-free herds.

TABLE 35.4

Recommended Drug Dosages for Treatment of Cerebrocortical Disease

	Dosage	Route	Frequency
Anticonvulsant Drugs			
Diazepam or midazolam[a]	0.01-0.4 mg/kg	IV or IM	Twice daily or as needed
Pentobarbital sodium[b]	2-10 mg/kg	IV	Three times daily
Phenobarbital[a]	Loading dose, 20 mg/kg	IV	One time
	Maintenance dosage, 1-4 mg/kg	IV, PO, or IM	Divided twice daily
Antiinflammatory or Antiedema Drugs			
Methylprednisolone[a]	1-30 mg/kg	IV	One time
Dexamethasone[c]	1-4 mg/kg	IV or IM	Twice daily
Mannitol[a]	0.25-0.5 g/kg 20% solution	IV	Twice daily
Furosemide[d]	1 mg/kg	IV, IM, or SC	Twice daily
Flunixin meglumine[e,f]	1 mg/kg	IV or IM	Twice daily
Phenylbutazone[a,g]	2-4 mg/kg	IV or PO	Twice daily
Dimethyl sulfoxide (DMSO)[a]	1-2 g/kg	IV	Twice daily
Acetylsalicylic acid (aspirin)[a]	7-10 g/500 kg	PO	Twice daily

Many of the drugs and dosages listed below are not approved by the U.S. Food and Drug Administration (FDA) for use in food-producing animals for the treatment of cerebrocortical disease (lettered superscripts are explained in the table footnotes). Off-label use of drugs in food-producing animals should follow specific guidelines in the jurisdiction where the drugs are being administered.

Additional notes on use of these drugs in food-producing animal in the Umited States:

[a]Diazepam, phenobarbital, methylprednisolone, mannitol, phenylbutazone, dimethyl sulfoxide (DMSO), and aspirin are not FDA-approved for use in food-producing animals in the United States.

[b]Pentobarbital is approved at dosages of 0.44-1.1 mg/kg as a general anesthetic and 0.11-0.275 mg/kg as a sedative-relaxant in beef and dairy cattle.

[c]Dexamethasone is approved as an antiinflammatory for use in calves and in beef and dairy cattle administered IV or IM at a dose of 5-20 mg per animal or as an oral bolus or powder at 5-10 mg/animal on day 1 and 5 mg/day thereafter as required.

[d]Furosemide is approved at a dosage of 500 mg/animal once daily or 250 mg/animal IV or IM twice daily for no more than 48 hours after parturition for treatment of parturient mammary edema in beef and dairy cattle.

[e]Flunixin meglumine is approved at 1.1-2.2 mg/kg IV as a single dose or divided evenly into two doses administered 12 hours apart for up to 3 days for the control of inflammation associated with endotoxemia. It is also approved as a transdermal pour-on material for use in beef and dairy cattle for the control of pyrexia associated with bovine respiratory disease complex or pain associated with foot rot.

[f]Monitor for signs of gastric or abomasal bleeding (fecal occult blood).

[g]An initial oral loading dose of 10 to 20 mg/kg, followed by 2.5 to 5 mg/kg PO daily or 10 mg/kg PO every 48 hours thereafter, has been recommended for cattle. Because of the prolonged plasma half-life in ruminants, serial administration of the drug should be accompanied by careful monitoring of renal function and gastrointestinal bleeding. Use of phenylbutazone in dairy cattle over 20 months of age is prohibited in the United States by the FDA. Other use in food-producing animals in the U.S. would be off-label, in which case the guidelines set forth in the Animal Medicinal Drug Use Clarification Act should be followed.

IM, Intramuscular; *IV*, intravenous; *PO*, oral; *SC*, subcutaneous.

Bovine Spongiform Encephalopathy ("Mad Cow" Disease)

Christine F. Berthelin-Baker • John R. Middleton

Definition and Etiology Bovine spongiform encephalopathy (BSE) is a transmissible spongiform encephalopathy (TSE) of cattle that was first recognized in 1986 in Great Britain.[1] The TSEs are a group of slowly progressing, invariably fatal, neurodegenerative diseases that can affect humans and animals. They are also called *prion diseases* because of the accumulation of abnormal prion protein in the CNS. Since the prion hypothesis was first formulated in 1982, prions have been widely accepted as the etiologic infectious agents of the TSEs.[2] The prion is an altered conformation (PrP-BSE) of the normal prion protein (PrP), a host-encoded membrane protein that does not carry any nucleic acid. PrP-BSE replicates by inducing a post-translational conformational change in the normal protein PrP to form the abnormal prion PrP-BSE.[2-4] After a characteristically prolonged incubation period, the abnormal isoform of the protein aggregates and accumulates in the CNS of affected animals, creating progressive neurologic dysfunction.

Epidemiology Current evidence indicates that BSE resulted from a single agent.[5-10] BSE may have originated from feedstuffs containing rendered carcasses of scrapie-infected sheep, or it might have been a preexisting sporadic and rare disease unrecognized in the bovine population. The BSE epidemic was traced to the recycling of BSE-infected carcasses into cattle feed, which occurred mostly in the 1980s in the United Kingdom.[6] Cattle in other countries were affected as a result of the importation of infected feedstuffs or cattle, followed by later recycling the agent in their own rendered ruminant feedstuffs. At the time of writing, the OIE reported that BSE had been detected in 28 countries, including the United States.[11] Since 1986, more than 181,000 cases of BSE have been confirmed in Great Britain.[11] These cases were distributed among 37,170 farms.[12] The incidence of BSE was highest among the cattle cohorts born between 1986 and 1989, and the outbreak peaked in 1992, when 36,680 cases were detected by screening suspected clinical cases (passive surveillance) in Great Britain. Active surveillance has revealed a sustained and sharp decrease in the number of cases since 2001.[12] The decline in the Great Britain epidemic is directly related to the successive bans on the feeding of ruminant-derived meat and bone meal to cattle. The initial 1988 ban took effect in 1989 in the United Kingdom and has been tightened and refined since then. Similar feed bans have been adopted by many countries around the world. A list of countries that have reported home-born or imported cases of BSE and the number of cases reported each year is available and regularly updated on the website of the OIE.[11]

VetBooks.ir

BSE has affected predominantly dairy cattle because of their longer life span and feeding practices, which in Great Britain included feeding animal-derived protein to youngstock. No clear genetic predisposition to BSE has been demonstrated in cattle, in contrast to scrapie in sheep, although offspring of affected cattle seem to be at increased risk for the disease. The epidemic (classical) form of the disease is considered to be a foodborne disease of cattle, associated with the ingestion of meat and bone meal contaminated with the BSE prion. This is substantiated by the steady decline in the incidence rate of BSE in endemic countries since the enactment of bans on feeding ruminant protein to ruminants.[11]

Rigorous, active surveillance programs have been initiated in many countries to screen cattle and beef products for the BSE agent. As a result of this large-scale testing, two extremely rare prions were discovered on the basis of protease resistance patterns and glycopatterns.[13-16] These novel agents have been termed *H-BSE* and *L-BSE*, and animals from which these agents have been identified are said to have *atypical BSE*.[5] These cases have been detected in multiple countries by rapid prion detection tests conducted on aged (>8 years) cattle that were tested either during slaughter surveillance or through targeted surveillance of downer cattle. Investigations regarding the origin and pathogenesis of atypical BSE are ongoing. Owing to the advanced age of affected cattle and the low known prevalence of atypical BSE, it has been speculated that atypical BSE may arise spontaneously.[5]

Pathogenesis The exact function of the normal prion protein is unknown, as are the mechanisms of abnormal prion protein (e.g., PrP-BSE) induced neurodegeneration and CNS dysfunction in TSEs. On the basis of research in transgenic mice expressing bovine PrP, the PrP-BSE is thought to undergo limited propagation in the distal ileum before spreading to the CNS, probably by moving through the gut-associated lymphoid tissue into the peripheral nerves.[17,18] Studies of naturally infected cattle, combined with experimental oral challenge studies in cattle, have revealed that BSE infectivity may exist in the brain; spinal cord; retinal tissue; optic nerve; cervical, thoracic, and trigeminal ganglia; facial and sciatic nerves; and the distal ileum. The skeletal muscles, spleen, and lymphatic tissues did not demonstrate infectivity.[19,20] Intracerebral inoculation of cattle has also been demonstrated to result in infectivity of the tonsillar tissue.[21] After a prolonged incubation period, accumulation of PrP-BSE in the CNS creates progressive and irreversible neurologic dysfunction.

Clinical Signs As with all TSEs, BSE has a long incubation phase. It occurs mostly in 4- to 6-year-old cattle (age range, 20 months to 18 years), although the atypical forms tend to occur in cattle older than 8 years. The clinical signs of BSE usually have an insidious onset.[22,23]

The detection of clinical signs of BSE and the array of clinical signs reported are influenced by how closely the cattle are being observed and the handler's awareness of the insidious and nonspecific nature of the clinical signs. Subtle early behavioral changes are unlikely to be observed in large herds. Affected cattle may become apprehensive, stay apart from their herdmates, and become fearful of their handlers. As the disease progresses, cattle often become extremely excitable, especially when restrained or placed in confined quarters or an unfamiliar environment. Cattle with BSE may refuse to move through previously familiar doorways and become impossible to restrain. Unprovoked aggression is less frequent. Hyperesthesia is most marked around the head and neck. A light touch on the hindlimbs may induce violent and often repetitive kicking, which may also be observed during milking. Animals may overreact in response to sudden visual, tactile, or auditory stimuli. The startle reaction may be gauged by a hand test (punching fist abruptly toward the animal's head without touching it), flashlight test, a hand clap, or a loud metallic "bang." Normal animals rarely startle in response to such stimuli, or they may startle once or twice when the stimulus is repeated. Cattle with BSE frequently startle violently and repeatedly, with no habituation to a repeated stimulus. In some cases, the response may escalate to an extreme aberrant startle, with headshaking and seizure-like head bobbing, which may be followed by violent turning, running around, and falling.

Other possible clinical signs of BSE include ptyalism, increased head rubbing, muscle fasciculations, and excessive vocalization. Other behaviors observed in animals with BSE may include frequent and repetitive head tossing, licking of the nostrils, yawning, flehmen response, head butting, and restlessness.[24] Because of the hyperexcited state of these animals, tachycardia is expected; however, relative bradycardia (60 beats/min) may be observed. Affected animals often lose weight and have reduced milk output. Ataxia and tremors occur in more advanced cases. Tremors most often involve the head and neck and may become generalized, especially with exercise. Ataxia is most marked on turns, when the animal goes over steps, or on uneven terrain; it may also be accentuated with exercise. Animals with BSE may become recumbent and unable to feed if the disease is left to run its course. Recumbency may also be triggered by an intercurrent illness or an injury during a fall. The clinical signs of BSE may be more difficult to recognize in animals that have become recumbent than in less advanced cases,[25] and systematic targeted surveillance of downer cattle (fallen stock) have allowed for the detection of previously unsuspected cases of BSE in various countries.[26]

Diagnosis No in vivo test is approved for the diagnosis of BSE. The diagnosis can be confirmed only by postmortem examination and is based on microscopic brain examination or tests that identify the abnormal prion in brain or spinal cord tissue.[1,27] Rapid prion tests include Western blot, paraffin-embedded tissue (PET) blot, and ELISA.[28-31] Rapid tests have enabled the detection of BSE through surveillance in targeted at-risk populations such as fallen (downer) cattle.

Histopathologically, BSE is characterized by neuronal degeneration and intraneuronal vacuolation in specific brain areas. The vacuolation is accompanied by or preceded by the accumulation of PrP-BSE.[6,7,32] The obex of the medulla is currently considered to be the tissue of choice for detection of the BSE agent.[33]

Nervous system diseases that could be confused with BSE include viral encephalopathies (pseudorabies, rabies, Borna encephalitis, bovine immunodeficiency virus encephalitis), listeriosis, polioencephalomalacia, lead poisoning, CNS parasitic migration, brain tumors and abscesses, and vitamin A deficiency. Hepatic encephalopathy and other metabolic imbalances may also be confused with BSE. Because of the insidious nature of BSE, affected cattle may appear to recover coincidentally with blanket therapy for suspected metabolic imbalances and later exhibit relapse. This must be kept in mind whenever therapy for metabolic imbalances initially appears to be successful but is followed by one or more relapses.

Treatment and Control BSE is always fatal, and no treatment is available.

Various measures have been taken to protect public health by removing potentially infected animals and tissues from the food chain. The disposal of BSE-infected tissues and the sourcing of bovine tissues and body fluids for the preparation of medicinal products must take into account the extreme resistance of TSE agents. All TSE agents remain infectious after exposure to a wide range of inactivating treatments and environmental changes such as autoclaving, rendering, storage for months to years, exposure to ultraviolet light, freezing,

thawing, prolonged boiling, and incubation with formalin.[34-36] Because of the public health risk, the carcasses of animals suspected of having BSE should be disposed of in an alkaline-hydrolysis tissue digester designed to inactivate TSE agents.[37]

In countries that have had an outbreak of BSE, the complete exclusion of ruminant tissues from ruminant feed has aided progress toward eradication of BSE, as previously noted. In the United Kingdom the initial feed ban of 1988 was found to be insufficient and was reinforced by successive measures. The 1996 ban on feeding mammalian meat and bone meal to all farmed animals was introduced to prevent contamination of ruminant feed at feed mills and down the supply chain to the farm. Because of the long incubation period of BSE, the implementation of feed control measures did not reduce the incidence of this disease immediately.

Public Health Consideration and BSE in Other Nonbovine Hosts Since the onset of BSE epidemics, new TSEs have been identified in animals other than cattle. Strain typing in mice showed that these new TSEs were caused by the BSE agent,[38,39] which has proved to be a relatively promiscuous TSE agent, capable of experimentally infecting mice, sheep, goats, pigs, cats, mink, and primates.[5] The disease in humans, termed *new-variant Creutzfeldt-Jakob disease* (vCJD), was first identified in 1996 in the United Kingdom, where it had affected 178 people as of April 2018.[40] Other countries have detected vCJD cases in people who had lived in the United Kingdom between 1980 and 1996, as well as in citizens who never traveled to the United Kingdom. The emergence of vCJD has put worldwide emphasis on the prevention and detection of TSEs in animals. The route of infection of people by BSE has not been clearly traced, but a case-control study demonstrated that the consumption of food that included infected cattle nervous tissue was associated with increased risk of vCJD.[41] This and other evidence has led to successive "Specified Risk Materials" bans in many countries, aimed at preventing contamination of human food with nervous system or other specified high-risk tissues from ruminant animals.

Scrapie

Definition and Etiology Scrapie is a TSE that naturally affects sheep, goats, and mouflons. It is the oldest known TSE, described more than two centuries ago. The causative agent is considered to be an abnormal prion (PrP-Sc) distinct from that of BSE.[1] At least three distinct types of the scrapie agent have been identified in the natural hosts.[1] Although sheep are susceptible to experimental challenge with the BSE agent, natural BSE has not been reported in sheep.[1]

Epidemiology Scrapie occurs endemically in sheep flocks worldwide, with the exception of Australia and New Zealand.[1] Sheep are the natural host of scrapie, but the infection can be maintained in goats that have no direct contact with sheep, which indicates that transmission in goats is both lateral and vertical.[2-4] Scrapie cases occur sporadically in infected flocks. Only one or a few animals are affected at any given time. Outbreaks may occur if scrapie is introduced into a genetically susceptible flock.

Although no breed is known to have a predisposition to scrapie, the genetic makeup of the host controls differences in susceptibility and resistance to scrapie in various breeds.[1,5,6] The molecular basis of this resistance is largely controlled by the PrP gene.[7] Polymorphisms at three codons of this gene (136, 154, and 171) appear to be the main determinants of the susceptibility of sheep to scrapie.[1] According to current evidence, the genotype $VV_{136}RR_{154}QQ_{171}$ (or $AA_{136}RR_{154}QQ_{171}$ in some breeds) is most susceptible, and the genotype $AA_{136}RR_{154}RR_{171}$ is highly, but not completely, resistant.[1] Susceptibility is most clearly linked with variation at codons 136 and 171 in breeds studied to date; the genotype of a particular animal is often referred to as *RR*, *QR*, or *QQ* to designate the alleles at site 171. Pedigree, phenotypic expression of the disease, or genetic testing may be used to identify sheep with "resistant" PrP genotypes. Genetic polymorphisms or the PrP gene may also influence susceptibility to scrapie, the incubation period for scrapie, or both in goats.[8]

Pathogenesis In contrast to BSE, which is restricted to the gut-associated lymphoid tissue and nervous tissue, the scrapie agent can be identified in infected sheep in various nonneural tissues such as those of the lymphoreticular system, kidney, and placenta.[9,10] This difference has facilitated the development of lymphoid tissue biopsy techniques to detect scrapie (described later). Most transmission of scrapie appears to take place during the birthing season.[1] The scrapie agent is probably spread by the placentas and birthing fluids of infected animals,[11,12] and oral uptake is considered the probable route of entry.[11-13] Transport of PrP-Sc to the CNS probably occurs along the vagus nerve from the GI tract,[14] and in most cases the agent can be demonstrated in the vagal nucleus of the brainstem early in the stage of neuroinvasion.[15] It then spreads into higher brain centers. Dysfunction of the CNS appears to correlate approximately with accumulation of PrP-Sc in the brain; however, subtle dysfunction can occur with little or no characteristic histologic changes. The exact mechanism that causes neurologic dysfunction remains to be fully defined.[9]

Clinical Signs Most animals with scrapie are 1 to 5 years old. The clinical course varies but is typically slow and may last several months. Early behavioral changes are often accompanied by weight loss. Animals with scrapie may stay apart from the flock and become nervous and restless.[16] Pruritus of increasing intensity is a common feature; affected sheep may rub on fixed objects, scratch with their horns or hooves, and bite or lick themselves excessively. The head, withers, flanks, back, rump, base of the tail, and lower limbs are typically affected, showing secondary wool loss, dermatitis, and skin infections or excoriations.[2,16] Head and face rubbing and shaking may also cause ocular lesions or aural hematomas. When scratching the pruritic areas (mostly the back and rump), the animal may display a "scratch reflex" (or "nibble reflex"), which may include reflex nibbling, lip licking, and rhythmic head movements. This reflex is often, but not always, present in scrapie cases. This response may also be observed in other CNS diseases and in pruritic skin diseases, particularly ectoparasitism, so it should not be considered specific for scrapie.

Other clinical signs of scrapie include bruxism, ptyalism, and regurgitation. Tremors may start with the head and generalize to the whole body. Apathy, exercise intolerance, hypermetria, and ataxia may develop. Animals with the most severe and advanced cases show stupor, episodic collapse, and convulsions. Death may occur during a convulsion or as a result of starvation. The clinical signs of scrapie in goats are broadly similar to those in sheep.[2,3,17-19] Scrapie has been identified in fallen (down) sheep as well.

Diagnosis Because the scrapie agent can disseminate in lymphoid tissue before the development of clinical disease, immunohistochemistry studies may show PrP-Sc in biopsy samples containing lymphoid tissue from the tonsils,[20] nictitating membranes,[21] retropharyngeal lymph nodes,[22] or rectoanal junction.[23,24] However, these tests have limited sensitivity, primarily because of variable lymphoid involvement among infected sheep, a phenomenon that may be associated with the host's genetic makeup.[25] Microscopic examination of the brain and spinal cord is the classic diagnostic method for scrapie. The scrapie agent is possible to identify only when tissues are

collected soon after death, before autolytic changes take place. Neuronal vacuolation and PrP-Sc deposits are found in specific brain nuclei.[26-31] Collection of brainstem tissue (particularly the obex), tonsillar tissue, and medial retropharyngeal lymph nodes is currently recommended for testing suspect sheep in the United States.[32] In autolyzed tissues, PrP-Sc can be identified by immunohistochemistry testing, Western blot tests, or ELISA.[33-36] As with BSE, heightened active surveillance for scrapie has revealed at least one atypical strain of scrapie (termed *atypical scrapie*).[37]

Nervous system diseases that could be confused with scrapie include pseudorabies, rabies, Borna encephalitis, listeriosis, polioencephalomalacia, lead poisoning, cerebrospinal nematodiasis, gid (coenurosis), brain tumors, brain abscess, maedi-visna virus infection, vitamin A deficiency, pregnancy toxemia, and other metabolic imbalances. When pruritus is the only clinical sign, skin diseases such as psoroptic and sarcoptic mange, ringworm, myiasis, pediculosis, and atopy may be considered in the differential diagnosis. Because of the insidious nature of the illness, animals with early scrapie may initially appear to respond to a variety of treatments. This must be kept in mind whenever specific therapy for another suspected illness appears initially to be successful but is followed by relapse. When therapy of an alternative condition fails, the final diagnosis must rely on detailed examination of postmortem samples, as discussed previously.

Treatment and Control Scrapie is a fatal and irreversible disease for which there is no known treatment.

Because there is no effective treatment for scrapie, control measures designed to prevent the spread of the disease are especially important. Scrapie is a reportable disease. Eradication measures vary from country to country. Animals suspected of having scrapie are destroyed. Contaminated pastures or paddocks may be left empty of livestock, but the scrapie agent is unlikely to be inactivated in the environment. Contaminated stalls, corrals, and sheds should be disinfected with sodium hypochlorite diluted at 4% available chlorine. In the United States and Canada, scrapie-affected and related animals are destroyed, and their flocks are quarantined. Lines of sheep genetically resistant to the development of clinical scrapie have been developed,[38,39] and genotype testing is currently used to select for resistance to the disease.[1]

Public Health Considerations Although scrapie has been endemic in various areas of the world for more than two centuries, epidemiologic studies have not shown any correlation between the incidence of Creutzfeldt-Jakob disease in humans and that of classical scrapie in sheep; the zoonotic potential of atypical scrapie remains under investigation.[1] It is nevertheless prudent to take precautions to minimize the potential for human exposure to scrapie because of the high fatality rate characteristic of TSEs and the potential for emergence of novel strains of prions with unknown host ranges.[1]

Pseudorabies (Aujeszky's Disease, Mad Itch, Bulbar Paralysis)

Christine F. Berthelin-Baker • Lisle W. George

Definition and Etiology Pseudorabies is an acute, severe, and usually fatal encephalitis caused by an encapsulated DNA virus, Suid herpesvirus type 1, a member of the genus *Varicellovirus*, subfamily Alphaherpesvirinae, family Herpesviridae.[1,2] This virus can infect the CNS and other organs (e.g., respiratory tract) of virtually all mammals except humans and most primates. Domestic and feral swine are the natural hosts and may become latent carriers. The virus can also infect cattle, sheep, cats, dogs, goats, wildlife (e.g., raccoons, opossums, skunks, rodents), and, in rare cases, horses.[3,4]

Epidemiology Pseudorabies has a worldwide distribution and, although cases occur only sporadically, is an economically important disease because of the regulatory quarantine and other restrictions imposed on animals from affected herds. This disease was endemic in the United States, but it has been successfully eradicated in domesticated swine. In the United States, all states are currently classified as free of pseudorabies in domesticated swine (OIE status V), although pseudorabies virus remains present in feral pigs in parts of the country.

The viral infection in cattle is perpetuated partly by the occurrence of latent infections in pigs, which can be recrudesced by stressful conditions.[5] The virus is occasionally transmitted from swine into ruminants because of the proximity of the two species in many livestock operations.[6,7] The natural routes of transmission include nose-to-nose, fecal–oral, and venereal.[2,8] Indirect transmission usually occurs by inhalation of aerosolized virus. The virus may travel via aerosols up to 2 km (1.2 miles) in certain weather conditions and may survive up to 4 days in straw bedding. It is inactivated by drying, sunlight, and high temperatures (≥37° C). Dead-end hosts such as dogs, cats, and wildlife can transmit the virus between farms, but aside from feral swine, these animals survive only 2 to 3 days after becoming infected.

Latency of the viral infection in ruminants is not an important mechanism for perpetuation of an outbreak because most affected animals die within 48 hours of disease onset. In the few that survive longer, shedding in saliva occurs for up to 6 days after infection. The virus is unlikely to be transmitted directly from infected and uninfected cattle.[7] Wild mammals such as raccoons may play a role in pseudorabies survival and transmission;[9] rats, however, develop transient infections and do not appear to transmit or perpetuate the virus.[10] The pseudorabies virus may survive in contaminated meat products for up to 7 weeks. The role of this prolonged survival in perpetuating outbreaks in ruminants is unknown.

Pathogenesis Ruminants are susceptible to pseudorabies infection after intradermal, subcutaneous, intranasal, or oral exposure to the virus. After subcutaneous, oral, or nasal infection, the virus spreads centripetally to the CNS by axonoplasmic transport. During the acute infection, the virus may be present in the nasal mucosa, secretions, and saliva.

Clinical Signs The incubation period ranges from 90 to 156 hours, and the illness may last 8 to 72 hours, although some affected animals have been found dead without having exhibited any clinical signs.[6,11] The initial clinical sign in ruminants is usually acute and severe pruritus that induces self-trauma, dermal abrasions, swelling, and alopecia.[11] Other signs may include fever, bellowing, bloat, feet stamping, excessive salivation, twitching, chewing of the tongue, ataxia, circling, nystagmus, and strabismus.[12,13] Some affected animals exhibit aggression, but most become depressed. As the disease progresses, affected animals may exhibit hyperesthesia, tenesmus, excessive licking of the nostrils, continuous mastication, vocalization, coma, convulsions, and opisthotonos. Most cases are fatal. The clinical signs of pseudorabies in cattle closely resemble those of rabies, polioencephalomalacia, salt poisoning, meningitis, lead poisoning, hypomagnesemia, and enterotoxemia.

Clinical Pathology The pseudorabies virus can be isolated from the pharyngeal or nasal secretions of affected animals and can be easily cultured from infected nervous tissues. Strains of pseudorabies virus are antigenically distinct from other herpesviruses but share common antigens with the IBR virus. Heterospecific antibodies to the IBR virus may cross-neutralize

VetBooks.ir

the pseudorabies virus and confound serologic tests. For virus culture, tissues should be collected from sensory ganglia or the dorsal horn of the spinal cord. Segments serving the pruritic sites should be collected preferentially because these areas contain the highest concentration of virus.

Pathology Gross findings include excoriation, alopecia, edema, and hemorrhage at the pruritic site. The neuropathologic changes include nonsuppurative encephalitis, neuronal degeneration, and eosinophilic intranuclear (Cowdry type A) inclusion bodies. The lesions are most pronounced in the dorsal nerve rootlets and the dorsal horn.[11]

Treatment and Control There is no treatment for pseudorabies, which is usually fatal in livestock, but rare recoveries have been reported.[13]

The most effective method of preventing pseudorabies virus infection in ruminants is eliminating their exposure to swine. Contaminated pens can be disinfected with 10% sodium hypochlorite solution, quaternary ammonium compounds, tamed iodine, or phenolic compounds.[14] At least 5 minutes of contact time should be allowed before the disinfectant is rinsed from the contaminated surfaces. Fumigation with formaldehyde for 6 hours effectively kills the virus, as does 360 minutes of contact with ultraviolet light.

Ovine Encephalomyelitis (Louping Ill)

Definition and Etiology Louping ill is an acute, fatal encephalomyelitis of sheep that occasionally infects humans, wild ruminants, horses, and cattle.[1-3] The disease has been reported in England, Scotland, Ireland, Norway, Turkey, and Bulgaria.[4-6] The etiologic agent of louping ill is a neurotropic, single-stranded RNA virus (flavivirus) that is transmitted primarily by the tick *Ixodes ricinus*, as well as by *Rhipicephalus appendiculatus*, *Ixodes persulcatus*, and *Haemaphysalis anatolicum*. Most outbreaks occur in swampy areas with dense populations of infected ticks and wild animals. Infection through blood contamination of hypodermic needles, other fomites, and blood products has been reported.[7] Minor genetic variations of the viruses exist in different geographic areas, constituting four subtypes.[8]

Epidemiology Louping ill affects principally yearling sheep in the spring, although lambs and adults can be affected. Maternal immunity wanes when lambs are approximately 3 months old. Infection develops weeks to months after sheep have been placed on pastures inhabited by infected ticks. In an outbreak, the prevalence of clinical louping ill is low, but the seroprevalence of antibodies in adult sheep in endemic areas is high, which indicates a continuous, low-level exposure to the virus, and many animals are affected without showing symptoms. Factors such as climate, tick population, and immune status of the flock all play a role in the severity of an outbreak.[7] The attack rate may reach 60% of the population, but the mortality rate rarely exceeds 15%. Adults tend to be more heavily parasitized by the host ticks and thus play a major role in virus survival and transmission.[9] Pigs, goats, cattle, horses, and red deer also become infected with the virus and can develop similar clinical disease.

In sylvatic cycles of virus transmission, viral amplification takes place through certain wild mammals and red grouse.[1,10,11] The hare serves as an important source of virus for the red grouse.[12,13] The red grouse is infected by ingesting, rather than by being bitten by, the infected tick.[14]

The high incidence of louping ill in the spring and summer months probably corresponds to the peak activity of ticks. The virus may persist for long periods in the arthropod vector, but it is unclear if transovarial transmission of the agent occurs. *I. ricinus* is a three-host tick with a life cycle of 3 years. These ticks do not walk, and so dissemination requires animal transport. After a blood meal, the tick molts and then rests on vegetation until the next meal, approximately 12 months later. The activity of the ticks tends to increase greatly in the spring whenever the ambient temperatures are above 7° C (43° F).

Pathogenesis Ticks become infected when feeding on a viremic host. The virus survives in the salivary glands of the tick and can overwinter there, being transmitted to a new host when the tick becomes active the following year.[7] After inoculation into susceptible sheep, the louping ill virus migrates into the regional lymph nodes and spleen and then replicates. Viremia occurs 6 to 20 days after invasion into the lymphatic tissues.[2] Viral replication in the brain causes nonsupportive inflammation and neuronal degeneration. Rapid antibody production is associated with recovery.[15] Concomitant infection of sheep with the agent of tick-borne fever *(Anaplasma phagocytophilum)* results in a greater level of viremia and increased mortality from the louping ill virus.[16] The virus is transmissible in unpasteurized milk from sheep and goats.[17]

Clinical Signs In sheep, the initial clinical signs of louping ill include fever, anorexia, depression, constipation, and generalized muscular tremors. The ensuing signs are characteristic of CNS disease and include ataxia, conscious proprioceptive deficits, head tremors, hypermetria, and hyperexcitability. The hypermetria results in a characteristic "bunny-hopping gait," which gives the disease its name ("loup" in vernacular Scottish means *leap*). Further progression of clinical signs is associated with cerebrocortical dysfunction; these signs include head pressing, hyperesthesia, recumbency, convulsions, coma, and death. Survivors have residual neurologic deficits. The duration of the illness is approximately 12 days.

Clinical Pathology Both hemagglutination inhibition and complement fixation tests can be used to detect virus in infected animals.[7] High levels of virus-specific IgG and IgM can be detected in the CSF of affected animals.[18] Viremia peaks at approximately 3 days after inoculation and disappears by 7 days. Because animals are usually not viremic at the time the nervous system lesions develop, virus samples are collected most efficiently from the brain or spinal cord.

Pathology Gross lesions are absent at necropsy. The histologic lesions of louping ill reflect meningeal inflammation with mononuclear cells.[19,20] Microscopic lesions are most severe in the Purkinje cells, motor nuclei, and ventral horn cells. The forebrain is spared.[21] Virus in tissue can be detected by virus isolation, immunohistochemistry, and RT-PCR.[7,22,23]

Treatment and Control There is no treatment for louping ill encephalitis, but supportive care should be provided.

A formalin-inactivated vaccine given to pregnant animals in the last trimester has been recommended for preventing louping ill encephalitis.[24] A single dose of the vaccine provides responses that are protective for at least 2 years. Other methods of preventing the disease include frequent acaricidal dipping of sheep and clearing of pastures to reduce the population of infected intermediate hosts.

Louping ill has not been detected in the United States, but it is a reportable disease. Any suspicion of this disease should be reported to state and federal authorities.

Public Health Considerations The disease has zoonotic potential; infection of humans is rare but can occur through tick bites, unpasteurized infected sheep or goat milk, or fomites. Mild occupational infections have been noted in shepherds, veterinarians, and laboratory workers who cultivate the virus.

Rabies

Christine F. Berthelin-Baker • Lisle W. George

Definition and Etiology Infection with rabies virus results in severe and usually fatal neurologic disease. Most mammals are susceptible and are infected through bites from other animals during or near the clinical phase of illness. The rabies virus and other highly neurotropic rabies-related viruses belong to the genus *Lyssavirus*, family Rhabdoviridae (bullet-shaped RNA viruses). Wildlife provides a natural reservoir for rabies, and each rabies strain is maintained in one or more particular reservoir hosts. Although they can readily cause rabies in other species, wildlife-adapted strains of rabies usually die out when passed into species to which they are not adapted. Other "rabies-related" lyssaviruses can cause a neurologic disease identical to rabies. They include the Lagos and Duvenhage viruses of bats in parts of Africa, the Mokola virus of rodents and shrews in Africa, and the lyssaviruses of European and Australian bats.[1-3]

Epidemiology Rabies is a reportable zoonosis that has been detected worldwide, with some exceptions (primarily islands). It currently does not occur in Sweden, Norway, the United Kingdom, Ireland, Australia, New Zealand, or Iceland.[1] The disease is endemic in other parts of the world, including the United States, Canada, and Europe but remains epizootic in Central and South America, Africa, and parts of Asia, especially where a tropical climate and a high population of infected feral mammals enable viral propagation and transmission.[2,4] The rabies virus is shed in the saliva and does not survive when dried or exposed to ultraviolet light. The most common method of viral transmission to domestic animals is through the bite of an infected feral or wild mammal. Humans and laboratory animals have also developed fatal infections after respiratory exposure to viral aerosols. Low levels of rabies virus are also shed in the milk of infected animals and occasionally infect offspring nursing from infected dams.[5,6] Laboratory animals, foxes, and skunks can also be infected experimentally by ingestion of infected tissues from animals with rabies.[5,6] In the United States, survival of the virus in the wild may depend on cycling of infections in skunks, bats, raccoons, and foxes, which are also common sources of livestock infections.[7,8]

Certain strains of rabies virus have low virulence in skunks and bats; as a result, these animals are symptomless carriers serving as reservoirs. The rabies virus is also transmitted directly among bats through aerosols in caves. The bats may die off from rabies during periods of high viral contamination. In the United States the most common wild reservoirs are foxes in Alaska and along the border of Mexico, raccoons in the East, and skunks in the central and western regions.[4] Mandatory vaccination of dogs has virtually eradicated canine rabies from industrialized countries, where rabies transmission from domestic dogs to livestock is rare.[1,9] Island nations have remained free of rabies by imposing a 6-month quarantine on imported dogs and cats. In South America, rabies outbreaks in cattle often result from vampire bat bites, causing up to 50,000 cattle deaths annually. Human rabies cases may result from bites inflicted by infected pets, feral dogs and cats, bats, or wildlife. Cases resulting from contact with infected cattle or horses are rare.[4,9,10]

Pathogenesis After subcutaneous or intradermal inoculation, the rabies virus replicates locally. Subsequently, it binds to the acetylcholine (and other) receptors of the peripheral nerves and then migrates to the CNS through peripheral nerves, spinal rootlets, and the spinal cord. After entry into the nerve cell rootlets, the virus travels to the brain along nerve tracts and into CSF. From there it spreads centrifugally along the rootlets of the cranial nerves to the salivary glands and the nasal epithelium. While inside cells, the rabies virus evades the immune system by blocking certain signaling proteins necessary for those cells to respond to interferons.[11] The virus must replicate in the brain before it can reach the salivary and nasal secretions. Therefore whenever an animal bites a person, the attacking animal can always be euthanized and tested for the potential of rabies virus transmission, and it not necessary to wait for disease progression before testing an animal for rabies, as historically recommended when histologic examination for Negri bodies was the main diagnostic test for rabies. Negri bodies are aggregates of viral proteins and nucleic acids, most commonly observed on histologic examination of the hippocampus of rabies-infected animals. In humans, most cases become apparent within 1 to 3 months of infection, but a small proportion of cases have had incubation periods in excess of 6 months, extending to several years in rare cases.[1] The rabies virus replicates in the cell bodies (gray matter) of the CNS. Dysfunction of these neurons results in behavioral changes and variable abnormalities of the cranial and the peripheral nerves, with multifocal loss of lower motor neuron and autonomic function. Death results from cardiorespiratory paralysis as the virus infects the medullary centers of the brainstem.

Clinical Signs Livestock cases of rabies have been reported mostly in cattle and occasionally in horses, sheep, and goats.[3,4] Rabies should be included in the differential diagnosis of any unexplained acute, rapidly progressive intracranial disease, especially in the presence of autonomic instability, dysphagia, hydrophobia, paresis, or paresthesia.[3,12] The incubation period ranges from a few days to 6 months, depending on the pathogenicity of the inoculum and the distance from the site of inoculation to the brain. The incubation periods are shortest in animals bitten on the head, whereas the longest incubations have been reported after bites on the extremities of the pelvic limbs.

The disease is usually fatal after a clinical course of 1 to 8 days. Occasionally, an affected animal is found dead without having exhibited any clinical signs previously. Early clinical signs of rabies in livestock may be nonspecific sensory and behavioral changes, including anorexia, restlessness, depression, separation from the herd, and mild ataxia. In ruminants, rumination may cease. Many affected horses appear colicky. Affected animals may show regional paresthesia with pruritus, creating excoriation and hair loss. As the disease progresses, affected animals may become hyperexcitable, fearful, or enraged *(furious rabies)* or mentally depressed *(dumb rabies)*. Cattle rabies frequently manifests as dumb rabies with flaccid paraparesis, tetraparesis, and tetraplegia *(paralytic rabies)* as it progresses. Therefore the examiner should consider appropriate personal protective equipment (coveralls, boots, gloves, mask, and eye protection) when examining downer cattle in rabies-endemic areas.

In an experimental study, all cattle and sheep infected with the rabies virus exhibited excessive salivation and behavioral changes, and the majority also displayed tremors, bellowing, aggression, hyperesthesia, and pharyngeal paresis/paralysis.[3] Tetraplegic animals may bellow and show frantic motor activity of the legs when stimulated. Animals with dumb rabies are depressed, inappetent, and often febrile (>39.4° C [103° F]), and they may exhibite head and neck drooping, ptosis, flaccid facial musculature, profuse salivation, and yawning. They may also demonstrate repeated nibbling motions with the lips. Other signs include tenesmus, paraphimosis, priapism, odontoprisis, head pressing, circling, basewide stance, difficulty rising, and falling episodes. Flaccidity of the tongue, tail, anus, and urinary bladder may also be evident, as may blindness, strabismus, and nystagmus.

The first clinical sign of paralytic rabies in horses may be an unexplained ataxia or shifting leg lameness, soon followed by paraparesis or paraplegia.[13] Spinal reflexes and tone in the

VetBooks.ir

affected limbs may be decreased or absent. Most affected animals become recumbent in 3 to 5 days. Initially, the recumbent animal may be able to eat and drink with help, but it soon becomes anorectic and develops encephalopathic signs, followed by generalized seizures and coma[14,15] (Fig. 35.11).

Regardless of the clinical manifestations, rabies is a rapidly progressive and fatal disease leading to cardiorespiratory failure, and death usually occurs within 10 days. In all disease forms in livestock, the clinical signs rapidly worsen over 1 to 3 days, ending in recumbency and coma. A pharyngeal–laryngeal paralysis may develop, resulting in stertorous breath sounds, inability to drink (hence the common name of *hydrophobia*), and accumulation of frothy saliva at the commissures of the lips.[16]

One summary of 21 cases of rabies in horses enumerated the frequency of particular clinical signs observed as the presenting complaint (Table 35.5). Rabies can be differentiated from other encephalitic disorders only by specific postmortem tests or virus isolation, which is usually not possible before death occurs. In horses, the clinical signs of rabies are often indistinguishable from other encephalopathies such as hepatoencephalopathy, leukoencephalomalacia, togaviral encephalitis, equine herpesvirus 1 (EHV-1), protozoal and other meningoencephalomyelitides, and space-occupying masses. In ruminants, rabies may resemble pseudorabies, herpesvirus encephalitis, infectious thromboembolic meningoencephalitis, nervous ketosis, grass tetany, hypocalcemia, polioencephalomalacia, nervous coccidiosis, or even focal spinal cord or peripheral nerve diseases. Most horses with fatal encephalopathy die within 5 days of the onset of signs, but cases lasting as long as 14 days have occasionally been observed.[17]

TABLE 35.5

Clinical Signs of Rabies in Horses

Clinical Signs	Frequency of Occurrence
Ataxia, paraplegia	11/21
Lameness	5/21
Pharyngeal paralysis	2/21
Recumbency	21/21
Colic	2/21
Hyperesthesia	17/21
Tail and anal paralysis	12/21
Fever	11/21

From Green S, Smith LL, Vernau W, et al. 1992. Rabies in horses: 21 cases. *J Am Vet Med Assoc* 200:1133.

FIG. 35.11 Ten-month-old mixed-breed calf with terminal rabies virus encephalitis. The calf is comatose and showing opisthotonos.

Clinical Pathology There is no valid antemortem test to diagnose rabies in livestock. Rabies usually remains immunologically and serologically silent throughout the incubation and clinical phase of the illness. Clinicopathologic tests are not specific for rabies but may help rule out other, more common diseases. The CSF may be normal or may show moderate mononuclear pleocytosis (5 to 30 cells/μL) and increased protein levels (60 to 200 mg/dL), occasionally with neutrophils, eosinophils, or xanthochromia. Laboratory personnel should be warned that rabies is part of the differential diagnosis when CSF is submitted for analysis.

Pathology Rabies causes a nonsuppurative meningoencephalomyelitis. Microscopic changes include edema, meningeal congestion, focal areas of hemorrhage, perivascular cuffing, gliosis, neuronophagia, and neuronal degeneration. These changes are most severe in the dorsal root ganglia and can be observed in most CNS regions.

A definitive diagnosis of rabies may be based on the finding of Negri bodies on histologic examination of brain tissue (of note, these are not always present, especially in animals euthanized early in the disease course) or through a positive direct or indirect fluorescent antibody test conducted on fresh smears of CNS tissues (thalamus, hippocampus, brainstem, pons, medulla, and cerebellum).[18-20] If results of these tests are negative or inconclusive and humans have been exposed, additional testing can be performed with intracerebral inoculation of mice with CNS tissue from the suspected case. The direct fluorescent antibody test on brain tissue has become the standard against which the value of other rabies tests is evaluated.[18] In cases of human exposure, public health authorities should always be contacted before sample collection and submission. Most diagnostic pathologists accept the refrigerated head (or even whole body, for small animals and bats) or refrigerated brainstem and cerebellum collected through the foramen magnum in mature cattle and horses. Care should be taken to prevent any human exposure to body fluids and CNS tissue of any animal with rabies on the list of differential diagnoses, especially in areas where rabies is known to be present in any domestic or wildlife species; open wounds or small healing sores may be portals of entry for the rabies virus.

Treatment and Control There are no specific treatments for rabies, and once an animal is infected, the disease is usually fatal. Although widespread rabies vaccination of livestock may not be economically justified in low-incidence areas, vaccination of valuable livestock or animals that travel or are in regular contact with humans (e.g., at petting zoos or in animal shows) should be considered, particularly in or near rabies epizootic areas. A list of licensed rabies vaccines for the protection of animals against rabies is regularly updated by state veterinary authorities.[21] Strict adherence to label directions for use of these vaccines is mandatory. In some jurisdictions, immunization of large animals is considered by regulatory authorities to be valid only if the vaccine is administered by a licensed veterinarian.

The disposal of livestock that have been bitten by rabid animals depends on the bitten animal's vaccination history, local and national regulations, and the animal's value. In the United States and Canada, the disease must be reported to the state or province/territory public health department. Management of exposed livestock must be coordinated with public health officials. Any livestock bitten by a wild animal should be considered to have been exposed to rabies, regardless of the availability of the biting animal for testing. If a bitten horse had been vaccinated before the bite, it should be revaccinated immediately and kept under observation for 90 days. Other exposed, unvaccinated animals with low economic value should be euthanized; if the animal is valuable, the bite wound may be washed with copious amounts of water and iodine or

quaternary ammonium disinfectants, after which the animal should be quarantined for at least 6 months, and the brain should be examined if it dies.[21] The prolonged quarantine period is based on case reports of prolonged incubation periods in certain species.[1]

Initial vaccination of animals shortly after rabies virus exposure is not recommended because it is less effective than prophylactic vaccination, and idiopathic responses to the vaccine may complicate interpretation of the animal's disease status after exposure.[1] When human exposure to rabies virus is suspected, the biting animal must be euthanized and its brain examined for evidence of infection. A vaccinated or valuable animal may be quarantined for 6 weeks under veterinary supervision, and the animal must be euthanized and its brain examined if it develops clinical signs suggestive of rabies during that period. The World Health Organization (WHO) publishes and regularly reviews its recommendations for vaccination and prophylaxis in humans after actual or suspected exposure to the rabies virus.[2]

Control of rabies by immunization of susceptible wildlife through the use of baits containing modified live vaccines has been successful in certain cases.[1,4,22,23] Such approaches may provide a means for large-scale immunization of wildlife or feral animal populations for eventual eradication of the disease.

Sporadic Bovine Encephalomyelitis (Buss Disease; Polyserositis; *Chlamydophila pecorum* Infection)

Definition and Etiology Sporadic bovine encephalomyelitis (SBE) is caused by *Chlamydophila pecorum* biotype 2, an organism previously named *Chlamydia psittaci* and *Chlamydia pecorum*.[1] The disease was first reported in the United States in 1940.[2] A similar but not identical viral disease occurs in cattle in Australia and has been named *bovine ephemeral fever*.[3-5]

Epidemiology Infected cattle shed the organism in urine, feces, nasal secretions, and milk. It can also be found in the feces of calves that are exposed to clinically affected herdmates but show no symptoms. The agent tends to remain endemic on a single farm, and sporadic outbreaks of disease may occur only on those premises. Outbreaks of SBE are rare, but the attack rate in an epizootic ranges from 5% among adults to 25% among calves. The mortality rate is highest in calves and approximates 30% for all age groups.[6] The pattern of these outbreaks varies: from a few cases annually to acute, recurrent epizootics with high case-attack rates that subside after 3 to 4 weeks.

Pathogenesis The mode of transmission and the genesis of pathologic lesions are unknown in natural cases, but postmortem lesions indicate the role of hematogenous dissemination of the organism to the CNS and other tissues. The extracellular form, termed an *elementary body*, is metabolically inert and can be shed in the feces and urogenital secretions of multiple animal species.[1] The pathogenesis of infection and invasion into the host's bloodstream is not well understood.

Clinical Signs Affected animals show signs of a multisystemic disease. The initial clinical signs in cattle are fever (39° C to 41.5° C [102.1° F to 106.7° F]), diarrhea, anorexia, depression, and stiffness. Animals in the early stages may show signs of a respiratory disease characterized by nasal discharge, dyspnea, and cough. These animals occasionally have a pain response to percussion of the hoof, as well as swelling of the coronary band or polyarthritis and tenosynovitis.[2] Auscultatory abnormalities may include high-pitched wheezes and crackles over the lung fields or pleural and pericardial friction rubs. Because of the fibrinous peritonitis and pleuritis, the clinical signs in some affected animals may resemble those of hardware disease. These animals may grunt or groan when sudden pressure is applied to the xiphoid region. Progression of the disease is related to development of the meningoencephalitis and is characterized by ataxia and conscious proprioceptive deficits, circling, head tilt, opisthotonos, hyperesthesia, stiff neck, convulsions, and coma. Affected animals may die after 4 to 10 days.

Clinical Pathology and Diagnosis The detection of reticulate bodies in the exudate cells of pleural and peritoneal effusions is highly suggestive of SBE. The agent can be most readily detected in clinical samples by PCR, although inoculation of laboratory animals may also be used.[1] Serologic testing is difficult to interpret because antibodies to *C. pecorum* may cross-react with other *Chlamydophila* spp. on certain serologic tests.[1]

Pathology Growth of the organism in the arteriolar endothelium causes vasculitis, hemorrhage, edema, and accumulation of fluid in the body cavities. Diffuse fibrinous pleuritis, peritonitis, and meningitis are also present. Microscopic changes include perivascular mononuclear cell infiltration and neuronal degeneration.

Treatment and Control Early cases of SBE can be treated with oxytetracycline (20 mg/kg/day IV, SC, or IM for a minimum of 7 days). Efficacy is indicated by a reduction of fever within the first 24 hours of treatment.

There are no known effective control measures for the prevention of SBE. The chlamydial agent is susceptible to a number of disinfectants, including 2% sodium hydroxide (NaOH), 5% cresol, and 0.3% quaternary ammonium compounds.

Meningitis (Suppurative Meningitis; Bacterial Meningitis)

Definition, Etiology, and Epidemiology Bacterial meningitis is defined as inflammation of the meninges surrounding the brain or spinal cord, or both, that results from bacterial invasion of these tissues.[1] If the infectious process extends into brain tissue, the condition is termed *meningoencephalitis;* if it extends into the ventricles of the brain, it is termed *meningoventriculitis*. Differentiation of meningitis from the other two conditions almost always necessitates advanced imaging techniques or histologic examination, but the conditions result in similar clinical signs.[2] It is relatively rare in large animals. It is most often the result of hematogenous infection in neonates, as a consequence of septicemia with partial or complete failure of passive transfer of colostral antibodies or of septicemia resulting from translocation of invasive bacteria from the GI tract, respiratory tract, or umbilicus.[2,3] Hematogenous infection of the meninges, brain, or both also occurs sporadically in adults; such events may be associated with septicemia from a primary focus of infection such as the udder, uterus, or GI tract. As with neonates, underlying immunodeficiency may predispose adult animals to this disease.[4,5]

Bacterial meningitis can also result from direct extension of infectious agents into the calvaria, such as extension of pyogenic infections into the calvaria from infected skull fractures,[6,7] osteomyelitis from sinusitis or otitis media/interna,[8] or osteonecrosis caused by thermal cauterization during dehorning (particularly in goat kids).[9] Improper placement of trephination holes, cribriform plate fractures, and extension from infected coccygeal vertebrae are additional routes of meningeal infection. In horses, septic meningitis is a potential sequela to surgical removal of progressive ethmoidal hematomas and has also been reported as a consequence of local spread

of infections of the paranasal sinuses, nasal cavity, periocular tissues, and submandibular lymph nodes.[10]

Many different bacteria have been isolated from the blood, meninges, brain, and spinal cord of affected large animals. In neonatal calves and foals, Gram-negative enteric bacteria such as *Escherichia coli*, *Salmonella* spp., and *Klebsiella* spp. are considered common isolates.[1,2] *Mycoplasma* spp. may be isolated in goat kids. *Histophilus somni* is a potential cause of meningitis in juvenile cattle in feedlots and is reviewed later in this chapter, as are CNS infections caused by *Listeria monocytogenes*. A variety of Gram-positive and Gram-negative bacteria may be involved in adults, a fact that underscores the importance of cytologic examination, Gram staining, and aerobic and anaerobic culture of CSF samples obtained early in the clinical course of disease.[1,2,11]

Pathogenesis Bacterial turnover leads to liberation of exotoxins and endotoxin, which, in concert with various inflammatory mediators, including cytokines, damage the neural parenchyma. Vascular sequelae to infection may include thrombotic or hemorrhagic infarctions. After several days, inflammation of the arachnoid trabeculae and choroid plexus can result in decreased CSF absorption and hypertensive hydrocephalus.[1,3]

Clinical Signs The earliest clinical signs of meningitis are often nonspecific and may reflect the signs induced by a primary infection site (e.g., diarrhea in neonates with invasive bacterial enterocolitis). Fever is common, as is anorexia and loss of a coordinated suckle in a neonate.[3] Reluctance to lift or bend the neck may be evident, and manipulations by the examiner may induce responses suggestive of hyperesthesia.[2,3,12] Slight tactile stimulation of the skin may result in strong spasmodic extension of the limbs, fasciculations of the underlying musculature, or even generalized frantic motor activity. The patient's behavior may vary from extreme depression to hyperexcitability. A subtle intentional head tremor is often observed in affected foals. Dysfunction of one or more cranial nerves may result in facial muscular tremors, nystagmus, facial palsy, blindness, anisocoria, or strabismus. Progression of the clinical signs is associated with a decreased sensorium, propulsive walking, coma, seizures, and status epilepticus. Sequelae to septicemia, such as septic arthritis or polyarthritis, uveitis, panophthalmitis, hypopyon, cardiac murmurs secondary to valvular endocarditis, and pyuria/proteinuria, may be detected as well.

The clinical signs of bacterial meningitis closely resemble those of viral encephalomyelitis caused by such agents as rabies, West Nile, and togavirus encephalomyelopathies (EEE, VEE, and WEE, described earlier in this chapter). Metabolic encephalopathies may also mimic bacterial meningitis including hypomagnesemia, hypocalcemia, hypoglycemia (which may occur simultaneously with septic meningitis in neonates), hepatic encephalopathy, renal encephalopathy, and encephalomalacias (e.g., salt poisoning, polioencephalomalacia). Congenital neurologic disorders of neonates may be considered; however, these disorders do not typically induce fever, inflammatory leukogram patterns, or inflammatory changes in the CSF.

Clinical Pathology Meningitis is diagnosed on the basis of examination of the CSF (for normal values, see Table 35.1). The CSF of animals with meningitis may be turbid and white to amber in color, may foam when shaken, and may clot. Xanthochromia may be observed in some specimens. The WBC counts in CSF of calves with purulent meningitis are typically greater than 100 neutrophils/μL, and protein concentrations range from 20 to 270 mg/dL.[3] The differential cell counts in the CSF are either predominantly neutrophilic or mononuclear. Because of bacterial consumption of glucose in the CSF, the concentration of glucose in the CSF is often less than 50% of the corresponding concentration in the serum. Gram staining of CSF should be conducted in all cases. Abnormalities in the blood are inconsistent and reflect secondary conditions such as septicemia, diarrhea, or concurrent fluid therapy. These changes could include leukopenia or leukocytosis, left shift, toxic changes in the neutrophils, hyperkalemia, respiratory acidosis, hypoglycemia, and hyponatremia or hypernatremia.

The numerous differential diagnoses discussed previously are distinguished from bacterial meningitis by compilation of data obtained from physical examination, serum immunoglobulin measurement, serum biochemistry analysis, complete blood cell count, and, of most importance, cytologic examination, Gram stain, and culture of CSF.

PCR assays of CSF may be used to identify specific suspected organisms, as was done for diagnosis of meningitis caused by *Borrelia burgdorferi* in a horse.[5]

Pathology Gross lesions of primary infection in other organs or lesions suggestive of generalized sepsis may be apparent. When meningitis is secondary to trauma, the site of organism entry may be detectable. The meningeal vessels appear to be congested, and the meninges are swollen, opalescent, and petechiated. The CSF is cloudy or amber and may contain fibrin clots. Microscopic changes of CNS tissues include infiltration by neutrophils and lymphocytes, inflammation of the meningeal vessels, scattered hemorrhages, and bacterial colonies around the blood vessels of the meninges and the brain parenchyma.

Treatment and Control Early clinical suspicion of bacterial meningitis and rapid administration of appropriate antimicrobials are necessary to improve chances of survival and to minimize long-term neurologic impairment.[1,2,11] In a human study of pneumococcal meningitis, a delay of antimicrobial treatment of more than 3 hours after hospital arrival was associated with a higher rate of morbidity 3 months after admission.[13] Therefore it may be prudent to initiate appropriate antimicrobial therapy if the animal shows signs compatible with bacterial meningitis and then, if that diagnosis is subsequently refuted by ancillary diagnostic data, withdraw or modify antimicrobial therapy.

Treatment of bacterial meningitis is difficult, and the mortality rate is high, so treatment should be initiated only after owners are appropriately counseled. Antimicrobial sensitivity tests performed on isolates from CSF may provide valuable information on ideal drugs; however, drug selection must account for whether the drug will reach therapeutic concentrations in the CSF (discussed further later). Because prompt treatment of meningitis is critical, antibiotic therapy can initially be based on the Gram-staining characteristics of bacteria in CSF, when available, and on the initial 24-hour culture results, when possible. When expert laboratory cytologists are not immediately available, CSF can be placed into two microhematocrit tubes and centrifuged for 10 to 15 minutes. The tubes can then be scored with a file and broken at the interface of the fluid with the clay sealant, and the cell-rich fluid from the two ends of the broken tubes can be smeared for cytologic examination and Gram stain. In rabies-endemic areas, clinicians should take appropriate precautions when handling CSF.

Domestic animals have a well-defined blood-CSF barrier, and antibiotics that reach high plasma concentrations may not necessarily reach bactericidal concentrations in the brain. However, under conditions of local inflammation, this barrier becomes considerably more permeable by certain antimicrobials.[1,11] As a general rule, in order to maximize distribution of antimicrobials across this barrier into infected meningeal or neural tissue, the highest dosage of antimicrobial established for the species in question should be used.[1,11] Toxicity potential or excretory organ dysfunction may limit dose escalation of

VetBooks.ir

certain classes of drugs such as aminoglycosides. Intravenous administration is preferred in order to obtain peak blood concentrations and spur greater diffusion of drugs across this barrier. Because normal neural tissue lacks endogenous immune capacity, bactericidal antimicrobials have been considered superior to bacteriostatic drugs, although successful use of bacteriostatic drugs has been reported.[1,11] The primary factors influencing CSF penetration of drugs in the healthy state are the lipid solubility (increased penetration with more lipid solubility) and molecular size (increased penetration with smaller size). However, the penetration capacity of a given antibiotic is not the sole determinant of appropriate antimicrobial selection because the blood-CSF barrier is made more permeable in bacterial meningitis. In fact, high-dose therapy with certain β-lactams, some with limited lipid solubility, either as monotherapy or in combination with antimicrobials of other classes, is currently recommended for many bacterial agents that cause meningitis.[11]

At present, use of all antimicrobial agents in treatment of bacterial meningitis in food animals and horses represents off-label use, and legal restrictions on use should be considered in all cases. Furthermore, the paucity of clinical reports and the variety of treatments used in those reports complicates the goal of making evidence-based decisions for treatment of this disease in horses and food animals. Therefore guidelines from published reviews of treatment in horses,[1] cattle,[3] and human medicine[11] are presented here.

When possible, meningitis caused by Gram-negative enteric bacteria should be treated with specific third-generation (ceftazidime, ceftizoxime, ceftriaxone, cefoperazone, cefotaxime) or fourth-generation (cefepime) cephalosporins. For horses, ceftriaxone (50 mg/kg IV q6h) or cefotaxime (40 mg/kg IV q6h)[1] have been used. Because of its high degree of protein binding in serum, ceftiofur (at 2 mg/kg IM) does not appear to spread into the CSF of normal horses.[1] Its performance in penetration of the inflamed blood-CSF barrier remains to be determined. In the United States, off-label use of third-generation cephalosporins in food-producing animals is prohibited except under very specific circumstances, and thus current drug use guidelines within a given jurisdiction should be followed.

As an alternative, penicillin G sodium or potassium (20,000 to 40,000 IU/kg IV q6h) or sodium ampicillin (20 mg/kg IV q8h) may be used; success is considered to be highly dependent on the susceptibility of the causative organism, a parameter that is often unknown in the initial treatment decision process. If enteric organisms are suspected in a neonate, and if third- or fourth-generation cephalosporins are not available or are too costly for use, ampicillin is recommended; its Gram-negative spectrum is considered superior to that of penicillin G. Coadministration of an aminoglycoside can be considered for such neonates, with due consideration of nephrotoxicosis potential and, in animals intended for food, withdrawal time.[1,11] Although aminoglycoside antimicrobials are highly effective against Gram-negative bacteria and are bactericidal, their efficacy in the treatment of purulent meningitis is diminished by their polar characteristics and low attainable CSF concentrations. Nonetheless, combination therapy consisting of a β-lactam and an aminoglycoside may provide effective broad-spectrum coverage[11]; the latter drug may at the very least reduce the circulating burden of Gram-negative bacteria in the bloodstream and elsewhere. Intrathecal administration of preservative-free aminoglycosides, although still used on occasion, has not been shown to produce tangible clinical benefit in comparison with intravenous use.[11]

Alternative treatments for meningitis caused by Gram-negative enteric bacteria, according to anecdotal data in horses only, include enrofloxacin (5 mg/kg, with due consideration of potential cartilage damage and reduction of seizure threshold,[1] IV q12h), or trimethoprim-sulfonamide (5 mg/kg according to trimethoprim component, IV q12h).[3] In horses, chloramphenicol (25 to 50 mg/kg PO q6h) may be considered for use.[1] If β-lactam–resistant organisms are suspected, imipenem (10 to 20 mg/kg IV q6h) may be used, but its efficacy in treating meningitis in foals remains undetermined,[1] and it carries the potential to lower the patient's seizure threshold.[11] In the United States, off-label use of fluoroquinolones (e.g., enrofloxacin) and use of chloramphenicol in food-producing animals, as well as use of off-label use of sulfonamides in dairy cattle older than 20 months, are all prohibited by the Food and Drug Administration.

Meningitis caused by Gram-positive bacteria may be treated with high doses of intravenous penicillin, ampicillin, or the trimethoprim-sulfonamide combinations described earlier in accordance with the same provisos for food-producing animals. Third- and fourth-generation cephalosporins can be considered because these retain activity against certain Gram-positive organisms.[1] For humans, moxifloxacin penetrates the blood-CSF barrier and has greater Gram-positive activity than earlier fluoroquinolones.[11] Other antimicrobials showing promise against specific Gram-positive agents in human medicine include daptomycin and linezolid.[11]

Anaerobic infections are uncommon and probably result from penetrating or necrotizing wounds of the skull bones. Such infections in horses should be treated with metronidazole (15 to 25 mg/kg PO q6h)[1]; penicillin or ampicillin would be appropriate therapy in food-producing animals. Treatment of meningitis caused by *Chlamydophila* or *Mycoplasma* spp. has not been critically investigated in large animals, but the decision to treat with oxytetracycline, doxycycline, fluoroquinolones, or florfenicol depends on the animal class being treated. In general, treatment for 2 weeks is considered to be an empirical standard[3]; however, if aminoglycosides are included in the treatment regimen, the patient should be monitored carefully for nephrotoxicosis.

Adjunct therapy for bacterial meningitis includes analgesics, antiinflammatories, and antipyretic agents; fluid therapy; anticonvulsant therapy for seizures; protection against self-induced trauma (including corneal trauma); and nutritional support. Maintenance of euvolemia and euglycemia is considered vital for treatment success.[11] Hypoxemia and hypercapnia are deleterious and should be prevented whenever possible; mechanical ventilation of severely affected patients may be necessary. Osmotic diuretics such as mannitol or glycerol should be administered if CSF pressure, neurologic examination findings, or fundic examination findings are suggestive of cerebral edema. Use of narcotic agents for analgesia should be weighed against their potential to increase cerebral blood flow and therefore intracranial pressure. Although outcomes vary according to the causative organism, concurrent administration of dexamethasone may improve clinical outcome, although this remains controversial.[11] NSAIDs may be a preferred choice if dexamethasone-related complications (e.g., laminitis in horses) must be prevented. Lmited food intake and the pain associated with this condition increase the potential for gastric ulceration, and prophylactic antiulcer medication should be considered in horses.

Treatments for seizures, cerebral edema, and inflammation are listed in Table 35.4.[14-18] The maximum desirable trough concentration of phenobarbital is 40 µg/mL, and the minimum therapeutic level is 15 µg/mL.[15,16] After initial sedation, long-term control of convulsions in horses can be maintained by oral phenytoin (2.8 to 16 mg/kg three times daily) or IV phenobarbital (11 mg/kg once daily).[16-18] The trough plasma concentration of diphenylhydantoin should also be measured repeatedly during continuous drug therapy; the maximum desirable trough level is 10 to 20 µg/mL,[17] and the optimum plasma concentration is 5 to 10 µg/kg. In critical care settings,

VetBooks.ir

constant-rate infusions of selected anticonvulsive drugs and drug combinations can be considered. The concentration of plasma immunoglobulins should be measured in neonatal patients with bacterial meningitis, and plasma should be administered if those values are subnormal for the species.

A guarded prognosis at best is warranted for most cases of bacterial meningitis. In a retrospective study of 32 calves with septic meningitis, only 5 (16%) survived until discharge, and all 5 subsequently died or had to be euthanized.[2] In a case series in Spain, only 2 of 7 treated foals survived to discharge.[19] The survival rate among adult horses may be higher.[10] Early detection is considered pivotal for successful treatment; therefore a poor prognosis is warranted for animals with severe neurologic impairment. However, because concurrent metabolic derangements (e.g., hypoglycemia) may cloud the clinical picture, aggressive antimicrobial treatment—including achievement of euvolemia, euglycemia, and control of convulsions (if present) and normalization of acid-base, blood gas, and electrolyte status—may be attempted for valuable animals, with the prognosis refined on the basis of response to therapy.

Because cases of bacterial meningitis are usually secondary to other infections as discussed previously, prevention is centered on early detection and intervention for the primary disease. Ensuring adequate passive transfer of immunoglobulins in neonates is also important for reducing the risk of bacterial infection, septicemia, and meningitis.

Pituitary Abscesses

Pituitary abscesses occur sporadically in ruminants and are rare in horses. *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) is the bacterium most frequently isolated, but *Corynebacterium pseudotuberculosis*, as well as *Streptococcus* spp., *Staphylococcus* spp., *Actinomyces* spp., *Bacteroides* spp., *Fusobacterium* spp., *Acinetobacter* spp., *Pasteurella* spp., *Pseudomonas* spp., and *Actinobacillus* spp. have occasionally been isolated.[1]

The clinical signs of pituitary abscess occur suddenly and progress for 7 to 10 days before the affected animal dies.[1] The initial signs are ataxia, head-neck extension, basewide stance, inappetence, depression, head pressing, and recumbency.[1-3] Most affected animals have asymmetric deficits of one or more cranial nerves, which result in dysphagia, blindness, anisocoria, absence of pupillary light reflexes, mydriasis, flaccid tongue, or a combination of these. Nystagmus, facial paralysis, facial hypalgesia, ventrolateral strabismus, or head tilt may also be observed.[1,4] Approximately half of the affected animals have bradycardia (pulse rate, <60 beats/min).

The CSF protein concentration in affected cattle ranges from 70 to 502 mg/dL, and nucleated cell counts range from 6 to 12,640/μL (6% to 84% neutrophils).[1] The antemortem diagnosis is based on the observation of bradycardia, blindness, and nonresponsive pupils in conjunction with evidence of pyogenic inflammation in the CSF.

Some authors have postulated that the infectious agent gains entry to the sella turcica hematogenously and then localizes in the rete mirabile, which is the complex of blood vessels encircling the pituitary gland.[1] A direct relationship exists between the complexity of the rete mirabile and the incidence of pituitary abscessation in different mammals. Horses and dogs lack a well-defined rete and correspondingly have a low risk for developing a pituitary abscess, whereas the opposite situation is true in cattle. In one study, 55% of cattle with a pituitary abscess had pyogenic foci in other organ systems or in the sinuses, teeth, or soft tissues of the face,[1] which indicates that the abscesses may result from a retrograde bacterial embolization through branches of the facial veins.

Ataxia is caused by interruption of extrapyramidal motor nuclei in the brainstem by the expanding abscess. Extension of the abscess into the communicating retroorbital rete may result in exophthalmos. Extradural extension of the abscess along the brainstem causes loss of the cranial nerve function. Bradycardia may be caused by interference with diencephalic cardioacceleratory centers.

Animals aged 9 months to 12 years have been affected, but most cases occur between the ages of 2 and 5 years.[5] Pituitary abscess appears to have a slightly increased prevalence among castrated and intact males.[1] Pituitary abscess has been related to infections that develop in bulls after insertion of a nose ring.[3] Prophylactic administration of penicillin and attention to aseptic procedure during insertion of the ring can reduce disease incidence. Because of the high mortality rate associated with pituitary abscesses, treatment is not usually attempted.

Brain Abscesses

Streptococcus equi is the most common cause of brain abscesses in horses, probably because the occurrence of strangles in this species.[1] *T. pyogenes* (formerly *A. pyogenes*) is a common cause of brain abscesses in cattle by means of extension of a sinus infection through the calvaria. Brain infections of cattle with *Bacteroides* spp. have also been reported.[2] The neurologic dysfunction caused by brain abscesses typically has a slower onset and is more commonly asymmetric than that caused by meningitis. However, onset of signs can also be acute.[1] Forebrain abscesses compress the cerebral cortex, causing a caudal displacement of the brain and functional loss of one or both occipital lobes, which may result in cortical blindness in one or both eyes. Because of the high proportion of crossed fibers in the optic nerve decussation, unilateral cortical abscesses may result in vision loss in the contralateral eye. Increased CNS compression by the mass may induce ipsilateral mydriasis caused by interference with the oculomotor nerve. Further increases in the size of the lesion cause more generalized cortical signs, including blindness, propulsive walking, circling, head tilt (toward the lesion side), depression, coma, head pressing, or sudden unexplained mania (Figs. 35.12 and 35.13). Abscesses at the base of the brain may cause additional abnormalities of cranial nerve function, including vestibular disease. Ophthalmoscopic examination may reveal papilledema in the ipsilateral eye.[2] Advanced imaging studies such as CT and MRI, if available, may be helpful for antemortem diagnosis.[3-5]

In later stages of the illness, animals may assume lateral recumbency and display a decerebrate posture characterized by hypertonicity, hyperreflexia, opisthotonos, coma, and convulsions. At this stage the disease is difficult to differentiate

FIG. 35.12 Head pressing in a pony caused an abscess in the right cerebral hemisphere. *(Courtesy Dr. R.H. Whitlock.)*

VetBooks.ir

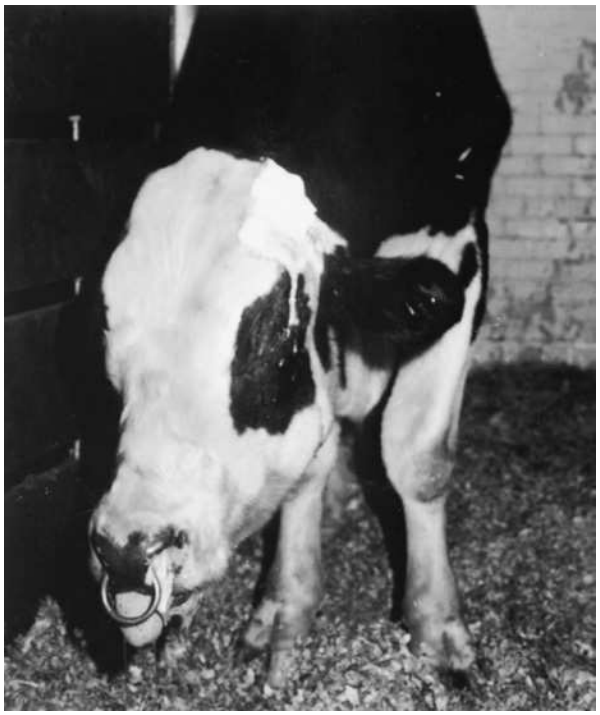

FIG. 35.13 Severely obtunded bull that developed a brain abscess from extension of a frontal sinusitis. The abscess extended to the base of the brainstem and affected cranial nerves V and XII, which resulted in dropped jaw and tongue paralysis. The bull was also severely depressed, blind, and ataxic and had facial analgesia.

from septic meningitis. CSF findings in animals with brain abscesses are variable, ranging from normal to very abnormal, with high protein concentration and marked pleocytosis.[1,5,6] Treatment of brain abscess includes antibiotics and supportive care (see Meningitis section). In one clinical report, a brain abscess in a horse was localized with CT scanning and successfully drained through a craniotomy.[7]

Nervous Coccidiosis

Definition and Etiology Nervous coccidiosis is a neurologic syndrome of calves and yearling cattle, sheep, and goats that is associated with enteric infections by *Eimeria* spp. The condition is most often observed in western Canada and the northwestern United States and is particularly prevalent in feedlots. The incidence of nervous coccidiosis is highest in the winter months. In contrast to that of enteric coccidiosis, the rate of mortality from nervous coccidiosis is relatively high (≈70%).[1] The pathogenesis of the encephalopathy may be related to the elaboration of a labile neurotoxin by the parasite.[2] The clinical signs and history of nervous coccidiosis are similar to those of other neurologic diseases that affect the function of the cerebral cortex.

Epidemiology Nervous coccidiosis occurs most frequently in feeder cattle, but dairy and pastured beef calves, lambs, and kids are also be affected on occasion. In one survey, 0.3% of the calves were affected with the intestinal form of nervous coccidiosis. Nevertheless, outbreaks with a large percentage of calves developing CNS disease have been reported.[3] In western Canada, CNS signs have been reported in 21% of cases in herd outbreaks of intestinal coccidiosis.[4] Most cases occur in middle to late winter.

Pathogenesis The pathogenesis of the encephalopathy is unknown. The nervous form of coccidiosis cannot be transmitted to mice by injection of CSF from infected calves; however, a heat-labile neurotoxin has been identified in the serum of calves with nervous coccidiosis.[2] The coccidia do not directly invade the CNS.

Clinical Signs The onset of the nervous system signs is usually preceded by diarrhea, tenesmus, and hematochezia. Some calves with severe diarrhea develop prolapsed rectums. Initial signs of CNS dysfunction include depression, incoordination, twitching, and hyperesthesia. As the clinical signs worsen, the animal becomes recumbent and develops numerous cerebrocortical signs, including opisthotonos, periodic tremors, horizontal nystagmus, frothing at the mouth, bellowing, snapping eyelids, and muscular fasciculations.[3,5-7] Blindness is rare. Stimulation of the patient may precipitate a tonic-clonic seizure.[3,5-7] Affected animals may die after 1 to 5 days of encephalopathy. Convulsive calves may regain consciousness but relapse days later.[8]

Clinical Pathology Fecal flotations from the patient and herdmates show a large burden of coccidial oocysts. Fecal egg counts of affected animals may range from 5000 to 4 million per gram of feces. To exclude the possibility of other neurologic diseases with similar clinical manifestations, blood should be collected for measurement of electrolytes (calcium, magnesium, potassium). The acid-base status, plasma glucose, and blood lead concentrations should be measured. Acute meningitis and salt poisoning may be ruled out by CSF analysis. The plasma vitamin A concentration should be measured in any animal that has not had exposure to green forage. Polioencephalomalacia, ethylene glycol poisoning, lead poisoning, rabies, pseudorabies, petroleum distillate poisoning, and clostridial enterotoxemia should be considered in the differential diagnosis.

Pathology No macroscopic lesions are observed in the CNS of calves with nervous coccidiosis. The microscopic lesions of the brain are mild and nonspecific and include edema, congestion, and occasional shrunken neurons. Parasitic invasion of the ileum, cecum, and colon results in lesions in these organs.

Treatment and Control Treatment should include supportive fluid, macromineral, and electrolyte therapy. The coccidial infection should be treated with sulfadimethoxine (55 mg/kg PO or IV, followed by 27.5 mg/kg PO or IV q24h). Alternatively, sulfamethazine (110 mg/kg PO q24h for 5 days, or 1 lb/100 gallons of drinking water) or amprolium (50 mg/kg/day PO for 7 days) can be administered. Treatment administered via drinking water will be effective only if animals are willing and able to drink. Diazepam, sodium pentobarbital, or phenobarbital may be used to control tonic-clonic convulsions (see Table 35.4). Response to treatment is poor, and the case fatality rate can be high in calves that develop tonic-clonic seizures. Specific chemotherapeutic regimens and methods of preventing intestinal coccidiosis are described in Chapter 49.

Sporozoan Infections of Ruminants (*Sarcocystis* Infection)

Definition and Etiology The three recognized species of *Sarcocystis* that infect cattle—*Sarcocystis cruzi*, *Sarcocystis hominis*, and *Sarcocystis hirsuta*—are sporozoan parasites with definitive hosts of dogs, primates, and cats, respectively.[1,2] For three other *Sarcocystis* species—*Sarcocystis capricanus*, *Sarcocystis ovicanus*, and *Sarcocystis tenella*—dogs are the definitive host, and secondary hosts include goats and sheep.[3]

When a carnivore ingests flesh from infected cattle, *Sarcocystis* spp. cysts in muscle are broken down by digestive enzymes, and motile bradyzoites are released. The bradyzoites infect intestinal mucosal cells and differentiate into sexual stages. The gametes fuse to form an oocyst, which is shed onto pastures as

sporocysts. When eaten by a ruminant, the sporocysts hatch in the proximal small bowel and penetrate into the medium-sized mesenteric arteries, where they enter endothelial cells and form sporozoites. The sporozoites then mature in three successive waves. Each wave of development spreads downstream. The third-generation merozoites enter the soft tissues and encyst as sarcocysts. The total period of development in the ruminant requires 10 weeks. The life cycle is completed when a carnivore ingests uncooked meat containing viable sarcocysts. Disease may develop in cattle during the maturation of the cyst in the muscles, at approximately 9 to 11 weeks after infection.

Epidemiology Estimates of infection rates range from 70% to 98% in cattle in the United States.[1] When infected flesh is eaten by carnivores, the encysted sporozoites complete their life cycle.[1] The prepatent period of the parasite in the carnivore (primary host) ranges from 9 to 45 days. The primary host may shed the sporulated oocysts in the stool for as long as 2 months after a single infection. The oocysts withstand freezing but are rapidly killed by sunlight and drying.[1] Reexposure of previously infected canids results in a large fecal output of sporocysts. Ingestion of approximately 250 g of infested meat by a dog can result in an output of 100 to 6000 sporocysts per gram of feces. Wild canids are even more susceptible than domestic dogs and may serve as a major mechanism for propagation of *Sarcocystis* spp. in range cattle in the western United States.

Pathogenesis The pathogenesis of *Sarcocystis* is poorly understood. Pathologic changes in the skin and muscle and in serum chemistry profile are speculated to result from a combination of parasite-directed immunologic responses and diffuse vasculitis. Abortions probably occur because of luteolysis that results from the increased concentrations of prostaglandin $F_{2\alpha}$, caused by vascular infection by the parasite.[4]

Clinical Signs Most cases of *Sarcocystis* spp. infestation are asymptomatic in both definitive and secondary hosts. However, if a large number of sporocysts are ingested by a nonimmune ruminant, clinical illness may develop. Clinical signs include fever (>39.5° C [103.5° F]), anorexia, weight loss, symmetric lameness, and diarrhea. Neurologic signs include ataxia, muscular weakness, tremors, hyperexcitability, hypersalivation, recumbency, tonic-clonic seizures, leg biting, blindness, opisthotonos, and nystagmus.[5,6] Cattle may lose the hair of the tail switch ("rat tail"). Sheep may show wool break.[1-3,5,6] Animals with chronic infections may develop edema of the limbs, poor weight gain, muscular atrophy, and pallor.[1-3,5,6] Second-trimester abortions may occur in cattle and small ruminants beginning 28 days after ingestion of infectious sporocysts.[7] The fetuses may appear either normal or autolyzed.

Clinical Pathology Serum activity of liver enzymes is increased. The packed cell volume and the serum protein concentration are often decreased. In the early stages of infection, there is a marked normocytic, normochromic anemia. The anemia is thought to be caused by extravascular hemolysis.[8]

Antibodies to solubilized freeze-dried *Sarcocystis* spp. antigens have been detected by indirect hemagglutination, ELISA, and an AGID test.[9-11] IgM responses first occur by 3 to 4 weeks after infection and peak by 11 to 15 weeks.[9-11] The concentrations of *Sarcocystis*-specific IgG begin to rise by 5 to 6 weeks after infection. Background titers of normal cattle range from 1:54 to 1:486, and titers of infected cattle often exceed 1:10,000.

Pathology The pathologic lesions in the CNS are similar for all species of sporozoans; they include granulomatous meningoencephalomyelitis, focal malacia, perivascular cuffing, neuronal degeneration, and gliosis. The changes are generally most severe in the cerebellum and midbrain but can occur anywhere in the CNS, including the spinal cord. The pathologic diagnosis is based on the finding of meronts and merozoites in the affected sections of neural tissue.[12,13]

Pathologic lesions elsewhere include hemorrhages on the sclera, serous surfaces, and muscles; fluid in the body cavities; and lymphadenopathy. The muscles have alternating light and dark stripes. Macroscopic changes may not be evident in animals with chronic sarcocystosis. If changes are not evident, postmortem diagnosis is based on the finding of intravascular schizonts or intramuscular hemorrhages without significant inflammation. Ultrastructural examination of affected areas of CNS reveals an intracellular colony with rosette orientation of agents in the cytoplasm of infected astrocytes.

Treatment and Control Treatment of infected sheep with salinomycin (1 to 2 mg/kg) has also been recommended.[14] Amprolium (100 mg/kg once daily for 30 days) may reduce the severity of *Sarcocystis* spp. infection[15] but may not completely eliminate the clinical disease.

The best method of controlling *Sarcocystis* spp. infection is to protect the food supply of ruminants. Scavenging of carcasses by carnivores should also be prevented by deep burial or incineration. Feed bunks should be kept clean and raised approximately 1 to 3 feet (30 to 90 cm) off the ground. All carnivorous pets that have access to the feed or pastures should be fed cooked meat or processed dry food. In range pasture situations, prophylactic feeding of monensin or elimination of predatory or scavenging carnivores may be necessary.

Neospora Infection of Cattle (Protozoal Abortion)

Neospora caninum is a protozoal parasite that causes disease primarily in dogs and cattle.[1] The predominant clinical sign of *Neospora caninum* infection is a midterm to late-term abortion (3 to 8 months of gestation). Fetal lesions consist of focal nonsuppurative necrotizing encephalitis, nonsuppurative myocarditis and myositis, and mononuclear cell infiltrates disseminated in other tissues.[2,3] Occasionally, stillborn calves are mummified. (See Chapter 43 for more on abortion.)

Nonfatal infection in the fetus results in neurologic dysfunction of the newborn. The clinical signs of neurologic disease vary because of the random and widespread distribution of the parasite within the CNS. Affected calves are often unable to stand and suckle and have abnormal spinal reflexes. Flexural contractions of the forelimbs, domed skull, and torticollis have also been reported in spontaneously occurring cases.[4,5] Calves born alive are usually born with the CNS signs, which initially are mild but then worsen after birth. Pathologic lesions associated with the fetal infection include focal areas of brain discoloration, focal cavitation with cyst formation, and reduction of gray matter. Microscopic changes in the CNS of affected calves include nonsuppurative inflammation of the gray and white matter, focal lymphocytic meningitis, and neuronal necrosis. Changes in other tissues include nonsuppurative myocarditis, myositis, and hepatitis. Protozoa can be observed in microscopic sections of the stained tissues.

Neospora organisms have been isolated in pure form in cultured cells.[6] Antibodies have been produced by intubation of laboratory animals, and the agent can be identified microscopically through immunoperoxidase staining on the fixed tissues. The CSF changes in affected calves range from normal to mild pleocytosis.[7] Similar conditions have been described in sheep[8,9] and goats.[10,11]

VetBooks.ir

Babesia Encephalitis (Babesiosis; Piroplasmosis; Texas Cattle Fever; Tick Fever; Redwater)

Parasitemia of cattle caused by the protozoans *Babesia bovis*, *Babesia argentina*, and *Babesia* is usually subclinical, but results in devastating economic losses worldwide.[1] The disease is transmitted to cattle by the cattle fever ticks *Rhipicephalus* (*Boophilus) annulatus*, *Rhipicephalus microplus*, and *Rhipicephalus decoloratus*. Babesiosis occurs in the Americas, Europe, Africa, Asia, and Australia. Ticks acquire *Babesia* infection from an infected animal and then pass the agent to their offspring through the ovaries. The protozoan is passed to susceptible cattle by adult ticks and nymphs. Most infections result in intravascular and extravascular hemolysis and in kidney and liver failure. See Chapter 37 for more detail.

A small proportion of *Babesia* infections cause acute encephalitis.[2,3] CNS signs begin suddenly and include fever (41.7° C [107° F]), anorexia, depression, ataxia, conscious proprioceptive deficits, mania, convulsions, and coma. Sudden death is occasionally observed. The nervous system signs are accompanied by engorgement of the scleral vessels, icterus, proteinuria, and hemoglobinuria. Encephalopathic diseases that closely resemble babesiosis include rabies, nervous coccidiosis, polioencephalomalacia, lead poisoning, bovine herpesvirus encephalitis, theileriasis, heartwater disease, salt poisoning, and chlorinated hydrocarbon toxicity.

The pathogenesis of the CNS signs is unclear; however, possible causes include capillary thrombosis and infarction, disseminated intravascular coagulation, anoxic encephalopathy, and direct invasion of the CNS by the parasite. Thrombi are disseminated throughout the CNS. Expression of parasite proteins on the surface of infected RBCs facilitates binding of RBCs to capillary endothelial cells.[4] The proclivity of *Babesia*-infected RBCs for binding to brain capillaries, particularly those in the cerebellum, is supported by the high incidence of parasite-positive RBCs found in the brains of infected cattle.[5] These findings and the observation of increased prothrombin and partial thromboplastin times, thrombocytopenia, and decreased fibrinogen concentrations suggest that disseminated intravascular coagulation may play a role in the pathogenesis of the CNS disease.[6-8] Vascular blockage in the CNS, caused by severe sludging of RBCs within brain capillaries, appears to be central to the pathogenesis of neurologic disease in infected animals.[9] Studies of *Babesia ovis* in sheep, in which neurologic disease did not occur, failed to demonstrate RBC blockage of brain capillaries.[10] This further supports the belief that CNS vascular pathology is key to the development of neurologic signs in bovine babesiosis.

Babesia encephalitis is a reportable disease in the United States. Suspected cases should be referred to the appropriate state and federal authorities.

Ehrlichia (Cowdria, Rickettsia) ruminantium Infection (Heartwater Disease)

Definition, Etiology, and Epidemiology

Ehrlichia ruminantium is a rickettsial parasite that causes a fatal encephalitis in goats, sheep, and cattle.[1] The disease originated in sub-Saharan Africa and has spread to cattle in the West Indies (Guadeloupe, Antigua, and Marie Galante).[2] *E. ruminantium* is transmitted by *Amblyomma* ticks.[3,4] Although a number of *Amblyomma* species have been implicated in the transmission of heartwater disease, the ones that cause most cases are *Amblyomma variegatum* and *Amblyomma hebraeum*. The intermittent feeding behavior of the tick makes it particularly difficult to control. *Amblyomma* ticks require three separate blood meals to complete their life cycle. The gravid females fall from the host and lay the eggs in rotting vegetation, particularly in areas where the hosts are bedded for the evening. Recently hatched larvae crawl onto foliage and await a host. After their first feed the larvae detach, molt into nymphs, and await a second host. After refeeding, the nymphs detach and molt into adults. The adults remain under rotting vegetation until they are activated by carbon dioxide exhaled by a large mammal. They are further attracted to the host by pheromones from male ticks that remain permanently attached to the host. Animals that do not have male tick infestations are poor attractants for nongravid females. Once attached to the proper host, the females seek the male, breed, feed, and fall from the host when it lies down for the evening. Ticks that feed from *Ehrlichia*-infected hosts develop ovarian infections and transmit the agent to their offspring. This serves to perpetuate the agent over successive seasons.[5]

Many species of vertebrates, including snakes, iguanas, lizards, and birds, are reservoirs for *E. ruminantium* because these animals may serve as the first two hosts for the *Amblyomma* tick.[6] A vector-wildlife cycle facilitates the survival of *E. ruminantium* even when domestic livestock are absent from the environment.[7]

Pathogenesis

After inoculation into a ruminant, the rickettsial agent infects reticuloendothelial cells and proliferates by binary fission within membrane-bound vacuoles.[8,9] Release of the parasite from degenerating macrophages and neutrophils causes successive waves of parasitemia that infect endothelial cells and cause vasculitis.[9,10] Nervous system lesions may be caused by permeability changes in the cerebral capillaries. Changes in the other soft tissues include hydropericardium, hydrothorax, and subcutaneous edema.[1]

Except for Angora goats, which are highly susceptible to *Ehrlichia* infection, animals reared in indigenous areas usually have a high level of immunity and do not succumb to the infection.[11] Animals that survive the initial infection no longer show symptoms but remain rickettsemic for as long as 223 days (sheep), 246 days (cattle), and 8 days (goats). Calves younger than 3 weeks of age, lambs younger than 8 days of age, and kids younger than 6 weeks of age are inherently resistant to *E. ruminantium* infection, regardless of the amount of colostral protection they have received.[12,13]

Clinical Signs

Animals with the peracute form of *E. ruminantium* infection die suddenly without premonitory signs. The acute form of the disease is characterized initially by fever, anorexia, depression, and respiratory distress. Cyanosis may also be noted. Nervous system signs, which may appear within a few days, include hyperesthesia, snapping closure of the eyelids, rapid extension of the tongue, behavioral changes, muscular fasciculations, hypermetria, ataxia, conscious proprioceptive deficits, and head pressing. As the disease progresses, the animals become recumbent and comatose. Convulsions may occur in the terminal phase. These episodes are characterized by opisthotonos, nystagmus, chewing movements, and frothing at the mouth. Mild forms of the disease are characterized by transient diarrhea, malaise, and fever, with no CNS involvement. The mortality rate in sheep ranges from 6% to 80%. Animals that recover are immune to reinfection for at least 58 months.[14] Losses may reach 60% of susceptible cattle and 40% of goats. The mortality rate among Angora goats may exceed 90%. Enterotoxemia caused by *Clostridium perfringens* type D is important in the differential diagnosis in small ruminants.

Pathology

Pathologic changes of heartwater disease include hydropericardium, hydroperitoneum, hydrothorax, pulmonary edema, perirenal edema, hemorrhages in the pleura and peritoneum, and hemorrhagic enteritis. Microscopic changes include microgliosis, necrotizing vasculitis in the brain, hemorrhage, edema of the neuropil, microcavitation, and focal

VetBooks.ir

necrosis of the granular layer of the cerebellum. In clinical cases, the parasite can be definitively diagnosed only through biopsy of the cerebral cortex or by collection of the cortical tissues at postmortem examination.[15] Simple techniques for collection of such biopsy specimens have been described.[16-18] Squash preparations of the biopsy sample should be stained with either methyl green pyronine or Giemsa stain before microscopic examination of the tissues.[19,20]

Diagnostic tests developed to identify infected livestock include an IFAT in which infected bovine aortic endothelial cells serve as indicators, several ELISAs, and tests involving PCR methodology.[21-24] Of these, PCR is the most accurate.

Treatment and Control The administration of oxytetracycline (6 to 10 mg/kg IV twice daily for 3 or 4 days) may be beneficial for treatment of the early stages of the disease. The long-acting formulation of oxytetracycline is also effective, but for best results it should be administered as soon as the animal becomes febrile. Treatment is usually futile if the first dose of oxytetracycline is administered after the onset of neurologic signs.[25] Despite the depository nature of the long-acting formulation, two or more doses 48 hours apart are necessary to achieve a good clinical response. Cattle should be re-treated if they develop a fever after the first dose has been administered.[26] Many animals with CNS signs die despite intensive antibiotic therapy. Angora goats are highly susceptible to heartwater disease. In South Africa, Angora producers routinely treat all animals every 14 days during the summer with oxytetracycline. Animals that remain essentially tick free never develop adequate immunity to the *Ehrlichia* organism.

A small degree of tick infestation and exposure of the animals to low numbers of the agent, combined with judicious oxytetracycline therapy, appears to favor the development of immunity over time.[27] One method of immunization is to use a controlled infection of a virulent strain (Onderstepoort Ball 3 strain) of the *Ehrlichia* organism and treatment with long-acting oxytetracycline (800 mg per adult goat) at the beginning of clinical disease and 10 days later.[28] Vaccination with this isolate produces immunity against exposure to homologous, but not heterologous, strains of *Ehrlichia*.[29-31] More recent strategies have included vaccination with inactivated organisms, live attenuated organisms, and fragments of *E. ruminantium* nucleic acid, but none has produced great success.[32-36]

Control of ticks on pastures is the most desirable means of controlling heartwater disease. Complete eradication of the ticks in most regions of sub-Saharan Africa is neither possible nor desirable. Cattle that are reared in areas where *Ehrlichia* infection is endemic acquire immunity over time. In these areas, the ticks should be sufficiently abundant to enable a low level of heartwater infections in most cattle but not so populous as to introduce severe, overwhelming infections. Integrated methods for tick control have been recommended. These include exclusion of wildlife from paddocks, artificial induction of host resistance to ticks, application of insecticidal ear tags, and conventional acaricide application. Application of insecticides as the sole method of tick control has not proved highly effective. Resistance to the acaricides may develop with prolonged use.

Heartwater is a reportable disease in the United States. Suspected cases should be referred to the appropriate state and federal authorities.

Cerebral Theileriasis (Turning Sickness; Draaisiekte; East Coast Fever; Corridor Disease; January Disease; Tropical Fever)

Definition, Etiology, and Epidemiology Cerebral theileriasis is an encephalitic disease of cattle caused by the piroplasma parasites *Theileria annulata* and *Theileria parva*.[1,2] Theileriasis occurs mainly in Africa (Kenya and Tanganyika) and India, where it is characterized by a high mortality rate and is known as East Coast Fever. *Theileria sergenti* is found in Korea and Japan. *Theileria mutans*, a parasite of cattle in the southwestern United States, is relatively nonpathogenic.[3] A mild form of theileriasis, locally called "January disease," occurs in cattle in Mozambique. This condition is caused by the subspecies *T. parva bovis*. Corridor disease is caused by *T. parva lawrencei*, and *T. annulata* is the cause of Mediterranean Coast fever or tropical theileriasis.

European breeds of cattle *(Bos taurus)* develop a more severe disease than do comparably infected Indian breeds *(Bos indicus)*. Both types of cattle appear to be equally susceptible to infection but differ in their ability to control the course of disease.[4] *Theileria* organisms are transmitted to susceptible cattle by the ticks *Hyalomma anatolicum*, *Hyalomma lusitanicum*, and *A. hebraeum*.[5]

Pathogenesis *Trypanosoma* spp. manipulate the immune system both to evade destruction and to promulgate infection. Organisms escape the host immune response by altering immune system activation so that infected cells avoid recognition and destruction.[6-8] Clonal expansion of infected lymphocytes is promoted, and these cells disseminate throughout the body.[9]

Clinical Signs The clinical signs of *Theileria* infections include lymphadenopathy, nasal discharge, lacrimation, tachycardia, fever, subcutaneous edema of the face, gangrenous dermatitis, sloughing of facial skin, dyspnea, pallor, CNS disease, and emaciation.[10] The neurologic syndrome is characterized by ataxia, hypermetria, conscious proprioceptive deficits, depression, head pressing, hyperesthesia, blindness, nystagmus, circling, and aggressiveness. In the terminal stage, the animals become recumbent and develop opisthotonos, tonic-clonic seizures, and coma. In rare cases the parasite may localize in the spinal cord. The CNS signs result from vasculitis and lymphocytic inflammation of the brain.[11-13] Clinically recovered animals remain persistently infected.

Pathology The postmortem lesions of theileriasis include capillary engorgement, scattered punctate hemorrhages on the surface of the brain, thrombosis of the meningeal vessels, hemorrhage in the cerebral ventricles, pulmonary edema, peripheral lymphadenopathy, and infarctions of the kidney and spleen. The brain of an affected animals appears to yellowish.[13] On microscopy, blue cytoplasmic inclusion bodies (Koch blue bodies) are observed in the lymphocytes adjacent to the hemorrhagic areas.

The nervous form of theileriasis is difficult to diagnose definitively because the parasite is only sporadically visible in sections of nervous tissue from the infected animals. Parasitemia is occasionally detected in microscopic examination of blood smears from infected calves. Reliable blood tests are not currently available. Biopsy of the cerebral cortex has been recommended as a confirmatory test for the disease. The CSF of affected animals is normal or has an increased protein concentration ranging from 1400 to 12,452 mg/dL, with normal numbers of WBCs.[12]

Treatment and Control Parvaquone (10 to 20 mg/kg IM in two injections 48 hours apart) and buparvaquone (at a single dose of 2.5 mg/kg) are approximately 90% effective for the treatment of theileriasis.[14] Some studies have shown buparvaquone to be the most effective treatment.[15,16] Parvaquone can be combined with furosemide, which improves survival of cattle that develop pulmonary edema, a common consequence of theileriasis.[17] Menoctone (10 mg/kg IV or IM) is also curative. Single doses were effective in one study, but repeating

the treatment daily for 5 days eliminated posttherapeutic recrudescence.[18]

Prevention of *Theileria* infection has been based largely on the use of live attenuated vaccines, which produce a solid, cell-mediated immunity.[19] These vaccines are used in an "infection and treatment" manner, whereby vaccination must be combined with administration of long-acting tetracyclines.[20] Recent efforts at vaccine development have focused on the creation of subunit vaccines involving a variety of *Theileria* antigens.

The naphthoquinones are the preferred chemotherapeutic agents in vaccinated animals and include parvaquone, halofuginone lactate, and buparvaquone.

Tick control is vital for prevention. Weekly spraying with coumaphos and insertion of ear tags impregnated with cypermethrin have been effective for controlling ticks and preventing *Theileria* infections in calves in Tanzania. If the tags are removed, the calves become infected with *T. parva* within 3 months. Woodford[21] suggested that intensive tick control could minimize the incidence of theileriasis until the calves can be successfully vaccinated. However, inadequate or incorrect application of products and tick resistance to chemicals present challenges to effective tick control. The disease is exotic to North America.

Cerebral Trypanosomiasis (Sleeping Sickness)

Definition, Etiology, and Epidemiology Trypanosomiasis is a hemoprotozoan disease of African cattle that also infects the CNS. The disease is transmitted to cattle by the bite of the tsetse fly (*Glossina* spp.). The agents that infect cattle include *Trypanosoma vivax*, *Trypanosoma congolense*, and *Trypanosoma brucei*. An especially severe neurologic form of the disease has been caused by the inoculation of cattle with *T. congolense*, followed 1 year later by infection with *T. brucei*, or by simultaneous inoculation with the two agents.[1]

Clinical Signs Encephalitic signs of the disease develop 2.5 to 5 months after infection and include ataxia, conscious proprioceptive deficits, knuckling (partial collapse of a joint into a flexed position), depression, circling, and head pressing. Some animals may show signs of behavioral change, lose the herd instinct, and develop hyperesthesia and constant repetitive movements. Other signs associated with progression of trypanosomiasis are semicoma, coma, recumbency, opisthotonos, and intermittent tonic-clonic convulsions, which occur 2 to 3 days before death. Affected animals are emaciated, anemic, and icteric at death.[2]

Experimental infection with trypanosomes causes a marked fever (as high as 40.5° C [105° F]). Other common nonneurologic signs include anemia, petechiation of the mucous membranes, occult fecal blood, melena, and epistaxis. Some affected animals exhibit chronic weight loss without other clinical signs.

Clinical Pathology Hematologic abnormalities include anemia, hypoalbuminemia, hyperbilirubinemia, and increased plasma concentrations of aspartate transaminase and urea nitrogen.

Acutely infected animals may develop thrombocytopenia and prolongation of the prothrombin and partial thromboplastin times, which indicates that disseminated intravascular coagulation may be responsible for the vascular changes that occur before death. The anemia is characterized by increases in mean corpuscular volume and mean corpuscular hemoglobin, with increases in serum iron concentrations early in the infection.[3,4] In one study, changes in the concentration of WBCs or protein in the CSF did not occur in animals with the encephalitic form of trypanosomiasis.[1] However, in another study, these parameters were significantly altered in cattle infected with *T. brucei*.[5] The alterations included an increase in total protein (range, 37 to 44 mg/dL) and pleocytosis (range, 0 to 3060 mononuclear cells per microliter). The abnormalities in the CSF may be present in infected cattle not currently displaying clinical neurologic signs. Antitrypanosomal antibody may be found in the CSF of affected cattle with the use of IFAT.

Pathology The pathologic lesions of trypanosomiasis are a nonsuppurative encephalomyelitis, serosanguinous pericardial fluid, serosal hemorrhages, pulmonary edema, centrilobular coagulative necrosis, splenomegaly, necrotizing myocarditis, and glomerulonephritis.[6] Macroscopic lesions of the CNS include subtle thickening and grayish discoloration of the meninges. The meningeal vessels are congested. Microscopic lesions of the CNS reflect moderate diffuse meningoencephalitis. The pathogenesis of the encephalitis is not understood.

Trypanosomes may be cultured from the blood and CSF of infected cattle. The number of hematogenous parasites is highest in animals with a dual infection by *T. congolense* and *T. brucei*. The clinical diagnosis of trypanosomiasis may be confirmed by inoculating blood or CSF specimens into laboratory mice and observing the recipients for parasitemia with direct darkfield examination of the patient's blood. Identification of motile trypanosomes in the buffy coat zone of a microhematocrit capillary tube with darkfield illumination is apparently the most accurate of all diagnostic methods. Trypanosomes can be differentiated by their morphologic features, manner of attachment to erythrocytes, and type of motility.[7] Infected cattle develop acquired resistance to homologous, but not heterologous, isolates of trypanosomes.

Treatment and Control Of the drugs available for the treatment of trypanosomiasis, isometamidium chloride is most often used. The recommended dose ranges from 0.25 to 1 mg/kg IM; a single dose of 1 mg/kg exerts a protective effect for up to 6 months.[8] The higher dose (1 mg/kg) is necessary to increase weight gain and prevent recurrent infection. The treatment was particularly effective when combined with weekly surveillance, followed by treatment of animals confirmed to be infected.[9] Side effects of isometamidium include tachycardia, salivation, lacrimation, pollakiuria, muscle fasciculations, convulsions, diarrhea, and, in rare cases, death. The drug apparently does not cause abortion in pregnant cows or otherwise affect the calf.[10]

Other drugs used include suramin sodium, diminazene aceturate (7 mg/kg), quinapyramine sulfate, and homidium chloride (1 mg/kg). These drugs provide residual protection from reinfection for approximately 2 months; however, recurrent infection and resistance, especially to diminazene, have been reported.[11-14] Combinations of these drugs (e.g., diminazene followed by isometamidium) reduce the number of resistance-related therapeutic failures. Relapses also occur, undoubtedly because many of the chemoprophylactic drugs are unable to penetrate the blood-brain barrier in sufficient concentrations to eliminate the parasite in the CNS tissues.

Because of the variable responses to treatment and the ability of *Trypanosoma* organisms to develop drug resistance, all control programs must include methods of controlling the tsetse fly.[13] Because the tsetse fly prefers to feed from the ventral torso or the legs, insecticide-impregnated ear tags have been ineffective for preventing infection; other means of application of insecticide are necessary.[15] Other fly control methods include aerial spraying with endosulfan, ground-based spraying with 4% dichlorodiphenyltrichloroethane (DDT), or use of scented insecticidal traps.[14] However, cost and environmental concerns have limited the usefulness of these techniques.

Selection of resistant lines of cattle is possible. The taurine N'Dama and West African shorthorn breeds have innate resistance to trypanosomiasis and are the sole breeds of cattle

VetBooks.ir

in areas of tsetse fly range.[16] Resistant breeds of small ruminants include the Djallonke, Red Maasai, Blackhead Persian, and East African sheep and goats.[17] Imported breeds of livestock usually cannot be maintained, even in areas of low tsetse fly risk, without intensive drug therapy.[18]

Polioencephalomalacia (Cerebrocortical Necrosis)

Christopher Cebra • Guy H. Loneragan • Daniel H. Gould • John R. Middleton

Definition and Etiology Polioencephalomalacia (PEM) is a common and important neurologic disease of ruminants[1,2] with a worldwide distribution. An animal with clinical manifestations of PEM is often referred to as having "polio" or being a "sleeper" or "brainer."

Polioencephalomalacia is a descriptive term for histologic lesions[1,3] that may arise from a variety of etiologies. Literally, the name means softening or necrosis (malacia) of regions of the gray matter ("polio-") of the brain ("encephalo-"). Thus a definitive diagnosis of PEM requires histologic examination of brain tissue. The possible causes of PEM include, but are not limited to, excessive sulfur consumption (manifested by elevated ruminal sulfide production),[4-8] altered thiamine metabolism,[9] salt poisoning or water deprivation,[10] amprolium administration,[11-13] rations composed of molasses and urea,[14] and lead intoxication.[15] Of cases in which a cause can be determined, most involve altered thiamine metabolism, excessive sulfur consumption, or both.

Epidemiology PEM has a worldwide distribution. The condition occurs both in individuals and as herd outbreaks. In one instance, approximately 2000 of 2200 sheep grazing were clinically affected with PEM.[4] No predilection by gender or breed is observed. The condition affects cattle, sheep, goats, deer, camels, and camelids.[5,11,16-19] Although PEM occurs predominantly in animals that eat a high-concentrate supplement, the condition can also occur in unsupplemented animals on pasture.

The age ranges for susceptibility to PEM have been reported as 3 weeks to 5 years in sheep, 3 weeks to 8 years in cattle, and 2 months to 2.5 years in goats. The occurrence peaks at the age of 18 months or younger in cattle and sheep but depends on the production system.[1,8,20] The incidence of PEM has been reported as high as 90% in some sheep flocks, with mortality rates ranging from 1% to 10%.[4] In one report, the incidence of PEM was reported to be high in sheep exported by sea from Australia to the Middle East, where the underlying cause was postulated to be thiamine deficiency caused by alterations in rumen synthesis secondary to the shipboard feeding conditions.[21]

Pathogenesis The fundamental lesion with PEM appears to be neuronal edema with necrosis. In most cases, the edema is thought to result from ATP depletion and decreased activity of the sodium-potassium pump in cortical cells. The bony calvaria limits tissue expansion, and neuronal swelling leads to pressure necrosis.

The brain is susceptible to PEM because of its high energy and oxygen requirements. Brain tissue makes up only approximately 2% of body weight but accounts for 20% to 30% of body glucose utilization and 20% of oxygen utilization in adults.[22] The brain relies heavily on glucose as an energy substrate, and the blood-brain barrier limits the ability to utilize alternative energy substrates. In comparison with liver or muscle, the brain has relatively small glycogen stores—only approximately a 10-minute supply—and it is entirely dependent on circulating oxygen. Under normal conditions, the extracellular fluid contains approximately 100 times as much glucose as the oxygen required for complete aerobic glycolysis. Thus oxygen delivery or utilization limits the rate of ATP production under most circumstances much more than does glucose availability,[23] and factors that inhibit oxygen utilization (e.g., hydrogen sulfide, lead) affect neuronal ATP production.

Much of the early work on PEM focused on the importance of thiamine (also known as vitamin B_1, thiamin, and aneurin). In adult ruminants, thiamine is produced by rumen microbes at a rate that is marginally faster than the rate of consumption; very little is stored.[24] Preruminants depend on dietary thiamine. Thiamine compounds play several important roles in the glycolytic pathways. Thiamine pyrophosphate (thiamine diphosphate) is an important coenzyme for transketolase, the rate-limiting enzyme in the hexose monophosphate pathway (pentose phosphate shunt) of glycolysis, and for the α-ketoacid dehydrogenases of the Krebs cycle. The role of thiamine in the hexose monophosphate pathway was long thought to be key in the development of PEM, but this pathway actually accounts for less than 3% of cerebral glycolysis.[25] Hence, it is unlikely that impairment of this pathway alone could lead to such severe disease. However, decreased function of the Krebs acid cycle through inactivity of the α-ketoacid dehydrogenases could cause the necessary reduction in ATP production. Thiamine triphosphate may also play a role in neuronal function independent of its enzymatic function.

The dependence of ruminants on microbial thiamine production led to investigation of factors that might decrease production, absorption, or function. Proposed mechanisms include ruminal production of bacterial thiaminases, production or ingestion of inactive thiamine analogs, ingestion of preformed plant thiaminases, decreased intake of preformed thiamine by preruminants, impaired absorption or phosphorylation of thiamine by rumen bacteria, increased fecal excretion of thiamine, and decreased ruminal production of thiamine diphosphate. The inactive thiamine analog most frequently reported is amprolium.[11-13]

Two types of bacterial thiaminases have been described. Thiaminase I, produced by *Bacillus thiaminolyticus* or *Clostridium sporogenes*,[26] catalyzes the cleavage of thiamine at the methylene bridge between the pyrimidinyl and the thiazole ring. A basic cosubstrate is necessary to combine with the pyrimidinyl derivative to form a new compound[27], and many common medications, including benzimidazoles, levamisole, and promazines, appear to be able to serve as this cosubstrate. Several plants also apparently make a thiaminase similar to thiaminase I. These include bracken fern *(Pteridium aquilinum)*,[28,29] horsetail *(E. arvense)*,[29] and Nardoo fern *(Marsilea drummondii)*.[30] Of these, only the Australian Nardoo fern has been strongly linked to outbreaks of PEM. Thiaminase II is produced by *Bacillus aneurinolyticus*, which proliferates in response to excessive grain intake.[31] Thiaminase II catalyzes the hydrolysis of the methylene bridge between the two ring structures of the thiamine molecule. The specific relationship of this thiaminase to the clinical syndrome of PEM as observed in the field is unclear.

Complete correlation has not been established among production of ruminal and fecal thiaminase, tissue and plasma concentration of thiamine, and development of clinical encephalopathy.[32,33] Some affected animals may show normal amounts of thiamine in the plasma but have greatly decreased levels in the erythrocytes and other tissues, which is evidence of the diversity of causes of PEM.[34]

Dietary sulfur and sulfates are an important factor in the development of many cases of ruminant PEM. Beef cattle require 0.15% to 0.20% of dietary sulfur on a dry matter basis.[35] Sources of sulfur include elemental sulfur,[4] feed additives such as gypsum and ammonium sulfate,[5,36] feedstuffs such as corn by-products,[35] cruciferous crops,[37,38] molasses,[14] and fertilizers. Water is an important contributor to sulfur intake, usually in the form of sulfates.[7,39,40]

VetBooks.ir

There are two primary metabolic pathways of sulfur in the rumen.[40-45] The *assimilatory pathway* involves reduction of sulfate to sulfides and incorporation into sulfur-containing organic compounds such as cysteine and methionine.[43] These are ultimately incorporated into microbial crude protein. The *dissimilatory pathway* is an energy-producing pathway in which microorganisms use sulfate as a terminal electron acceptor, in a manner similar to how mammals use oxygen.[46] The end product is liberated sulfide ion. At a ruminal pH of 5.2, 97.2% of sulfide ions are in the form of hydrogen sulfide and move freely to the rumen gas cap.[42,47] Hydrogen sulfide is readily absorbed and transported to the liver and oxidized to sulfate.[47,48] Some hydrogen sulfide may be lost through eructation,[48,49] but the significance of this route has been questioned.[50] Excess sulfur is excreted in the urine and large intestine[51,52] or recycled to the rumen.[53,54] A period of adaptation is required for maximum production of hydrogen sulfide after exposure to sulfur.[44,51,54-56]

Because sulfur and sulfate demonstrate low cellular toxicity, it is unlikely that sulfur-associated PEM results from sulfate or sulfur toxicity. However, sulfides are highly toxic.[57-59] The chances of sulfur-associated PEM are higher after sulfide toxicity.[6,8,49] It has been proposed that the pathogenesis of sulfur-induced PEM involves inhibition of cytochrome *c* oxidase, an enzyme in the electron transport chain; this chain is important for regenerating the intermediaries of aerobic glycolysis and the final round of ATP production. Because oxygen availability already limits aerobic glycolysis in the brain, inhibition of the electron transport chain could profoundly alter neuronal ATP production.

For highly toxic sulfide to reach the brain, it must escape hepatic oxidation. This is achieved by two mechanisms. A surge in ruminal sulfide generation usually follows a period of adaptation to high-sulfur diets. This surge may overwhelm the hepatic detoxification capacity. Because cattle inhale the majority of eructated ruminal gas,[60] it has been proposed that eructated hydrogen sulfide may be inhaled and absorbed via the pulmonary tree, bypassing hepatic circulation and leading to neurotoxicity in the brain; however, this concept has been questioned.[61]

In feedlot cattle, a summer peak in PEM cases was associated with consumption of water containing 2500 mg/L of sulfate.[7] The total sulfur intake of these steers was estimated to be 0.6% on a dry matter basis during the hottest days of the year. Most PEM cases occurred between 15 and 35 days after arrival in this feedlot. In another investigation, 11% of weaned calves consuming a diet containing 0.9% sulfur on a dry matter basis developed clinical manifestations of PEM.[8] Lesions were confirmed in one steer that died. Addition of gypsum (calcium sulfate) to feeder cattle rations at a final concentration exceeding 2% organic sulfate resulted in a significantly greater risk of developing PEM. The addition of sodium sulfate (0.6% to 0.8%) to diets may induce PEM within 11 days.[49,55,62,63] An outbreak of PEM in Canada was traced to high sulfur concentrations in well water in combination with accumulation in forage.[8] One survey described an outbreak of cerebrocortical necrosis in cattle eating diets containing 7200 mg/kg of sodium sulfate.[40]

The recommended maximum tolerance level of sulfur is 0.4% of dry matter intake.[35] Other effects of excessive sulfur intake are decreases in feed intake and weight gain. Accurate diagnosis of sulfur toxicity requires measurement of sulfur in all food and water sources. Sulfur from water must be included when total sulfur intake is calculated. One third of the molecular weight of sulfate is sulfur. Accordingly, if an animal drinks 30 L of water a day containing 2000 mg/L of sulfate, this contributes 60,000 mg of sulfate, or 20 g of sulfur. Furthermore, if this animal consumes an average of 10 kg of dry matter daily at 0.15% sulfur, the feed or forage contributes 15 g of sulfur, and thus the total sulfur intake is 35 g, or 0.35% on a dry matter basis. This scenario illustrates that water may be a substantial contributor to total daily sulfur intake.

Some authors have suggested that sulfides result in thiamine destruction, thereby directly implicating a thiamine deficiency in the pathogenesis of sulfur-associated PEM. Rumen thiamine production was slightly reduced by the inclusion of excessive sulfur in the ration.[64] However, the authors deemed the measured reduction to be clinically insignificant; they suggest that sulfur-associated PEM occurs independent of thiamine metabolism. One study suggested that the reductions in activities of pyruvate dehydrogenase, α-ketogluterate dehydrogenase, and cytochrome *c* oxidase in the cerebral cortex is associated with the pathogenesis of sulfur-induced PEM.[65]

PEM induced by feeding of molasses and urea is thought to be related to the high sulfur content of the molasses and to the depletion of propionate and other glucogenic precursors[14]; it is not considered to be caused by thiamine destruction. The tissue thiamine concentrations of animals with molasses-related PEM are normal,[66] and signs are preventable by concomitant feeding of glycerol, which is converted to glucose in the rumen. Outbreaks of PEM in range cattle have been associated with ingestion of the plant *Kochia scoparia*.[67,68] The pathogenesis of this condition is unknown; however, some authors have suggested that the plant has the capacity to accumulate sulfur.[40]

Some cases of PEM cannot be linked either to problems with thiamine or to sulfur toxicity. Other compounds, such as lead, affect electron transport in a manner similar to that of sulfides and therefore also impair ATP production. Water intoxication creates a similar histologic lesion, but the pathogenesis of edema is related more to the generation of osmotic compounds and fluid shifts with rapid fluctuations in blood and neuronal osmolality (see Salt Poisoning [With or Without Concurrent Water Deprivation] section).

Clinical Signs

PEM appears to manifest both subacutely and acutely.[1,8] In the subacute form, signs may develop within hours or over several days. In the early stages of the disease, the affected animals detach from the herd or flock, become anorectic, and stagger. Neurologic signs are symmetric. Affected animals are blind, walk with the head held erect, and demonstrate a slight hypermetric gait. Progression of the condition is associated with bilateral cortical blindness, head pressing, opisthotonos, bilateral dorsomedial strabismus, miosis, repetitive chewing, profuse ptyalism, and odontoprisis.[1,5,69-71] Despite the defective menace response, the animals usually have normal palpebral reflexes. Affected animals may also develop a variable nystagmus. The rectal temperature is normal unless excessive muscular fasciculations have developed. The pulse and respiratory rates are usually increased. An odor of hydrogen sulfide may be detected on the breath if the PEM is associated with excessive sulfur consumption.

Although most of these animals respond favorably to aggressive therapeutic intervention, clinical signs may progress to recumbency, tonic-clonic convulsions, and death. In facilities with certain types of fencing, such as cables, affected animals may push or press on their airway with such force that they die of asphyxiation.

In the acute form of PEM, animals are found recumbent and comatose.[1,8] These animals often exhibit episodic tonic-clonic convulsions, and they remain recumbent and hypertonic between seizures. The prognosis is poor for acutely affected animals and those with advanced subacute manifestations. Survivors may remain irreversibly decorticated and are culled because of poor performance, chronic anorexia and ataxia, or blindness. However, mildly affected animals may remain productive members of the herd.

Because the clinical manifestations of PEM may be subtle and nonspecific, they can be confused with other disorders. PEM is often confused with lactic acidosis that develops after consumption of excessive amounts of readily fermentable carbohydrates. Animals with lactic acidosis may appear ataxic

VetBooks.ir

and obtunded, in addition to having a foul-smelling, watery stool and a distended, fluid-filled rumen. PEM can occur concurrently with carbohydrate engorgement but may go undiagnosed, or PEM may be confused with lactic acidosis or primary ruminal tympany in acutely affected animals that have remained laterally recumbent for some time.

The major differential diagnoses for PEM include enterotoxemia type D (focal symmetric encephalomalacia in small ruminants), salt poisoning/water deprivation, head trauma, bacterial meningoencephalitis, coccidiosis with nervous system involvement, vitamin A deficiency, ethylene glycol poisoning, locoism, rabies, and IBR encephalitis.

Clinical Pathology Although a definitive diagnosis requires histologic examination of brain tissue, a presumptive diagnosis before death may be based on the history and clinical signs or response to therapy. If PEM is diagnosed, the investigation should proceed at the animal, herd, and environmental level to identify evidence supportive of sulfide toxicity, thiamine deficiency, lead toxicity, or water deprivation/salt toxicosis.

Sulfide concentrations in the ruminal fluid and gas cap in experimentally induced sulfur-associated PEM have been shown to be high.[49,72] However, unpublished data supported a finding of a decrease in gas cap sulfide concentrations in naturally developing PEM associated with increased sulfur consumption.[73] This is probably caused by the rapid metabolism of sulfate to sulfide in the rumen and resultant absorption or eructation of hydrogen sulfide. Animals with naturally developing PEM are likely to have been anorectic for some time, which results in a decrease in oxidized and reduced forms of ruminal sulfur.

In clinically healthy penmates of affected cattle, the concentration of hydrogen sulfide in the rumen gas cap can be estimated; this is an effective chute-side diagnostic procedure whose results can indicate excessive sulfur consumption.[8] This method provides real-time results that may aid direction of further animal and environmental investigations. In short, an area in the left paralumbar fossa is prepared for ruminocentesis. An 18-gauge, 3.5-inch spinal needle is inserted through the body wall and into the rumen gas cap. A modified gas sampler is attached to the spinal needle by means of an extension set, and a known amount of gas is drawn through a hydrogen sulfide detector tube.[72] It is important to adjust the values to account for any dead space of the sampling instrument, such as the extension set and other modifications. Hydrogen sulfide concentrations greater than 1000 ppm are indicative of excessive sulfur consumption.[74]

Blood samples may be analyzed for lead concentration and possibly estimation of thiamine status. Thiamine status is generally evaluated with one of several available methods, including determining the total blood thiamine concentration through a thiamine-dependent *Lactobacillus* bioassay.[75] The erythrocyte thiamine pyrophosphate concentration may be measured by high-performance liquid chromatography.[76]

Another method of evaluating thiamine status is to determine erythrocyte transketolase activity.[77] In this test, the specific activity in the active (holoenzyme) and inactive (apoenzyme) forms is compared with the activity of the two forms after addition of thiamine to the homogenates. A large increase in specific transketolase activity after addition of the thiamine pyrophosphate suggests thiamine deficiency. Theoretically, in animals with thiamine-associated PEM, the concentration of holoenzyme is decreased and that of the apoenzyme is increased. If thiamine deficiency is identified in an affected animal, caution should be used in interpreting the results, because a period of anorexia may result in a decrease in ruminal de novo synthesis.[78,79]

Changes in CSF of affected animals are usually vague. They include mild pleocytosis (5 to 50 WBCs/dL) with vacuolation and increased protein concentrations (>50 mg/dL).[9,80] Electrophysiologic studies of affected animals show a normal latency and decreased amplitude of the late peaks of the visual evoked potentials. These changes reflect decreased numbers of neurons capable of responding to the photic stimulation.[81]

Environmental investigations should include evaluation of all feed and water sources for sulfur concentrations or the possibility of lead contamination. The diet should also be checked for molasses, salt, and urea content.

Pathology In cases of sulfur-associated PEM, rumen contents may have an odor of hydrogen sulfide. In other cases, there may be evidence of grain overload, coccidiosis, or respiratory disease. Some of these lesions are related to management conditions, but they may also be related directly or indirectly to PEM. The macroscopic pathologic brain lesions of PEM include cortical swelling and softening, flattening, and yellowish discoloration of the gyri. Necrotic areas of the cerebral cortex demonstrate autofluorescence under ultraviolet light (365 nm).[82,83] In severe cases, the cerebellum herniates through the foramen magnum or the occipital cortex under the tentorium cerebelli. Necropsy months after recovery may reveal cerebral atrophy and submeningeal cortical cysts. The major microscopic lesion is a diffuse laminar necrosis. Other changes include intracellular and intercellular edema, neuronal necrosis, and neuronophagia.[3,70]

Treatment and Prognosis Regardless of the underlying cause, animals with the subacute form of PEM often respond favorably to parenteral administration of thiamine hydrochloride. These animals may remain blind and may have depressed sensorium for weeks or months.[84] Thiamine should be administered at 10 to 20 mg/kg IM or SC three times daily. In severe cases, IV administration of the first dose might be warranted. If given intravenously, thiamine should be administered slowly to avoid adverse reactions. If no improvement occurs initially, the treatment should be continued for at least 3 days. In some patients, recovery may take as long as 7 days, but most patients show improvement within 24 hours. A single administration of sodium dexamethasone (0.1 to 0.2 mg/kg IM or IV) or mannitol (1 g/kg of mannitol in a 20% solution IV) may help reduce cerebral edema. Anecdotal reports indicate that feedlot animals that have recovered from PEM are at increased risk for respiratory disease; therefore prophylactic antimicrobial administration may be indicated. Convulsions may be controlled with phenobarbital, pentobarbital, or diazepam (see Table 35.4). Animals with the acute form of PEM usually have more severe cortical and deep gray matter lesions than do animals with the subacute form.[8] Animals with the acute form generally do not respond to therapeutic regimens. Ruminants with PEM secondary to the molasses-urea diet do not appear to respond to treatment with thiamine. They may respond more favorably to parenteral administration of glucose or enteral or parenteral administration of a glucose precursor.

Prevention and Control Ultimately, the best way to prevent outbreaks is to manage the dietary intakes of susceptible animals appropriately. Ruminants should be allowed an adequate period of adaptation to high-concentrate rations. All feedstuffs and water sources should be carefully analyzed on a routine basis to estimate total sulfur intake. If excess sulfur consumption is a factor, steps should be taken to remove sources such as high-sulfur hay, ammonium sulfate, and molasses. If the excess sulfur intake is unavoidable, steps can be taken to limit its effects. Older members of the cow herd could be used to graze the high-sulfur pastures, and younger, more susceptible animals could be kept in lower-sulfur pastures or given hay supplementation. Personnel should be trained to identify PEM early and treat it appropriately.

VetBooks.ir

Thiamine may be given as supplementation (3 to 10 mg/kg of feed) in rations in which the concentrate/fiber ratio is high, but this has little or no effect in preventing PEM. Other recommendations for preventing PEM include addition of brewer's yeast to the ration and gradual adaptation of ruminants (at least 2 weeks) to high-concentrate diets. Gypsum, if present as a feed-limiting additive, should be removed from the diet. Elimination of supplementation and rotation of pastures have been sufficient for controlling some outbreaks.[20] Supplementation with cobalt in trace-mineral salt mixes may be necessary in deficient areas.

Salt (Sodium) Poisoning (With or Without Concurrent Water Deprivation)

Lisle W. George • John R. Middleton

Definition and Etiology

Salt (sodium) poisoning is a common CNS disease of livestock. Ingestion of sodium-rich solutions over time can cause production-related losses and even death. Ingestion of water containing more than 7000 mg/L of total dissolved salts is likely to result in acute salt poisoning.[1,2] Water that contains less than 3000 mg/L of total dissolved salts is considered safe for consumption. Salt poisoning can be associated with water deprivation.[1,3,4] If access to free water is constantly available, animals may tolerate up to 13% dietary NaCl intake.[5]

The acute toxic doses of oral NaCl have been reported as approximately 2.2 g/kg body weight for cattle and horses and approximately 6 g/kg for sheep.[5] With water restriction, the toxic dose is considerably lower, and poisoning has resulted from ingestion of 0.9% NaCl in water-restricted cattle.[6] Chronic toxicity can occur at lower dietary NaCl levels than can acute toxicity. Ingestion of water with NaCl concentrations above 1% uniformly results in toxicosis if no other source of ion-free water is provided.[7,8]

Ingestion of water containing 0.7% NaCl impairs the fertility of females,[8] and water containing 0.25% NaCl suppresses milk production in cattle.[9] Dairy calves have been poisoned by daily feeding of 4 L of milk replacer containing 2.6% NaCl.[10] Animals are most susceptible to salt poisoning during the summer because of the increased insensitive loss of water at that time. Salt poisoning in ruminants is most frequently a syndrome of concurrent "water intoxication": a period of restricted access to water, followed by unrestricted access to water.[1,3,4] In such cases, the dietary intake of sodium can be relatively modest, but disease occurs once water enters the extracellular fluid and moves into the brain tissue.

Epidemiology

Animals are tolerant of high dietary sodium levels if they have concomitant access to fresh drinking water. Feedstuffs that are common sources of excessive sodium include whey, saline-preserved fish or fish meals, bakery by-products, and certain milk replacers.[11] Confined calves may be poisoned by improperly formulated milk replacers or oral electrolyte solutions.[11,12] Brine is used extensively as a flush during the drilling of oil wells, and cattle eagerly ingest large amounts of oil well sludge in the western and southwestern United States.[13-15] Effluents from drilling rigs may contain as much as 100,000 ppm NaCl. Drilling effluent is also contaminated by heavy metals and magnesium salts, which complicate the clinical syndrome of salt poisoning.

Concurrent neurologic disease may predispose animals to reduced water intake, as occurred in a group of goats with locoweed (*Oxytropis* spp.) poisoning who became water deprived because of reluctance to move to a water source. They developed clinical and pathologic evidence of sodium poisoning when moved subsequently to an area where water was easily available.[3] Sodium poisoning caused by water restriction may result either from freezing of water sources in northern climates or from intentional water restriction of veal calves.[12] Ingestion of brackish or tidal water is a cause of sodium poisoning in cattle pastured in the coastal regions of the world.

Pathogenesis

In salt poisoning, disease can occur acutely after ingestion of a large quantity of NaCl or chronically after long periods of reduced water consumption with low to moderate sodium intake. Thus hypernatremia results from an imbalance in sodium and water regulation. Increases in plasma sodium concentration cause movement of intracellular water into the extracellular fluid causing cellular dehydration. Cerebral dehydration is transient but is probably the cause of clinical signs in acute sodium overload. Intracellular hyperosmolality can reduce energy-dependent sodium transport mechanisms and glycolysis.[16] These mechanisms normally provide energy by which the sodium ion is removed from the cell cytoplasm.[17]

Within a few hours, osmotic adaptation begins to occur, whereby there is a net flow of fluid from the CSF into the brain interstitium as a result of a reduction in hydraulic pressure caused by the initial cerebral dehydration, and cellular uptake of Na, K, Cl, and organic solutes *(osmolytes)* increases intracellular osmolality, pulling water into cells and restoring cell volume.[18] Hence, with chronic hypernatremia, the animal may not manifest symptoms in the presence of high plasma sodium concentrations because of osmotic adaptation in the brain. In such cases, however, rapidly reducing plasma sodium concentrations and thus plasma osmolality during treatment or when the animal drinks large volumes of ion-free water can result in movement of free water into the brain; this causes edema and neurologic deterioration because loss of the accumulated osmolytes occurs more slowly than the relatively rapid loss of excess Na and K ions taken up during osmotic adaptation.

GI signs may also occur when animals ingest large quantities of salt over short periods of time. The hyperosmolality in the intestinal lumen results in saline catharsis and osmotic diarrhea.

Clinical Signs

Acute ingestion of large amounts of salt causes GI and neurologic signs.[7,10,19,20] These include mucohemorrhagic diarrhea and colic, head-neck extension ("stargazing"), blindness, aggressiveness, hyperexcitability, psychomotor seizures (characterized by paddling and loss of consciousness), vocalization, ataxia, proprioceptive deficits, head pressing, constant chewing movements, nystagmus, muscle twitching, and coma. Death occurs as a result of respiratory failure. Before the onset of neurologic signs, cattle with chronic salt toxicosis may appear to be depressed and dehydrated.

Excessive salt intake may also interfere with productivity in the absence of acute neurologic signs. In one study, cattle were given either tap water (196 ppm of dissolved salts) or saline (2500 ppm NaCl), and their milk production was measured.[9] Cows given tap water had greater fluid intake and significantly greater lactational persistence and daily milk production than did cows given saline, despite the fact that the latter group showed normonatremia and normokalemia. This study illustrates the importance of provision of high-quality water for optimization of milk production.

Clinical Pathology and Diagnosis

The clinical diagnosis of salt poisoning depends on the demonstration of exposure to toxic concentrations (>7000 ppm or 0.7% of sodium), the presence of water deprivation, or the determination of serum or CSF sodium concentrations greater than 160 mEq/L (occasionally exceeding 200 mEq/L).[12] Ratios of CSF sodium to serum sodium that exceed 1 : 1 also suggest salt poisoning. The plasma sodium concentration may vary, depending on whether the patient had recently been given ion-free water before measurement. Some animals with acute neurologic

lesions may be normonatremic if they have recently drunk to repletion with ion-free water, whereas others that have not had ion-free water may be hypernatremic.

Ruminal sodium concentrations above 0.36% to 0.5% or brain sodium concentrations above 150 mEq/g or 1800 ppm[21] also suggest salt poisoning in cattle.[12,19,22] Rapid intake of low-sodium water during the rehydration phase of the disease may cause intravascular hemolysis with resultant hemoglobinuria; such findings raise the index of suspicion of salt poisoning.[2]

Pathology The pathologic changes of salt poisoning include cerebral edema and softening and flattening of the cortical gyri. Microscopic lesions include laminar cortical necrosis, poliomalacia, and, on occasion, meningeal or perivascular infiltration of eosinophils, mononuclear cells, or both.

Treatment and Control Treatment of animals affected by salt poisoning is difficult. Many animals die even after intensive medical treatment. Prognosis depends on severity of clinical signs at the start of treatment: Animals that already have significant cerebral edema have a guarded prognosis. Therapy should be aimed at limiting the ingestion of nonionic water and attempting to remove intracellular solutes slowly from the brain while simultaneously controlling cerebral edema and attendant CNS signs. To prevent brain swelling and herniation of the brain through the foramen magnum or the tentorium cerebelli, slow reduction of the CSF and plasma sodium is imperative. Slowly lowering plasma Na concentrations over time by means of intravenous fluids is recommended.

Slight underestimation of fluids is preferable to excess fluid administration. Serum sodium should be monitored regularly and correction effected over 24 hours or longer. Oral fluids can be introduced gradually toward the end of the first day of treatment; salt should initially be added to oral fluids to make them isotonic to blood. When IV replacement is not feasible, isotonic to hypertonic oral fluids should be administered at a maintenance level, divided into four to six feedings daily. Access to low-salt water is gradually allowed after 3 to 4 days. Any worsening of clinical signs is an indication to increase the salt level in fluids, and IV mannitol (0.5 to 2.0 g/kg as a 20% solution) or oral glycerin (1 mL/kg diluted 50:50 with water) may be necessary to reduce cerebral edema.[2]

High-sodium crystalloid solutions (HSCS) have been used for individual treatment of severe hypernatremia, which might develop in salt poisoning.[23] Sodium (as dry salt or, if metabolic acidosis is present, as sodium bicarbonate) is added to normal (0.9%) saline to create a final sodium concentration in the HSCS that is 10 to 15 mEq/L lower than the patient's serum sodium concentration. Dry table salt (17 mEq NaCl/g) can also be added to 0.9% saline to achieve the desired sodium concentration in the HSCS. The HSCS is administered at 1 to 3 mL/kg/h while the patient's neurologic status and serum sodium concentration are monitored carefully over the first day or two of treatment; reduction of serum sodium concentration by 0.5 to 1 mEq/L/h is considered optimal.[24] Small volumes of water are subsequently offered to aid in gradual reduction of the sodium concentration in extracellular fluid; this gradual decline is thought to prevent development of an abrupt osmolar gradient that favors water entry into brain cells.

The use of solutions containing 5% glucose is contraindicated because this represents ion-free extracellular fluid, which can exacerbate brain edema. Administration of corticosteroids (dexamethasone, 0.04 to 0.08 mg/kg by slow IV injection twice daily for 2 to 3 days) may be helpful in animals with acute cerebral edema. If the neurologic signs diminish and the plasma sodium level returns to normal, the animal may be given fresh drinking water. Thiamine (10 mg/kg SC) may be a useful adjunctive therapy.

Control measures are centered on ensuring appropriate dietary sodium intake and *ad libitum* availability of ion-free drinking water. Cattle should be fenced away from polluted ponds and oil wells. Cattle on coastal pastures should have access to fresh ion-free well water. The total daily dietary salt intake should not exceed 4% of dry matter intake. Drinking water must contain less than 7000 ppm of sodium unless the dietary sodium load is reduced correspondingly. Oral rehydrating fluids and milk replacers for calves should be mixed with ion-free water in strict accordance with the manufacturer's recommendations. Assessment of water cleanliness and availability should be a component of a daily animal husbandry plan.

Vitamin A Deficiency

Definition and Etiology Vitamin A (retinol) is found in green plants and can be synthesized from plant carotenoid precursors in the liver and intestinal mucosa. Precursors of vitamin A are usually fed in cattle rations as β-carotene or as retinoids. Vitamin A deficiency occurs primarily in growing ruminants in feedlots. Deficiency develops under these conditions because the growing animal has a higher requirement for the vitamin, and feedlot-reared animals may have limited access to succulent plants. Exposure to ultraviolet light inactivates vitamin A in stored feedstuffs. Diets that are naturally low in vitamin A include cereal grains, beet pulp, and cottonseed hulls. Conditions in which the immune system is challenged, as when exposure to pathogens is high, also increase the requirement for vitamin A. Other scenarios conducive to vitamin A deficiency include prolonged grazing on dry pastures or cereal grains other than corn, exclusive feeding of cereal grains that have been stored at high temperature and humidity, or prolonged feeding of mineral oil as a preventive for frothy bloat.

Epidemiology The vitamin A requirement for common livestock species ranges from 40 to 110 IU/kg daily.[1-3] The minimum recommended daily dose of vitamin A for growing calves up to 1 year of age, for pregnant sheep, and for growing horses is 40 IU/kg. Pregnant cattle and pregnant and lactating horses require 40 to 50 IU (13.76 to 17.2 μg/kg) of vitamin A daily.[2] Lactating cattle require 80 IU (27.5 μg/kg) of vitamin A daily. Horses are susceptible to vitamin A deficiency, but the condition is rare; this situation is thought to be the result of differing conditions of management rather than an inherent resistance to the deficiency. The daily dietary requirement for carotene in cattle, sheep, and swine is 0.12 mg/kg.[2] Pasture forage, silage, and properly cured hay (<1 year old) contain large amounts of carotene. Common constituents that have low concentrations of vitamin A are sorghum, brewer's grain, and wheat straw.

Livestock are protected from short-term deprivation of vitamin A by their ability to accumulate the vitamin in the liver; however, it is estimated that the dietary intake required to initiate storage is at least three times the minimum daily intake requirement.[2] Vitamin A–replete cattle fed a diet devoid of vitamin A begin to show clinical signs of deficiency after approximately 180 days. Cattle grow and fatten normally and show no adverse effects until hepatic stores are depleted, but offspring born to these animals may show severe deficiencies. Papilledema and blindness develop rapidly after the hepatic stores are depleted.[2]

Vitamin A deficiency is categorized as a primary or secondary condition. Primary deficiencies of vitamin A develop in cattle confined in dry lot corrals, those pastured on dry grass forage for prolonged periods, and those kept indoors and fed unsupplemented, vitamin-depleted cereals and dry forage in which the activity of carotene has been depleted. Vitamin activity in feedstuffs can vary by season; for example, cattle grazing on green pastures are consistently replete with the vitamin, whereas

VetBooks.ir

VetBooks.ir

those grazing on dry pastures at the end of summer may become marginally deficient. Approximately 80% of the vitamin A activity in hay is lost during field curing.[4]

Destruction of carotene is hastened by many environmental and physical factors, including heat, sunlight, trace mineral supplements, and humidity.[5] Other factors that affect the stability of vitamin A in feedstuffs include pelleting and exposure to rancid fat in the feed.

Secondary deficiencies of vitamin A result from interference with vitamin absorption, inhibition of the conversion of β-carotene to retinol (vitamin A) in the small intestine, or an increased requirement in the presence of limited vitamin intake. The conversion of carotene to retinol is impaired in vitamin A–deficient patients.[6] Sheep may be more resistant to vitamin A deficiency because they convert β-carotene more efficiently than do cattle.[6] Fever, lactation, high ambient temperatures, and inadequate dietary energy may increase the daily requirement for vitamin A.[5] Other factors that can affect availability of vitamin A or the requirement for the vitamin include diets with low forage content, high proportion of corn silage to hay in the diet, increased exposure of animals to pathogens, and periods in which immunocompetence is reduced (e.g., the peripartum period).[3] Secondary deficiencies in vitamin A may be caused by impaired vitamin absorption, which may result from long-term feeding of mineral oil.

Pathogenesis Vitamin A is responsible for the regeneration of rhodopsin in the retina and in normal function of osteoblasts and osteoclasts, epithelial tissues, the choroid plexus, and reproductive tissues. Vitamin A deficiency causes a thickening of the dura mater, which results in diminished CSF absorption from the arachnoid granulations and the nerve rootlets. Narrowing of all the bony foramina of the skull occurs in immature animals, although bone remodeling does not occur in adults. The combined effects cause an increase in CSF pressure.[7] Closure of the optic foramen may lead to transection of the optic nerve. The high CSF pressure is transmitted into the optic nerves and results in papilledema.

Three causes of blindness have been associated with vitamin A deficiency. Nyctalopia (night blindness) is presumably caused by the decreased formation of vitamin A aldehyde in the regeneration of the visual pigment rhodopsin; this type of blindness is usually reversible. Second, degenerative changes in the outer retinal layers also cause blindness; this is reversible if treated in the early stages. The third cause is associated with stenosis of the optic foramen and compression of the optic nerve; this condition is irreversible.[8]

Clinical Signs Signs in deficient calves include anorexia, ill-thrift, blindness, diarrhea, and pneumonia. The syndrome in adults is characterized by "stargazing" posture, blindness, diarrhea, anasarca, nystagmus, strabismus, exophthalmos, loss of pupillary light reflexes, and intermittent tonic-clonic convulsions. The seizures may last for only a few minutes and can be followed by partial recovery.[9-11] Animals may die during seizures. Stimulation of the animals frequently precipitates seizures.[12,13] Death is often preceded by hyperesthesia and coma.[6,9,10] Inadequate vitamin A supplementation of calves is associated with unthriftiness, intermittent fevers, and a higher incidence of diarrhea.[14] Vitamin A–deficient adults appear to be in good body condition unless parasitism or some other nutritional deficiency is superimposed on the low vitamin A intake.[1,7] Secondary factors that can influence the appearance of the animals include concomitant nutritional deficiencies, parasitism, and pneumonia.

The ocular changes of vitamin A deficiency are characteristic. The pupils become dilated and unresponsive. As papilledema develops, the optic disk becomes pale, and its borders become indistinct, particularly in the upper quadrants,[9,11,15] which gives it the appearance of an inverted heart. The swollen disk may cast a shadow on the adjacent retina. The color of the disk fades. In advanced cases, the disk may become atrophic and appear dull, gray, flattened, and smaller than normal.[16] The retinal blood vessels become tortuous or appear to be occluded as they course over the disk. Retinal detachment and subretinal hemorrhages are possible.[9]

Reproductive disturbances can occur, including fetal malformations, abortions, loss of libido, testicular degeneration, and decreased sperm counts. Calves born to vitamin A–deficient dams are blind, have domed foreheads and thickened carpal joints, and are weak at birth.[17]

Vitamin A deficiency can be clinically differentiated from PEM and salt poisoning by comparing the menace response with the pupillary light reflex. Calves with lead poisoning and PEM generally have intact pupillary light reflexes because of normal function of the mesencephalon and optic nerves, whereas vitamin A–deficient cattle have no pupillary light responses because of retinal degeneration and constriction of cranial nerve II at the level of the optic foramen.

Clinical Pathology Assay of vitamin A and β-carotene concentrations in the plasma and feed is the most direct method of diagnosing the dietary deficiency. The concentrations of plasma vitamin A and β-carotene in normal animals range from 25 to 85 μg/dL and 150 and 397 μg/dL, respectively.[10] Plasma concentrations in vitamin A–deficient and β-carotene–deficient animals usually are lower than 7 and 70 μg/dL, respectively. The hepatic concentrations of vitamin A and β-carotene in normal calves range from 60 to 200 μg/g and from 4 to 800 μg/g of tissue, respectively. In deficient calves the hepatic concentrations of vitamin A and β-carotene range from 2 to 14 μg/g and from 0.5 to 32 μg/g, respectively.[7] There are no consistent changes in the blood chemistry analysis or the hemogram of deficient animals. Changes in the CSF of vitamin A–deficient animals include mononuclear cell pleocytosis (40 to 50 nucleated cells/dL) and increased protein concentration (140 mg/dL).[18] CSF pressure may also be increased (>200 mm Hg).[19]

Pathology The major pathologic changes in the fundus of vitamin A–deficient calves include papilledema, small flame-shaped hemorrhages around the optic disk, venous congestion in the area of the swollen optic disk, degeneration of the retinal ganglion cells, focal retinal thinning, and fusion of parts of the retina to the choroid plexus.[15] Other changes associated with vitamin A deficiency include doming of the frontal bones, enlargement of the carpi, cerebellar and cerebral compression, partial transtentorial herniation of the cerebellum, cystic dilation of the hypophyseal cleft, focal ruminal hyperkeratosis, and increased keratinization of the squamous epithelium of the penile and the preputial mucous membrane. Corneal ulceration and clouding have been observed in the eyes of calves with naturally occurring deficiencies.[18] Vitamin A deficiency also can cause anasarca, squamous metaplasia of the salivary ducts, degeneration of the germinal testicular epithelium, degenerative changes in the intestinal epithelium in lambs, and reduction in intramuscular fat in cattle.[20-22]

Microscopic changes in the CNS include attenuation of the optic nerve with necrosis and demyelination. Focal accumulations of phagocytic cells containing lipofuscin and hemosiderin are present in the necrotic area. The optic nerve is attenuated along its entire length. The meninges are thickened by fibrosis and mononuclear cell inflammation. The microscopic changes in the bones include wider-than-normal spacing of the central canals and reduction of osteoclastic lacunae.

Treatment and Control Cattle with severe blindness caused by damage to the retina or optic nerves do not regain

VetBooks.ir

their vision when treated with vitamin A; however, cattle with acute encephalopathy and simple papilledema may respond favorably after a short period of vitamin supplementation.[2] Affected cattle should receive 440 IU/kg of vitamin A parenterally and then 6000 IU/kg parenterally every 50 to 60 days until the diet has been enriched. High-dose oral therapy is important because carotene and oil suspensions of vitamin A are not efficiently utilized when administered by parenteral injection.[23] Administration of large doses orally is important because conversion of β-carotene to vitamin A is inhibited in deficient calves. The recommended concentration of vitamin A in milk replacers for preruminant calves is 11,000 IU/kg dry matter.[14]

Prophylactic dietary supplementation of vitamin A should be considered in all cattle that lack access to green feed. Dietary supplements could include leafy, freshly cured hay, green pasture, or alfalfa meal. Concentrate feeds formulated with exogenous, stabilized vitamin A are commercially available. Recommended concentrations (per kilogram of dry matter) of vitamin A in feed are 2200 IU for feedlot cattle, 2800 IU for pregnant cows, and 3900 IU for lactating cows.[4]

Hydrocephalus and Hydranencephaly of Ruminants

Definition and Etiology Hydrocephalus/hydranencephaly is an apparently common abnormality of the CNS in large ruminants. It is probably underdiagnosed because many of the affected animals die of complications, and the primary condition is overlooked during clinical and pathologic examinations. One study reported that 97 of 155 calves with CNS lesions had hydrocephalus.[1] Hydrocephalus may be classified as hypertensive or normotensive.[7]

Normotensive Hydrocephalus (Hydranencephaly)

Normotensive hydrocephalus that develops as a result of a failure of cell growth or cellular necrosis is called *hydranencephaly*.[2] Most cases of hydranencephaly in domestic livestock are caused by in utero infection of the fetus by viral pathogens such as bluetongue, BVD, Akabane, Cache Valley, Aino, border disease, and Schmallenberg viruses.[1,3-13] The pathogenesis and epizootiology of bluetongue and BVD are discussed in detail in Chapter 32. The neurologic effects of border disease virus infection are discussed earlier in this chapter.

The loss of fetal neurons in utero results in flexural contractions of the limbs (arthrogryposis), which may manifest as dystocia. Affected neonates may be stillborn or born alive but weak, blind, unable to stand, and unable to nurse. They may exhibit a dysphonia, which resembles a bark. Neonates that are unable to nurse fail to ingest colostrum and often die from septicemia.

AKABANE VIRUS INFECTION. The Akabane virus is a member of the Simbu serogroup of the *Orthobunyavirus* genus in the *Peribunyaviridae* family.[3] It has been isolated from cattle in Africa, Japan, Israel, Korea, and Australia.[4-9] Hosts of Akabane virus include sheep, cattle, and goats. Infection of pregnant, nonimmune dams results in hydranencephaly or arthrogryposis of the fetus.[14] The disease is thought to be transmitted to the cow by various *Culicoides* spp. Experimentally infected calves develop porencephaly and encephalitis when exposed to the Akabane virus between gestational days 62 and 96.[15] Studies in naturally infected cattle showed that infection of calves between days 76 and 104 of gestation resulted in hydranencephaly or porencephaly, whereas infection between days 103 and 174 of gestation resulted in arthrogryposis.[16] Lambs are susceptible when exposed to the virus between gestational days 30 and 36.[9] The CNS lesions are apparently the result of a direct necrotizing effect of the virus on the developing neurons. The pathologic changes in the CNS of experimentally infected calves and lambs are similar to those of naturally acquired infections.[6,9] Adults occasionally abort when infected by the virus but do not develop clinical disease.

A syndrome of arthrogryposis, facial deformities, kyphoscoliosis, hydranencephaly, and hypoplasia of multiple regions of the brain and spinal cord has been described in Corriedale sheep in Australia. Although it resembles the disorder caused by congenital Akabane virus infection, results of breeding trials indicated autosomal recessive inheritance for the disease.[17]

AINO VIRUS INFECTION. The Aino virus causes stillbirths, premature calving, and congenital malformations, including arthrogryposis, cerebellar hypoplasia, and hydranencephaly, in calves of Japan and Australia.[18-20] Aino virus is antigenically and biologically distinct from Akabane virus, but the clinical syndromes of fetal infection by the two viruses are indistinguishable.

CHUZAN VIRUS INFECTION. Hydrocephalus, hydranencephaly, and cerebellar hypoplasia have been attributed to infection of pregnant cattle with the Chuzan virus.[21-23] This virus is a relative of the Akabane and Aino viruses and is a member of the Palyam subgroup of the genus *Orbivirus*. The virus has been isolated from *Culicoides oxystoma*, which may serve as the major vector. The clinical signs are characteristic of hydrocephalus.

CACHE VALLEY VIRUS INFECTION. A flock outbreak of arthrogryposis, myositis, hydranencephaly, and a variety of other brain malformations (microcephaly, cerebellar hypoplasia, porencephaly) in newborn lambs in the southwestern United States was attributed to in utero infection with the Cache Valley virus (family *Peribunyaviridae*).[24,25] Cache Valley virus was first isolated from mosquitoes from Utah and has since been isolated from caribou, horses, sheep, and cattle elsewhere. Antibodies have been found in white-tailed deer in the southwestern United States, but the role of deer in the survival of the virus and the transmission of the disease to livestock is unknown.[26] In one survey of sheep in the western United States, the seroprevalence for the Cache Valley virus was 19.1%.[24] Vectors for the virus include *Anopheles*, *Aedes*, *Culex*, and *Coquellettidia* mosquitoes.[27] Infection before 30 days of gestation may cause embryonic death, and infection between days 30 and 52 causes fetal malformations.[27]

BLUETONGUE VIRUS INFECTION. Hydranencephaly, arthrogryposis, or both may occur in ruminants when the dam is infected at specific times during gestation; abortions or fetal resorption can also occur. Serotypes 11 and 17 are the serotypes most frequently isolated from neonatal calves and lambs in field epizootics.[28,29] Bluetongue virus serotype 8 has caused devastating disease in ruminants in Central and Northern Europe; of importances is that neonates infected in utero may be born viremic, thereby providing *Culicoides* spp. with more abundant viremic hosts during the subsequent spring.[30] Calves, lambs, and kids infected in utero may be born normal or manifest one or more associated birth defects, including hydranencephaly, arthrogryposis, brachygnathia, prognathia, and excessive gingival tissue (see Chapter 32 for additional information).

BOVINE VIRAL DIARRHEA VIRUS INFECTION. Hydranencephaly, hydrocephalus, and cerebellar hypoplasia have been associated with fetal infection of cattle with the BVD virus.[31-34] Precolostral serum antibody titers for the virus in affected calves vary; some titers range from 1:32 to 1:256, but other calves may have persistent viremias without demonstrable antibody.

VetBooks.ir

SCHMALLENBERG VIRUS INFECTION. The Schmallenberg virus is an enveloped RNA virus belonging to the genus *Orthobunyavirus*.[10] The Schmallenberg virus is a member of the Simbu serogroup, which includes the well-known teratogenic Akabane virus. It is named after a town in west-central Germany where, in the autumn of 2011, signs of this viral disease first emerged in local cattle. Diagnosticians at the Friedrich-Loeffler Institute (the Federal Research Institute for Animal Health) subsequently identified this virus as a cause of transient fever, depression, reduced milk production, and occasional diarrhea in cattle. The virus was subsequently detected in several countries in continental Europe, the British Isles, the Mediterranean Basin, and Turkey.[12] During the fall of 2011, infections in small ruminants in the region were predominantly asymptomatic; however, once ruminant birthing commenced in late 2011 and early 2012, it became apparent that the virus had induced significant fetal morbidity and mortality, primarily in sheep but in goats and cattle as well.

Fetal infection with Schmallenberg virus may result in abortion or stillbirth; newborns may be weak, may have significant neurologic deficits, or may be normal and healthy. On the basis of the pathophysiologic features of Akabane viral infections, the outcome of fetal infection with Schmallenberg virus is considered to probably depend on the timing of viral infection in relation to the stage of fetal development.[10,11] Infection early in gestation, within the first trimester, appears to result in the most significant fetal deformities, with arthrogryposis of one or more limbs, torticollis, spinal malformations (scoliosis, kyphosis, lordosis, or a combination of these), brachygnathia inferior, and a multitude of CNS malformations.[10,11] Hydranencephaly, porencephaly, and hydrocephalus are among the more common neurologic malformations. According to the OIE, the clinical disease in ruminants can best be categorized as an *arthrogryposis/hydranencephaly syndrome*.[12] Fetal limb, neck, and spinal skeletal anomalies can result in dystocia. To date, there have been no reports of Schmallenberg virus causing human infections, and the virus is not currently considered to be a zoonotic threat.

As is the case with other members of the *Orthobunyavirus* genus, Schmallenberg virus is an arthropod-borne virus, and *Culicoides* spp. midges (e.g., *Culicoides obsoletus*) are currently considered the vector in Europe.[13] Other vectors, however, may also be involved. Vertical transmission of the virus from infected ruminant dam to ruminant fetus is considered to be the primary means of spread within animals. Horizontal transmission is a possible but less likely means of transmission.

OTHER INFECTIOUS AGENTS. A single case of hydrocephalus in a calf aborted at 7 months of gestation was associated with necrotizing encephalitis caused by *Neospora caninum*.[35]

Hypertensive Hydrocephalus

An increase in CSF volume that results from compressive or obstructive lesions in the ventricular system or from decreased CSF absorption is called *hypertensive hydrocephalus*.[2] Obstructive lesions of the ventricular system trap the CSF in the ventricles, causing an increase in CSF volume and pressure. Ischemia and CNS degeneration result from the high CSF pressure. The sites of obstruction are most often the lateral apertures, mesencephalic aqueduct, lateral ventricles, interventricular foramina, and fourth ventricle. The obstructions may be either congenital or acquired. Causes of acquired obstructive hydrocephalus include cerebral abscess, cholesteatoma (in equines), equine infectious anemia, *Coenurus cerebralis* infestation, meningitis, and lymphosarcoma. Hypertensive hydrocephalus may also be caused by acute inflammatory disease such as meningitis and vitamin A deficiency. In these diseases the increased pressure is the result of impaired CSF resorption.

Congenital Hypertensive Hydrocephalus

Congenital hypertensive hydrocephalus is a hereditary condition in Hereford, Charolais, Ayrshire, Dexter, Holstein, and Jersey calves.[36-38] The condition has also been recognized in Arabian foals.[39]

Clinical Signs

Hydrocephalic animals are often born dead or are weak and die shortly after birth. The most obvious signs in animals that survive include failure to bond to the dam, depression, diminished learning ability, partial failure of suckling, droopy head and ears, muscular fasciculations, head tremor, conscious proprioceptive deficits, blindness, ventrolateral strabismus, nystagmus, dysphonia, tongue flaccidity or paralysis, retention of food material in the cheeks and lips, limb spasticity, hyperreflexia, psychomotor seizures, recumbency, and coma. Occasionally, doming of the calvaria or protrusion of fluid-filled cystic structures through an open fontanelle is observed. Affected neonates often do not ingest sufficient amounts of colostrum and frequently die of septicemia.

In virally induced cases of hydranencephaly, associated skeletal deformities such as abnormally curved ribs, kyphoscoliosis, flexural deformities of the limbs, domed skulls, and brachygnathia may be observed. Patients with hydrocephalus caused by compressive lesions around the ventricular system may show unilateral or bilateral signs of increased intracranial pressure. The clinical signs of unilateral lesions include head tilt (toward the lesion side), ipsilateral mydriasis, and contralateral deficit of the menace response. Signs of hydrocephalus in foals are similar to those in calves. The cause of the condition in horses is unknown.

Antemortem diagnosis of brain malformations has been facilitated by CT and MRI. However, these techniques are rarely warranted or available for use in large animal species. A more practical technique involving ultrasonography, transorbital echoencephalography, has proved effective for the diagnosis of hydrocephalus and hydranencephaly in calves younger than 3 months of age.[40]

Clinical Pathology

The diagnosis of hydrocephalus in calves and lambs is typically based on the presence of characteristic clinical signs and a domed skull. Whenever hydranencephaly is suspected, blood should be collected for virus isolation, serologic testing, and quantitative immunoglobulin determination. Presuckle serum samples from neonates that have been infected by the Akabane or bluetongue virus in the latter part of gestation may be seropositive.[26]

Pathology

The pathologic lesions of hydranencephaly are similar regardless of the etiologic agent. They include microcephaly, cerebellar hypoplasia, hydrocephalus, hydranencephaly, and porencephaly of the cerebral and the cerebellar cortex. Microscopic lesions of hydranencephaly include segmental loss of dorsolateral ventricular ependyma, thinning of the periventricular white matter, porencephalic cysts, and nonsuppurative meningoencephalitis. Lesions in other parts of the CNS may include loss of ventral horn cells in the spinal cord and demyelination in the spinal cord. Nonsuppurative inflammatory changes may occur in cases caused by viral infections. Polymyositis has been described in affected calves; however, it is unclear whether these lesions are caused by viral infection or occur secondary to the denervation. The skeletal deformities associated with virally induced hydranencephalies include rigid extension or contraction of one or more limbs (arthrogryposis), abnormally curved ribs, domed skull, thickening of the calvaria, kyphoscoliosis, and brachygnathia.

Obstructive or compressive lesions may be observed with congenital or acquired hypertensive hydrocephalus.

VetBooks.ir

Treatment Except for one report of successful surgical intervention in a calf with a meningocele, no satisfactory therapy is available for the treatment of hydrocephalus or hydranencephaly in large animals.

Ammoniated Forage Toxicosis (Cow Bonkers)

Application of anhydrous ammonia to poor-quality forage improves the nutritional density of the material and reduces certain toxic fungal metabolites, specifically the prolactin-like toxins of the endophytic fungus *Acremonium coenophialum* in fescue hay.[1] Ammoniation increases dry matter intake, enhances digestibility, and increases the relative value of the protein content of the feed. However, overammoniation of the forage, at a rate exceeding 3% of the forage on a dry matter basis, may result in toxicosis. Studies now suggest that several dialkylimidazoles may be responsible for the neurotoxic effects of ammoniated feedstuffs, superseding previous theories that 4-methylimidazole is the primary neurotoxin.[2,3] Ammoniated feedstuffs containing high levels of molasses are more toxic than similarly treated grass hay. The toxin may be concentrated in milk; consequently, calves suckling from normal-appearing dams may show clinical signs of intoxication.

Affected animals are hyperesthetic and ataxic. At rest they assume a sawhorse stance, but when excited, they become hyperactive, appear to be blind, and circle propulsively. Other clinical signs include vocalization, dysphonia, and walking or running into objects. The periods of frenzy may result in recumbency and convulsions. The spasmodic episodes last for 15 to 20 minutes. Afterward, the affected animals rest quietly with occasional muscle tremors. Recurrences of the mania may be precipitated by loud noises or other startling stimuli. The concentrations of ammonia in the blood and CSF may be increased. Although specific treatments have not been identified, one report indicated that affected calves benefited from acepromazine (0.045 mg/kg IV) and thiamine (1.14 mg/kg IM). Thiamine dosages higher than described in this report[4] (such as 10 to 20 mg/kg SC q12h) have been used for treatment of other neurologic diseases and may be considered for use in this disease.

Lead Poisoning

Definition and Etiology Lead poisoning in ruminants is characterized by an acute encephalopathy. In contrast, lead poisoning in horses is characterized by chronic polyneuritis. Blindness, ataxia, and depressed sensorium are significant clinical signs in cattle, sheep, and goats, whereas in horses the poisoning is associated with weight loss, dysphagia, and secondary aspiration pneumonia. Cattle are most often poisoned because of their tendency to lick or chew on foreign objects, their access to lead-containing materials, and their propensity to drink contaminated petroleum distillates.[1]

Epidemiology Sources of lead are numerous and include lead arsenate defoliants, lead acid batteries, used motor oil, linoleum, roofing felt, paint, machinery grease, caulking compounds, improperly compounded mineral supplements, and foliage near lead smelters and battery-recycling plants.[2-10] High lead levels have been reported in grasses growing near busy roadways, but the clinical significance of these findings is unclear.[7,11,12] Factors that can increase the likelihood of ingestion of lead-contaminated feedstuffs include lack of alternative feed, hunger, and phosphorus deficiency.[13] The acute lethal dose of lead for cattle is estimated to range from 220 to 600 mg/kg in calves, 600 to 800 mg/kg in adult cattle, and 400 mg/kg in goats.[13,14] Lead poisoning has been reported in cattle exposed naturally to 6 to 7 mg/kg/day of lead on foliage and in calves given oral lead acetate at 2.7 to 20 mg/kg/day.[15] The interval for development of clinical signs ranges from 5 to 20 days and is related to the dose and ionic form of lead administered.[15] Ensiling of contaminated forage results in percolation and concentration of lead at the bottom of the silo.[16]

The toxicity of ingested lead is apparently influenced by dietary factors. Calves on a milk diet are more susceptible to lead poisoning than are calves fed hay and grain.[17] There appears to be a direct correlation between high levels of vitamin D and enhanced lead absorption, which may explain the greater occurrence of poisoning during the summer. Elevated copper concentrations in forage, such as may be found in pastures fertilized with pig slurry, may potentiate accumulation of lead in animals consuming it.[18]

The estimated cumulative toxic dose of lead for horses is 2.9 mg/kg/day.[19] Poisonings have been reported in horses grazing on pastures contaminated with 320 to 440 ppm of lead from a metal smelter; this amounted to a daily intake of 2 g (≈6.4 mg/kg). Metallic lead and "galena" (insoluble sulfide salt) are less toxic than acetate and carbonate lead salts.[20]

Pathogenesis Lead enters the body through the GI tract or, less often, through the respiratory tract. Metallic lead and the sulfide form are less well absorbed than the acetate, phosphate, carbonate oxide, and hydroxide salts. Metallic lead is poorly absorbed and causes toxicity only when a lead foreign body becomes entrapped in the stomach for prolonged periods. Interaction between lead and other minerals may occur. For example, high levels of dietary calcium reduce the GI absorption of lead. Concomitant exposure to lead and cadmium results in a worsening of the clinical signs of lead poisoning.[21]

Although intestinal absorption of lead is relatively inefficient, significant amounts can cross into the blood if sufficient quantities are ingested. Approximately 1% to 2% of the total oral dose of lead is absorbed within 24 hours.[22] Most of the lead absorbed from the digestive tract (90%) is bound to erythrocyte proteins, which results in a low lead concentration in the plasma, but higher concentrations in whole-blood specimens.[23] At the end of the erythrocyte's life span, the cell-bound lead is metabolized from the erythrocyte proteins and deposited in the bone as the triphosphate salt. The half-life of blood lead in adult cattle is extremely variable and unpredictable, ranging from 48 to 2507 days in one study.[24] Phenotypic or genotypic factors may affect metabolism and storage of lead. The variable time for clearance of lead has an obvious implication for public health because all carcasses of animals suspected or known to be exposed to lead must be tested before being cleared for human consumption.[25]

Lead also crosses the placental barrier and accumulates in fetal bone, liver, and kidneys but does not substantially accumulate in milk. However, cattle with higher blood lead levels may have greater concentrations in milk.[26]

The toxic effects of lead include inhibition of free sulfhydryl groups found in many enzymes, interference with zinc-containing metalloproteins, and steric inhibition of enzyme activity.[27] Enzymes of heme synthesis are particularly susceptible to injury. These include δ-aminolevulinic acid dehydratase and ferrochelatase. Interference with ferrochelatase inhibits the formation of heme from protoporphyrin, which results in a buildup of unmetabolized porphyrins.

Because of the interference with heme metabolism and the altered function of other erythrocyte proteins, the erythrocyte half-life is shortened, which may result in a normochromic, normocytic anemia in a small proportion of chronically poisoned animals.[28] Iron is not adequately used and is stored in sideroblasts in the bone marrow.[29] Lead also interferes with the activity of pyrimidine-specific 5′-nucleotidase, which results in basophilic stippling of red blood cells.[30]

After absorption, lead rapidly enters the brain at a dose-dependent rate. The lead deposition in the CNS results in acute cerebellar hemorrhage and edema from capillary dysfunction.[23] The pathogenesis of lead encephalopathy is multifactorial. Encephalitic signs probably originate from a combination of microvascular damage, cellular necrosis, brain swelling, neurotransmitter dysfunction, and decreased glucose uptake by the brain.[28]

Ingestion of lead also results in competitive inhibition of selenium uptake, thereby diminishing the absorption of selenium by up to 26%.[31] If selenium intake is marginal, lead toxicosis could manifest as overt selenium deficiency.

Clinical Signs The signs of lead poisoning in ruminants are characteristic of CNS derangement. During the first stages of lead poisoning, affected cattle stand alone and are depressed.[2] They may show hyperesthesia, muscular fasciculations, and rapid, spastic twitching of the eyelids or other facial muscles. Progression of the disease is associated with ataxia, conscious proprioceptive deficits, cortical blindness, head pressing, odontoprisis, coma, and convulsions.[22,32] Some affected animals display episodic running, hyperesthesia, and bellowing. Others die suddenly without premonitory signs. The more acute and severe the toxicity, the more acute, severe, and excitatory are the clinical signs.[13] Affected cattle may accumulate frothy saliva at the commissures of the lips. GI signs such as bloat, diarrhea, rumen atony, and colic occur in approximately 60% of lead-poisoned cattle; the presence of such signs is more indicative of lead toxicity than of other causes of cerebral dysfunction.[33] Infertility, abortions, and fetal malformations may result from exposure to lead.[13]

The clinical signs of lead poisoning in horses include weight loss, lack of coordination, laryngeal or pharyngeal paralysis, dysphonia, roaring, conscious proprioceptive deficits, loss of anal tone, facial paralysis, and difficulty with mastication.[34] Aspiration of pharyngeal debris caused by dysphagia may result in pneumonia. Fine muscular tremors occur intermittently. The poisoned animals die in psychomotor seizures. Horses that die of lead poisoning are emaciated.[3]

Clinical Pathology Diagnosis of lead poisoning is based on measurement of increased blood and tissue concentrations of lead. Tissue levels of lead in naturally poisoned cattle can reach 20 to 100 ppm in the liver, 30 ppm in the kidneys, and 5000 ppm in bone. When interpreting the results of a lead measurement, the reference ranges obtained with similar methods must be considered. Heparin is the anticoagulant of choice for collecting blood for lead measurement because it does not chelate the lead. The lead concentration of ruminal fluid from acutely poisoned cattle ranges from 0 to 11,875 ppm.[22]

In livestock that are chronically poisoned with low concentrations of lead, the lead concentration may be normal in blood but high in bone. In these cases the poisoning can be diagnosed by administration of calcium disodium ethylenediamine tetraacetic acid (EDTA), which solubilizes the bone lead stores and increases the concentration of lead in the plasma. The soluble lead-EDTA complexes are excreted in the urine. The urinary lead concentration may rise by 40-fold over pretreatment levels within a few hours. In cases of chronic lead poisoning, radiographs of the abdomens of smaller patients may reveal lead-containing radiodense foreign material in the GI tract.[35] "Lead lines"—radiopaque transverse bands at the metaphyses—may also be visible on radiographs of the long bones of young animals chronically exposed to lead.

When blood lead concentrations are normal in chronically poisoned animals, measurement of free erythrocyte porphyrins and erythrocyte concentrations of δ-aminolevulinic acid are the preferred methods of diagnoses. The concentration of porphyrins is increased in the blood, urine, and feces of animals with lead poisoning. The reference range of blood porphyrin concentrations in normal calves is 21.6 ± 11.6 to 45.6 ± 10.3 μg/dL for whole blood and 113 and 142.8 ± 32.4 μg/dL for erythrocytes.[29,32,36] In chronically exposed cattle without symptoms, the free erythrocyte porphyrin concentrations are frequently greater than 2000 μg/dL.

Reference ranges for aminolevulinic acid dehydrase are 45.8 ± 20.6 U, whereas activities ranging from 28 to 33 U have been reported in naturally exposed calves.[3] The urinary concentration of δ-aminolevulinic acid exceeds 500 μg/mL.[4,37] Measurement of aminolevulinic acid in the erythrocytes is more reliable than measurement in urine.[38]

Environmental sources of lead can be detected by direct measurement of the lead concentration of the soil or pasture forage. Forage from toxic pastures contains more than 30 ppm of lead, and in some cases the level may exceed 300 ppm.[4,39]

The hematologic abnormalities of lead poisoning are subtle. Most poisoned livestock have a normal hemogram. Lead-related changes, if present, are characteristic of hemolytic anemia with an inappropriately robust regenerative response. The morphologic abnormalities of erythrocytes include anisocytosis, poikilocytosis, polychromasia, hypochromia, Howell-Jolly bodies, metarubricytes, and basophilic stippling.[22,27] The shape changes begin within hours after ingestion of the lead and peak by 100 days.[22,27] Blood changes do not occur in all cases of the disease and are not necessarily specific indicators of lead poisoning in cattle, in which blood lead levels may be elevated without hematologic abnormalities.[40] However, hematologic abnormalities tend to be more consistent in chronic lead toxicity and in lead-poisoned horses.

Lead toxicity has a variety of effects on endocrine function in cattle. Elevated levels of serum triiodothyronine, thyroxine, estradiol, and cortisol have been demonstrated in cattle with elevated blood lead levels.[41] Parameters of liver function are also affected; serum alanine and aspartate transaminase (AST) levels are increased, whereas serum lipids, total protein, and albumin levels are decreased.

In poisoned animals, the concentrations of protein and WBCs in CSF are increased, ranging from 50 to 100 mg/μL and from 5 to 50 mononuclear cells/mL, respectively. Such changes are relatively nonspecific and found with other causes of cerebral cortical necrosis.

Pathology The macroscopic brain lesions of lead poisoning are mild and include brain edema, congestion of vessels of the cerebral cortex, and yellowish discoloration and flattening of the cortical gyri. Lesions tend to be most severe in the occipital lobes. Microscopic changes in the brain include capillary prominence, endothelial cell swelling, edema of the Purkinje cell layer of the cerebral cortex, laminar cortical neuronal necrosis, and edema of the white matter.[42]

Treatment and Control Therapy for lead poisoning includes removal of the lead from the digestive tract, chelation therapy with calcium disodium EDTA, and fluid and nutritional support of the patient. Treatment with calcium disodium EDTA (calcium versenate) has been shown to be superior to treatment with penicillamine or dimercaprol. The EDTA chelates osseous lead but not soft tissue–bound lead. After chelation, the unsaturated bone stores reequilibrate, with the lead remaining in the soft tissues. In cases of acute lead poisoning, several days are required before reequilibration results in a decreased blood lead concentration. The dose of calcium disodium EDTA is 66 mg/kg/day, divided into several doses daily for 3 to 5 days.[43] After five daily treatments, a 2-day nontreatment period is recommended to reequilibrate the soft tissue and bone lead. After the 2-day rest, daily treatments are given for another 5 days. The decision to continue therapy with EDTA should be based on the results of posttreatment blood lead analyses and

renal function tests. Another recommendation is for administration of two IV injections of calcium disodium EDTA (110 mg/kg per dose) given 12 hours apart for 2 days.[44] Therapy is then withheld for 2 days, after which the EDTA treatments are reinstituted for 2 more days. The comparative efficacy of this regimen is unknown.

The EDTA also chelates other divalent cations. Consequently, prolonged administration of the drug results in trace mineral deficiencies, especially of zinc. For this reason, after prolonged EDTA therapy, oral supplementation with zinc should be considered so as to prevent the development of parakeratosis.

Reports have indicated that thiamine therapy is an effective adjunctive treatment with EDTA in cases of acute lead poisoning of cattle.[14,45,46] Administration of thiamine (2 mg/kg daily) was more effective than treatment with disodium EDTA (62 mg/kg twice daily for 4 days) or thiamine plus disodium EDTA in inducing remission of clinical signs of experimentally induced lead poisoning.[47] For clinical treatment of lead poisoning, thiamine dosages of 500 mg for small ruminants and 1 g for cattle weighing 300 kg have been recommended[45]; an alternative dosage is 10 to 20 mg/kg SC q12h. Administration of daily doses of thiamine (100 mg/day or 5 mg/kg) has protected experimentally exposed calves from clinical signs of lead poisoning and reduced lead deposition in the soft tissues.[46,48,49] The nature of the protective effects of thiamine is unclear. Apparently, either lead interferes with thiamine synthesis or the tissue distribution and deposition of lead are reduced by the formation of rapidly excreted lead-thiamine complexes.

In ruminants, ingested lead is best removed from the digestive tract by means of a rumenotomy.[14] Magnesium sulfate laxatives are administered concomitantly to form insoluble lead sulfides. Patients that respond slowly to chelation and thiamine therapy should be given supportive care. These measures should include provision of 40 to 80 mL free water/kg/day for maintenance, oral hyperalimentation, and administration of diazepam or phenobarbital for convulsions (as discussed in the Meningitis section).

Toxic pastures can be made safe by removal of contaminated forage. This is best done by cutting, baling, and burying native grasses and then burning the stubble. The source of the lead should be established, and the affected animals should be carefully documented. In the United States, insurance liability responsibilities may be covered under homeowner or farm insurance.

Helichrysum argyrophyllum (Golden Guinea Everlasting, Vaal Sewejaartjie) Poisoning

Both naturally occurring and experimental poisoning of sheep and cattle in South Africa by plants of the genus *Helichrysum* results in blindness and a variety of CNS signs.[1,2] The clinical signs of intoxication include progressive tetraparesis, depression, nystagmus, mydriasis, blindness, intentional head tremor, and stargazing attitude. Older sheep may develop lens cataracts 2 to 3 months after eating the plants. The case-attack rate ranges from 1% to 29%. Plants are toxic only in the flowering stage. *Helichrysum* spp. have been shown to contain substances that bind at the GABA–benzodiazepine receptor, which is suggestive of a mechanism for toxic effects on the nervous system.[3]

Pathologic findings include widespread status spongiosus of brain white matter, particularly in subependymal areas and in the cerebellar peduncles and brainstem.[2] Myelin edema is present in some cases. Edematous swelling of the optic nerve causes compression of the nerve in the optic canal, with secondary damage to nerve axons and myelin. The toxic principle in *Helichrysum* plants also causes a primary retinopathy in some animals.

Flatpea (*Lathyrus sylvestris, Lathyrus collis*) Poisoning

Ingestion of flatpea results in a CNS disorder. The condition may manifest within 5 days after consumption of a diet of which 50% is flatpea vines. Toxicosis has been induced in sheep ingesting forage of 35% flatpea vines.[1] Livestock can develop a tolerance for the plant through rumen microbial detoxification. Nevertheless, acclimatized animals can be rendered susceptible by treatment with monensin or by a change in rumen microflora.[2]

The toxic constituent of the plant, 2,4-diaminobutyric acid, is known to inhibit ornithine transcarbamylase, an enzyme responsible for urea detoxification. Consequently, the blood ammonia concentration in clinically affected animals is increased.

The clinical signs of flatpea intoxication are depression, muscular tremors, and spasmodic torticollis. Affected animals become recumbent and are reluctant to rise. When stimulated to move, they display circling, head pressing, and odontoprisis. The urine may appear dark brown. The clinical disorder often culminates fatally in a seizure. During the interictal periods, affected animals may rest, rise, and resume normal behavior and gait. Treatment is empirical and supportive and could include 1 to 2 L of vinegar PO, diazepam (0.1 mg/kg IV) or midazolam (0.1 mg/kg IV or IM) every 4 to 6 hrs as needed and removal from the offending forage.

Lathyrus sylvestris is a leguminous plant with a high protein content that might be an adequate substitute for alfalfa in areas where the latter grows poorly.[3] *L. sylvestris* harvested in the vegetative state has been fed to lambs in combination with alfalfa and as a sole diet without ill effect.[4] Similarly, when fed as part of a mixed silage in which the concentration of diaminobutyric acid was approximately 1%, *L. sylvestris* produced an acceptable weight gain in cattle without signs of toxicity.[5]

Nitrofurazone Toxicosis

Nitrofurazone is an antimicrobial that has been fed to cattle for the treatment and control of respiratory or GI diseases. Treatment of food-producing animals with the nitrofurans is now prohibited by the U.S. Food and Drug Administration. Nervous system signs of nitrofurazone toxicosis occur after 1 to 3 weeks of continuous feeding at dosages exceeding 15 to 30 mg/kg.[1,2] Lower dosages (7.1 mg/kg) reduce feed intake but do not result in neurologic signs. Nitrofurazone inhibits enzymes of the oxidative glycolytic pathways and is thought to interfere with brain metabolism of carbohydrates.

Clinical signs of nitrofurazone toxicosis include hyperirritability, propulsive running, muscular tremors, blindness, convulsions, and death. With lower doses, the convulsions may appear intermittently, but as the condition progresses, the signs become continuous.

Coenurosis (Sheep Gid; *Coenurus cerebralis* Infestation; *Taenia multiceps* Infestation)

Definition, Etiology, and Epidemiology

Coenurosis is caused by invasion of the CNS by *C. cerebralis*, the larval stage of the tapeworm *Taenia multiceps*. The adult worms live in the intestine of domestic dogs and some wild carnivores, where they shed eggs into the feces. Ruminants eat the eggs from contaminated pastures. The eggs hatch in the small intestine of the ruminant, and the larval stages travel through the blood to the CNS, where they mature into *C. cerebralis*. The life cycle is completed when the ruminant dies and the brain is eaten by a scavenging carnivore. *Coenurus* cysts then develop into sexually mature adults in the bowel of the carnivore host.

Many animals including sheep, goats, cattle, horses, wild ruminants, and humans are susceptible to *C. cerebralis* infestation.[1-3] Outbreaks of coenurosis may occur in previously uninfected sheep that are suddenly exposed to contaminated fecal matter from carnivores. Cases initially occur as early as 2 weeks after the sheep are exposed and continue for as long as 4 months.

Pathogenesis Lesions in the CNS may result from three separate pathogenic mechanisms: encephalitis from invasion of the CNS by large numbers of larvae, hypertensive hydrocephalus resulting from interference with CSF drainage, and development of large cerebral cysts that increase intracranial pressure.

Clinical Signs Clinical signs can occur acutely, during the migratory phase of the larval stage in the intermediate host (e.g., the ruminant). Lambs 6 to 8 weeks old are most often affected by this form and develop fever, dullness, and mild neurologic deficits.[4] Acute encephalitis occasionally occurs, leading to sudden onset of severe neurologic signs and death within a few days. More frequently, the clinical presentation of coenurosis is that of a space-occupying brain lesion; signs include depression, anorexia, ataxia, unilateral or asymmetric loss of vision, facial hemiplegia, head tilt, circling, high-stepping forelimb gait, and hyperesthesia. When the spinal cord is the site of cyst development, hindlimb ataxia and paresis or paralysis are the main clinical signs.[5] As the disease progresses, the sheep assume lateral recumbency and become comatose.[6,7] In advanced cases, the calvaria directly over the parasite enlarges and softens.[3]

Pathology In the acute form of coenurosis, the main finding is coagulation necrosis and inflammation associated with the larval migration path through the CNS.[8] This may be visible grossly as yellow to red tracks in the brain parenchyma. Coagulation necrosis and surrounding inflammatory cells such as degenerate granulocytes, macrophages, and histiocytes are found microscopically. The mature cysts, up to 7 cm in diameter, are thin walled and contain clear fluid or, occasionally, purulent fluid. Protoscolices, up to many hundreds, can be visualized microscopically within the cysts, which are surrounded by severe and mainly nonsuppurative inflammation. The cysts deform and compress the underlying brain tissue.

Diagnosis The combination of a characteristic clinical syndrome and location in an endemic area supports a presumptive diagnosis. Radiographs in the lateral and posteroanterior planes may reveal radiolucent areas in the calvaria. The optimum diagnostic views in the posteroanterior projection occur whenever the base of the nose is level with the upper margin of the orbit. CT, if available, effectively demonstrates the presence of cysts.[9]

Treatment and Control Praziquantel (50 to 100 mg/kg PO q24h for 3 to 5 days) is effective in the treatment of coenurosis in sheep that do not yet have neurologic signs.[5,10] Concomitant administration of an NSAID or dexamethasone may enhance the posttreatment survival rate. The cyst can also be removed surgically by craniotomy.[11-15]

In endemic areas, the carcasses of affected animals should not be fed to dogs, and dogs in endemic areas should be treated repeatedly with a vermifuge to minimize the possibility of pasture contamination. Appropriate management practices have virtually eliminated this disease from North American sheep flocks.

Ceroid Lipofuscinosis

Ceroid lipofuscinosis is a lysosomal storage disease that has been reported in South Hampshire, Swedish Landrace, and Rambouillet sheep; Nubian goats; Devon cattle; and horses.[1-5] The disease is known to be inherited as an autosomal recessive trait in many cases[6] and is believed to be so in others.[7] It is characterized by the intracellular accumulation of abnormal autofluorescent lipopigments in lysosomes of neurons and other cells throughout the body. The storage material has been shown to consist predominantly of the subunit *c* of mitochondrial *c* synthase.[8,9] Affected animals display progressive ataxia and postural abnormalities, blindness due to retinal involvement in many cases, sensory depression, and, in the terminal stage, coma. Lesions seen on CT scans include enlargement of the lateral ventricles and reduced thickness of the cerebral cortex.[10]

Gross pathologic lesions in the CNS may include moderate enlargement of the lateral ventricles, flattening of cerebral gyri, and a yellow to brown discoloration of the brain parenchyma. Accumulation of protein storage material in neuronal lysosomes is evident on microscopic examination and is accompanied by neuronal necrosis and astrocytosis, which may be severe. The lesions sometimes have a lamellar appearance.[11] The disease is ultimately fatal, and no practical method of treatment is currently available.

Diseases Manifesting Principally With Brainstem and Cranial Nerve Dysfunction

Peripheral Vestibular Disease of Horses

Robert J. MacKay

Definition and Etiology Vestibular disease of horses is an acute, usually asymmetric, condition with several major causes: bacterial or mycotic infection of the middle/inner ear, polyneuritis equi, viral/idiopathic labyrinthitis, remodeling or fractures (or both) of the petrous temporal bone in association with THO, and external trauma to the skull with or without fracture of the petrous temporal bone.[1] Idiopathic labyrinthitis is probably an acute viral inflammation of the vestibular system that is severe, but complete recovery is common. Lightning strike is also an uncommon cause of vestibular signs in horses.[2,3] *Staphylococcus*, *streptococcus*, *Actinobacillus*, *Aspergillus*, *Enterobacter*, *Pseudomonas*, and *Salmonella* spp. and *C. pseudotuberculosis* have been isolated from cases of otitis media/interna in horses.[4] Some authors have speculated that THO results from extension of chronic low-grade bacterial otitis media to the adjacent temporohyoid joint[5]; however, remodeling and fusion of the temporohyoid joint are probably the result of repeated trauma, chronic degenerative processes, or both.[6,7] Primary otitis media/interna in horses is probably rare and, in contrast to this disease in ruminants, young age does not appear to be a risk factor. It is presumed that the middle ear is infected via the eustachian tube or hematogenously. With the exception of viral/idiopathic labyrinthitis, the proximity of the facial canal to the vestibular system means that the facial nerve (VII) is frequently involved in conditions causing vestibular signs. Because the first three cervical nerves contribute proprioceptive information to the caudal vestibular nuclei, upper cervical injury also can cause signs of vestibular ataxia.[8]

Clinical Signs Affected horses exhibit rotation of the poll (i.e., head tilt) toward the affected side, abnormal physiologic nystagmus, spontaneous horizontal or rotatory nystagmus with the fast phase away from the affected side, and vestibular strabismus with downward rotation (infraduction) of the eye ipsilateral to the lesion that can be exaggerated by elevation of the horse's chin. The gait is usually staggering and dysmetric, with a tendency, because of increased extension of the contralateral limbs, to lean or circle toward the affected side. Horses

VetBooks.ir

with any acute peripheral vestibular disease sometimes fall or even roll to the side of the lesion and may panic and thrash wildly in an effort to stand. Bilateral vestibular disease causes severe dysmetria and ataxia and complete absence of normal physiologic nystagmus. The horse may have wide swinging movements of the head.

Signs of vestibular disease are markedly exacerbated by blindfolding. Deafness is also apparent with bilateral involvement of the cochlear division of cranial nerve VIII. With unilateral vestibular disease, visual accommodation often occurs over a period of weeks, and affected animals may even return to racing. Signs of vestibular disease may still be elicited by blindfolding, however.

Concomitant ipsilateral facial paralysis is manifested by deviation of the nose toward the normal side, reduced flaring of the ipsilateral nostril during inspiration, and ipsilateral drooping of the lip, eyelids, and ears. Reflexes involving cranial nerve VII such as those of the lip and eyelids, the menace response, and ear reflexes are reduced or absent. Inability to close the eyelid causes exposure keratitis, which is particularly severe and usually involves deep horizontal corneal ulceration when there is damage to the secretomotor fibers of the facial nerve. With chronic facial paralysis, there is visible atrophy of the parotidoauricularis caudal to the vertical ramus of the mandible.

Horses with bacterial otitis media/interna may have other sites of infection, including the paranasal sinuses, guttural pouches, and lower respiratory tract. Extension of infection along a fracture defect or from otitis media/interna into the meninges is associated with development of additional neurologic signs, including obtundation, limb ataxia and weakness, and cranial nerve deficits, along with systemic signs of sepsis such as fever, tachycardia, and tachypnea.

Diagnosis and Treatment A complete blood cell count usually reveals leukocytosis and increased fibrinogen and serum amyloid A concentrations in cases of chronic otitis media/interna, whereas neutrophilic pleocytosis in CSF samples is evidence of secondary meningitis. Diagnostic procedures for horses with peripheral vestibular disease include skull radiography, CT, and endoscopic examination of the external ear canal and guttural pouch.[9] General anesthesia is required for diagnostic transtympanic centesis of the middle ear, although this procedure can rarely be justified.[5,10] The rate of tear secretion, which may be tested with a Schirmer tear test strip, usually exceeds 17 mm/min. BAER testing may help establish the location of vestibular system disease as peripheral or central.[11]

Antibiotic treatment of peripheral vestibular disease due to otitis media/interna should, if possible, be guided by antimicrobial susceptibility testing of bacteria cultured from the middle ear or from related disease processes such as sinusitis, guttural pouch empyema, or pneumonia. In the absence of such information, coverage should be provided against Gram-positive bacteria by penicillin G (22,000 U/kg IM bid as procaine penicillin or IV qid as potassium penicillin) or ceftiofur sodium (2.2 to 5 mg/kg IM sid to bid). Additional coverage (which includes staphylococci) can be provided by the addition of enrofloxacin (5.5 mg/kg IV or 8 mg/kg PO sid). Oral continuation of treatment can be conveniently provided by trimethoprim-sulfonamide drugs (30 mg/kg PO bid) or chloramphenicol (50 mg/kg PO qid). Treatment should continue for at least 30 days and ideally should be guided by results of repeated imaging of the affected petrous temporal bone. For cases refractory to antibiotic treatment, a procedure has been described for opening the affected osseous bulla by transendoscopic neodymium-doped yttrium aluminum garnet (Nd:YAG) laser surgery.[12]

Affected horses should be kept in a quiet, heavily bedded stall with good footing. Exposure keratitis may be treated or prevented under a partial tarsorrhaphy.

Equine Nigropallidal Encephalomalacia (Star Thistle Poisoning, Knapweed Poisoning)

Robert J. MacKay

Nigropallidal encephalomalacia (NPE) is a disease of adult horses characterized by facial and lingual dystonia and variable obtundation, behavioral signs, and ataxia. NPE is caused by ingestion of large quantities of the plants *Centaurea solstitialis* (yellow star thistle) or *Rhaponticum repens* (Russian knapweed; synonyms: *Acroptilon repens*, *Centaurea repens*).[1-4]

Clinical Signs The signs appear suddenly but always after long-term ingestion of large quantities of the plants. Characteristic signs of NPE include weight loss, mild to moderate obtundation, ataxia, yawning, lowered head, protruding tongue, tremor of the tongue and lips, and facial grimacing when feed is offered. The facial hypertonicity causes a retraction of the lips, which results in a fixed grimace with the mouth and lips held half open. Although affected horses can grasp food between the incisors, prehension, chewing, and swallowing of food are uncoordinated and inefficient. There may be constant chewing movements and food retained in the mouth, and cheek pouches may protrude from the commissures of the lips. Affected animals may attempt to drink by immersing their muzzles deeply into the bucket to force the water into the back of the pharynx. There also may be a transient tendency to walk compulsively, often in circles. Occasionally, horses with NPE are hyperexcitable.

After several days of progression, signs stabilize and do not then progress. Affected animals usually do not recover and are euthanized or die of starvation or dehydration.

Diagnosis The CSF of affected horses may have high nucleated cell counts.[3] There are no characteristic changes in complete blood cell count or serum chemistry profiles. MRI was used to make an antemortem diagnosis in one horse with NPE.[5]

Pathophysiology The toxic principle in yellow star thistle and Russian knapweed is not known with certainty, but there is some evidence for *repin*, a sesquiterpene lactone with high affinity for neural tissue.[6-8] Studies in rats suggest that repin exerts its neurotoxic effects by inhibiting dopamine release.[8] A role for neurotoxic amino acids, including aspartic and glutamic acids, has been proposed, but researchers could not confirm their presence in yellow star thistle.[9] Immunohistochemical staining of affected brains show that NPE is similar to environmentally acquired toxic parkinsonism of humans, whereby clinical findings are attributable to lesions in the globus pallidus and substantia nigra pars reticulata rather than to destruction of dopaminergic neurons.[10]

Necropsy Findings At necropsy, sharply demarcated areas of yellowish malacia are visible grossly in the substantia nigra and globus pallidus (extrapyramidal system). Lesions are symmetric in most but not all cases. Lesions in other brainstem nuclei are found in a small number of animals.[2,9] Microscopic lesions include neuronal necrosis, vacuolation with gliosis, liquefactive necrosis, and cavitation in well-developed lesions.[11]

Epidemiology NPE has been reported in horses of the United States, Australia, and South America. Yellow star thistle is a common plant in unirrigated pastures in the arid regions of the western United States. The plant is resistant to the effects of saline or alkaline soil conditions and requires minimal moisture. Russian knapweed belongs to the sunflower family and grows predominantly on flood plains, where it can extract

deep subterranean moisture. In the United States, the plants tend to remain green during the dry months, so most poisonings occur during the summer or late autumn. Most horses are reluctant to eat *Centaurea* and *Rhaponticum* plants unless other vegetation is unavailable, but some develop a craving and selectively seek it out. Horses that develop NPE are usually being fed a poor-quality, high-roughage diet. Affected horses range from 4 months to 10 years of age (median, 2 years).[11] The case-attack rates of yellow star thistle poisoning range from 3% to 31% of horses on infested pastures.[11] Feeding studies have demonstrated that as much as 59% to 200% of the body weight of yellow star thistle and 59% to 63% of Russian knapweed must be eaten over 3 to 11 weeks to cause clinical disease.[2,11] Continuous protracted exposure to the weeds seems to be important for expression of clinical disease. The plants retain their toxicity when dried.

Treatment and Prevention There is no known treatment. Prevention is best aimed at correcting the nutritional problem by daily supplementation with good-quality forage and by not pasturing horses in areas where either of the responsible plants grows.

Temporohyoid Osteoarthropathy

Robert J. MacKay • Lisle W. George

THO is a progressive syndrome of horses involving periosteal reaction and enlargement and sclerosis of the stylohyoid bone, tympanic bulla, and petrous portion of the temporal bone (Fig. 35.14).[1] Ultimately, there is fusion between the skull and hyoid apparatus, stricture of the external ear canal, and obliteration of the lumen of the tympanic bulla. These changes are thought to represent a primary degenerative process in the temporohyoid joint (THJ), although some cases may be secondary to chronic otitis media.[1-3] The tympanic membranes of horses with this condition are usually not inflamed, and ruptures and associated discharges from the external ear are uncommon.[1] Horses aged 6 months to older than 20 years have been affected; the mean or median age reported in all studies is 10 to 12 years.[1,4-8] Quarter Horse and Quarter Horse–type breeds accounted for more than 50% of cases in several but not all series.[4-7] Both joints are affected, albeit asymmetrically, in most horses with clinical THO, and some cases are accompanied by associated bilateral clinical signs, including deafness.[4-6,9] Fusion of the THJ causes interference with the interdependent coordinated movements of the tongue, hyoid apparatus, and larynx. Particular stress is placed on the fused joint or joints during chewing, swallowing, vocalizing, and combined head and neck movements. Veterinary procedures such as dental work and passage of a nasogastric tube also put unaccustomed pressure on the THJ. Any of these mechanical forces applied to the immobilized THJ may result in fractures through the petrous temporal bone or proximal stylohyoid bone. THO is also probably a risk factor for fracture of the petrous temporal bone during head trauma, especially in horses that flip over backward and strike the poll. The facial nerve (cranial nerve VII) and vestibulocochlear nerve (VIII) and apparatus are within the petrous temporal bone and can be impinged on by bony proliferation or lacerated by fracture. After fracture of the petrous temporal bone, there may also be extension of middle/inner ear infection around the brainstem with signs of meningitis or extradural abscess.

FIG. 35.14 Rostral view of left *(right)* and right *(left)* stylohyoid bones from a horse with left-sided temporohyoid osteoarthropathy. Note fusion of the temporohyoid joint on the affected side and the extensive remodeling and enlargement of the stylohyoid.

Clinical Signs Two sets of clinical signs are associated with the evolution of this disease process.[1] Early in the syndrome, including the period before ankylosis of the temporohyoid joint, affected horses may show reluctance to chew, dysphagia, headshaking, ear rubbing, sensitivity to pressure at the base of the ear, facial hyperesthesia, wild tossing of the head and neck under tack, reluctance to take a bit, dropping of feed, or even weight loss; most THOs, however, are probably subclinical until development of neurologic signs. Fracture of the proximal stylohyoid bone increases the likelihood of pain-associated clinical signs. Because of bony proliferation around the ear canal, the external ear may be unusually narrow and difficult to examine by endoscope.

After fusion of the THJ, the disease may manifest as sudden onset of asymmetric signs of cranial nerve VII or VIII dysfunction, or both. Almost all affected horses have degrees of facial paresis, with drooping of the ear, upper eyelid, and lower lip on the affected side and deviation of the muzzle to the contralateral side.[1,6,7] Buccinator weakness results in "quidding" (retention of feed material in the denervated cheek) and dropping of feed. Facial denervation may be evident as fine fasciculations of facial muscles and, after 2 weeks, obvious atrophy of the parotidoauricularis muscle behind the vertical ramus of the mandible. Facial paralysis is occasionally bilateral.[5] Schirmer tear tests commonly reveal reduced tear production (i.e., values of 5 to 19 mm; normal, ≥20 mm),[5] indicative of injury to the parasympathetic lacrimal (great petrosal) branch of the facial nerve. By the time of presentation, most such horses already have a deep horizontal corneal ulcer with corneal edema and miosis. Because of facial weakness, affected horses cannot mount the typical response to corneal ulceration—namely, blepharospasm and epiphora—and so ulcers often go undetected by horse owners. Signs of vestibular dysfunction accompany facial paresis in the majority of cases. Of 29 horses with THO that had involvement of VII, 23 (almost 80%) had vestibular signs.[6] Typically, affected horses exhibit sudden onset of head tilt, neck turn, body lean, and tight circling, all toward the affected side, and a staggering ataxic gait with preservation of limb strength. These signs may be revealed or exacerbated by blindfolding of the horse. In the acute stages, horizontal nystagmus may be present, with the fast phase away from the side of the lesion. In a study of 24 horses with THO and neurologic signs, all had electrodiagnostic evidence of partial to complete hearing loss on the affected side; 12 also had partial hearing loss on

the contralateral side.[10] Vestibular signs can occur without concurrent involvement of the facial nerve, although this is unusual.[10] Of interest is that 12/19 (61%) of horses with THO had concurrent left laryngeal hemiparesis.[10] Horses may also have difficulty eating and swallowing because of either pain (e.g., from acute stylohyoid fracture) or involvement of cranial nerves IX and X. A few horses have seizure-like convulsions at the onset of neurologic signs. Bacterial abscess adjacent to the brainstem or meningitis may be sequels to fracture of the petrous temporal bone and result in the death of the horse.

Diagnosis Endoscopic examination of the inside of the guttural pouches is the diagnostic imaging test of choice because of its convenience in standing horses and its high sensitivity for detection of THO.[6] Evaluation of the external contour of the THJ from within the guttural pouch can reveal asymmetric enlargement and discoloration of the stylohyoid bone and THJ and, in some cases, hyperemia, edema, or hemorrhage in the guttural pouch lining surrounding the joint. Previously healed fractures of the stylohyoid bone may be evident as angulation and distortion of the bone close to the THJ. CT of the THJ allows appreciation of changes not always evident on endoscopy (or plain radiographs), including involvement of both sides, enlargement of the ceratohyoid bone, fractures of the petrous temporal and stylohyoid bones, and the presence of fluid in the tympanic bullae.[4,11] A system has been developed to quantify the remodeling changes found in horses with THO.[4] The main disadvantage of CT is the expense and requirement for general anesthesia. Where standing CT units are available, this is less of a concern, although adequate positioning can be difficult in horses with severe vestibular dysfunction.[8] Radiographic examination of the skull with ventrodorsal, lateral, and lateral oblique views reveals cases in which the bony proliferation has progressed to cause osteitis and fusion of the temporohyoid joint. Optimal images are obtained with the horse under general anesthesia and in dorsal recumbency; however, adequate views can be obtained with the use of a dorsoventral projection while the horse is standing but heavily sedated. Sensitivity for detection of THO by plain radiography in one series was 20/24 (83%).[6] MRI and nuclear scintigraphy have also been used successfully for THO diagnosis but have not been widely applied.[6,8,12]

BAER testing of vestibulocochlear nerve function has been described for horses with THO and is the only way of evaluating auditory function in these horses.[5] It is also a sensitive method for detecting involvement of the contralateral side.

In horses with neurologic signs other than dysfunction of CNN VII and VIII, CSF tap, analysis, and possible culture are recommended. Two of four horses tested in one report had increased nucleated cell counts or protein concentrations suggestive of septic or nonseptic meningitis.[6] Xanthochromia and increased RBC counts are also expected in acute cases.[3]

Treatment and Prognosis Medical and surgical approaches to THO have been described.[1,3,13] Conservative medical therapy involves prolonged rest and treatment with an NSAID (e.g., 2 mg/kg phenylbutazone PO bid, or 1.1 mg/kg flunixin IV or PO bid for 3 days, then once daily for 1 to 2 weeks more) and broad-spectrum antibiotics (e.g., trimethoprim-sulfamethoxazole, 30 mg/kg PO twice daily for 30 days). The lever action of the hyoid apparatus on the petrous temporal bone can be resected surgically by complete removal (ostectomy) of the ipsilateral ceratohyoid bone or removal of a 1- to 2-cm section from the middle of the stylohyoid bone.[3,13,14] Because midbody partial stylohyoid ostectomies tend to heal,[14] the ceratohyoid procedure is now favored. If necessary, this surgery can be performed bilaterally when the horse is standing and sedated. With facial nerve paralysis and keratitis sicca, corneal ulcers are a medical emergency and must be treated or prevented with topical antibiotics, artificial tears, and, preferably, a multifocal partial split-thickness tarsorrhaphy.[3] For this purpose, shallow 3- to 5-mm-long incisions are made in the tensed lid margins of each eyelid immediately posterior to the line of tarsal gland openings. With 5-0 absorbable suture, a bite is taken in each eyelid deep in the incision, in the plane of the eyelid, and then the suture is carefully tied so that margins evert away from the corneal surface.[3] One or two shallow horizontal mattress sutures are then placed in the everted lid margin. The eyelids are joined in this manner at two or more sites, leaving open the nasal third of the palpebral fissure. The tarsorrhaphy is maintained permanently or until resumption of lacrimal and eyelid function, which may take up to 18 months.

Both medical and surgical approaches reportedly have returned most treated horses to athletic activity after a period of weeks to months, and so evidence to support the need for surgery in all cases is not yet clear.[1,6,7] On theoretical grounds, however, it is clear that a horse with THO will remain at risk for catastrophic relapse of neurologic signs as long as the hyoid apparatus and skull remain connected through a fused THJ. Relapse is particularly likely to occur if the temporal bone is fractured. In a series of horses with THO, 13 of 20 (65%), 1 of 25 (4%) and 1 of 8 (12.5%) horses treated by medical therapy, ceratohyoid ostectomy, and partial stylohyoid ostectomy, respectively, died as a consequence of THO.[9] In comparison with surgical therapy, medical therapy was significantly associated with nonsurvival.

If possible, the management of convalescent horses should be adjusted to minimize stress on any remaining THJ. Cribbing collars can be tried for crib biting, bitless bridles can be used for riding, and dental work and other professional procedures can be minimized and performed cautiously.

Horner Syndrome

Robert J. MacKay

Definition and Etiology Horner syndrome results from interruption of ocular sympathetic pathways. Sympathetic pathways to the head originate as first-order neurons (upper motor neurons) in the tectum of the midbrain. Axons descend to the first to third thoracic segments (T1 to T3) of the spinal cord, where they enter the gray matter of the dorsal horn, synapse on second-order (preganglionic) sympathetic motor neurons, and exit in the ventral spinal nerve roots. From there the nerves pass through the cervicothoracic and middle cervical ganglia (combined as the stellate ganglion) and ascend in the cervical sympathetic trunk (part of the vagosympathetic trunk) to the cranial cervical ganglion (CCG), where they synapse on the third-order (postganglionic) sympathetic nerve. In the horse, the CCG is part of a neurovascular bundle in the caudodorsal aspect of the guttural pouch; in ruminants, the CCG is located under the petrous temporal bone. The third-order fibers are distributed with the blood supply via canals through the petrous temporal bone to the sweat glands of the head, ciliary muscles, and periorbital smooth muscles, including an eyelid levator (superior tarsal muscle) and periarteriolar musculature. The sympathetic nerve supply of the head thus can be damaged within the brainstem or spinal cord (first order); in the cranial thoracic nerve roots, spinal nerves, or cervical sympathetic trunk (second order); or in the CCG, in the skull, or behind the eye (third order).

Specific causes of Horner syndrome include mycotic guttural pouch infections; traumatic lesions of the basisphenoid area; otitis media; cervical trauma; abscesses, tumors, or space-occupying lesions in the anterior aspect of the thorax; periorbital abscesses or tumors; parotid duct obstruction and inflammation; esophageal rupture; and complications associated with surgical ligation of the carotid artery.[1-7] Lesions involving first-order

sympathetic neurons in the ipsilateral brainstem are rare but have been reported as a consequence of metastatic neoplasia or with EPM in horses.[8,9] Horner syndrome has also occurred after intravenous injection of certain drugs, including xylazine, vitamin E or selenium, and phenylbutazone.[10-12] The sympathetic nerve supply to the eye is rare cases involved in the inflammatory polyneuropathy characterizing horses with polyneuritis equi (cauda equina neuritis) syndrome.[13,14] Tumors that have resulted in Horner syndrome include sclerosing respiratory epithelial carcinoma, squamous cell carcinoma, lymphoma, mesothelioma, and melanoma.[2,4-6,10,15,16]

Clinical Signs The clinical signs of Horner syndrome in horses vary but include miosis, ptosis, regional hyperthermia, excessive sweating on the ipsilateral side of the face, congested mucous membranes, inspiratory stridor, and dermatitis caused by chronic sweating. Although enophthalmos is reported to be a reliable sign of equine Horner syndrome, many (possibly most) affected horses do not exhibit prolapse of the nictitans and thus are probably not enophthalmic. The presence of this sign is apparently variable among species: Enophthalmos is part of Horner syndrome in cats and dogs[9] but not in humans and ruminants.[15,17] Ptosis is caused by the combined effects of loss of the eyelid levator function of the superior tarsal muscle and of variable enophthalmos. It is most reliably detected by comparison of the eyelash angles on each side. On the affected side, the eyelashes slope at a relatively downward angle. The palpebral reflex and the menace response are normal. If the vertebral nerve or its cervical sympathetic branches are damaged concomitantly, sweating may also be observed on the skin of the neck. Regional hyperthermia results from cutaneous and mucosal vasodilation, which in turn results from removal of sympathetic vasomotor tone. Sweating is thought to be caused by vasodilation and increased delivery of epinephrine to sweat glands. Facial sweating may begin to decrease 6 to 14 days after sympathectomy.[10,18,19]

In cattle, there is *dryness* of the ipsilateral planum nasale. This can be explained by the mediation of normal sweat gland secretion by postganglionic sympathetic fibers and α-adrenergic receptors in cattle.[19] The other signs in cattle are similar to those in horses. The clinical signs of experimentally induced Horner syndrome in sheep and goats are limited to mild ptosis.[19] Retrobulbar tumors may cause both exophthalmos and Horner syndrome.[15] On cold days, while exhaled breath from the external nares of cattle normally contains a mist of condensed water vapor, breath from the relatively warm nostril on the affected side may be mist free.[9]

Diagnosis The level of sympathetic interruption can be determined by pharmacologic testing.[9] Hydroxyamphetamine (1% solution) instilled into the eye will result in release of norepinephrine from intact postganglionic sympathetic neurons, causing pupillary dilation, but in no response when the postganglionic neurons are damaged. A positive response to this test indicates a preganglionic sympathetic lesion, and a lack of response indicates a postganglionic lesion. In animals with a postganglionic lesion, topical administration of 0.1 mL of 1 mg/mL epinephrine solution directly activates the iris musculature and produces mydriasis within 20 minutes, whereas the onset of dilation occurs in approximately 40 minutes in animals with preganglionic lesions. Similarly, topical administration of 2.5% to 10% phenylephrine solution will produce pupillary dilation in an eye with a postganglionic sympathetic lesion but not in a normal eye. The sensitivity to these direct-acting sympathomimetics in animals with postganglionic sympathetic lesions is increased as a result of the phenomenon of denervation hypersensitivity, in which numbers and sensitivity of norepinephrine receptors in the iris muscle increase for days to weeks after postganglionic nerve injury. A positive response therefore is not observed until several days after the injury. Parenteral administration of 1 mL of 1 mg/mL epinephrine solution causes affected horses to sweat profusely over the affected side of the face.[10] However, this test does not differentiate between preganglionic and postganglionic lesions.

The guttural pouches of horses and the pharynx of all patients should be examined endoscopically to exclude the possibility of pharyngeal or laryngeal paralysis or guttural pouch disease. The jugular furrows should be palpated for swellings. Insertion of a nasogastric tube during palpation may be helpful for detecting subtle lesions on the left side of the neck. The thorax should be examined with auscultation, ultrasonography and, if indicated, radiography. Cranial ribs can be evaluated for lesions by scintigraphy.[20] A neurologic examination should be performed to evaluate the function of the spinal cord. The skin temperature may be measured with thermography[1,6,21]; on the affected side, it is 1° C to 3.5° C higher than normal.

Treatment The treatment for Horner syndrome depends on the underlying cause of the denervation. Except for Horner syndrome related to IV injection of xylazine, the signs are often irreversible, even if the primary cause of the condition has been eliminated. With xylazine-associated Horner syndrome, the condition disappears spontaneously. The necrotizing effects of perivascular drug injections can be minimized by immediate dilution or irrigation, or both, with large volumes of saline infiltrated into the perivascular tissues. Antiinflammatory doses of flunixin and dexamethasone can be given systemically. Abscesses should be drained, and fungal infections of the guttural pouch should be treated as described in Chapter 31.

Guttural Pouch Mycosis

Robert J. MacKay

Definition and Etiology The clinical signs occur because fungi invade vital vascular and neural structures in the roof of one, or occasionally both, guttural pouches. There is no apparent age, sex, breed, or geographic predisposition to this disease.[1] Foals as young as 3 months of age have been affected.[2] *Aspergillus fumigatus* and *Emericella nidulans* (the sexual form of *Aspergillus nidulans*) are the fungi most commonly identified in pure or mixed culture.[3,4] Lesions are typically diphtheritic membranes of variable size, composed of necrotic tissue, cell debris, a variety of bacteria, and fungal mycelium (Fig. 35.15).[1]

The guttural pouch is partially separated into two compartments by the stylohyoid bone and occipitohyoideus muscle. Cranial nerves IX through XII, the cranial cervical ganglion and postganglionic sympathetic nerve, and the internal carotid artery are located in a fold that traverses the dorsomedial aspect of the medial compartment. For unknown reasons, this site is susceptible to colonization and destruction by invasive mycotic infections.[5] In approximately one third of cases, the fungal lesion is located in the lateral compartment, sometimes after extension from a primary site in the medial compartment.[1] At this location, the fungal mycelium may invade the wall of the external carotid artery or any of its branches and affect the facial nerve (VII). Facial nerve paralysis has also been observed as a result of direct invasion by a fungal guttural pouch infection into the overlying parotid lymph node and salivary gland.[6] Fungal plaques may also spread from one guttural pouch to the other by eroding through the apposed medial walls of the pouches.

Clinical Signs Initial signs are headshaking and unilateral nasal discharge. There is a tendency to hold the head in extension or lower to the ground than normal. Additional clinical signs are nasal discharge, dysphagia with nasal return of feed-stained saliva, head shyness, stridor, dysphonia, protrusion of the tongue from the mouth, and epistaxis.[6,7] Epistaxis may

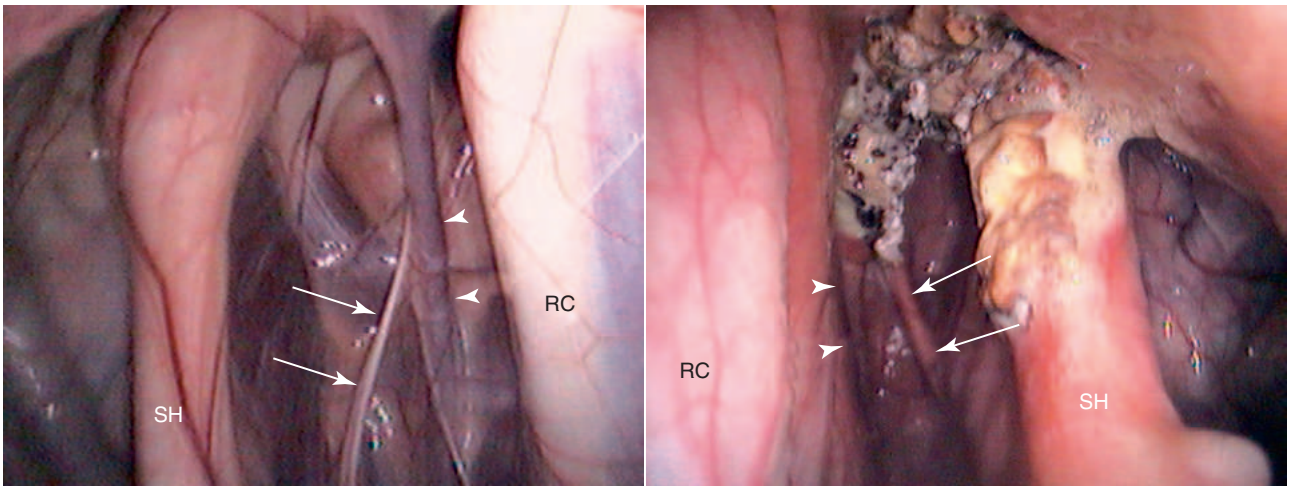

FIG. 35.15 **Endoscopic views of the caudal aspects of the left guttural pouch with a mycotic plaque over the neurovascular structures of the medial compartment of left guttural pouch *(right)* and normal right guttural pouch *(left)*.** There is also thickening of the left stylohyoid bone secondary to temporohyoid osteoarthropathy. *Arrows* point to the glossopharyngeal nerves, and *arrowheads* point to the internal carotid arteries. *RC*, Rectus capitis ventralis major muscle; *SH*, stylohyoid bone.

be bright red, high volume, and life-threatening. Other clinical signs include sensitivity to pressure over the parotid salivary gland, Horner syndrome (sweating, miosis, and ptosis on the side of the lesion), paralysis of the tongue on the affected side, and facial paralysis.[6-10] Atrophy of the brachiocephalicus and trapezius muscles secondary to denervation of the spinal accessory nerve (XI) has been described in a few cases. Horner syndrome is a development secondary to damage of the cranial cervical ganglion and postganglionic fibers. The sensorium is intact unless aspiration pneumonia develops or the fungus spreads into the brain.[11,12] Affected horses may die peracutely as a result of exsanguination from ruptured internal or external carotid arteries or their branches. Endoscopic examination of the larynx of affected horses may reveal dorsal displacement of the soft palate, inability to swallow, and laryngeal hemiplegia. Mycotic guttural pouch infection can be diagnosed definitively endoscopically by identifying the characteristic fungal mass in the caudodorsal aspect, usually of the medial compartment. Radiographic examination of the pouches shows a poorly defined border of the pouch in the abnormal area.

Treatment Before the onset of neurologic signs, the affected artery or arteries may be occluded on each side of the lesion by ligation/balloon-tipped catheter, embolization coils, or nitinol plugs.[1] Occlusion of the ipsilateral common carotid artery alone does not prevent fatal hemorrhage.[13] Complete arterial occlusion prevents fatal epistaxis, but it is not clear whether it affects fungal growth. Some studies have shown excellent, albeit delayed, rates of resolution of mycotic lesions in horses that underwent the procedure with or without additional antifungal therapy,[14,15] but in other animals the lesion may progress despite complete arterial occlusion.[8] Because some such lesions resolve spontaneously over time, the role of surgery in their resolution remains controversial.[1] Optic neuropathy and blindness of the ipsilateral eye are occasional sequelae of occlusion of the external carotid artery and its branches.[1] Lesions may be treated topically through an endoscope with povidone-iodine or triazole antifungal agents such as enilconazole, voriconazole, and itraconazole. Itraconazole is also affordable and safe when administered systemically. Nystatin, natamycin, miconazole, and fluconazole have little activity against *Aspergillus/Emericella* spp. Amphotericin B is effective, although systemic treatment is limited by its toxicity. Topical treatment may be repeated daily (or as frequently as is practicable) for up to several weeks. As the fungal mass degenerates, pieces can be carefully removed endoscopically with biopsy forceps in horses that have previously undergone arterial occlusion. Dysphagic horses may be fed via an indwelling esophagostomy tube while lesions are being treated.[16] Neurologic signs may be permanent, although improvement or recovery over many months has been reported in some horses.[15] Affected horses are often euthanized for humane reasons. (See Chapter 31 for more on treatment of guttural pouch mycosis.)

Listeriosis (Circling Disease; Silage Disease; *Listeria monocytogenes* Infection)

Lisle W. George

Definition and Etiology Listeriosis is an acute meningoencephalitis caused by the Gram-positive bacterium *L. monocytogenes*. The disease has a worldwide distribution, but occurs most often in temperate climates. Listeriosis typically affects ruminants, fowl, and humans but is rare in horses. The prevalence of listerial meningoencephalitis in infected herds does not usually exceed 1% of the adult animals at risk.[1]

Clinical manifestations of listeriosis include septicemia of neonates, abortion, neonatal death, ophthalmitis, uveitis, septicemia and diarrhea in ewes, and neurologic disease.[2] Neurologic listeriosis may manifest as a multifocal brainstem disorder, diffuse meningoencephalitis, or myelitis. The condition usually affects individual animals but occasionally affects several members of a herd.[3] Asymptomatic intramammary infections apparently occur and may be responsible for outbreaks of listeriosis in humans. Repeated intramammary inoculation of 10^6 to 10^7 colony-forming units of *L. monocytogenes* into cattle resulted in 500 to 50,000 colony-forming units of the organism in the milk for as long as 12 months.[4]

Epidemiology Among untreated cases, the fatality rate is almost 100%.[5] The survival rate is considerably higher among treated animals than among untreated patients. The disease in sheep and goats tends to be more acute and results in a higher case fatality rate than in cattle. Occasional outbreaks of listeriosis may occur in sheep without access to silage.[5,6] In these cases, the source may be the feces of carrier animals or rotting vegetation on the pastures or feed bunks. During an outbreak of listeriosis, the bacterium can be isolated from the

VetBooks.ir

feces of a large percentage of normal animals.[7] It is unclear whether this high rate of asymptomatic carriage represents a true carrier state or is simply the result of a high environmental contamination by nonpathogenic isolates.[7] The agent infects the udder but rarely causes clinical mastitis. In sheep, excretion of the bacterium in the milk is greatest during the immediate postlambing period.[8,9]

L. monocytogenes can survive for long periods in the environment and in carriers with no symptoms. The bacterium can multiply at low environmental temperatures and is resistant to environmental influences. *L. monocytogenes* is shed in the feces of carriers with no symptoms, especially at the end of pregnancy and at lambing. Once in the environment, the bacterium can survive for 2 years in dry soil. It is resistant to freezing and thawing in the soil, but it does not survive for more than 1 to 2 weeks in properly preserved silage. The bacterium proliferates in rotting vegetation in which aerobic conditions exist and the pH is above 5.4.[10-12] Common sources of contamination in forage include spoiled silage at the ends of trench silos, decaying forage at the bottom of feed bunks, or rotting hay at the periphery of hay stacks.[10,13] The incidence of listeriosis may be increasing because of the greater use of trench silos and bulk handling methods, in which the amount of spoilage is greater than in conventional upright silos. Although *L. monocytogenes* can be isolated from silage with a pH below 4, fewer bacteria are found in well-preserved forage.[14]

A selective enrichment medium has been developed for identifying and enumerating the *Listeria* organisms in silage. This medium enables semiquantitative enumeration of *Listeria* bacteria in 10 g of silage. Hemolysin production is measured by overlaying the colonies with bovine blood agar and reincubating the plates. With this method, outbreaks of listeriosis have been correlated with silage containing 1 million *Listeria* organisms and more than 1 million enterobacteria per gram of silage. The pH of such silage characteristically exceeds 7.8.[15]

There is a significant public health concern about *Listeria* contamination of milk products. The 4b serotype of *L. monocytogenes* is most often responsible for infections in humans.[16] Outbreaks have been traced to ingestion of unpasteurized milk, cole slaw, and soft, ripened cheese. Foodborne listeriosis outbreaks have also been linked to contaminated fruit and vegetables.

Pathogenesis

Listeria organisms produce a hemolysin, listeriolysin-O, which is a thiol-activated toxin (molecular weight, 58 kD) that, in certain amounts, produces disease. The molecular role of the toxin in dissemination of the infection and in cell death is not known.

It is unclear whether infection of the brain by *L. monocytogenes* occurs hematogenously or by ascent from the cranial nerve rootlets.[17] Morphologic studies of naturally occurring cases of encephalitic listeriosis have demonstrated the bacterium in the axons of the trigeminal nerve rootlets, which indicates possible centripetal migration.[17,18] Similar findings have been reported in animals infected experimentally.[19] Younger animals may be susceptible because eruption of the permanent teeth may expose trigeminal nerve rootlets. Lsteriosis has been experimentally induced by inoculation of the bacterium into the pulp cavity of sheep.[20] Infection of the CNS without bacteremia has been detected, which also indicates that centripetal migration of the bacterium is possible.[21] Some investigators consider axonal migration as an unlikely mode of pathogenesis because *L. monocytogenes* is not nutritionally dependent on nervous tissue and because of the ready ability to produce multifocal brain microabscesses by intravenous inoculation of the bacteria into susceptible hosts.[17,22]

Clinical Signs

The neurologic signs of listeriosis in adults reflect dysfunction of the caudal brainstem, cerebellar peduncles, or spinal cord.[5] Fever may be present early in the clinical course, and poor appetite and depression are common. CNS signs are usually asymmetric and include conscious proprioceptive deficits, head pressing, and cranial nerve deficits. Depressed consciousness is the result of lesions of the reticular activating system. Conscious proprioceptive deficits are caused by interference with the descending motor pathways and the ascending proprioceptive fibers in the brainstem and may precede or accompany cranial nerve dysfunction. Head pressing and propulsive walking or compulsive circling are caused by lesions of the basal ganglia. Severely affected animals may be recumbent and may display torticollis, head tilt, or other unilateral vestibular signs.

Cranial nerves V through XII are usually dysfunctional in listeric animals. Patients with loss of the trigeminal nerve (cranial nerve V) show dropped jaw or asymmetric jaw closure and facial analgesia or anesthesia. Facial analgesia is best detected by stimulation of the nasal septum with a pencil or piece of straw. Animals with lesions of cranial nerve VI exhibit a medial strabismus on the ipsilateral side of the lesion. Animals with lesions of cranial nerve VII have ptosis, loss of menace response, no palpebral reflex, drooped ear, loss of levator nasolabialis muscle function, and decreased lip tone (Fig. 35.16). Small ruminants with cranial nerve VII loss have a deviated philtrum. The paralysis of the orbicularis oculi muscle results in exposure keratitis.[23] The loss of levator nasolabialis function is best detected by observation of the muscular contraction on the dorsum of the nose during inspiration. Loss of lip and cheek muscle tone is best detected by observation of drooling from the ipsilateral side of the mouth and by palpation of the lips and nostrils.

Animals with cranial nerve VIII lesions display nystagmus that changes as the position of the head is altered. Other signs include a head tilt toward the side of the lesion and a tendency to circle or fall to the lesion side. The nystagmus may be horizontal, vertical, or rotatory and is usually inconstant. If the spinal reflexes can be tested, the affected animals show a

FIG. 35.16 Clinical appearance of the neurologic form of listeriosis in a Charolais bull. Note the drooped right eye and ear and the drooling from the right side of the mouth. *(Courtesy Dr. W.D. Wilson.)*

VetBooks.ir

mild to moderate hypertonia and hyperreflexia in the limbs opposite the side of the lesion. Animals with acute loss of cranial nerves IX, X, and XII develop stertorous breathing and dysphagia. Animals with dysfunctional cranial nerve XII have paresis or paralysis of the tongue. With unilateral lesions, the tongue protrudes from the side of the mouth ipsilateral to the lesion. Progression of listeriosis is associated with decreased consciousness, coma, and convulsions.

Lambs may selectively develop spinal myelitis without brainstem disease. This condition results in flaccid paraparesis or hemiparesis without attendant signs of brainstem dysfunction.[24] The clinical signs of myelitis include tetraparesis, tetraplegia, paraparesis, paraplegia, conscious proprioceptive deficits, and recumbency. The sensorium and appetite are normal in some affected animals and greatly depressed in others.[25] Primary ocular disease caused by *L. monocytogenes*, manifesting as keratitis, conjunctivitis, or uveitis, may occur in cattle or horses with no signs of neurologic disease.[26]

Clinical Pathology Examination of the CSF usually helps confirm a diagnosis of listeriosis, but the cell and protein concentrations of the specimens are not necessarily correlated with the severity of the clinical signs or prognosis. The protein concentration in the CSF may exceed 40 µg/dL, and WBC counts in the CSF may exceed 12 cells/µL with mononuclear pleocytosis.[1,27,28] Many cattle with advanced signs of listeriosis develop metabolic acidosis as a result of salivary bicarbonate loss.

Pathology Pathologic confirmation of listeriosis is based on identification of multifocal microabscesses in the brainstem and isolation of *L. monocytogenes* from infected brain tissue. The agent is only rarely isolated from CSF and is best recovered from refrigerated nervous tissues. Enrichment of the *Listeria* organisms may be accomplished by refrigerating slices of brain at 4° C (39.1° F) for 3 months while the tissues are cultured weekly. In contrast to septicemic listeriosis of monogastric animals, peripheral monocytosis is not observed in infected ruminants.

Pathology The lesions of listerial meningoencephalitis are most common in the pons and trapezoid bodies, but they can be located anywhere in the brainstem. Neurologic structures most often affected include the reticular formation and cranial nerves V and VII to X. Macroscopic lesions are limited to mild meningeal congestion and clouding of the CSF. Microscopic lesions include perivascular cuffing with mononuclear cells, multifocal asymmetric brainstem microabscesses, and mononuclear cell meningoencephalitis.[16] The microabscesses are composed predominantly of neutrophils. Other microscopic changes include degeneration of the neuropil and neuronophagia.

Treatment and Control The recovery rate is best if treatment is administered early in the disease course. Animals that are recumbent, comatose, or convulsive rarely survive despite intensive antibiotic and supportive therapy. In most cases, treatment must be administered for a prolonged period because recovery may take as long as 1 month. *L. monocytogenes* is susceptible to most of the common antimicrobial drugs. Recommended treatment is either oxytetracycline, 10 mg/kg IV twice daily, or therapy with penicillin G.[23] Specific recommendations for penicillin therapy include an initial dosage of 40,000 IU/kg (potassium penicillin G) IV three or four times daily for 7 days and then 22,000 IU/kg (procaine penicillin) IM once daily for 14 to 21 additional days.[23]

The plasma concentrations of bicarbonate and potassium should be measured, and specific corrective fluid therapy should be administered as indicated by acid-base and electrolyte assays. Good footing and nursing care are also beneficial.

Serologic responses to flagellin and listeriolysin-O develop after oral administration of virulent *L. monocytogenes* and confer protection against listerial bacteremia.[21] Vaccines of attenuated or killed bacteria have been used successfully to protect sheep and goats. Although these vaccines reduce the incidence of listeriosis in vaccinated flocks, they are not commercially available in the United States.

Although the case attack rate of listeriosis is low, occasional epizootics may occur in cattle, sheep, or goat herds, invariably in association with high rates of environmental contamination. In such cases, the hay and silage should be cultured for *L. monocytogenes*. Rotten vegetation should be discarded, and cattle should be fenced from contaminated areas.

Thromboembolic Meningoencephalitis (*Histophilus somni* Infection; Sleeper Calves)

Definition and Etiology Thromboembolic meningoencephalitis (TEME) is a fulminant neurologic disease of cattle that arises from septicemia caused by the pleomorphic, nonencapsulated, Gram-negative bacterium *H. somni* (formerly *Haemophilus somnus*).[1] Because it can disseminate via the bloodstream, this organism can incite infection in multiple organs. In addition to TEME, *H. somni* can cause pleuropneumonia, myocarditis, laryngeal abscesses, polyarthritis, polyserositis, and infections of the ear, eye, udder and urogenital tract.[1-6]

Epidemiology Although TEME occurs most frequently in feedlot cattle,[7] outbreaks in the western United States and Canada have been reported in both pasture and dry lot environments.[8,9] In a serologic study of feedlot cattle, seroconversion to *H. somni* occurred early in the feeding period (soon after placement).[10] This may be reflective of the role of stressors (e.g., comingling of animals from different sources, transport, or changes in feed) in the pathogenesis of this disease. Chapter 31 includes further details on the epidemiology of *H. somni* infections in cattle.

Pathogenesis Infection of cattle by *H. somni* probably occurs through the respiratory tract. Bacterial proliferation in the lungs and other soft tissues by serum-resistant isolates results in bacteremia. *Histophilus* possesses multiple virulence factors including the capability to induce apoptosis of endothelial cells.[6] Exposure of subendothelial collagen occurs subsequently, which results in microthrombus formation and organ damage through hypoxia and inflammation. The sites of the body most affected by the thrombosis are the brainstem, spinal cord, synovial membranes, pleura, and lungs. Although the name *thromboembolic meningoencephalitis* implies the passage of solid material in the vasculature to a downstream occlusion site (embolism), thrombus formation probably occurs directly at the site of the vascular lesion.

Clinical Signs Only the neurologic syndrome (TEME) is discussed here. Descriptions of other clinical syndromes of *H. somni* infection are discussed in Chapters 31, 39, and 43. The initial signs of TEME are fever (40° C to 41.6° C [104° F to 107° F]), anorexia, depression, and ataxia.[7,8,11,] In addition to depression, affected animals show a number of conscious proprioceptive deficits, including knuckling, circumduction, crossing over, and interference. Affected animals may fall while attempting to walk. Signs specifically associated with lesions of the cerebellum and caudal brainstem include head tilt, nystagmus, strabismus, blindness, muscular tremors, opisthotonos, coma, and convulsions.[12] Signs of infection in other organ systems (e.g., pneumonia, arthritis) may be present in the affected animal or in cohorts. Death may occur within 36 hours after the onset of neurologic signs.

VetBooks.ir

Clinical Pathology Examination of CSF may be helpful in substantiating a clinical diagnosis of TEME. Specific CSF changes characteristic of hemorrhage include high erythrocyte counts, xanthochromia, and increased concentrations of protein (>100 mg/dL) and neutrophils (>500 WBCs/μL). In untreated cases of TEME, the bacterium may be isolated from the brain, kidneys, pleural fluid, lung sections, aspirated tracheal exudate, urine, blood, and preputial washings. Standard transport swabs containing Amies medium are appropriate for culturing of clinical samples. Isolation of *H. somnus* from joint fluid and CSF is usually unsuccessful.[13] The kidneys and brain should be collected for postmortem examination because these tissues contain the highest concentrations of *H. somni*.[13]

Initial changes in the peripheral WBC count include neutropenia, left shift, and toxic changes in the neutrophils. In cattle that develop acute TEME, agglutinating antibody titers are invariably greater than 1:400 and increase fourfold by 2 to 4 days after infection.[14] Serum agglutination titers are greater than 1:1024 in convalescent cattle; they may be lower with inapparent infection or vaccination.[15]

Pathology Macroscopic pathologic lesions of the CNS include disseminated multifocal hemorrhages and infarctions in the spinal cord, brainstem, and cerebral cortex. Bacterial colonies are frequently observed in thrombosed blood vessels and the surrounding infarcted tissues. Ocular lesions are characterized by conjunctivitis, multifocal retinal hemorrhages, and areas of retinal edema. The CSF is cloudy and xanthochromic. A focal fibrinous meningitis is observed, and suppurative otitis may occur in some cases.

The earliest microscopic lesion of TEME is vasculitis that progresses to septic infarction and abscess formation. The lesions are usually found in the CNS, but in severe cases they may be disseminated throughout the body.

Nonneurologic lesions of *H. somni* infection include suppurative arthritis, synovitis, myocarditis, suppurative pleuritis, urogenital infections, and bronchopneumonia. Changes associated with the bronchopneumonia include infarction, cranioventral pulmonary consolidation, and hemorrhagic interstitial pneumonia. Other lesions include ecchymotic to petechial hemorrhages over the serous surfaces, purulent exudate in the joints, and ulceration of the laryngeal and tracheal mucosa with diphtheritic membrane formation.[16]

Treatment and Control During an outbreak, cattle must be examined frequently and should be treated when the neurologic signs first appear. *H. somni* is susceptible to many antibiotics and antimicrobial drugs. Drugs that have been reported to be effective for the treatment of TEME include tetracyclines, penicillin, aminoglycosides, and ampicillin. Parenteral oxytetracycline is regarded as the most cost-effective treatment for infected commercial cattle; the dosage is 10 mg/kg of a conventional formulation given IV twice daily for 3 days or 20 mg/kg of a long-acting formulation given SC. Some authors advocate the addition of chlortetracycline (2.2 mg/kg) to the feed for 10 successive days.[17] This, however, would constitute off-label drug use in feed and is currently prohibited by the U.S. Food and Drug Administration. Chlortetracycline is approved as an oral drench for the treatment of *H. somni* pneumonia in beef, non-lactating dairy cattle, and calves in the United States at a dosage of 22 mg/kg for 5 days.

Antibody responses protective against respiratory challenge have been generated by vaccination with anionic, heat-stable proteins derived from the bacterial cell wall.[18] Vaccination of cattle with commercial products affords substantial protection from experimentally induced *H. somni* septicemia and neurologic disease for more than 3 months[18-20] (See Chapter 48 for more information about vaccines). Mass prophylactic treatment of affected cattle with a parenterally administered, long-acting oxytetracycline formulation may be efficacious in preventing TEME in cattle at high risk for the disease.[21]

Otitis Media/Interna of Ruminants

Definition, Etiology, Epidemiology, and Pathogenesis Otitis media/interna is a common bacterial disease of cattle and sheep; it is less commonly observed in goats. The condition usually occurs as a sequela to upper or lower respiratory infections caused by *Mannheimia haemolytica*, *Pasteurella multocida*, *C. pseudotuberculosis*, *H. somni*, or *Mycoplasma* spp.[1-5] Subclinical otitis media/interna is common in feedlot-reared animals, particularly early in the feeding period.[1,3] Although viral infections are the cause of a large proportion of otitis media/interna cases in children,[5] the role of viral infections in ruminant otitis media/interna remains speculative; it is possible that viruses play a role in facilitating otitis media interna similar to that in facilitating lower respiratory tract disease. Because *Mycoplasma* spp. have been detected in clusters or outbreaks of otitis media/interna on dairy farms, contaminated milk is considered an important potential source of this organism in young stock.[4,6] Chapter 31 includes more detailed discussion on the role of *Mycoplasma* spp. in the bovine respiratory disease complex.

Otitis media/interna is considered to most commonly result from ascending infection of the middle ear from the nasopharynx via the eustachian (auditory) tube.[5] Infection that progresses from the external ear into the middle ear is less common but may occur secondary to aural infestation by ectoparasites. Once infection is established in the middle ear, it may extend into the inner ear as a result of erosion of bone or extension of the infection through the round or oval windows, or both. The constellation of clinical signs of otitis media/interna results from damage to the peripheral vestibular apparatus residing in the tympanic bulla and petrous temporal bone. In chronic cases, the peripheral vestibular apparatus can be damaged beyond repair, and neurologic deficits may be permanent. In rare cases, infection can extend into the CNS, which results in subdural abscess formation, meningoencephalitis, or brain abscess formation.[5] The vast majority of cases shows clinical signs of unilateral peripheral vestibular disease; however, subclinical inflammatory lesions may be present in the contralateral, clinically normal side. Bilateral, clinically apparent peripheral vestibular disease is rare. Additional signs of multisystemic disease caused by *Mycoplasma bovis*, *Pasteurella multocida*, or *H. somni* may be present (e.g., pneumonia, polyarthritis).

Clinical Signs and Diagnosis Headshaking (possibly producing an aural hematoma), an ear droop, and reduction in appetite may precede the clinical vestibular signs. Fever is inconsistent.[6] Patients with vestibular signs display unilateral head tilt (toward the side of the lesion), continuous horizontal nystagmus (fast phase away from the side of the lesion), and imbalance, manifested as a tendency to stumble, fall, or walk in a tight circle toward the side of the lesion. If the tympanic membrane ruptures, or in the rare case of otitis externa as a preceding condition, purulent exudate may be evident in one or both ears.

Affected animals may become recumbent and lie with the lesion side toward the ground; if turned, they return to the same position. Many animals with otitis media also develop ipsilateral facial nerve dysfunction, which results in ptosis, drooped ear, and flaccid lips and nostrils. In small ruminants, facial nerve paralysis results in deviation of the philtrum toward the normal side. Deviation of the philtrum does not occur in cattle because of the large amount of connective tissue surrounding the planum nasale. On occasion, affected animals

develop subtle or pronounced signs of cortical or brainstem disease as a result of extension of infection from the middle ear into the meninges. CSF analysis may reveal increased leukocyte counts in such cases.[6]

Although the clinical signs of peripheral vestibular disease are characteristic, it is important to differentiate this condition from that of central vestibular disturbance. Animals with peripheral vestibular disease are usually appetent, alert, and aware of their surroundings and do not have a significant deficit of postural placement. The nystagmus of these animals is constantly horizontal. In comparison, animals with central vestibular disturbances are depressed, have a nystagmus that varies in direction, and show marked conscious proprioceptive abnormalities.

Diagnostic imaging, including radiography, CT, and ultrasonography of the tympanic bulla, may be useful in confirming a diagnosis of otitis media/interna.[7]

Treatment and Control Treatment of bacterial otitis with procaine penicillin (44,000 IU/kg IM or SC daily) may be effective. Because bacteria that do not have a cell wall (*Mycoplasma* spp.) may be involved, however, initial treatment with an antibiotic other than a member of the β-lactam class might be warranted (e.g., tetracyclines, florfenicol, macrolides, and, where legal, fluoroquinolones), unless bacterial culture and sensitivity results or clinical response indicates treatment with a β-lactam class antimicrobial drug.[6] Relapses may occur, which warrants prolonged treatment (3 to 6 weeks). Treatment is effective in obtaining a complete cure of acute otitis but is less so in treating the chronic form. In chronic cases, infection may irreversibly damage middle or inner ear tissues, causing neurologic deficits that can persist despite resolution of infection with antimicrobial therapy. Osteomyelitis of the petrous temporal bone, abscess formation in the tympanic bulla, or a noninfectious cause (e.g., neoplasia) are other considerations for affected animals that do not respond to antimicrobial therapy.

Management practices aimed at reducing the risk for upper respiratory tract infection may aid in reducing the incidence of disease. In dairy herds with a history of otitis media/interna caused by *Mycoplasma* spp. in calves, pasteurization of waste milk fed to calves or feeding milk replacer instead of waste milk may be warranted.

Ear Mite Infestations of Ruminants

The ear mite of cattle is *Raillietia auris*, and that of small ruminants is *Psoroptes cuniculi*. Severe infestations perforate the tympanum and result in vestibular disease, facial paralysis, and ataxia.[1-4] Infestation can be recognized by observation of ulceration and purulent debris in the auditory canal next to the tympanum. Mites may or may not be visible during otoscopic examination. Malodorous discharge on the side of the face under the ear canal may be observed in some affected animals.

The accumulation of purulent debris and the swelling of auricular tissues block the transmission of sound to the tympanum.

Ear mite infestations in cattle are common and in some herds may affect most of the adults. The biologic importance of the infestation may be related to changes in the herding or mothering behavior of range cattle. The economic significance of the infestation is unknown.

Ear mite infestations have been successfully treated in goats with eardrops containing rotenone once daily for 5 to 10 days. Good clinical responses can be obtained in cattle with the same treatment. Fenthion drops have also been used successfully. In cases of parasitic otitis in which the discharge has been inspissated, lateral resection of the ear canal should be considered to establish adequate ventral drainage.[5] A single subcutaneous injection of ivermectin at 0.2 mg/kg has been shown to be an effective treatment for *P. cuniculi* otitis in both sheep and goats.[6,7]

The life cycle of the mite involves two free-living stages, the protonymph and deutonymph stages. These forms molt in the vegetation and reinfest cattle as they graze or bed during the evening.[8] Therefore tilling the soil of the infested pastures or re-treating cattle every 14 to 21 days with insecticide should be considered as part of an eradication scheme.

Diseases Producing Tremors and Ataxia; Cerebellar Diseases

Cerebellar Abiotrophy

Robert J. Mackay

The term *abiotrophy* refers to spontaneous premature degeneration resulting from an inborn error of development.[1] Syndromes of cerebellar abiotrophy have been described for Arabian,[2] Gotland Pony,[3] and Eriskay Pony foals.[4] In Arabian foals with cerebellar abiotrophy, degeneration begins only after formation of the cerebellum and is characterized by apoptosis of Purkinje cells.[5] The likely genetic basis for cerebellar abiotrophy in Arabian foals is a single-nucleotide polymorphism upstream of the *mutY* homolog gene *(MUTYH)*, in a region involved in transcriptional upregulation of the gene.[6] *MUTYH* encodes for a DNA glycosylase involved in repair of oxidative damage to genomic DNA during organogenesis and mitochondrial DNA during postnatal life. This gene is expressed abundantly in the cerebellums of normal horses; expression is significantly lesser in foals with cerebellar abiotrophy.[6]

The mode of inheritance of cerebellar abiotrophy is simple autosomal recessive.[2,6,7] The cerebellar abiotrophy allele was found in 19.7% of approximately 4200 Arabian horses and is well represented in Egyptian, Spanish, and Polish lineages.[6,7] Among tested horses, 1.4% were homozygous for the allele. Nine of these were clinically normal, which, together with the observed range of ages at onset, is evidence for variable expression of the cerebellar abiotrophy trait. The allele was also present at low frequency among Bahkir Curly Horses, a breed for which Arabian horses were foundation stock, and in Welsh Ponies and Trakehners, breeds that allow out-crossing with Arabian horses.[8]

Signs of cerebellar abiotrophy typically begin in foals between 6 weeks and 4 months of age; however, affected foals may show signs at or shortly after birth. Among 18 confirmed or suspected cases, signs were present at birth in 4 (22%) and began at the age of 3 months or younger in 10 (56%), at ages 3 to 6 months in 2 (11%), and after age 6 months in 2 (11%).[9-12] The first signs noticed are incoordination, basewide posturing in the thoracic limbs, and head tremors. The head tremor is usually a coarse bobbing in either the horizontal or vertical plane. When the head is extended (e.g., toward the dam's udder or toward offered food), the head tremor becomes more pronounced. Although foals with cerebellar abiotrophy can see normally, the menace response cannot be elicited in most cases. Affected foals walk with a swaying, lurching gait and may even wobble side to side or back and forth while standing still. Thoracic limbs may appear stiff, or there may be exaggerated flexion ("paddling") during the protraction phase. Gait abnormalities are most obvious when movement is initiated and during turns. Normal strength is preserved even in severely ataxic foals, and blindfolding does not exacerbate clinical signs. All clinical signs are exaggerated by stimulation of affected foals. Such hyperresponsiveness means foals with cerebellar abiotrophy are difficult to halter-train and lead; even normal handling often causes an affected foal to pull away or

VetBooks.ir

VetBooks.ir

even flip over backward. Severely affected foals that fall often panic and struggle for some time before standing.

The diagnosis in an Arabian foal with compatible clinical signs is strongly supported by demonstration of homozygosity for the cerebellar abiotrophy allele. This test requires submission of 20 to 30 hairs with roots to the Veterinary Genetics Laboratory at the University of California, Davis (http://www.vgl.ucdavis.edu/services/horse.php). Hematologic and serum chemistry findings are usually normal. Some foals have high CSF protein concentration and creatine kinase activity, which are consistent with active neurodegeneration at the time of CSF collection.[11] MRI, and possibly CT, of affected foals reveals atrophy of the cerebellum in foals with cerebellar abiotrophy.[13]

Signs may be stable after onset or get worse for up to several months. It is rare, however, for foals with cerebellar abiotrophy to become persistently recumbent. Modest improvement has been noted in some mildly affected horses once they become adults.[9] Foals with cerebellar abiotrophy seldom succumb to direct effects of the condition, but most are euthanized because of severe clinical signs and poor prognosis.

Gross appearance of the affected brain is usually described as normal; however, the ratio of cerebellar to whole brain weight is usually less than 8%, whereas normal ratios are 8% or higher. The characteristic histologic lesion is thinning of the cerebellar cortex, affecting both granular and molecular layers.[2,9-12] There is marked reduction in the number of Purkinje cells in the granular layer, and some of those remaining show degenerative changes (swelling, shrinkage, and hyperchromasia of the perikaryon). There is relative sparing of the Purkinje cells of the nodulus and flocculi.[11] Vacuolation may be noted in the olivary nuclei, and mineralized neuronal cell bodies may be found in the thalamus adjacent to the third ventricle.[10]

Cerebellar Hypoplasia Caused by Congenital Bovine Viral Diarrhea Virus Infection

Lisle W. George

A complete discussion of bovine viral diarrhea–mucosal disease (BVD-MD) can be found in Chapter 32. BVD virus infection of susceptible cows from 90 to 170 days of pregnancy results in abortion or stillbirth, hydranencephaly, or cerebellar hypoplasia in the fetus.[1,2] The BVD virus infects the developing germinal cells of the cerebellum and kills Purkinje cells in the granular layer, which results in necrosis and inflammation.[3] The microscopic lesions include necrosis of the external germinal cells, focal parenchymal hemorrhages, and folial edema.

The signs of cerebellar dysfunction are usually present at birth and include truncal ataxia, falling backward, opisthotonos, basewide stance, coarse intentional head tremors, hypermetria, hyperreflexia, and nystagmus or strabismus (Fig. 35.17).[4,5] If severely affected, the animal may be unable to stand or lie in sternal recumbency. Excitatory stimuli in these animals precipitate wild oscillations and side-to-side movements of the head, which can be mistaken for convulsions. The affected calves may have a deficient menace response and appear to be blind, especially with concomitant hydranencephaly or microphthalmia. The neurologic condition rarely improves after birth. Other fetal changes that may be induced by the BVD virus include thymic atrophy, retinal degeneration, corneal opacity, and failure to grow.[1,4] The diagnosis of cerebellar hypoplasia is based on identification of the specific clinical signs and the recognition of BVD antibodies in precolostral blood specimens. The virus may be cultured from the blood of some affected calves, but this appears to be dependent on whether an immune response to the virus has developed in the affected calf.

FIG. 35.17 Characteristic head position and basewide stance of a calf with cerebellar hypoplasia.

Storage Diseases and Inborn Errors in Metabolism

Robert J. MacKay

Inherited Myoclonus of Peruvian Paso Foals

Inherited myoclonus was described in two Peruvian Paso foals that demonstrated myoclonic contractions of the musculature in response to auditory or tactile stimuli.[1] These contractions were sustained with repeated stimulation. One foal could not stand without assistance, and the other had a "bunny-hopping" gait in the pelvic limbs. Analeptic drugs and tranquilizers were ineffective for controlling this condition. Inherited myoclonus was associated with a specific deficiency of spinal glycine receptors, which are responsible for synaptic inhibition in the CNS. Glycine is a major inhibitory transmitter providing reciprocal inhibition via type Ia afferent fibers and interneurons, as well as recurrent inhibition on motor neurons via Renshaw cells.

Congenital Encephalomyelopathy in Quarter Horses

Congenital encephalomyelopathy has been described in Quarter Horse foals.[2] The condition occurred in three foals born to two different mares and three unrelated stallions. Signs were present at birth and included recumbency and coarse tremors of the pelvic limbs. When the foals were assisted to stand, the hindquarters bounced off the ground. Thoracic limb function appeared normal; however, patellar reflexes were exaggerated. The affected foals were bright, alert, and responsive and had intact pain perception. They had no gross CNS lesions. Microscopic lesions included spongiform degeneration and axonal swelling of the spinocerebellar spinothalamic tracts within the medulla and spinal cord.

Lavender Foal Disease (Coat Color Dilution Lethal)

Lavender foal syndrome is an autosomal recessive disorder of Arabian foals that has been recognized for many years but reported only as recently as the mid-2000s.[3,4] Lavender foal syndrome is characterized by a dilute coat color, episodes of opisthotonos, hyperresponsiveness to touch, limb paddling,

VetBooks.ir

and rapid, uncontrolled eye movements. Affected foals are unable to assume sternal recumbency or stand. Despite the incapacitating neurologic signs, animals with lavender foal syndrome are able to vocalize and usually have a strong suckle response. The important feature of this condition that distinguishes it from neonatal encephalopathy and other causes of neonatal neurologic dysfunction is the dilute hair color. In a few cases, the color is the striking iridescent silver to pale lavender hue, as suggested by the name. *Coat color dilution lethal* may be a more appropriate name, however, because many affected foals exhibit other dilute coat colors, including pewter (pale slate gray) and pale chestnut (pink), and because complications from neurologic abnormalities invariably lead to death or necessitate euthanasia by approximately 72 hours. Abnormal findings at necropsy are nonspecific and minimal. A single base pair deletion in the *MYO5A* gene is responsible for lavender foal syndrome.[5,6] This deletion results in a frame shift and truncation of the protein at a premature stop codon 12 amino acids beyond the deletion. Loss of *MYO5A* disrupts melanosome trafficking and endoplasmic reticulum transport in cerebellar Purkinje cells, thus leading to the clinical signs of cerebellar seizures. Reported allelic frequencies are 5.2% among Egyptian Arabian horses in the United States,[6] 1.62% among European Arabian horses, and 0% among European Thoroughbred and Standardbred horses. Testing for the *MYO5A* gene mutation is available commercially and is performed on plucked mane and tail hairs.

Overo Lethal White Syndrome

Overo lethal white syndrome is an inherited syndrome of American Paint foals from parents with the frame overo coat pattern.[7,8] Affected foals are totally or almost totally white and die within days from complications of intestinal aganglionosis.[7] Aganglionosis is characterized by a complete lack of submucosal and myenteric ganglia from the distal small to large intestine. Foals with vero lethal white syndrome are homozygous (designated OO) for a dinucleotide mutation, which causes an isoleucine-to-lysine substitution at codon 118 in the gene for endothelin receptor B.[9,10] Although heterozygotes for the lys118 mutation (nO) are mostly frame overos, the mutation is also found at lower frequency in other white patterned horses, including tobianos and solid pattern breeding stock.[11] The mutation is not usually found in breeds without white pattern variants, although overo lethal white syndrome was reported in the offspring of a registered Quarter Horse. Genetic testing is the only reliable method for detecting carriers. Plucked mane or tail hairs are submitted to commercial laboratories for testing.

Definition and Etiology

Robert J. MacKay • Lisle W. George

Locoism (Swainsonine Toxicity)

Chronic ingestion of various plants worldwide can result in an acquired neurovisceral storage disease. Plants incriminated so far include members of *Astragalus* and *Oxytropis* genera (locoweeds) in the western United States, Canada, Africa, Asia, and Australia; *Ipomoea carnea* in Mozambique; the darling pea in Australia (*Swainsona* spp.); and *Ipomoea* spp., *Turbina cordata*, and *Sida acuta* (also known as *S. carpinifolia*) in Brazil.[1-8] The disease was also diagnosed in a horse in Belgium; however, the causative plant was not identified.[9] Horses are most susceptible, but cattle, sheep, goats, and deer can also be affected.[10]

Conditions that promote locoweed poisoning are hot, dry weather and a scarcity of alternative forage. Horses may be more prone to graze on locoweed than are cattle, particularly when other green forage is scarce, and may increase their consumption over a single season.[10] Chronically exposed livestock become addicted to locoweeds and feed selectively on the plant over successive grazing seasons.[11]

Locoweeds represent only a small proportion of the species in the *Astragalus* or *Oxytropis* genera; many *Astragalus* spp. contain nitrotoxins or are selenium accumulators, and many other members of both genera are nontoxic. The indolizidine alkaloid *swainsonine* (also known as *locoine*) has been identified as the cause of locoism. Swainsonine acts by potent inhibition of mammalian α-D-mannosidase and of Golgi mannosidase II.[5,12] Swainsonine synthesis in *Astragalus* and *Oxytropis* plants is dependent on the fungal endophyte *Undifilum oxytropis* or closely related *Undifilum* spp.[13,14] Swainsonine, along with slaframine (slobber toxin), is also produced by *Rhizoctonia leguminicola*, a fungus that causes black patch disease of red clover.[15] Whether plants other than *Astragalus* and *Oxytropis* spp. are also colonized by swainsonine-producing fungi has not yet been clarified. Other toxins identified in locoweeds have included β-galactosidase and β-glucosidase; aminonitrile, a toxin that causes abortion and teratogenesis; and miserotoxin, a cause of respiratory disease.

Oxytropis and *Astragalus* plants are legumes that have herbaceous stems and alternate pinnately compound leaves.[16] The fruits are characteristic leguminous pods that contain kidney-shaped seeds with pods marked by characteristic longitudinal grooves. The plant is eaten because it is the first vegetation available in the spring. Neurologic signs do not usually develop in cattle until 3 weeks after the animals first begin grazing on the plant and may not occur until long after ingestion of the plant has stopped. In parallel with changes in the concentration of endophyte in locoweeds, toxicity may vary from year to year and even within one season.[17]

Clinical Signs Experimentally and naturally poisoned horses show clinical signs by 2 to 3 weeks after continuous ingestion of locoweed.[2,10] The clinical signs include ataxia and obtundation alternating with periods of frenzied or manic activity.[7] Some affected horses demonstrate a high-stepping gait suggestive of cerebellar dysfunction.[7] At rest, there is intention tremor of the head; flaccidity of the nose and lips; repetitive, dystonic movements of the lips and tongue; and dysphagia. The clinical signs worsen when affected horses are handled or transported. Signs in goats are similar, including ataxia, hypermetria, hyperesthesia, and muscle tremors.[1,2] When the chin is raised for 30 seconds and then suddenly released, even mildly affected goats fall into recumbency with additional signs of nystagmus, opisthotonos, tetanic spasms, and seizures. Sedation is usually ineffective for controlling the hyperexcitability of locoism. Horses that survive locoweed poisoning retain altered behavior and an irregular gait. Abortions, stillbirths, and neonatal deaths can occur in all species exposed to these toxic plants, regardless of whether the dams have clinical signs of neurologic disease.[2,3,18]

Neurologic signs in adult cattle include ataxia, limb hypermetria and weakness, obtundation, dull staring eyes, and loss of herding instinct. Heavy losses from abortions or malformed calves have also been described. The indolizidine alkaloids are secreted in the milk and may cause unthriftiness and weak suckling behavior in calves. Calves that have been exposed to the toxin in utero are weak and fail to thrive. Some may have flexural contractions of the limbs and lateral rotation of the carpus.[8,19,20] Ingestion of locoweed by certain cattle at high altitudes may result in the development of cor pulmonale.[21] Many cattle with mild signs of locoweed poisoning recover completely by 60 days after removal from the involved pastures. Poisoned sheep have a stargazing attitude and appear to be blind, nervous, and stiff. The normal flocking behavior is absent.[12] Affected sheep may salivate excessively. Testicular atrophy has been reported in affected rams.[22] The immunosuppressive actions of swainsonine predispose affected animals to

pyogenic infections such as pneumonia, keratoconjunctivitis, and foot rot.

Clinical Pathology Microscopic examination of stained blood smears may reveal cytoplasmic vacuolation of lymphocytes. These changes are found in the majority of lysosomal storage disorders but might be considered diagnostic of locoweed poisoning in animals with characteristic clinical signs and historical evidence of exposure. Serum activities of alkaline phosphatase and AST are high; elevated concentrations reflect liver dysfunction in association with prominent vacuolation of hepatocytes.[23] Definitive diagnosis can be established by assays of blood from affected animals for α-D-mannosidase activity and swainsonine concentration. The half-life of swainsonine in the serum is 16 to 20 hours.[24] This means that an animal suspected of locoweed poisoning must have a blood sample taken within 2 days of eating locoweed for swainsonine to be detected.

Pathology The microscopic abnormalities of the soft tissues of acutely poisoned animals are similar to those of the inherited lysosomal storage diseases of cattle, including cytoplasmic vacuolation of neurons, particularly cerebellar Purkinje cells, and cells in various other tissues.[2,7] Paraffin-embedded tissues can be examined with lectin photochemistry testing to characterize the stored material within the vacuoles.[25] Vacuolation of renal tubular epithelial cells may occur as early as 4 days after the start of daily feeding of 0.34 kg of locoweed to horses and may be present in animals exposed to toxic plants but clinically normal.[26] Pulmonary lesions associated with chronic ingestion of locoweed that may predispose to high-altitude disease (brisket disease) in cattle include alveolar emphysema, bronchiolar constriction and hypertrophy, and interlobular edema and fibrosis. Pyloric or gastric ulcers have been reported in affected cattle.[8,26] Placental edema, fetal ascites, and hydrops allantois have been described in exposed pregnant cattle.

Treatment There is no known effective long-term therapy for locoweed poisoning. Animals remain affected for a prolonged period or even permanently after removal of the plants. One author recommends tranylcypromine (60 mg PO), a monoamine oxidase inhibitor, and protryptyline (60 mg PO) or reserpine (1.25 mg PO per animal once daily) for treatment of chronically affected animals.[27] The efficacy of these treatments is unknown. Addition of a mineral supplement and a natural clay (clinoptilolite) to the diet of cattle ingesting locoweed did not prevent toxicity.[28]

Prevention Nonaddicted livestock normally do not eat locoweed if other forage is available. The condition may be prevented by supplemental feeding during the early spring and late summer. One report has described conditioning aversion to locoweed in horses with lithium chloride administered simultaneously with grazing on *Oxytropis sericea*.[29] Whether this is a practical management tool in large numbers of animals has yet to be determined.

Staggers Syndromes (Grass Staggers)

Robert J. MacKay

Forage-associated staggers syndromes are common and have been associated with protective fungal secondary metabolites, bacterial antibiotic corynetoxins, or neurotoxic chemicals produced by the forage itself. Some associated plant or fungal toxins also induce agalactia, fever, low productivity, and other physiologic effects because of a prolactin-like effect.

Tremorgenic Mycotoxicoses

At least 20 tremorgenic mycotoxins are known; they are produced by several different fungi, have the same biologically active moiety, and give rise to similar clinical manifestations.[1,2] Indole-diterpenoid tremorgens are secondary fungal metabolites that act by blocking potassium outflow from cells via inhibition of cell membrane large-conductance calcium-activated potassium channels.[3,4] The most important classes of tremorgens are the *lolitrems* (perennial ryegrass staggers) and *paspalitrems* (*Paspalum* staggers, Bermudagrass staggers). Other indole-diterpene tremorgens that may be elaborated on moldy feeds by saprophytic fungi and occasionally cause staggers in livestock include penitrems, janthitrems, aflatrem, and verruculogen. The major tremorgenic mycotoxicoses are similar or identical clinically; therefore clinical signs are discussed in detail only in the Perennial Ryegrass Staggers section.

PERENNIAL RYEGRASS STAGGERS. Perennial ryegrass staggers (PRS) is a syndrome of tremors and ataxia that result from ingestion of endophyte-infected perennial ryegrass *(Lolium perenne)* by horses, cattle, sheep, deer, goats, and alpacas.[5] PRS is a common condition of livestock in New Zealand and Australia and occasional outbreaks occur in Northern Europe, the northwestern United States, South America, and Europe.[6-9] The case attack rate may reach 100%, but the mortality rate is generally low and attributable only to accidents. Substantial economic losses may be incurred, however, when production animals with PRS cannot be safely moved. For example, herd- or flock-wide outbreaks have prevented milking of dairy cows and mustering of sheep for necessary procedures such as anthelmintic treatment, shearing, or breeding.[5] Conditions that increase toxicity of perennial ryegrass pastures include high proportions of endophyte-infected plants; late seasonal growth; hot, dry summer and fall after wet spring; ryegrass domination of pastures; ambient temperatures higher than 23° C; ryegrass that is allowed to flower before consumption; and close grazing.[9] Endophytes are most abundant in the leaf sheath and florets and lowest in the blades. Disease outbreaks occurs from June to September in the northern hemisphere and from December to June in the southern hemisphere.

PRS typically appears acutely 5 to 10 days after introduction of livestock onto endophyte-rich pastures; onsets as early as 48 hours and as late as 2 weeks after exposure have been recorded. The source of tremorgenic toxins is the symbiotic endophytic fungus *Neotyphodium lolii*.[5] The fungal infection confers resistance to predation of grass by insects, including the Argentine stem weevil, and so there is selective pressure for expansion of toxigenic cultivars. *N. lolii* produces three classes of alkaloids with approximately parallel profiles of production: *tremorgens*, *ergopeptides*, and *peramine*. The most abundant and active indole-diterpene tremorgen produced by endophyte-infected plants is lolitrem B.[10] Lolitrem B concentrations of more than approximately 2 mg/kg (ppm) of dry matter in forage reliably cause staggers in sheep, cattle, and horses.[11] The concentration of lolitrem B in pasture increases from spring through fall. Plant infection rates below 25% (typical in northern hemisphere pastures) are associated with sporadic cases, whereas plots with 90% infection rates are common in Australasian pastures and are associated with outbreaks of PRS.

Ergovaline and other ergopeptide alkaloids (also see Chapter 54) produced by endophytes cause signs comparable with those of heat stress syndrome, a condition in cattle in the southwestern United States that graze on tall fescue infected with the endophyte *Neotyphodium coenophialum*.[9] The resulting clinical signs are diarrhea, hyperthermia, high heart and respiratory rates, poor weight gain, and reduced milk production. The high mortality rates (up to 30% of affected sheep) reported during PRS outbreaks in Australia in 1986, 1993, and 2002

VetBooks.ir

have been attributed to heightened susceptibility to heat stress caused by ergopeptides in endophyte-infected perennial ryegrass.[9] Horses experimentally fed endophyte-infected *L. perenne* seeds during cool conditions in New Zealand developed limb edema and exudative heel lesions, signs that reflected the vasoconstrictive "fescue foot"–like effects of ingested ergopeptides.[11] Peramine, a pyrrolopyrazine alkaloid, is a potent insect-feeding deterrent with substantial protective effects against the destructive Argentine stem weevil. Strains of endophyte-free perennial ryegrass have been propagated but are difficult to maintain without extensive insecticide use. Cultivars of *L. perenne* that are infected with strains of *N. lolii* have been produced that contain peramine but not tremorgen or ergopeptide. These cultivars (e.g., AR1, AR37) therefore have multiple advantages over traditional endophyte-infected strains, in that they do not cause staggers or ergopeptide-associated production loss and substantially protect against stem weevil predation.[12] AR1 is not as broadly insect resistant as is wild-type *N. lolii*, however, and root aphid infestation is notably unaffected.

Clinical signs first occur approximately 5 to 10 days after livestock are introduced to infected pasture (or after they eat infected ryegrass seeds or straw[7,11]) and become progressively more severe until the animals are removed from the endophyte source. The carefully observed signs reported for experimentally induced PRS in horses are typical of mild to moderate signs shown by animals of all affected species during natural PRS outbreaks.[11] Initially, affected animals exhibited fine, then coarse, fasciculations and tremors of skeletal muscles, particularly those of the shoulders, chest, and thoracic limbs. Tremors were particularly apparent during eating, after exercise, or in a thoracic limb that was offloaded by the horse and rested. Fine tremors of the eyeballs were evident during ophthalmoscopic examinations but otherwise difficult to appreciate.[11] Other early clinical signs included a basewide gait, truncal sway both at rest and during walking, and rapid, stumbling, corrective foot placements. Blindfolding or elevation of the chin exaggerated these signs, a finding consistent with bilateral vestibular dysfunction. Affected horses were hyperresponsive to the withers slap used to test the laryngeal adductor ("slap") reflex. With progression of PRS, signs of general proprioceptive ataxia—including delayed limb protraction, interference between pairs of limbs, and circumduction of pelvic limbs on the outside of circles—became apparent. The gait also became jerky and more interrupted, but hypermetria, a characteristic cerebellar sign, was not observed in these mildly and moderately affected horses. The authors speculated that signs reported in severely affected livestock—namely, limb stiffness and unpredictable, inconsistent limb movements, hypermetria, head tremor, falling, and generalized tetanic convulsions[6,13]—are consistent with cerebellar involvement.[11] The authors therefore proposed a time- and dose-related progression through the three "qualities" of ataxia (vestibular, general proprioceptive, then cerebellar) during the course of PRS in an individual animal.[11] Of note was that normal muscle strength was preserved in affected animals, and they remained bright and alert.

In all cases, signs are exacerbated by handling. Attempts to force affected animals through gates or onto trailers may precipitate recumbency. While down, the animals exhibit rigid extension of the legs with occasional flailing, opisthotonos, and tonic-clonic convulsions. Frothy exudate from the mouth has also been described. After approximately 10 to 20 minutes, the animal recovers if left undisturbed, stands, and walks back to the herd or flock.

Recovery occurs over days to weeks; longer recoveries are typical of severely affected animals. Most animals are normal within a week of removal from toxic pasture. Treatment is not usually necessary, but it is important not to disturb or frighten animals with tremors and to handle them as infrequently and carefully as possible. If practicable, they should be kept on level ground in an area free of potential hazards, especially water hazards. If handling is necessary, hyperresponsiveness can be controlled by sedation. Tremors can be suppressed temporarily by diazepam (0.02 to 0.1 mg/kg IV for horses or 0.1 to 0.2 mg/kg IV for small ruminants).

PASPALUM STAGGERS. *Claviceps paspali* ergots parasitize *Paspalum* spp. grasses and produce paspalitrems, indole-diterpene tremorgens that cause staggers syndromes in livestock similar or identical to perennial ryegrass staggers described earlier. Susceptible grasses include dallisgrass *(Paspalum dilitatum)*, bahiagrass *(Paspalum notatum)*, water couchgrass *(Paspalum distichum)*, and knotgrass *(Paspalum paspaloides)*.[14-16] *Paspalum* staggers has been recognized in the United States, South Africa, Great Britain, Australia, and New Zealand.[14,17-19] Natural outbreaks occur most commonly in cattle, but *Paspalum* staggers has been reported in three foals and two adult horses grazing on dallisgrass in Australia,[20] and sporadic cases are observed regularly by the author in horses on bahiagrass pastures in Florida.

C. paspali first attacks the pistil of the grass flower and replaces the ovary with a sclerotium (ergot). The fungus secretes a sticky fluid, the "honeydew," which contains a large number of spores but little toxin. The fluid hardens into a mature sclerotium containing a high concentration of tremorgenic metabolites. Toxic stands of dallisgrass or other *Paspalum* grasses can be recognized by the presence of numerous small, reddish brown or black sclerotia measuring 3 to 5 mm in diameter on the seed head of the plant. The most abundant indole-diterpene metabolite in sclerotia is paspalitrem B, but paspalitrems A and C, paspaline, and paxilline are also produced.[15,21] *C. paspali* sclerotia also produce ergot alkaloids, albeit at low concentrations (on the order of 10 µg/kg of dry weight, in comparison with 150 mg/kg for paspalitrem B in one report[22]). Particular animals apparently develop a craving for the infested seed heads and graze them selectively. Toxin production is greatest when there is a wet period after formation of the seed heads. The toxin remains active in cured hay. Mowing the toxic pastures and removing or burning the infested seed heads is effective for preventing further exposure to the tremorgen.

Clinical diagnosis is made by observation of clinical signs, visible detection of the toxic agent in the feed, or detection of indole-diterpenes by thin-layer chromatography. Animals recover spontaneously within days to several weeks after being removed from the pasture.

BERMUDAGRASS STAGGERS. Bermudagrass *(Cynodon dactylon)* occasionally becomes toxic for livestock.[19] Cattle are considered most susceptible, followed by sheep, goats, and horses. As is the case for *Paspalum* staggers, bermudagrass staggers results from ingestion of paspalitrems in grass parasitized by fungal ergots, in this case *Claviceps cynodontis*. *C. cynodontis* is closely related to *C. paspali*, and the chemical profiles of indole-diterpenoid and ergot alkaloids produced by the sclerotia of these two fungi are similar. The clinical and epidemiologic aspects of bermudagrass staggers and *Paspalum* staggers are likewise similar.[22]

Animals may develop clinical signs as early as 36 hours after consuming toxic forage. Experimentally poisoned goats have developed clinical signs 8 days after being fed 772 g/head/day of toxic hay.[23] The toxin survives drying, and hay that is cut from offending pastures may remain toxic for as long as 9 years.[24] Pastures that are toxic remain so for successive seasons unless the vegetation is burned off and the ground is tilled and reseeded. The clinical signs occur suddenly, usually simultaneously, in several animals in the herd. In some cases, most of the animals on a single pasture may be affected, whereas animals on an adjacent pasture remain normal. The mortality rate is low, and deaths usually result from self-inflicted trauma.

Affected animals recover 2 days to 2 months after removal from the affected pasture or hay. Management is as for PRS.

Tremorgenic Mycotoxicoses Associated With Saprophytic Fungi

Most tremorgenic mycotoxins are synthesized by common saprophytic fungi of the genera *Penicillium* and *Aspergillus* that elaborate mycotoxins onto improperly harvested or stored livestock feeds. Some *Penicillium* spp. can also act as opportunistic plant pathogens, most notably as a cause of ear rot in corn. Ingestion of moldy cornstalks is probably the most common source of fungus-related tremors in livestock. The fungi proliferate in the corn but do not produce tremorgens until the stalks touch the ground. After production at or near the soil surface, the toxins translocate in plants through root absorption.[25] Cases associated with *Aspergillus* molds (usually *Aspergillus clavatus*) have occurred worldwide, linked to feeding on sprouted grains and the by-products of beer production, both of which provide an environment for growth of the mold.[26,27] Clinical signs are indistinguishable from those of *Paspalum*, perennial ryegrass, and bermudagrass staggers.[16,25,28,29] Indole-diterpenoid tremorgens produced by *Penicillium* and *Aspergillus* spp. can be classified into four major groups: the aflatrem-paxilline group, the verruculogen-fumitremorgen group, the territrem group, and the tryptoquivaline group. Of these, the most important fungal tremorgens are aflatrem, penitrem A, fumitremorgen B, and verruculogen. In some cases, additional non–indole-diterpenoid mycotoxins elaborated by these fungi cause a wider spectrum of clinical signs. For example, *A. clavatus* caused a highly fatal mycotoxicosis of cattle in South Africa that was associated with widespread degeneration and necrosis of skeletal muscle and CNS motor neurons.[15]

Diagnosis is by demonstration of indole-diterpenoid tremorgens by thin-layer chromatography (sometimes in combination with a mouse tremorgen assay). Mycelial elements of *Penicillium* and *Aspergillus* molds may survive degradative conditions in the GI tract and can be identified and cultured from the feces of affected animals.

Corynetoxicoses (Annual Ryegrass Toxicity, Flood-Plain Staggers, Blown Grass Staggers)

Corynetoxicoses are severe, often fatal neurologic disorders of livestock in Australia and South Africa.[30] A related syndrome occurred in Oregon from the 1940s through the 1960s but apparently has not recurred since.[31,32] Corynetoxins are produced by plants of several genera—including *Lolium rigidum* (annual ryegrass), *Polypogon monspeliensis* (annual beard grass), and *Lachnagrostis filiformis* (blown grass)—that are colonized by a nematode (*Anguina* sp.) and a bacterium *(Rathayibacter toxicus)*.[33-35] Affected sheep and cattle with the same clinical syndrome in Oregon had been fed a fescue *(Festuca nigrescens)* infected with a grass seed nematode and a *Rathayibacter*-like organism.[31,32] Corynetoxin-producing *R. toxicus* is transported into host plants by nematode L2 larvae and ingested by sheep, cattle, and occasionally horses.[30] The colonized plant forms a hollow gall in response to larval invasion of the seed. Bacteria are thus carried into the galls, where they proliferate into a distinctive yellow to orange mass.[30] *R. toxicus* organisms produce a series of closely related corynetoxins that are glycolipids in the tunicaminyluracil class of antibiotics. Corynetoxins potently inhibit lipid-linked *N*-glycosylation of glycoprotein, and their toxicity in animals probably results from the depletion of essential *N*-glycosylated proteins. It takes up to 15 years after introduction of the nematode-bacterial complex to a pasture before clinically significant amounts of toxin are produced.[36] A method of evaluating toxic pastures has been developed; it is based both on enumeration of contaminated seedheads and on ELISA to quantify *R. toxicus*.[37]

Although the serum half-life of corynetoxins in livestock is only approximately 4 hours, repeated exposure leads to an accumulation of the toxin, and up to 12 weeks of continued ingestion may be necessary for the onset of clinical disease.[30] Also, the concentration of the toxin increases in the seedheads during the summer and is greatest as the plant dries and the seeds ripen. Outbreaks associated with the feeding of hay made from toxic pasture may occur at any time. Stock losses are highest in sheep, although cattle deaths can be substantial. Outbreaks in horses occur occasionally and generally involve only a few horses.[38,39] Clinical signs appear to reflect the cerebellar and thalamic lesions that are evident histologically.[39] All ages are affected, and morbidity and mortality rates are usually high. When an affected flock is driven, or when cattle are rounded up or otherwise stressed, some animals collapse in sternal or lateral recumbency. They often have muscle tremors, opisthotonos, head nodding, tetanic and clonic convulsions, limb extension, hypermetria, odontoprisis, nystagmus, and ptyalism. Animals may regain their footing after several minutes and stagger away with a stiff-legged, jumping, or swaying gait. These animals often wander aimlessly, exhibiting stupor and ataxia. In mildly and moderately affected animals, clinical signs usually resolve within a week of removal from affected pasture; however, relapses may occur in animals that appear to have recovered, and it may take several months for severely affected animals to recover. Treatment with magnesium sulfate solution (50 to 100 mg/kg, IV in horses, SC in ruminants, repeated as needed) is reportedly effective in some cases.[38,40] The most practical strategy for controlling annual ryegrass toxicity is to break the nematode's life cycle by killing the ryegrass for two or three growing seasons. Otherwise, pastures remain perpetually toxic. Integrated control measures that have been recommended for prevention of annual ryegrass toxicity include applying herbicides in the spring, seeding the pastures with legumes, burning the infected pasture grasses during early autumn, and applying ryegrass-selective herbicides in the summer months, combined with heavy winter grazing.

Pathologic changes associated with corynetoxin poisoning include widespread petechial hemorrhages and jaundice and friability of the liver. Histologically, CNS changes are surprisingly mild and nonspecific. Most lesions are cerebellar with proteinaceous fluid around vessels, especially in the meninges. There is diffuse vacuolation of hepatocytes and bile duct proliferation.

Kikuyu Grass Poisoning

A multiorgan disease characterized by peracute onset obtundation, ataxia, drooling of saliva, sham drinking, ruminal distention, and colic occurs in cattle and, to a much lesser extent, sheep and goats of New Zealand and Australia that are grazing on kikuyu grass *(Pennisetum clandestinum)*.[41] According to a review of nine reports involving 2719 cattle at risk, the morbidity rate was 23% and the case fatality rate was 70%.[41] The cause and pathogenesis are poorly understood.

Canarygrass Staggers (*Phalaris* Staggers)

Phalaris poisoning has been reported in Australia, New Zealand, South Africa, Norway, Argentina, and the United States, in association with the ingestion of *Phalaris* spp. grasses by sheep and cattle, most notably *Phalaris aquatica* (bulbous canarygrass or hardinggrass) and *Phalaris arundinacea* (reed canarygrass).[42] These outbreaks have been characterized by either sudden death due to peracute brain dysfunction (termed *polioencephalomalacia-like sudden death*) or myocardial dysfunction (termed *cardiac sudden death*).[43,44] Sheep are considered to be the most susceptible species, but cattle are also affected.[45] Only the cardiac sudden death syndrome has been reported in horses.[46,47] In the United States, outbreaks of canarygrass staggers have been reported in sheep and feedlot lambs in California *(P. aquatica)*,[48,49] as

VetBooks.ir

well as sheep and cows in Louisiana *(Phalaris caroliniana)*[50] and cows in West Virginia *(P. arundinacea)*.[45]

It has been suggested that phenylethylamines or derivatives of tyramine are involved in sudden death syndromes.[42,51] Staggers occurs in either an acute and reversible form or a chronic, irreversible, and typically lethal form. The latter, more common presentation usually occurs as outbreaks. Delayed or chronic *Phalaris* staggers is associated with tryptamine alkaloids produced by the plant.[42,51] These alkaloids structurally resemble serotonin and act as serotonergic receptor agonists, and accumulation within serotonergic tracts of the CNS eventually results in staggers signs. Rapid growth of canarygrass favors the formation and accumulation of toxin. Other factors that enhance the toxicity of canarygrass pasture include fog, humidity, or rain, followed by sunny, warm weather or sunshine on nitrogen-fertilized pastures.[52] Grazing animals are not usually affected until *Phalaris* spp. grasses constitute more than 50% of the diet.[53] The concentration of tryptamine alkaloids may be reduced by curing the forage as hay. In contrast, ensiling canarygrass does not reduce the amount of toxin.[54]

Staggers occurs after exposures lasting from 5 days to 33 weeks. Signs may be delayed for as long as 4 months after removal from the toxic grass.[50] Characteristic early clinical signs in sheep are constant anxious observation of handlers and continuous twitching ear movements. Signs progress to include hyperexcitability, exaggerated responses to auditory or tactile stimuli, fine muscular fasciculations (particularly of masseter muscles), licking of the lips, wrinkling of the facial muscles, repetitive chewing, inability to swallow, flaring of the nostrils, ptyalism, nystagmus, intention tremor of the head, ear and tail twitching, basewide stance, reduced menace response, and deficient pupillary reflexes.[55] The gait of affected sheep is described as stiff-legged, with both hindlimbs moving in unison at gaits above the trot ("bunny-hopping"). Affected sheep and cattle may buckle at the knees and assume sternal recumbency with the hindquarters elevated.[45,53] They then fall into lateral recumbency and flail wildly while attempting to stand. Poisoned cattle also become uncoordinated and may have distinctive stabbing movements of the tongue and inability to prehend forage.[56] They salivate profusely and drop feed from the mouth. Affected animals eventually die from starvation. There may be increased protein concentration (40 to 100 mg/dL) and nucleated cell count (up to 50 mononuclear cells/μL) in CSF of affected animals.[48] Animals may survive the initial signs but have neurologic signs that wax and wane for up to 10 months. For confirmation of a diagnosis, tryptamine alkaloids in suspect grasses can be quantified by ELISA.[57] Concentrations greater than 30 to 50 mg/100 g dry weight of forage are considered toxic for sheep.[52,55]

The pathologic lesions in the CNS of affected animals are characteristic and include focal, demarcated, blue-green or slate-gray discoloration in the brainstem and corticomedullary junction of the kidney; intracytoplasmic accumulations of yellow-brown pigment in the dorsal root ganglia, brainstem nuclei, and ventral horns of the gray matter of the spinal cord; neuronal loss; focal gliosis; and swelling of axonal sheaths in the ventromedial aspect of the spinal cord.[45,48,53] The pigment is thought to originate from deamination of the toxic alkylamines, but their presence is not strongly correlated with the development of neurologic deficits.[55]

Administration of cobalt to animals on toxic grass pastures is protective. In the presence of cobalt, rumen microflora inactivate toxic alkaloids. Weekly administration of 28 mg of cobalt to each animal was required experimentally to prevent clinical signs in exposed sheep.[58,59] Additional recommendations include removal of affected animals from the offending pasture, sedation with a phenothiazine tranquilizer, and administration of sodium pentobarbital or diazepam to convulsive animals. *Phalaris* plants may also contain potentially toxic concentrations of nitrate or cyanide. In any outbreak of suspected *Phalaris* toxicosis with sudden death, cyanide and nitrate poisonings should also be considered.[43]

Differential Diagnoses for Staggers Syndromes

Grass staggers is easily recognized by clinical signs. The specific plant involved must be identified through examination of the pasture forage. Tremorgenic diseases of adult cattle are common throughout most of the world. In addition to the syndromes discussed earlier, plants that may cause staggers syndromes include toxic storage syndromes, such as locoism induced by the swainsonine-containing plants *Swainsona luteola*, *Swainsona galegifolia*, *Astragalus* spp., and *Sida* spp. and the tremor syndrome induced by *Solanum dimidiatum*, *Solanum fastigiatum*, and *Solanum viarum*. Hypomagnesemia causes grass staggers and has been reported to cause cerebellar degeneration under some circumstances. The genetic storage diseases α- and β-mannosidosis, generalized glycogenosis, globoid cell leukodystrophy, and neuronal lipodystrophy may also be important in the differential diagnoses for ataxic animals with tremor and cerebellar signs.

Multiple Congenital Central Nervous System Defects

Multiple congenital defects that are suspected or documented to have a heritable (genetic) basis have been described in large animals. Many, but not all, of these disorders involve signs referable to cerebellar dysfunction; others may have signs referable to spinal cord dysfunction. These defects along with others are listed in Table 35.6.

Diseases Manifesting Principally With Spinal Cord or Peripheral Nerve Signs

Equine Herpesvirus Myeloencephalopathy

Robert J. MacKay

Equine herpesvirus 1 (EHV-1) is a member of the Alphaherpesvirinae subfamily of Herpesviridae. Along with another alphaherpesvirus, EHV-4, it is a common cause of upper respiratory disease in horses (see Chapter 31); of more importance is that because of a tendency to cause cell-associated viremia and vasculitis, EHV-1 infection is associated with late-term abortion, death of neonatal foals, and spinal cord disease. Outbreaks of the last of these syndromes, known as *equine herpesvirus myeloencephalopathy* (EHM), have become more frequent and severe since the 1990s. The U.S. Department of Agriculture has suggested that EHM is an emerging disease on the basis of the following criterion: "A disease [that] changes in severity [or] type of animal that can be infected, or [reflects] other changes in pathogen behavior."[1]

Clinical Signs Acute onset of ataxia and tetraparesis of variable severity most often characterizes the neurologic form of EHV-1.[2,3] Signs usually appear between 6 and 10 days after infection. The severity of clinical signs can range from subtle pelvic limb ataxia and weakness to complete recumbency without limb or head movement. Nonneurologic signs, including nasal and ocular discharge, limb edema, colic, ocular lesions, and anorexia, may also be observed.[2-7] Horses may be febrile at presentation, but most are normothermic. Fever, often biphasic in profile, is the most consistent premonitory sign of neurologic disease, although not all febrile horses develop myeloencephalopathy. Coughing and nasal discharge or abortion sometimes accompany the neurologic signs or may have occurred during the preceding 2 weeks.[5,8,9]

TABLE 35.6

Congenital Diseases of Large Animals With CNS Signs and Known Mode of Inheritance

Diseases With Predominant Intracranial Signs	Species and Breeds Affected	Clinical Signs/Ancillary Tests	Age at Onset	Mode of Inheritance	References
Ceroid lipofuscinosis	Ovine: South Hampshire, Swedish Landrace, Rambouillet Caprine: Nubian Cattle: Devon Horses: breeds not described	Progressive ataxia, blindness, depression, coma	Variable	Autosomal recessive	1-10
Citrullinemia	Cattle: Holstein	Progressive depression, bellowing, abnormal tongue and facial movements, convulsions, death Increased blood ammonia and citrulline concentrations	Newborns	Autosomal recessive	11-19
Exophthalmos and strabismus	Cattle: Jersey, Holstein, Brown Swiss, Shorthorn	Protrusion and crossing of the eyes	>6 mo	Unknown	20, 21
Cerebellar abiotrophy	Cattle: Holstein, Angus, Limousin	Intention tremors, hypermetria, basewide stance; may or may not progress	Variable	Suspected autosomal recessive	22-26
Bovine familial convulsions and ataxia	Cattle: Angus, Charolais, Polled Hereford, Angus Cross	Stillbirth/abortion with occasional dorsiflexion of the spine Intermittent cerebellar signs and convulsions	Variable, may improve with age	Autosomal dominant with incomplete penetrance	27-33
Cerebellar abiotrophy/ hypoplasia	Horses: Arabians, Arabian cross	Head tremor, ataxia, hypermetria	>2 mo	Autosomal recessive	34-39
Familial ataxia	Cattle: Hereford	Ataxia, abnormal head posture, pupillary dilatation	Newborns	Unknown	40
Micrognathia/cerebellar hypoplasia	Cattle: Angus	Stillbirth, brachygnathia, cerebellar hypoplasia	Stillborn	Suspected autosomal recessive	41
Alpha mannosidosis	Cattle: Angus, Murray Grey, Simmental, Galloway, Holstein	Stunted growth, ataxia, head tremor, hypermetria	1 wk to 15 mo	Autosomal recessive	42-49
Beta mannosidosis	Cattle: Salers Goats: Anglo-Nubian	Recumbency, deafness, narrow palpebral fissures, intentional head tremor, rotatory head movements, ocular defects, joint abnormalities, domed skull	Newborns	Autosomal recessive	50-71
Generalized glycogenolysis (beta-galactosidase deficiency, GM1 gangliosidosis)	Sheep: multiple breeds Cattle: Holsteins	Lethargy, anorexia; head carried low and extended; blind, collapse when head moved	>1 mo	Suspected autosomal recessive	72-83
Bovine generalized glycogenosis (type II glycogenosis, Pompe disease)	Cattle: Shorthorn, Brahman	Weakness, tremors, ataxia, right-sided heart failure	2-3 mo	Autosomal recessive	84-93
Globoid cell leukodystrophy (Krabbe disease)	Sheep: Polled Dorset	Depression, head tremor, ataxia, hyperesthesia	>4 mo	Unknown	94, 95
Neuronal lipodystrophy	Cattle: Angus, Beefmaster Sheep: Breeds not described	Depression, blindness, circling, seizures, coma	>10 mo	Unknown	96-98
Shaker calf syndrome	Cattle: Horned Hereford	Recumbency, hypermetria, hypertonia, hyperesthesia, muscle tremors	Newborns	Unknown	99

TABLE 35.6

Congenital Diseases of Large Animals With CNS Signs and Known Mode of Inheritance—cont'd

Diseases With Predominant Intracranial Signs	Species and Breeds Affected	Clinical Signs/Ancillary Tests	Age at Onset	Mode of Inheritance	References
Maple syrup urine disease	Cattle: Hereford, Polled Shorthorn	Viscous, dark, malodorous urine; fever, depression, opisthotonos, myoclonus, convulsions; spongiform changes in brain	Newborns	Autosomal recessive	100-116
Hereditary neuraxial edema	Cattle: Polled and Horned Herefords, Hereford × Friesian	Inability to rise; hyperesthesia, myoclonus, extensor rigidity, and apnea/dyspnea when stimulated	Newborns (may be stillborn)	Suspected autosomal recessive	117-125
Epilepsy	Cattle, horses	See text			
Narcolepsy/cataplexy	Horses, cattle, sheep	See text			
Diseases With Predominant Spinal/Motor Nerve/Muscle Signs					
Inherited myoclonus	Horses: Peruvian Paso	Myoclonus in response to stimuli, bunny-hopping gait; may not be able to stand without assistance	Newborns	Unknown; deficiency of receptors for the inhibitory neurotransmitter GABA	126
Congenital encephalomyelopathy	Horses: Quarter Horse	Inability to stand; when assisted to stand, hindlimb tremors cause the hindlimbs to bounce off the ground; increased patellar reflexes	Present at birth (i.e., newborn)	Unknown	127
Systemic neuraxonal dystrophy	Sheep: Suffolk	Progressive hindlimb ataxia leading to recumbency	>1 mo	Suspected autosomal recessive	128-129
Weaver syndrome (bovine progressive degenerative myeloencephalopathy)	Cattle: Brown Swiss, Angler	Progressive paraparesis, hindlimb ataxia with proprioceptive deficits, muscle tremors, recumbency	>5 mo	Autosomal recessive	130-146
Progressive spinal myelinopathy	Cattle: Murray Grey	Inability to stand; progressive hindlimb hypertonia and proprioceptive deficits	Newborns	Autosomal recessive	147-148
Bovine spinal muscular atrophy	Cattle: Brown Swiss, Red Swiss, Braunvieh, Holstein	Progressive muscle atrophy leading to recumbency	>2 wk	Autosomal recessive	149-157
Spinal dysmyelination	Cattle: Braunvieh, Braunvieh Cross	Inability to stand, generalized tremors, muscle atrophy	Newborns	Autosomal recessive	158-160
Neuropathy/myopathy/glomerulopathy	Cattle: Gelbvieh	Progressive hindlimb ataxia and paraparesis, muscle atrophy, reduced anal tone; proteinuria	Few weeks to 1 yr	Unknown	161-162
Progressive ataxia	Cattle: Charolais, Charolais Cross	Progressive paraparesis and hindlimb ataxia, proprioceptive deficits; muscle/tail tremors on rising	>6 mo	Suspected autosomal recessive	163-172
Spastic paresis (Elso heel)	Cattle: multiple breeds	Intermittent extensor spasticity and hypertonia of one or both hindlimbs; hyperextension of hock during weight bearing	>3 wk	Unknown	173-195
Inherited periodic spasticity (crampy syndrome, barn cramps, Krampfigkeit)	Cattle: dairy breeds	Intermittent muscular spasms of hip and upper hindlimb muscles, simultaneous kyphosis	>3 yr	Suspected autosomal dominant with incomplete penetrance	196-200
Hereditary lethal spasms (Doddler syndrome)	Cattle: Jersey	Inability to stand, head and neck spasms when stimulated, convulsions, death	Newborns	Suspected autosomal recessive	201-202
Congenital abnormalities of the vertebrae and/or spinal cord	Multiple species	See text			

CNS, Central nervous system; *GABA*, gamma-aminobutyric acid.

VetBooks.ir

The neurologic signs reflect injury to the white and gray matter of the spinal cord and include limb and truncal ataxia and paresis, bladder distention, urinary incontinence, weakness of the tail and anus, and reduced perineal sensation. Affected horses may exhibit either penile paresis or persistent erection (priapism) during the first several days of clinical signs. Pelvic limbs are more severely affected than thoracic limbs, and signs are usually symmetric. In mild and moderately severe EHM, bladder distention is often present, with spastic detrusor tone and without urethral relaxation (dyssynergia). Bladder atony and incontinence also occur, particularly in recumbent horses, and the associated dribbling of urine leads to secondary perineal scalding. Bladder rupture has occurred in such horses. Anal sphincter and caudal rectal tone may also be reduced, with consequent obstipation and gaping of the anus.

Signs of brain dysfunction such as seizures, blindness, and cranial nerve dysfunction occur in some severe cases of EHM.[10,11] Ocular lesions such as mydriasis, hypopyon, uveitis, and optic neuritis may also be present. The occurrence of multifocal chorioretinopathy, visible several weeks after onset of neurologic signs as foci of depigmentation, appears to be a particularly sensitive indicator of previous EHV-1 viremia.[12]

The clinical signs typically stabilize within 48 hours, and in most instances recumbency, if it occurs, begins during this period. Some horses continue to deteriorate and eventually die or are euthanized. In survivors, improvement begins within the first 5 to 7 days and may continue for weeks or even months. Many horses make a full clinical recovery; however, an unknown proportion still have residual signs of limb weakness or ataxia. A horse that does not become recumbent during the first 2 days has a much better prognosis for survival.

Diagnosis EHM can be diagnosed tentatively on the basis of characteristic neurologic signs, history, and supporting findings on physical examination. A CSF analysis that shows xanthochromic fluid with high protein concentration and normal or slightly high nucleated cell count (albuminocytologic dissociation) is typical and almost pathognomonic for EHM,[10,13] although in occasional cases, protein concentration is normal, mononuclear pleocytosis is present, or both occur.

Conventional, nested, or quantitative PCR amplification of EHV-1–specific gene sequences (usually glycoprotein B) in nasal swabs and EDTA-anticoagulated blood is the diagnostic technique of choice for horses with suspected EHM.[13] Both nasal swab and blood samples should be submitted at the acute stage of disease; nasal swab samples alone are sufficient to monitor for release from quarantine in some jurisdictions. Nasal swabs are more likely to collect virus than are nasopharyngeal swabs.[14] Swabs for this purpose should be approximately 6 inches long with a synthetic shaft. After collection, the swab should be placed in viral transport medium and sent to the diagnostic laboratory. If transport media are not available, the swab can be broken into a sterile tube and transported. Positive samples can be analyzed separately or simultaneously for a single-nucleotide variant in the viral DNA polymerase gene, DNA_{pol} D_{572}, which defines the best known and most important neuropathogenic strain of EHV-1. Real-time PCR provides quantification of viral DNA load and allows additional interpretation of the relevance of positive results.[13] These molecular diagnostic tests confirm active EHV-1 infection (and viremia when the blood test result is positive) but do not confirm the diagnosis of EHM specifically.

Additional aliquots of nasal swab and anticoagulated blood samples should also be submitted for traditional virus isolation in tissue culture. Virus isolation is important to allow full characterization of outbreak viruses, including susceptibility to candidate antiviral drugs.[15]

A fourfold or greater increase between acute and convalescent serum virus-neutralizing or complement-fixation (CF) antibody titers in samples taken 7 to 21 days apart is presumptive evidence of EHV-1 infection.[13] These tests are of limited value, however, because they do not distinguish between EHV-1 and EHV-4 responses, and results are delayed several weeks. An ELISA that distinguishes between infections with these two viruses is now available (SVANOVIR EHV1/EHV4-Ab, Svanova Biotech, Uppsala, Sweden) and is the serologic diagnostic of choice. A practical approach to an outbreak that may involve many horses is to submit serum from both clinical and in-contact/cohoused horses for serologic study and samples for PCR only from horses with clinical signs of fever or EHM. Such an approach provides additional support for the diagnosis and defines the extent of exposure to the virus during the outbreak.

Pathophysiology After initial colonization of the epithelia of the upper respiratory tract, EHV-1 spreads to and amplifies in regional lymph nodes before circulating in the blood within leukocytes. The magnitude and duration of the leukocyte-associated viremia are positively related to the risk for EHM.[13,16] Virus is presumed to enter endothelial cells of small arterioles of the CNS after binding to its surface class I major histocompatibility complex receptor. Endothelial infection incites destructive innate and specific immune inflammatory responses, which in turn initiate coagulation and widespread arterial microthrombosis and hemorrhage. Viral replication within neurons has not been demonstrated in EHM; rather, neuronal injury is secondary to ischemia that, in turn, is secondary to vasculitis and thrombosis.

Epidemiology Herpesvirus infection is enzootic in the horse population. Infection usually occurs through the respiratory epithelium when the animal comes in contact with the virus in aerosolized droplets or via fomites contaminated with fluids from an abortion or in ocular, nasal, or other respiratory tract secretions.[3,10] Foals probably become infected with virus shed from their dams during recrudescence of latent infections.[13] Most horses in the United States first become infected before 1 year of age and remain infected with latent virus in the trigeminal ganglia or in lymphoid tissues around the head.[13,15] Surveys of necropsies of adult horses indicate that more than 50% of normal horses are latently infected by EHV-1 in one or both of these sites.[13]

EHM is rare, but cases have been reported worldwide. Outbreaks occur more commonly in Europe and the United States than in Australia and New Zealand.[13] Viral polymorphism undoubtedly accounts for differences in neurovirulence. Viruses with one allele of a single-nucleotide polymorphism in the viral DNA polymerase gene, D_{752},[17] were found to be 162 times more likely to cause EHM than were viruses with the alternative allele, N_{752}.[18] The mechanism for enhanced neuropathogenicity of D_{752} is related partly the fact that viremia in infected horses is of higher order than that in horses infected with N_{752}, but it is not due to greater neurotropism. It is common for horses to be latently infected with both variants (D_{752} and N_{752}), and there is no evidence that horses latently infected with the neuropathogenic strain pose a higher risk of being the source of future EHM outbreaks.[13] Polymorphism elsewhere in the genome probably also modulates neurovirulence.[9] During outbreaks, the virus appears to be spread readily, and both morbidity and mortality rates can be high.

Horses of any age, gender, and breed are susceptible. In some studies females in general, or mature pregnant or lactating mares, are most often affected.[7,16,19] The principal risk factor for development of EHM is fever, especially the second peak of a biphasic fever.[6] The onset of neurologic signs often follows closely the decline from peak temperature. Additional purported risk factors in at least some outbreaks were older age,[6,7] cooler seasons (all but summer), introduction of horses to a herd,[7,8]

and inconsistent outbreak-specific breed susceptibilities.[7,8,13] Foals are rarely affected. Mules and donkeys are infected and shed virus but in the United States apparently do not develop EHM.[20] In contrast, EHM is relatively common and highly fatal in donkeys and mules in Ethiopia.[21] Frequent (up to four times annually[6,19]) and recent[19] vaccination against EHV-1 have been reported as independent risk factors. Stress-associated recrudescence of latent infections and subsequent shedding without clinical signs has been difficult to confirm experimentally but undoubtedly is important in the initiation of some outbreaks, especially those occurring after long-distance transportation or in closed herds. Experimentally infected horses may nasally shed virus for 3 weeks or longer after infection; however, viral shedding was not found after 9 days after onset of clinical signs in 20 horses with EHM.[22]

Primary attack rates, as judged by occurrence of fever (usually defined as rectal temperature >40.6° C [101.5° F]) among at-risk horses, may be up to 90%; an average of 10% of these infected horses develop EHM, and mortality rates for horses with EHM are between 20% and 80%; a typical rate is 50%.[3,13] There is no report of EHM caused by modified live virus vaccines currently approved for use in horses.

Necropsy Findings Gross and histologic lesions are not always limited to the CNS. Ocular lesions such as hypopyon, iritis, and chorioretinitis have been reported. Cystitis and scrotal edema may be present. Focal areas of hemorrhage may be found throughout the brain and spinal cord parenchyma and meninges. Vasculitis and thrombosis in the small arteries and veins of the spinal cord and brain result in ischemic lesions in the CNS.[23,24] Equine herpesvirus is infrequently cultured from the CNS, but PCR, in situ hybridization, and immunohistochemistry studies can be performed on CNS tissues obtained post mortem to confirm the presence of the virus.[13]

Treatment Acyclovir is guanosine analog with in vitro activity against EHV-1 that has been used successfully for treatment of herpes simplex encephalitis in humans. Adequate blood levels of acyclovir can be achieved in horses by oral dosing with valacyclovir (30 mg/kg q8h for 2 days and then 20 mg/kg q12h) or IV administration of acyclovir (10 mg/kg q12h) but not by oral acyclovir.[25] Although valacyclovir is safe and effective when used as preventive treatment, limited data suggest that it is not effective in horses with ataxia (i.e., EHM).[26,27] In view of the scant evidence available, however, valacyclovir treatment is still worthwhile when economic circumstances permit. Pharmacokinetic and pharmacodynamic data have been obtained for several other antiherpetic drugs, but their effectiveness for EHV treatment has not been investigated.[26]

Supportive care is the most important aspect of treatment for EHM. Measures include bladder decompression by sterile catheterization at least twice daily for horses with bladder distention or incontinence, evacuation of the rectum, administration of intravenous or oral fluids, and enteral or parenteral nutritional support. Recumbent horses must be appropriately padded, and decubital lesions must be prevented or treated. Horses that are recumbent but able to support their weight when lifted should be managed with an abdominal sling.

Administration of antiinflammatory drugs soon after the onset of neurologic signs may be beneficial.[28] NSAIDs (e.g., flunixin meglumine, 1.1 mg/kg IV q12-24h) should be used especially if the horse is febrile or if a painful condition is clinically suspected. Corticosteroids are often used because of presumed suppression of vasculitis, and although no objective data for their efficacy are available, there is a solid theoretical basis for their use.[13,28] Dexamethasone (0.05 to 0.1 mg/kg IV or IM) can be given every 12 to 24 hours for 3 to 5 days; the dosage is then tapered for 1 to 3 days. There are unquantifiable risks related to steroid-induced immunosuppression, including increased susceptibility to bacterial infection of the urinary tract and reactivation of latent virus. Because of uncertainties as to its benefits and risks, steroid treatment should be reserved for horses that are recumbent or in imminent danger of becoming so. DMSO (1 g/kg as a 10% solution in polyionic fluids by slow IV infusion) every 12 to 24 hours is often administered, although its efficacy also has not been documented.

Administration of antibiotics should be considered if the horse is recumbent or has urinary tract or respiratory tract involvement. Chronic cystitis, sometimes associated with bacteria resistant to common antimicrobials, is a common complication of urinary incontinence and bladder catheterization in horses with EHM. Management of such cases is discussed in Chapter 34.

The lesions of EHM are characterized by extensive microvascular thrombosis,[29] and so aspirin or heparin may be used in an effort to prevent worsening of spinal cord lesions (see next section).

Control and Prevention Vaccines currently used to prevent EHV-1 respiratory and abortion syndromes are not claimed to prevent EHM, and there is no reliable evidence that they do. A small study concluded that modified live virus vaccine provided modest, albeit significantly better, protection against experimentally induced EHM than did a killed low-antigen vaccine,[30] although the duration and robustness of such protection, if any, are not yet clear. Vaccination with inactivated "high-antigen" vaccines (i.e., those with a label claim for prevention of herpesvirus abortion), enhanced adjuvant vaccines, or modified live vaccine does have the important effect of reducing nasal shedding and thus potentially limiting the spread of infection during an outbreak. This rationale has also been used to justify booster vaccination of at-risk horses during an outbreak. Because of persistent evidence-based concerns about inducing or exacerbating EHM by excessive and recent vaccination, however, this practice remains controversial.[6,19]

Immunostimulants are sometimes administered to horses at risk for EHM on the basis of the theory that immune system activation will prevent viral reactivation or replication,[13] but supportive evidence is lacking. A history of nutritional supplementation with a product containing zinc protected horses exposed during an EHM outbreak from developing the disease according to a retrospective study of horses involved in the 2011 Ogden, Utah, outbreak.[19]

Valacyclovir and valganciclovir are prodrugs of the antiviral agents acyclovir and ganciclovir that have adequate bioavailability in horses when given orally.[25] Although these agents have in vitro activity against EHV-1, valacyclovir and ganciclovir were not effective at preventing EHM when either one was administered 4 to 6 days after viral inoculation (i.e., at the onset of the second temperature rise).[31] Ganciclovir, but not valacyclovir, reduced the severity of ataxia. In contrast, valacyclovir significantly reduced the severity of neurologic signs when begun either the day before challenge or at the onset of fever and continued for 1 to 2 weeks.[27] Therefore if these drugs are used for prevention, they should be begun no later than the onset of the initial fever.

Protocols for management of premises with EHM cases are now well established and tested. Comprehensive and regularly updated guidelines are available from the American Association of Equine Practitioners (AAEP; http://www.aaep.org/). In addition, the British Horserace Betting Levy Board publishes Codes of Practice on Equine Diseases (https://codes.hblb.org.uk/). In brief, the essentials of these protocols are (1) to isolate affected horses; (2) to monitor temperatures twice daily on all quarantined horses; (3) to submit diagnostic samples; and (4) to implement robust biosecurity procedures.[13] There is still uncertainty about the length of

quarantine required after the last occurrence of fever in any horse. AAEP guidelines currently call for 28 days. A workable but expensive alternative is to require 14 days after the last fever in any quarantined horse and then test all horses for nasal shedding by PCR on swabs taken on 2 to 4 successive days.[13] It is essential that all guidelines are followed meticulously; with each new fever, a 28-day quarantine must start over. Biosecurity procedures for EHM caused by neuropathogenic and nonneuropathogenic strains should be the same.[12] Additional guidelines are available for measures designed to prevent or reduce the likelihood of outbreaks and to lessen the effect of outbreaks that do occur.[13]

Equine Protozoal Myeloencephalitis

Robert J. MacKay

Equine protozoal myeloencephalitis (EPM) is the most common infectious neurologic disease of horses in the United States. The Apicomplexa protozoan *Sarcocystis neurona* is the usual cause, with sporadic cases caused by *Neospora hughesi*.[1,2] Species of *Sarcocystis* have an obligatory two-host life cycle.[3] *S. neurona* reproduces sexually in the small intestine of the definitive host, the opossum (*Didelphis virginiana* in North America and *Didelphis albiventris* in South America), and results in the passage of oocysts/sporocysts with feces. Asexual proliferation occurs in the intermediate host and culminates in the formation of sarcocysts in muscle. The nine-banded armadillo, striped skunk, raccoon, and domestic cat are natural intermediate hosts that cover the geographic range in which EPM occurs.[4-7] The primary and secondary hosts for *N. hughesi* are not known. The horse usually functions as an aberrant dead-end intermediate host for *S. neurona:* With the exception of a single foal with *S. neurona* muscle sarcocysts,[8] only precystic stages (i.e., merozoites and schizonts) have been found in the CNS of horses with EPM.

Pathogenesis

The pathophysiologic and immunologic mechanisms of *S. neurona* infection in horses are not completely understood. Horses ingest the infective sporocyst stage of *S. neurona* in food and water that have been contaminated by opossum feces. Congenital *S. neurona* infection is rare, but it is well established that *N. hughesi* may be transmitted transplacentally.[9] The mechanism of entry into the CNS of the horse is probably related to leukocyte-associated parasitemia. Once in the CNS, *S. neurona* can localize and replicate in any region, from cerebrum to spinal cord. True peripheral nerves and nerve roots are not infected; however, cranial nerves I and II (olfactory and optic), which are part of the CNS, can be affected. The location and extent of lesions determine the type and severity of clinical signs. Histologically, protozoa are usually associated with mixed inflammatory cellular responses and neuronal destruction. Schizonts (multicellular proliferative bodies) or free merozoites are common observed in the cytoplasm of neurons or mononuclear phagocytes and in capillary endothelial cells but rarely in other inflammatory or CNS cells.[3]

Both cellular and humoral immunity appear to be important for control of infection by *S. neurona*. Because of the intracellular location of the parasite, competent cell-mediated adaptive immune responses are considered essential for its elimination.

Epidemiology

EPM is a disease of horses that have spent time in North or South America. There are isolated reports of horses elsewhere in which EPM was diagnosed but that have no history of travel to the Americas, and the nature of infection in these cases remains unclear.[10,11] Horses of all breeds can be affected by EPM, and there is no sex bias. There are few reports of EPM in ponies or mules, which suggests that these equids may be less susceptible to EPM than are horses. Ages at onset of EPM have ranged from 2 months to at least 30 years, although it is rare in horses younger than 2 years old. One study identified an increased risk of EPM in horses aged 1 to 5 years and older than 13 years.[12] EPM typically occurs as individual cases, but clusters of cases have occasionally been reported.[13]

The reported prevalence of *S. neurona* infection as evidenced by *S. neurona* antibodies in horses in various locations throughout the United States varies from 0 to 89.2%.[14,15] Rates are generally high in areas with dense human populations, abundant water sources, and moderate rainfalls; seropositivity rates are low in arid, sparsely populated regions. The geographic variation in prevalence corresponds closely to the still-expanding range of the definitive host, the opossum. Despite the high rate of infection by *S. neurona*, the lifetime risk of a horse for developing EPM in these areas may be only approximately 1% (estimated from the mean 0.14% one-year incidence reported in the *National Animal Health Monitoring System 1998* survey[16]).

The factors that influence the relationship between infection with *S. neurona* and development of EPM are not well understood. *S. neurona* lacks the genetic diversity found among *Toxoplasma gondii* isolates, but it may nonetheless be capable of *T. gondii*–like clonal expansion of virulent strains,[17] although conclusive evidence for this has not yet been found in the setting of equine infections. Results of risk factor analysis for EPM vary by study, but factors likely to increase exposure to opossums, their environment, and their feces are consistently identified.[18-21] Other risk factors include previous diagnosis of EPM on the premises; primary use of the horse, with showhorses and racehorses at relatively high risk; recent transport; and recent adverse health events such as medical problems, parturition, and management changes. Collectively, these risk factors indicate that physiologic stress may play an important role in the onset of EPM.

Diagnosis

Antemortem diagnosis of EPM remains challenging. Criteria for diagnosis include finding clinical signs consistent with EPM, ruling out other diagnoses, positive response to treatment with anti-EPM drugs, and finding *S. neurona*–specific antibodies through immunodiagnostic testing. Proof of diagnosis post mortem is demonstration of protozoa in CNS lesions, often obtained with immunohistochemical staining or PCR. Even when the organism is not observed, the diagnosis is frequently made presumptively if characteristic inflammatory changes are found.[22,23]

Two types of immunodiagnostic tests are available for EPM: those that rely on threshold values of serum anti–*S. neurona* antibody (IFAT, ELISAs for antibody against various *S. neurona* surface antigens) and those that purport to detect specific antibody made within the CNS (Western blot, serum-to-CSF antibody ratios, *C* values).[24] Blood samples for serum tests are easily obtained, but the diagnostic assays are based on the yet-to-be validated principle that horses with EPM have distinctly higher serum antibody concentrations than do exposed/subclinically infected horses.[25] However, because seroprevalence of EPM is relatively low in comparison with that for *S. neurona*, a positive serum test result has a proportionally higher positive predictive value for EPM.[24] On the other hand, a negative test result is strong evidence that the horse does not have *S. neurona* infection and thus does not have EPM. The rationale for tests of the second type, each of which requires a clean CSF sample, is that identification of CNS-origin antibody is the only way to distinguish horses with EPM from exposed horses. The most popular tests of each type—namely, serum IFAT and ELISA for single-nucleotide surface antigens 2 and 4/3 (snSAG2,4/3)—have good (i.e., >80%) sensitivity

VetBooks.ir

and specificity for EPM among horses with solid postmortem diagnoses.[26,27] One drawback of the IFAT is that it is unable to differentiate between antibodies against *S. neurona* and those against *Sarcocystis fayeri* (a relatively nonpathogenic species).[28] In one study, the researchers used samples from necropsy-confirmed EPM-positive and EPM-negative cases to specifically compare results of IFAT and snSAG2,4/3 tests. Accuracy values for serum IFAT, serum snSAG2,4/3 ELISA, IFAT ratio, and snSAG2,4/3 ratio were 68%, 56%, 88%, and 97%, respectively.[23] Comparable tests for *N. hughesi* also are available commercially (*N. hughesi* IFAT and NhSAG1 ELISA) but have not been fully validated for EPM diagnosis. It is clear, on the basis of both flawed concepts and unsupportive clinical data, that neither CSF Western blot nor serum SAG1 ELISA is a reliable diagnostic test for EPM.[29-31] In contrast to the situation with Western blots, snSAG (and presumably IFAT) ratio test results are relatively robust in the presence of a small amount of contaminating blood; however, false-positive results do occur in cases of moderate or severe blood-brain barrier injury. For samples from horses with blood-brain barrier injury (as detected by high CSF albumin concentrations or high albumin quotient values[32]), additional total IgG testing is performed on the serum/CSF sample, and a *C* value is calculated.[33] CNS antibody production is indicated by *C* values greater than 1.

At the time it was last investigated, PCR testing of CSF for *S. neurona* DNA had high specificity but low sensitivity for the diagnosis of EPM.[34] False-negative findings are common because free parasitic DNA is destroyed by enzymes in the CSF and merozoites rarely enter the CSF. Testing by PCR of tissue samples is useful for postmortem diagnosis.

Ancillary procedures such as survey cervical radiographs, lameness examination, and serologic testing may be necessary to rule out competing differential diagnoses. In horses with signs of brain involvement, suggestive lesions may be seen with advanced imaging techniques.[35] Consistent abnormalities are not found in complete and differential WBC counts or in serum chemistry panels in horses with EPM. CSF values are abnormal in some horses with EPM. It has been reported that up to 35% of horses at a referral hospital have increased protein concentration (>65 mg/dL) or nucleated cell count (>6 cells/μL).[36] In the author's experience, in horses with mild clinical signs of EPM (i.e., those that typically are encountered in practice), a low percentage have any abnormality on routine CSF analysis. CK activity may be high in CSF, reflecting diffusion of the BB isoenzyme from damaged CNS gray matter.[37] Unfortunately, inadvertent inclusion of a small plug of epidural fat or dura during CSF collection can dramatically elevate CK activity, thus reducing the specificity of the test.

Clinical Signs Protozoa may infect any part of the CNS and thus produce almost any possible neurologic sign. The disease usually begins insidiously but also may present acutely and be severe at onset. Signs of spinal cord involvement are much more common than are signs of brain disease. Horses with EPM involving the spinal cord have asymmetric (usual) or symmetric truncal and limb weakness and ataxia. If all lesions are behind the second thoracic spinal cord segment (T2), only the pelvic limbs are affected. If a lesion (or lesions) is located in front of T3, all four limbs may be affected. In the rare instance when the spinal cord behind the second sacral spinal cord segment (S2) is involved, the animal exhibits signs of cauda equina syndrome, which may include degrees of rectal, anal, bladder, and penile paralysis and reduced sensation of the skin of the tail and perineum. When gray matter of the ventral horn of the spinal cord is damaged for more than 1 to 2 weeks, obvious focal muscle atrophy and electromyographic changes in denervated muscle may develop. Common locations for atrophy in horses with EPM are the gluteal, biceps femoris, infraspinatus/supraspinatus, and serratus ventralis muscles. Lesions in the spinal cord may also result in demarcated areas of spontaneous sweating or loss of reflexes and cutaneous sensation.

Neurologic signs noticed at walking or during neurologic examination include any to all of the following: asymmetric stride length, toe dragging, circumduction of pelvic limbs, and hypometria (also described as floating or marching) of thoracic limbs. Other signs are noted only when the horse is ridden: difficulty maintaining a specific lead, cross-cantering or cross-galloping, and difficulty negotiating turns. Some signs that are usually attributed to primary musculoskeletal disease, such as back soreness or upward fixation of one or both patellas, can be caused by weak or asymmetric use of muscle groups in horses with EPM that are in training.

A relatively common manifestation of brain disease in horses with EPM is a brainstem syndrome with signs of obtundation and asymmetric vestibular (VIII) nerve dysfunction (Fig. 35.18). There may also be facial paralysis (VII); dysphagia (X); tongue paralysis (XII); laryngeal paralysis (X); strabismus (III, IV, and V); failure of globe retraction (VI); and deviation of the mandible (VII). With involvement of the rostral brainstem or cerebrum, EPM may manifest as seizures, visual deficit/abnormal menace response, reduced perception of touch on the opposite side of the face, or behavioral abnormality.

Without treatment, EPM usually progresses. Progression to recumbency occurs over hours to years and may occur steadily or in a stop-start manner.

Treatment Since 2000, the folate inhibitor combination sulfadiazine/pyrimethamine, the triazine coccidiostats ponazuril and diclazuril, and the nitrothiazole nitazoxanide have all been licensed by the U.S. Food and Drug Administration (FDA) for the treatment of EPM, and commercial products have been launched.[9,38] Nitazoxanide was withdrawn in 2009. Multicenter studies of sulfadiazine/pyrimethamine, ponazuril, nitazoxanide, and diclazuril reported improvement rates of 57.1% to 61.5%.[38]

Label directions for dose and duration of FDA-approved drugs should be followed. Ponazuril in a loading dose of 15 mg/kg (three times the normal dose) reaches steady-state concentrations several days earlier than is the case with conventional dosing.[39] Many dosage permutations and combinations of these products and pharmacologically similar products are administered in clinical practice, although efficacies have not been investigated. A sodium salt formulation of diclazuril has been shown to have good oral bioavailability and may have potential as a feed additive.[40] Some veterinarians administer IV a compounded form of diclazuril, although there are no published data for its safety or efficacy. Of interest is that steady-state concentrations of diclazuril in plasma and CSF were not different for the low-dose rate (0.5 mg/kg) and the FDA-approved dose rate (1 mg/kg).[41] These data support the use of the 0.5-mg/kg dose as treatment or preventive. Experiments have demonstrated enhancement of the antiprotozoal effect of combinations of pyrimethamine with either diclazuril or ponazuril in treatment of other coccidian infections,[42] and so ponazuril or diclazuril is sometimes combined with sulfadiazine/pyrimethamine. Such treatments constitute unapproved or off-label use, albeit of FDA-approved products.

Another drug used commonly as an anticoccidial in calves, decoquinate, was evaluated in horses with presumptive EPM, at dosage of 0.5 mg/kg PO daily for 10 days, in combination with the immunomodulator levamisole, 1 mg/kg PO daily.[43] Success rates of 93.6% and 89.3% were reported on the basis of improved neurologic gait score at the end of treatment and reversion of serum snSAG1,5,6 titers, respectively. Decoquinate was also shown to have potent inhibitory and killing activity in vitro against two different isolates of *S. neurona*.[44] If this

drug combination continues to perform well in wider use, it will obviously become an important treatment option.

Horses may exhibit relapse soon after the initial course of treatment is discontinued or up to several years after improvement or apparent resolution of signs. Although no data are available to guide treatment of relapses, it is common practice to change or add antiprotozoal drugs. In order to prevent future relapses, antiprotozoal therapy can be provided prophylactically. Protocols include FDA-approved formulations of sulfadiazine/pyrimethamine, 2 days/week at the standard dosage, or diclazuril daily at 0.5 mg/kg. A similar rationale can be used to treat horses only around the time of stressful events that may predispose to relapses.

Of the available drugs, only pyrimethamine has significant adverse side effects. Toxicity reflects both direct effects of the drug and its inhibition of mammalian dihydrofolate reductase, which induces folate deficiency. Signs include convulsions and recumbency, reproductive and neonatal disorders, oral ulcers, and bone marrow suppression, including (in decreasing frequency) leukopenia, neutropenia, anemia, and thrombocytopenia.[45-47] Horses treated with sulfadiazine/pyrimethamine should be fed good-quality green forage (e.g., alfalfa hay or pasture), which is likely to be rich in folate. Supplementation with folic acid during treatment confers no advantage, and some evidence from other species indicates that this practice could increase the possibility of toxicity.[46] Most cases of bone marrow suppression resolve if treatment is suspended for 1 to 2 weeks. Folic acid (100 mg daily) is appropriate for treatment of folate deficiency once pyrimethamine is discontinued. If signs are severe, treatment with folinic acid (100 mg IV or PO daily for 5 days) is indicated.

In mild acute cases of EPM (grade 1), additional therapy is unnecessary. In horses with moderate or severe signs, NSAID and antioxidant treatment is usually provided for the first 1 to 2 weeks. If the horse has grade 3 EPM or worse, a corticosteroid may be added. Vitamin E is often given throughout the period of antiprotozoal treatment for additional antioxidant effect. Oral administration of vitamin E has been shown to result in increased concentrations of α-tocopherol in serum and CSF.[48] As a relatively crude way to address putative immunodeficiency and "boost" cellular immunity, immune modulators are sometimes given to horses with EPM.

Prognosis On the basis of drug efficacy studies and clinical experience, it is reasonable to expect that approximately 60% of moderately or severely affected horses will improve at least one grade after treatment. Only 10% to 20% of such horses completely recover, and 10% to 20% of successfully treated horses suffer at least one relapse. The outlook for mildly affected horses (grade 1) is considerably better, particularly if treatment is begun promptly. Although no data for the latter, more common class of treated horse have been published, at least 80% of such cases can be expected to improve, and at least 50% recover completely, with low possibility of recurrence.

Prevention An inactivated vaccine was marketed under conditional approval by the U.S. Department of Agriculture. The conditional license lapsed in March 2008, and the vaccine is no longer available. When tested in horses dosed with *S. neurona* and stressed by transportation, vaccination did not prevent development of clinical neurologic signs.[49]

Prevention of *S. neurona* infection may be possible by daily administration of a drug such as diclazuril or ponazuril.[50,51] The disadvantage of this approach is that normal immune responses to the organism may be prevented. An alternative approach is metaphylaxis, wherein intermittent doses of drug are given to allow an initial round of protozoal proliferation and normal immune responses to take place but prevent invasion of the CNS. Ponazuril given at 20 mg/kg every 7 days but not every 14 days significantly reduced *S. neurona* antibody in the CSF of *S. neurona*–challenged horses, which suggests the potential utility of such an approach.[52]

Common-sense measures can be instituted to prevent contamination of feed with *S. neurona* sporocysts. Opossums can be trapped and removed or kept away by free-ranging dogs. Spilled grain, fallen fruit, and animal or bird feed should be removed, and horse food sources should be monitored and secured. The utility of controlling intermediate hosts in an effort to reduce environmental sporocyst load is doubtful; however, if populations of host animals on a problem premise are large, then such animals should be trapped and removed. Products useful for cleaning of areas potentially contaminated with sporocysts have been described.[53]

Cervical Stenotic Myelopathy

Robert J. MacKay

The term *wobbler* (also *wobbler syndrome*) describes horses with ataxia caused by any of a group of developmental anomalies and degenerative conditions involving the cervical vertebrae.[1] Several other descriptions are used in wobbler terminology. The most important of these are *cervical vertebral malformation and malarticulation*, *cervical stenotic myelopathy* (CSM), and the inelegant but descriptive *cervical vertebral stenotic myelopathy*. CSM is the most common noninfectious neurologic disease of horses. The prevalence of CSM among 1289 Thoroughbred horses born on four breeding operations was 1.3%.[2]

Two overlapping CSM syndromes are recognized, differing greatly in developmental histories. *Type I* is characterized by focal or multifocal stenosis of the vertebral canal, principally between C1 and C6, that is worse on flexion (*dynamic* stenosis). Affected horses are typically younger than 2 years of age. In *type II*, bony and soft tissue impingement into the vertebral canal results from remodeling of the articular process joints of the caudal cervical vertebrae (usually C5 to T1) and stenosis of the cranial vertebral orifice. This impingement is present in all positions of the neck (*static* stenosis) but may also have

a dynamic component in that it worsens during hyperextension. Horses with static stenosis are usually young to middle-aged at the onset of wobbler signs.

Both syndromes probably involve some combination of aberrations in cartilage and bone development and external trauma that may precede clinical ataxia by many months (perhaps even in utero in the case of type I CSM[1]).

Pathogenesis Type 1 CSM is another manifestation of the group of disorders of endochondral ossification (i.e., osteochondroses) that occur in young, growing horses and include physitis, contracted tendons, osteochondritis dissecans, subchondral bone cysts, and malformation of the cuboidal bones of the carpus and tarsus.[3] Study of wobbler matings has revealed a propensity for rapid growth and superior performance among offspring but no clear evidence that CSM was genetically predetermined.[4] Of interest is that other developmental orthopedic diseases were overrepresented. A genetic predisposition to development of CSM clearly exists, but because CSM is probably genetically and environmentally multifactorial, pure genetic influences have been difficult to discern. Because rapid growth and large size appear to be risk factors for foal osteochondrosis,[5] studies have tentatively implicated high protein and caloric intake in the development of CSM.[1] Marginally low levels of trace minerals such as copper may come into play during rapid growth.

As a result of presumed genetic, physical, and dietary factors, osteochondrosis of the articular processes and metaphyseal growth plates occur early in affected foals. Genetic predisposition, rapid growth, maternal nutrition, calcium/phosphorus imbalance, low dietary levels of copper, and high dietary levels of zinc have all been implicated as developmental orthopedic diseases in foals, but their roles as risk factors for CSM are not clear.[6-9] Osteochondrosis of the vertebral physes of rapidly growing foals and weanlings results in multiple vertebral abnormalities, including flaring and enlargement of the caudal metaphyses and epiphyses of the vertebral bodies (equivalent to physitis of the limbs) and disparity of longitudinal growth of the vertebral bodies and dorsal laminae. These deformities cause focal stenosis of the vertebral canal and susceptibility to dynamic compression, respectively. In severe forms, the latter abnormality forces pairs of vertebrae into a permanently flexed, malarticulated, kyphotic position in which severe vertebral canal stenosis (both static and dynamic) is likely to occur. Flaring of the caudal metaphyseal-epiphyseal unit contributes to the narrow caudal orifice of the canal within an affected vertebra that is common in horses with CSM.

Osteochondrosis of the articular process joints may result in joint instability and later osteoarthritis and remodeling. Associated with degenerative joint disease of the articular process joints are gross enlargements due to osteophyte development. Affected articular processes may be relatively brittle and susceptible to trauma. Fractured articular processes are found quite frequently in diseased intervertebral joints at necropsy, although the fractures often cannot be seen in lateral radiographs. Pedicle fractures caused by trauma probably contribute to the massive asymmetric remodeling and enlargement of some of these joints. The canals within affected vertebrae may deform to a funnel shape with a small stenotic cranial orifice. There may also be hypertrophy and fibrosis of the synovial membrane and joint capsules of the articular process joints, and fibrovascular proliferation of the ligamentum flavum. These soft tissue structures or fluid-filled cysts associated with them may cause static stenosis and compression of the spinal cord and spinal nerves. Synovial and epidural cysts are prone to cause dramatic waxing and waning of clinical signs of spinal cord compression.[1]

Necropsy Findings Horses with CSM have one or more focal compression–type lesions in the cervical spinal cord.[10] The gross appearance of such lesions is of flattening and palpable softening of the cord. They are characterized histologically by swollen and disrupted axons and phagocytosis of myelin in white matter. Mild hemorrhages are sometimes observed in acute lesions. In chronically affected animals, the white matter demonstrates continued degeneration of neuronal fibers, proliferation of capillaries with prominent fibrous coats, and astrofibrosis. More severely affected horses also have neuronal necrosis, loss of cell bodies, and sometimes astrofibrosis in the gray matter. Massive focal lesions also occur with cavitating necrosis of white matter, particularly in lateral funiculi and occasionally in gray matter. Markedly asymmetric lesions are found in horses with prominently asymmetric clinical signs. Cranial to the focal lesions, neuronal fibers (axons and myelin) in ascending (proprioceptive) tracts exhibit secondary degeneration for variable distances, depending on the extent and age of the focal lesion. Caudal to the lesion, there is secondary fibers in descending (motor) tracts exhibit degeneration. This fiber degeneration results from the severing of neuronal fibers from their cell bodies by the focal lesion. It is most prominent in dorsolateral funiculi cranial to the lesion and in deep lateral and ventromedial funiculi caudal to the lesion.

According to one report, the most common histologic lesions in the articular processes of horses with CSM were osteochondrosis, osseous cyst–like structures, fibrous tissue replacement of trabecular bone, retained cartilage matrix spicules, bone cysts, and osteosclerosis.[11]

Clinical Signs Most animals with type I CSM are 6 to 18 months old, whereas those with type II CSM are typically 18 months to 5 years; however, there are many exceptions to these ranges, and both conditions can occur in a single animal. In four large breeding farms, the onset of type I CSM occurred in horses aged 202 to 986 days (average, 434 days), whereas type II CSM cases began at ages 1085 to 1299 days (average, 1188 days).[12] A study of 811 horses in the United States indicated that horses of the Thoroughbred, warmblood, and Tennessee Walking Horse breeds were significantly more likely to have CSM than were Quarter Horses; Standardbreds and Arabians were significantly less likely to have CSM.[13] Large warmblood breeds are notably affected by type II CSM.[14] Males are overrepresented.[14,15] Affected horses are often well grown, and some have a history or signs of other developmental orthopedic diseases such as osteochondritis dissecans or physitis.

Clinical signs of ataxia and paresis typically begin insidiously but may manifest suddenly. In the latter case, there is often a history of some minor fall or training incident that confuses the diagnosis (the fall could have been a precipitating cause or a result of the disease). After signs have been recognized, they typically progress for a period of months and then may stabilize or even regress. Spontaneous complete recovery is rare[1]; waxing and waning signs are frequent. In general, horses with CSM appear physically normal; however, enlarged intervertebral joints in the caudal cervical spine and severe flexion angulations, particularly at the C2-C3 and C3-C4 levels, are occasionally externally visible and palpable. Pain in response to pressure over the transverse processes and reluctance to flex the neck laterally are common findings in horses with type II CSM. In rare cases, impingement on caudal cervical spinal sensory nerves by enlarged intervertebral joints in type II CSM is sufficient to cause signs of thoracic limb lameness.

The principal neurologic signs are ataxia, weakness, and spasticity of the limbs. These signs reflect involvement of axons of upper motor neurons and general proprioceptive tracts in the white matter of the spinal cord underlying the site or sites of compression. Because of the more superficial location of general proprioceptive tracts from the pelvic limbs, the pelvic limbs are generally more affected than the thoracic limbs.[1] Dynamic stenosis is usually associated with symmetric signs,

VetBooks.ir

VetBooks.ir

whereas static stenosis may cause asymmetric signs. Severe arthrosis of the joints between the C6 and C7 levels or between the C7 and T1 levels occasionally causes signs more severe in the thoracic than in the pelvic limbs. The first sign noticed may be stumbling or clumsiness when the horse is moving into or out of a box stall. During exercise gallops, the rider may comment on a feeling of looseness or "losing the back end" around turns. Reluctance to change leads, cross-cantering or cross-galloping, or even falls after stumbling are other early signs in horses being ridden. With progression, affected horses may exhibit gait at the walk that is obviously stiff and uncoordinated; the prominent truncal sway; or "wobble," which explains the common name for CSM in horses. Because of pelvic limb extensor weakness, some wobblers catch their patellas or have persistent upward patella fixation.

In addition to the signs already mentioned, careful neurologic examination usually discloses some or all of the following:

- Abnormal pelvic movements during walking, best observed from behind, including excessive swiveling of an imaginary line on the median plane from between the tuber sacrale to the tailhead, excessive rotation of the pelvis around its long axis (visible as exaggerated amplitude of the rise and fall of the tuber coxae), and side-to-side truncal sway.
- Decreased resistance to lateral pressure exerted by pulling of the tail while the horse is walking.
- Apparent stiffness of the limbs during the swing phase of the stride in the thoracic or pelvic limbs. This may be associated with scuffing of the toes. When the horse's head is raised during walking, especially down a gentle slope, the stiff hypometric gait in the thoracic limbs may be exaggerated and is sometimes described colloquially as a "marching," "floating," or "tin-soldier" gait.
- Circumduction of each outside pelvic limb when the horse is walked in small circles.
- Interference between the thoracic limbs and pivoting around the pelvic limbs when the horse is moved in tight circles.
- Absence of the thoracolaryngeal ("slap") reflex.

In horses with markedly asymmetric compression (usually horses with asymmetric caudal intervertebral arthritis), there also may be marked asymmetry of stride length between the pelvic limbs.

Diagnosis Radiography of the cervical spine is the most important diagnostic tool. CSM can usually be diagnosed presumptively on plain laterolateral radiographs of the cervical spine from the finding of focal stenosis of the vertebral canal. The diagnosis is buttressed by additional demonstration of malformation, osteochondrosis dissecans, or arthrosis of the articular process joints; metaphyseal and epiphyseal flaring of the caudal aspect of vertebral bodies; relative elongation caudally of the dorsal laminae; or angulation between pairs of vertebrae. Oblique projections (usually lateral–50 degrees–ventral to laterodorsal) enable more accurate description of remodeling and other changes in the articular process joints and should be included as "standard of practice" in studies of horses with arthroses of the articular process joints.[16] Standardized measurements of articular process joints in oblique projections have been published, but poor repeatability and inaccuracy of these measurements have so far limited their usefulness.[17]

Intravertebral sagittal ratios for vertebrae behind C2 are calculated as the ratio of minimal sagittal diameter of the vertebral canal to maximal sagittal diameter of the cranial half of the vertebral body].[18] Both measurements are made perpendicular to the long axis of the vertebral canal. The denominator normalizes for variations in horse size and distance between object and image. Values for sagittal ratio of less than 0.52 from C4 to C6 and less than 0.54 at C7 are predictive of spinal cord compression with 89% sensitivity and specificity in the diagnosis of spinal cord compression, according to the original description.[18] In practice, cutoff values of 0.50 for C3-C6 and 0.52 for C7 are typically used.[1] Even horses with static stenosis, which may produce predominantly transverse compression from large joints, usually have at least one abnormal intravertebral sagittal ratio.[18]

Intervertebral sagittal ratio measurements are made between pairs of vertebrae in order to capture the effect of *fixed* flexion or extension angles on the diameter of the vertebral canal.[19] For a pair of vertebrae fixed in a kyphotic angle, the primary measurement (numerator) is the shortest distance between the caudal aspect of the dorsal lamina and the craniodorsal aspect of the vertebral body of the caudal-adjacent vertebra. For a fixed lordotic intervertebral joint, the corresponding measurement is the shortest distance between the caudodorsal aspect of the vertebral body and the most cranial point on the dorsal lamina of the caudal-adjacent vertebra. This measurement is then divided by the maximal sagittal diameter of the cranial half of the vertebral body of the cranial-adjacent vertebra to calculate the intervertebral sagittal ratio.[19] Normal values for means and lower bounds of the 95% confidence intervals for intravertebral and intervertebral sagittal ratio from C3 to C7 have been published.[1,19] Any value below these lower bounds is highly predictive of spinal cord compression.

A semiquantitative scoring system has been developed for use in foals 3 to 7 months of age to predict the risk of developing CSM.[20] Intravertebral and intervertebral sagittal diameters are recorded as described earlier, but vertebral body length (rather than sagittal diameter) is used as denominator to render these diameters as ratios.[20] Up to 10 points are assigned for decreased sagittal ratios and up to 5 points for each of the following signs of cervical vertebral malformation: dorsal flaring of the caudal vertebral body, caudal extension of the dorsal lamina, angulation between adjacent vertebral bodies, delayed ossification, and enlargement of articular processes. A score of 12 or higher (maximum, 35) is predictive of the development of CSM. This study revealed a strong tendency for the diameter of the vertebral canal to be greater in female foals than it was in males.[20] A multicomponent and detailed system of measurements in plain and myelographic studies devised by Japanese workers[21,22] accurately identifies foals and yearlings with CSM, but it has not been widely adopted in other countries.

When plain radiographs are abnormal, contrast myelography may be used to support the diagnosis, to establish the number and locations of sites involved and the severity of lesions in each, and to define the soft tissue contribution to spinal cord compression. These factors are especially important if surgical stabilization is contemplated because myelography may reveal a site of disease different from that suspected from plain films. With the horse under general anesthesia, 30 to 60 mL of iohexol (Omnipaque) or iopamidol (Isovue) radiocontrast solution are injected slowly into the atlantooccipital subarachnoid cistern after a similar volume of CSF has been removed. After injection has been completed, the head is raised for 5 minutes to facilitate caudal flow of dye, and then the head is lowered and radiographs are taken.

Laterolateral views of the cervical spine are taken in neutral, flexed, and extended positions. Spinal cord impingement due to dynamic compression is clearly defined in lateral views if the dorsal and ventral dye columns are completely extinguished at diametrically opposed sites in flexed views. For cases of incomplete compression of the dorsal column, several different diagnostic criteria have been used, none of which is completely satisfactory.[23,24] The traditional standard of complete compression of the ventral dye column and 50% or more compression of the dorsal column at diametrically opposed sites is sensitive but has poor specificity (i.e., it can yield many false-positive results). Other likely, more accurate alternatives are (1) comparison with reference ranges for minimal dural diameters and minimal flexed dural diameters for horses either above or below

VetBooks.ir

320 kg and (2) 30% or greater reduction in dural diameter in neutral views at the site of interest (usually intervertebral) in comparison with the midbody dural diameter in the caudal-adjacent vertebra. Sites affected in order of frequency are the C3-C4, C4-C5, and C5-C6 levels. Multiple sites may be affected in a single horse. The typical myelographic feature of *static* stenosis is focal spinal cord compression throughout the full range of vertebral motion. Any dynamic component at these caudal sites is relieved by flexion of the spine. The C6-C7 articulation is involved most frequently, and C5-C6 and C7-T1, to a lesser extent. At these sites, absolute narrowing of the minimal dural diameter or 30% reduction in comparison with the cranial-adjacent midbody measurement are the best diagnostic criteria.[1] In cases in which the plane of compression is transverse rather than dorsoventral, the dural diameter is usually abnormal; however, less objective criteria may have to be considered when measurements are normal. These include widening of the spinal cord diameter and fading of the dye columns over the area of lateral compression. Unfortunately, the diagnostic accuracy of plain radiographic or myelographic diagnoses of CSM has been unimpressive in comparison with that of postmortem spinal cord histopathologic study.[15]

Advanced imaging with CT[25] or MRI[26] have been described, but in mature horses, gantry dimensions usually limit their use to vertebrae in front of C4. The current rapid pace in development of MRI and CT equipment capable of evaluating the cervical spine of mature horses may in the near future substantially enhance the evaluation of CSM.

A technique has been described for endoscopic evaluation of the epidural and subarachnoid spaces of the cervical spinal cord, and this procedure was applied to a horse with CSM.[27,28] Although the technique may have application in selected cases, it has no place in the routine diagnosis of CSM.

Needle electromyography is most useful for investigation of muscles deprived of lower motor neuron activity, but it has little application to the diagnosis of CSM. The most promising electrodiagnostic testing application in this setting is transcranial magnetic stimulation.[29,30] Descending motor tracts are stimulated by current pulsation from a coil placed on the scalp. The onset latency of electromyographic responses in limb muscles is related to the integrity of spinal motor pathways. Latencies for horses with CSM were significantly longer than those for normal horses.[31]

CSF analysis generally yields normal results. At most, xanthochromia and elevated protein levels (70 to 130 mg/dL) are observed.

Treatment

MEDICAL. Corticosteroids and NSAIDs may provide transient improvement in the signs of CSM but do not treat the underlying problem.

Large degenerative intervertebral joints can be seen ultrasonographically, and corticosteroid (e.g., triamcinolone or methylprednisolone acetate) can be injected intraarticularly under ultrasound guidance, as has been described.[32] The theoretical indications for this procedure include relief from pain of arthritis and reduction in the soft tissue components of arthritic joints so as to provide at least temporary reversal of their impingement on the spinal cord and spinal nerves in the case of CSM and thoracic limb lameness, respectively. Although descriptive support for all of these possibilities was provided in an observational series,[33] no fully objective evidence has been provided for reversal of the signs of CSM, and it is inconceivable that permanent relief could be provided.

Some mildly affected horses can stabilize and even improve both radiographically and clinically if confined and placed on restricted but nutritionally complete feed.[1] There are reports of complete recoveries with this conservative approach and, in one report, 30% of conservatively treated mildly affected Thoroughbreds went on to race.[34] For affected horses younger than 1 year (and preferably younger than 6 months), a restrictive "paced-growth" diet can be tried in order to retard growth rate and prevent CSM in clinically normal foals with radiographic evidence of stenosis of the vertebral canal or to treat foals with mild clinical signs of CSM.[35] This diet reduces energy intake to 65% to 75% of National Research Council recommendations and increases levels of trace minerals. The essential elements are as follows: (1) immediate weaning if the foal is still suckling and (2) feeding free-choice grass hay (e.g., coastal Bermuda hay) plus 3.5 lb daily of a ration balancer that is high in micronutrients and low in calories (e.g., Buckeye's Gro 'N Win). At 1 year of age (based on birth date), the supplement is reduced over 1 week to 1 lb daily. Foals should be confined in a stall except for limited round-pen or equivalent turnout time, certainly without access to pasture. Good results are claimed for slightly affected foals, although breaking, training, and racing are set back several months and the foals look poor as yearlings.[35]

SURGICAL. Ventral interbody vertebral fusion is the principal procedure. In this surgery, pairs of vertebrae are fused in extension by implantation of a cylindrical stainless steel or titanium basket (Cloward Bagby basket) filled with autogenous cortical bone fragments.[36,37] Osseous union of the vertebral bodies and stabilization of the articular process joints occurs after this surgery, although nonunion is an occasional postoperative problem. A modification involves use of a threaded titanium implant that screws into a prepared circular, threaded kerf around an isthmus of preserved bone. By leaving the isthmus and its blood supply intact, it is expected that complete bony fusion occurs more quickly. A plate may be secured over the implant, but this does not prevent retrograde migration of the implant.

The surgery provides immediate relief from dynamic stenosis and may improve static stenosis over months by causing atrophy of arthritic intervertebral joints. In the latter case, intraarticular administration of corticosteroid may hasten atrophy of the enlarged joint. The surgery results in improvement in neurologic status in 44% to 90% of horses with dynamic compression and 12% to 62% of treated horses return to athletic function.[36-39] Overall, the success rate offered by most surgeons is approximately 60%, with normal myelographic columns expected by 2 months after surgery and complete osseous union by 1 year postoperatively. On average an improvement of 1 to 2 grades is expected.[38] Results of surgery for dynamic compression were significantly better than those for static compression in one published series.[40] Although there is a general impression that increasing time since onset of signs, higher neurologic grade, and multiple surgical sites are negative indicators for response to stabilization surgery, published results are not consistent with regard to any of these issues.[36] Even three-site surgeries can be successful, although neck mobility is diminished.[41] The use of a locking compression plate has been described with initial promising results.[36] If the results of locking-plate surgery continue to be positive, such procedures may become more widely available, obviating the need for the specialized equipment needed for implant surgery.[36]

Dorsal subtotal decompressive laminectomy[42] provides immediate relief for static compression but technically is extremely difficult and fraught with severe postoperative complications.

Neuroaxonal Dystrophy/Equine Degenerative Myeloencephalopathy

Robert J. MacKay

History and Epidemiology

Since the original description in 1976, neuroaxonal dystrophy (NAD)[1] and the related condition equine degenerative myeloencephalopathy (EDM)[2]

VetBooks.ir

have been reported throughout the world in horses and ponies of many different breeds and in other equids, including a donkey, Przewalski's Horses, and zebras.[3-6] The clinical signs of NAD and EDM are identical, and the associated CNS lesions are thought to be on a continuum wherein EDM lesions are more widely distributed than are those of NAD.[3,4] For the rest of this section, the condition is referred to as *NAD/EDM*.

Clinical signs usually begin within the first year of life: with only a few reported exceptions, all have begun by the age of 3 years.[7] A hereditary basis for the condition has been strongly suggested by the results of breeding studies or pedigree analyses in Morgan, Appaloosa, Quarter Horse, and Lusitano horses.[4,8,9] The mode of inheritance is suspected to be polygenic or autosomal dominant with variable penetrance.[4,5,8,10] A familial basis has also been suspected because of clustering of cases among the progeny of particular Standardbreds, Paso Finos, Norwegian Fjord horses, Arabians, Welsh ponies, and Haflingers.[6,11]

Overcrowding, pelleted feed, poor-quality hay, and lack of access to fresh green forage were thought to be risk factors on two affected premises.[12] In another study, significant risk factors were exposure to insecticides/repellents, exposure to wood preservatives such as creosote, and time spent on dirt lots.[7] Time spent on green pasture was a protective factor. In contrast, several clusters of cases in Oregon and California occurred in horses on pasture.[6,9] In the latter instance, the pasture was growing on volcanic soil that was deficient in selenium and vitamin E.[6]

With rare exceptions,[7,13] NAD/EDM is consistently associated with marginal or low serum/plasma vitamin E concentration. Published normal ranges of α-tocopherol vary with age, location, season, diet, and use; however, a commonly accepted scheme classifies results greater than 2 μg/mL as normal, 1.5 to 2 μg/mL as marginal, and less than 1.5 μg/mL as deficient.[12,14] Healthy horses sharing feedstuffs and environment with affected horses usually also have low levels of vitamin E,[5,15] although foals in an Appaloosa family with hereditary NAD/EDM had significantly lower plasma vitamin E than did age-matched normal pasturemates,[15] and Quarter Horse foals that developed NAD/EDM had significantly lower CSF vitamin E concentrations than did heathy foals maintained on the same vitamin E–deficient diet.[5]

Cause and Pathogenesis

NAD/EDM most closely resembles ataxia with vitamin E deficiency of humans and other animals.[4,6,14] The neuroprotective effects of vitamin E are related to inhibition of oxidation of CNS membrane lipids and facilitation of axonal transport of macromolecules.[14] Direct support for the antioxidant role of vitamin E in horse CNS is provided by the results of global transcriptome analyses of affected and normal spinal cords that suggest a protective role for vitamin E in preventing accumulation of oxidized cholesterol (oxysterol) in the setting of lipid peroxidation and demylination.[16] Although familial isolated vitamin E deficiency of humans is caused by mutations in the α-tocopherol transfer protein gene, expression of the messenger RNA of this gene was similar between one unaffected horse and two horses with NAD/EDM from a group of related Quarter Horse weanlings and yearlings.[6] Low serum levels of vitamin E in horses with NAD/EDM is not explained by impaired intestinal absorption: oral vitamin E tolerance tests were normal in affected horses.[15]

Clinical Signs

NAD/EDM is characterized by an acute, occasionally insidious-onset, symmetric ataxia and paresis of the trunk and limbs. Clinical signs typically appear between the ages of 1 and 12 months but have occurred in neonates and mature horses.[3,4] Posture and gait are wide based, and affected limbs demonstrate notable hypometria (spasticity). Signs are typically considerably more severe in the pelvic limbs, and the thoracic limbs may be clinically normal. In two reports, it was noted that limb weakness was observed only in horses with moderate or severe ataxia and was not recognized in many horses that were mildly ataxic.[4,6] Some horses with NAD/EDM adopt a two-beat lateral ("pacing") gait at walking speed. Long spinal reflexes such as the cervicofacial, laryngeal adductor (slap), and cutaneous trunci reflexes may be reduced or absent, especially in long-standing cases. Neurogenic muscle atrophy is not characteristic of NAD/EDM, and cases were reported in horses with body condition scores of 5 to 6 out of 9.[4,6] Signs of brain dysfunction were not reported until the early 2010s. Of 88 Quarter Horses with NAD/EDM (NAD), 77 were described as dull or obtunded and minimally responsive to light flashes, sudden movement, or loud noises.[6] An EEG obtained from one affected horse revealed dominant states of drowsiness to slow-wave sleep. Reduced or absent menace responses were noted in 33 of the 88 Quarter Horses and in 4 of 6 Lusitanos with NAD/EDM.[4,6] Vision, pupillary light reflexes, ophthalmologic examination findings, and electroretinograms were normal.

Signs may not worsen after initial onset; others progress for days to months before stabilizing. Only rarely does the condition progress to recumbency.

Laboratory Findings

There is no antemortem diagnostic test for NAD/EDM. Plasma/serum vitamin E concentrations of NAD/EDM horses and pasturemates are often marginal or low. Because vitamin E concentrations within individual horses vary considerably over time (especially if they are low), it is recommended that three blood samples be taken over the course of 24 hours.[14,15] Samples must not be visibly hemolyzed and should be stored so that the blood is not in contact with the rubber stopper. Plasma CK and AST activities may be slightly to moderately high because of increased recumbency.[9]

Diagnosis

Diagnosis during life is presumptive only and is made primarily by suggestive signalment and clinical signs with exclusion of competing diagnoses. NAD/EDM should be suspected in horses with symmetric limb ataxia that began within the first year of life and for which results of standard neurologic workups (cervical vertebral radiographs, CSF analysis, immunoassay for *S. neurona* antibody) have not implicated another diagnosis. Low or marginal serum/plasma vitamin E concentration (≤2 μg/mL) is supportive of the diagnosis.

Necropsy Findings

Necropsy reveals no abnormal gross findings. Histologic changes develop in the spinal cord and brainstem.[4,6,9,13] Lesions in the lateral and medical cuneate, gracilis, and thoracic nuclei are characterized by spheroid formation with vacuolation, loss of somata, astrogliosis, and lipofuscin pigment accumulation. In addition, axonal necrosis and demyelination of the dorsal and ventral spinocerebellar tracts, the cuneocerebellar tracts, and and the ventromedial funiculi of the cervicothoracic spinal cord may be present. Calretinin immunohistochemical staining was used to show that the cell bodies of degenerated axons in NAD/EDM-affected horses probably are located in the dorsal root ganglia.[17] No histologic lesions were found to explain observations of dull mentation[18] and abnormal menace responses[4,6] in reported case series.

Treatment and Prevention

It is unlikely that NAD/EDM can be cured even if treated early. Slight to no improvement was observed in affected horses given vitamin E supplements of 2000 to 8000 IU daily.[9,12] The type of vitamin E and the method of supplementation have important effects on its bioavailability. Natural vitamin E (RRR-α-tocopherol) is up to twofold more active than synthetic vitamin E (d,l-α-tocopherol

VetBooks.ir

or all-rac-α-tocopherol). Absorption requires fat, and so bioavailability of vitamin E is negligible or low unless it is given with feed or vegetable oil.

In accordance with the notion that NAD/EDM is associated with some interaction between inherited metabolic defect and vitamin E deficiency, vitamin E supplementation appears to be at least partially effective prophylaxis and is recommended in circumstances that involve familial predisposition, processed feed, lack of access to pasture, and exposure to insecticides or wood preservatives. In one study, the incidence of NAD/EDM was reduced from 36% over 3 years to 9% by supplementation of foals with 1500 IU vitamin E daily.[12] Similar results were observed in two other clusters of cases.[6,12] Sensible genetic, nutritional, and other management practices alone could greatly reduce or eliminate the risk of NAD/EDM.

Spinal Cord Trauma

Robert J. MacKay • Lisle W. George

Vertebral trauma is a relatively common cause of spinal cord dysfunction in both livestock and horses. The spinal cord is normally protected by a complex of bones and ligaments that can be conceptualized in biomechanical terms as two columns: dorsal and ventral.[1] The ventral column consists of the vertebral bodies, intervertebral disks, and dorsal and ventral longitudinal ligaments, whereas the dorsal column consists of alternating bony complexes (arches, articular processes, and dorsal spinous processes) and ligamentous complexes (supraspinous ligament, interspinous ligaments, ligamenta flava, and joint capsules). According to biomechanical models that have been used for assessment of spinal trauma in humans and small animals, acute spinal instability occurs when there is disruption of *both* of these columns by external mechanical forces. The corollary is that a single intact column provides stability. This two-column system has not been validated for large animals. Fractures of vertebral transverse processes and dorsal and ventral spinous processes and partial fractures of vertebral bodies or arches (i.e., stress fractures) do not cause spinal instability or neurologic signs.[2]

Most, but not all, traumatic spinal cord injuries are accompanied by vertebral fracture, subluxation, or dislocation.[3] Conversely, many spinal injuries are associated with pain, reduced mobility, and abnormal neck position but do not cause acute neurologic signs. In large animals, cervical spinal cord trauma is usually caused by hyperextension or hyperflexion of the spine in the sagittal plane with superimposed vectors of compression, distraction, rotation, or shear. With vertebral hyperextension, compressive force is applied to the dorsal column and distractive force to the ventral column, whereas the reciprocal forces apply to hyperflexion injuries. In all cases, the likelihood of associated spinal cord compression is higher in animals with abnormally narrow vertebral canals. Disk prolapse and fibrocartilaginous embolization of the spinal cord are rare in large animals and, when they occur, are usually associated with degenerative changes rather than with acute trauma, as may occur in dogs.[4-6] Young animals are subject to fractures involving epiphyseal or growth plates (i.e., Salter-Harris fractures). Vertebral infections may be seeded along these cartilaginous plates hematogenously or by direct traumatic implantation, and osteomyelitis may progress to the point of pathologic vertebral fracture. Poorly balanced nutrition or undernutrition decreases bone density and increases susceptibility to vertebral fractures.

Horses

In racehorses, cranial or vertebral fractures have accounted for 2.5% to 3% of deaths at flat races and 16% to 23% of deaths at chase and hurdle starts.[7] In a 3-year study of fatal fractures/dislocations in the spine of 125 horses at racing events in Britain, 23% involved the cervical vertebrae, whereas the remainder involved the thoracolumbar vertebrae.[8] Necropsies of 60 horses with vertebral trauma in Australia showed that 33 injuries involved cervical vertebrae; 10, thoracic; 10, lumbar; and 2, sacral.[9] In general, cervical vertebrae are more prone to fractures during accidents at jumping events (e.g., cross-country, showjumping, foxhunting, steeplechasing, and hurdling). The occipitoatlantoaxial region is most often involved in the following situations: (1) broad forehead impact, as in collisions with the ground, other horses, or fixed objects; (2) rearing and flipping over backward; or (3) when major distraction forces are applied to the head, as occurs in tied horses jerking backward on a halter. The atlantal ring or body of the axis may be fractured, the dens may fracture transversely anywhere along its length (including at the synchondrosis in young horses), or the dens may subluxate or dislocate from its usual position in the fovea dentis of the atlas. Fracture of a single articular process is the most common fracture from C3 to C7. In young horses (especially those younger than 2 years), a characteristic and spectacular hyperextension fracture results in severe extension angulation of the intervertebral joint.[10,11] On the more cranial of the affected vertebrae, the dorsal lamina and caudal articular processes are fractured and lifted dorsally. It is thought that this "deroofing" lesion provides natural decompression of the spinal cord while the surprisingly sturdy dorsal half of the intervertebral disk provides residual stability of the ventral column of the cervical spine.

In the thoracolumbar spine, T1 to T3, T10 to TI6, and T18 to L6 appear to be relatively susceptible. Lumbar vertebral fractures reported in 38 Quarter Horse and 29 Thoroughbred racehorses primarily involved L5 and L6 and were the third most common musculoskeletal cause of death in Quarter Horses during the 22 years of data collection.[12] All cases had abnormalities on the ventral aspect of the vertebral bodies, which suggests that preexisting pathologic conditions at the L5-L6 junction probably predispose horses to catastrophic fracture. Foals and young horses at pasture are prone to collide with fixed objects or other horses, get kicked by adult horses, or pitch forward headfirst into the ground, all while running at high speed. Such accidents often occur at night. Typical hyperflexion and hyperextension injuries of the cervical spine result from these falls, and cranial thoracic and midback fractures result from striking solid objects or being kicked. Horses may suffer contiguous or noncontiguous injuries of multiple vertebrae after high-speed impacts. Any horse that falls backward or struggles violently against a caudal barrier (e.g., in a trailer) may sustain sacrococcygeal fractures with damage to the cauda equina. There are reports that avulsion of the cauda equina can be caused by lifting or dragging a recumbent horse by its tail. It is worth noting that horses may have serious spinal injuries while alone in a stall, without observed or external evidence of an accident, so trauma should always be considered in cases of acute onset of spinal cord signs, regardless of the environment.

Livestock

The common sites of spinal fractures in calves are C2 to C4, T10 to T13, and L3 to L6 vertebrae. Vertebral fractures (particularly compression fractures) are especially common in 3- to 6-month-old ruminants as a result of nutritional problems including vitamin D, calcium, and copper deficiency or low calcium-to-phosphorus ratio.[13] Nutrition-related fractures usually involve several animals and may also involve the ribs and long bones. Traumatic cervical vertebral fractures of cattle and small ruminants may be caused by injuries sustained in falls, roadway accidents, butting of other animals, collisions with moving farm machinery, predation, or accidents in tie-stalls, stanchions, or squeeze chutes.[13-15] Spinal injury is especially likely to occur if the head is restrained in the chute or stanchion

VetBooks.ir

when the animal falls. Fractures or dislocations of the lumbar or sacrococcygeal spine frequently occur in cattle that slip in wet cemented areas and in performance-age bucking bulls.[14,16] Many of these fractures occur in cows in estrus during mounting by herdmates. Spontaneous fractures of vertebrae weakened by congenital defects (e.g., hemivertebrae) or osteomyelitis also are common problems in calves.[17] Traumatic dislocations, subluxations, or fractures of the atlantooccipital and atlantoaxial joints of pygmy goats may occur when the horns are held during restraint. Thoracolumbar fractures, particularly with epiphyseal separation of the middle to caudal thoracic vertebrae, may occur in calves transiting the birth canal during correction of dystocia.[18-20]

These fractures are mainly related to excessive traction and rotational force.[21] Luxation of a sacroiliac joint in the dam may occur with the use of extreme force during manual extraction of a calf. Mature Holstein bulls and rams may have a fused thoracolumbar spine and stenotic vertebral canal because of ankylosing spondylitis. This condition results in progressive pelvic limb paresis and ataxia.[22] These animals are at risk for traumatic lumbar vertebral fracture, spinal cord injury, and recumbency if they are required to mount for semen collection or breeding.[23] As described for horses, vigorous traction on the tail (e.g., when trying to assist a downer cow to stand) has the potential to cause stretching or avulsion of the cauda nerve roots and signs of cauda equina syndrome.

Pathophysiology

The primary phase of spinal cord injury is the direct effect of the mechanical events of the original trauma.[24] The primary phase is irreversible, but additional rounds of primary injury can be prevented or minimized by surgery and external stabilization of the spine. The principal mechanical forces that are involved in acute traumatic injury are concussion, compression, shear, laceration, distraction, and contusion of the spinal cord. The secondary phase of spinal cord damage comprises the injurious molecular and biochemical events that are set in motion by the primary injury and occur in the first few hours after initial injury. The goal of medical therapy is to limit the damage that occurs from secondary injury. The most important events during this phase of injury are vascular damage with hemorrhage and microthrombosis, loss of autoregulation of blood flow, excessive release of the excitotoxic neurotransmitters aspartate and glutamate, increased neuronal intracellular calcium concentration, cellular damage from reactive oxygen species, and acute neutrophilic inflammation.

Clinical Signs

The most common sign of vertebral trauma in all large animal species is localized pain and limited mobility of the affected part. The atlantoaxial vertebral canal of horses is subject to fractures, subluxations, and dislocations, many of which do not cause signs of neurologic dysfunction, presumably because of the large cross-sectional area of the vertebral canal at this level of the spine.[25] Two quite rare disorders result from spinal cord trauma and confound the rules of neuroanatomic localization: spinal shock and Schiff-Sherrington syndrome. *Spinal shock* refers to loss of muscle tone and segmental spinal reflexes caudal to a focal severe transverse spinal cord injury, usually between T3 and L3.[26] Although seldom described in the veterinary literature, it does occur in large animals, but, in contrast to the situation in humans, areflexia usually lasts less than 30 minutes, after which there is progressive recovery of segmental reflexes; persistence of signs is referable to a focal spinal cord lesion. With such a lesion, the thoracic limbs may be hypertonic, which reflects release from the inhibitory effect of tracts originating in the lumbar segments. This combination of paraplegia and thoracic limb stiffness is known as *Schiff-Sherrington syndrome*.[27] At least in small animals, signs regress by approximately 10 days. Spinal shock and Schiff-Sherrington syndrome may occur together or separately.

Diagnosis and Treatment

The first priority is the safety of attending personnel, which means that large patients that are thrashing and disoriented may need to be heavily sedated or anesthetized to allow for initial assessment, IV catheter placement, and treatment of any life-threatening conditions. Small ruminants theoretically can be taped to a backboard to immobilize them in lateral recumbency during initial procedures. Handlers must be careful not to exacerbate cervical vertebral trauma when restraining injured animals via lead rope and halter.

An indwelling IV catheter should be inserted and secured, and IV fluids and initial treatment should be provided as needed. Volume support and maintenance of normal arterial pressure and hematocrit are essential in all forms of CNS injury.[28] Any animal with spinal injury and neurologic signs should be provided with full doses of analgesics. NSAIDs (e.g., flunixin meglumine, 1.1 mg/kg IV or PO bid) have the dual advantages of analgesic effect and inhibition of potentially injurious cyclooxygenase activity.[24] Additional analgesia can be achieved if necessary by doses of butorphanol, morphine, or lidocaine or ketamine constant-rate infusions. The use of methylprednisone sodium succinate in this setting in human medicine remains highly controversial, although slight long-term benefits have been reported for a regimen of 30 mg/kg, followed by 5.4 mg/kg/h for 23 hours.[29,30] Patients are at an increased risk for pneumonia, sepsis, and hyperglycemia. The use of methylprednisolone is becoming less popular because the risks of complications outweigh the potential benefits[31]; high-dose methylprednisolone sodium succinate is not recommended in large animals with acute spinal cord injury. As is the case for brain injuries, antiinflammatory doses of dexamethasone (0.05 to 0.1 mg/kg IV or IM once daily) should be administered routinely.

As soon as possible, a careful neurologic examination should be performed to localize the lesion. It is important that this examination be complete even if the site of injury seems obvious because multiple discontinuous spinal cord segments or the brain, or both, may be injured in a single traumatic incident.[32]

When technically possible, it is prudent to radiograph the entire vertebral column. In large animals under field conditions, views are generally restricted to laterolateral projections of the cervical vertebrae. Radiographs show the amount of spinal displacement at the time they are taken, however, not the amount of displacement that occurred at the time of injury. The two-column model can be used to assess spinal instability.[1] Myelography is usually not necessary if it is determined that the spinal injury can be treated conservatively or if there is a substantially displaced fracture or luxation that is an obvious candidate for surgery. Myelography should be performed in animals with marked neurologic deficits and normal or equivocal radiographs. Additional information can be obtained from oblique and ventrodorsal radiographic views, C-arm fluoroscopy, CT, MRI, and osseous-phase nuclear scintigraphy. Techniques that necessitate general anesthesia in a large animal with spinal instability generally should be avoided unless there is an immediate surgical option.[10]

After these initial evaluations, the clinician has sufficient information to make recommendations for euthanasia, conservative treatment, or surgical management. Obviously, humane considerations, economic issues, and the intended use of the patient are driving considerations in this situation. In all cases, if quadriplegia and loss of deep pain are present, or in view of radiographic evidence of likely spinal cord transection, early euthanasia is appropriate. Otherwise, with the issues of handler safety and humane treatment kept paramount, it is reasonable to wait 12 to 24 hours to allow time for recovery of function before delivering a hopeless prognosis and euthanasia recommendation. Once the decision has been made to continue treatment, most large animals are still managed conservatively; surgery is an option in selected cases.

VetBooks.ir

CONSERVATIVE MANAGEMENT. For large animals with vertebral column injury, 1 to 2 months of each of the following is recommended: full-time stall confinement; stall confinement with daily hand-led walking; turnout into a small paddock or round pen during the day with stall confinement at night. Pain control and sedation should be provided as needed. In horses that have difficulty getting to their feet, frequent use of an abdominal sling is essential. Such horses must be able to support their own weight once they are in the standing position. In cattle, a flotation tank can be used for the same purpose.

SURGERY. In the absence of evidence-based guidelines for surgical intervention in large animals, it is worth considering the potential adverse consequences of *not* performing surgery. Although conservative management has often been successful, the following negative outcomes have been observed in horses with spinal injuries managed conservatively: (1) sudden recumbency days to weeks after dens fracture, subluxation, or dislocation[2,33]; (2) limb ataxia and weakness after callus formation and joint remodeling around a fractured articular process[11]; (3) progressive torticollis, head tilt, or both after articular process and vertebral body fractures in the midcervical region; (4) limb ataxia and weakness after fibrous proliferation at the site of previous atlantoaxial subluxation; (5) abnormal head position and stiffness of the upper neck after upper cervical injury; and (6) a domino effect wherein there is progressive stenosis of the vertebral canal at the intervertebral joint or joints immediately caudal or cranial to a traumatized intervertebral joint that has healed in a marked flexed or extended angle.[11,20]

In view of these developments, reasonable indications for surgical intervention in horses are (1) prevention of neck stiffness or deformity; (2) prevention of callus formation or joint remodeling that may impinge on the spinal cord; (3) decompression, stabilization, or both of the atlantoaxial joint after dens fracture, subluxation, or dislocation[25,33,34] and (4) decompression or reduction and stabilization of vertebral fractures/subluxations in response to deteriorating neurologic signs. Techniques have been described for each of these surgical procedures (generally with successful outcomes) in the cervical spine of horses.[10,35-37] Canine surgical techniques can be adapted for use in the lumbosacral spine of valuable small ruminants, calves, and foals. In particular, the use of polymethylmethacrylate and Steinmann pins and plating of the dorsal spinous processes have wide potential application to thoracolumbar injuries in animals weighing less than 70 kg.[38] Surgical decompression of the cauda equina by dorsal laminectomy of the sacrum has been described. In adult horses, the tuber sacrale of the pelvis interfere with the approach to the first and possibly the second sacral vertebrae, but the caudal part of the sacrum can be decompressed.[39] In foals and heifers, sacral fractures may be reduced and stabilized with plates and screws.[40]

Prognosis For horses with spinal trauma without neurologic dysfunction that are treated conservatively, there is a fair to good likelihood that neurologic signs will not develop; however, there is also a fair chance that the neck will remain stiff, become deviated or rotated, or both. The prognosis for horses with spinal cord trauma associated with luxations or fractures of the vertebral body, arch, or articular processes must remain guarded to poor for return to use. Healing of such fractures frequently results in some degree of vertebral malalignment, sometimes with lordosis, kyphosis, scoliosis, or torticollis. Even after apparent healing and resolution of neurologic signs, delayed callus formation and degenerative changes in adjacent articulations can result in delayed spinal cord compression. When the injured spine is appropriately stabilized, improvement may continue for up to a year. In a small quadruped, it is estimated that even 10% survival of axons across a lesion site in the spinal cord may be compatible with walking. The limbs behind a permanent spinal cord lesion will be ataxic and weak to lateral pressure but spastic and stiff during walking and able to resist dorsal pressure.

Ankylosing Spondylitis of Holstein Bulls

Lisle W. George

Ankylosing spondylitis is an inflammatory disease of joint tissue associated with fusion of lumbar vertebrae in Holstein bulls. Approximately 4% of all Holstein bulls intended for artificial insemination are culled each year because of spondylitis.[1] The clinical onset of the condition is insidious. The first signs of the disorder are a stilted gait, reluctance to move, and dragging of the toes of the rear limbs. Affected bulls are slow to mount teaser dummies for collection. The condition is progressive, and over several months the animals develop paraparesis and ataxia. With mounting, the ankylosed area of the spine may fracture, leading to acute recumbency. Pathologic changes associated with the condition include calcification of the ventral vertebral ligaments between the T11 and L3 vertebrae. The condition appears to be hereditary. All bulls with the condition possess the class I major histocompatibility complex BoLA A8 phenotype. In comparison, the phenotypic frequency of BoLA A8 in the general population of normal Holstein bulls is only 44%.[2]

Spinal Tumors

Robert J. MacKay • Lisle W. George • Mary O. Smith

With the exception of lymphosarcoma in cattle, tumors involving the spinal cords of domestic animals are rare. In the horse, tumors within the spinal cord or dura (i.e., intramedullary or extramedullary-intradural) have included meningioma, ependymoblastoma, angioma, angioblastoma, ganglioglioma, schwannoma, and neurofibroma.[1] Reported extradural tumors are lymphosarcoma, plasma cell myeloma, neurofibroma, fibrosarcoma, melanoma, hemangiosarcoma, and carcinoma.[1-4] The tumor that most commonly affects the spinal cord of ruminants is lymphosarcoma, but others, such as histiocytic sarcoma, glioma, neuroblastoma, and embryonal neuroectodermal tumors, have been reported.[5-9]

Clinical Signs The clinical signs of tumorous invasion are usually referable to a single-site spinal cord lesion, although extradural tumors such as lymphoma can extend over multiple spinal cord segments.[9] The rate of onset of the neurologic dysfunction varies. Some neurofibromas, melanomas, and lymphosarcomas invade centripetally along the peripheral nerve rootlets. Affected patients develop slowly progressive limb ataxia and weakness caudal to the location of the lesion, which eventually leads to tetraplegia or paraplegia. In rare cases, the onset of tetraplegia may be peracute and unaccompanied by prodromal neurologic signs. Lymphosarcoma has a predilection for the lumbar segments of the spinal cord and the cauda equina in cattle older than 5 years (Fig. 35.19). A diagnosis of spinal cord tumor should be considered in cases of progressive neurologic disease characterized by flaccid tail and anus, dysuria, perineal scalding by urine, distended bladder, perineal analgesia or anesthesia, and paraparesis. Most animals with spinal tumors are mature to older adults; immature animals are affected in rare cases, mainly by embryonal tumors.[8-11]

Clinical Pathology Examination of CSF may be useful when the tumor has infiltrated the cauda equina and is located in the lumbosacral cistern. In these cases, tumor cells may sampled for biopsy as the needle is inserted into the lumbosacral space. In other cases the CSF may be normal, or albuminocytologic

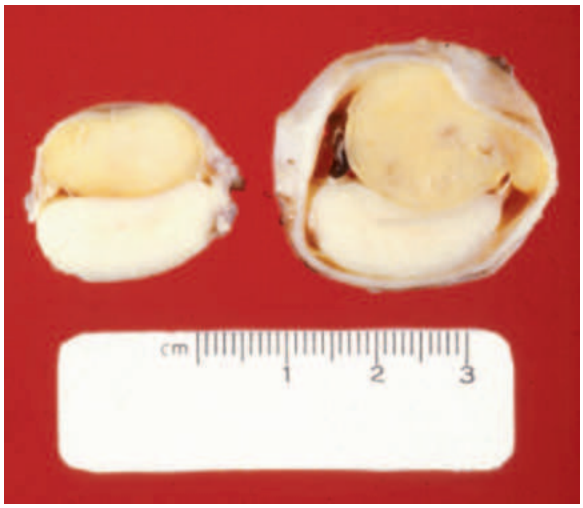

FIG. 35.19 Epidural lymphosarcoma in a 5-year-old Holstein dairy cow. The tumor had spread from neoplastic periaortic lymph nodes and had expanded to compress the caudal lumbar and cranial sacral spinal cord segments, which resulted in signs that resembled bilateral sciatic paresis. Tumorous masses are above the compressed spinal cord in the two transverse sections shown.

dissociation can be expected (elevated CSF protein levels with normal to mildly elevated nucleated cell count) with or without variable degrees of hemorrhage and xanthochromia. After necropsy, various immunohistochemical techniques can be used to identify the tumor type when routine histologic examination is insufficient.

Treatment There is currently no treatment for most spinal cord–associated tumors of large animals; however, protocols could be adapted from those used for other forms of lymphoma in horses or for other solid tumors in small animals. In one study, a cow survived for 57 days after three treatments with L-asparaginase at 10,000 IU/m^2 surface area. The nearly 2-month period of survival allowed the investigators to successfully superovulate the cow. When treating food animals with L-asparaginase, the benefits of the antimetabolite drug must be weighed against the potential for teratogenicity of the fetus, toxicity for humans, and the certainty of relapse in the patient.[12]

Verminous Meningoencephalomyelitis

Robert J. MacKay

Verminous meningoencephalomyelitis is caused by the meanderings of one or more parasites through the CNS and is therefore an extremely variable clinical entity. Depending on the number, size, and location of the parasites and the duration of their migration through the brain or spinal cord, a spectrum of signs is possible, ranging from a nonprogressive localizing neurologic deficit to rapidly fatal, diffuse encephalitis. Verminous meningoencephalomyelitis usually occurs sporadically and has been associated with strongylid *(Strongylus vulgaris)*, metastrongylid *(Angiostrongylus cantonensis, P. tenuis)*, filarid (*Setaria* spp.), tylenchid (formerly rhabditid; *Halicephalobus gingivalis*), and spirurid *(Draschia megastoma)* nematodes, as well as warble fly larvae (*Hypoderma* spp.).

Strongylus Vulgaris

Verminous myeloencephalitis due to *S. vulgaris* in the CNS is a rare, aberrant event resulting from embolization to the CNS of L4 or L5 larvae from verminous thrombi in the left ventricle, proximal aorta, or any of the aortic branches that supply the CNS.[1,2] *S. vulgaris* larvae in the aorta migrate subintimally upstream from locations in the proximal cranial mesenteric artery.[2] As a result of disintegration of thrombi in these aberrant locations, clot fragments and larvae migrate to the CNS. Three outcomes are possible: (1) acute massive infarction, ischemia, and edema of the brain; severe neurologic dysfunction; and death after a brief clinical course; (2) nonlethal or even subclinical embolization of the CNS that is followed by entry of one or more larvae into the CNS parenchyma, which wander therein for up to several months, producing associated neurologic signs; or (3) subclinical embolization and parasite migration. Subclinical larval migration occurs in relatively forgiving parts of the cerebral hemispheres and ends when the parasite dies or migrates out of the CNS.

A single larva can migrate through many levels of the CNS; in one case, an L5 *S. vulgaris* larva was estimated to have traveled 8 cm per day for several days along the spinal cord of a donkey.[3] Virtually any clinical sign is possible, and signs are likely to change dramatically over time or even stop and then restart or spontaneously resolve. A larva may exit the CNS only to reenter at a different location and continue its migration. The donkey mentioned earlier was paraparetic and sitting like a dog because of larval damage through the midlumbar spinal cord; signs improved for a few days when the larva migrated out of the spinal cord, but then the animal collapsed into recumbency when the larva reentered and migrated within the cervical spinal cord.[3] Thrombosis, infarction, and tortuous hemorrhagic or discolored tracts may be evident on gross examination. Microscopic findings include linear tracts of hemorrhage lined by neutrophils, macrophages, occasional eosinophils, and reactive glial cells. CSF changes associated with *S. vulgaris* migration include xanthochromia, protein concentration ranging from 32 to 550 mg/dL, and increased nucleated cell count (42/μL to 10,000/μL).[1-4] The differential counts range from 70% to 80% neutrophils, 12% to 19% mononuclear cells, and 1% to 2% eosinophils. Verminous myeloencephalitis due to *S. vulgaris* virtually disappeared after the introduction of the macrocyclic lactone anthelmintics in the 1980s; however, the increasing practice of selective deworming may enable the reemergence of large strongyles.[5]

Hypoderma Lineatum and *Hypoderma Bovis* (Cattle Grubs)

Hypoderma lineatum (common cattle grub) and *Hypoderma bovis* (northern cattle grub) are parasites of cattle that occasionally migrate in the horse (also in goats and deer). In the late spring or early summer, adult *Hypoderma* spp. flies (known as *warble flies* or *heel flies*) deposit eggs on hairs on the limbs or lower body. First-stage larvae hatch in 5 to 7 days, penetrate the skin, and migrate in a dorsal direction along fascial planes, often following the paths of blood vessels or nerves.[6] Over approximately 1 year, migrating larvae moult once or twice and arrive in subcutaneous tissues along the back. Their dorsally directed path may sporadically take larvae through the foramen magnum or other foraminae of the skull to penetrate and meander in the brainstem. Because of the large size of *Hypoderma* spp. larvae and their propensity for migration within the caudal fossa of the skull, neurologic signs are usually severe, progressive, and fatal.[6,7] Typically, affected animals exhibit profound obtundation and signs of asymmetric cranial nerve dysfunction (e.g., head tilt and circling) that worsen quickly and lead to recumbency and death. Since the advent of pour-on and injectable systemic organophosphate insecticides in the 1950s and macrocyclic lactones in the 1980s for systematic treatment of cattle, *Hypoderma* populations have decreased dramatically in the United States and have been eradicated in several European countries, and so intracranial myiasis is now unlikely to occur in industrialized countries. *Hypoderma diana*, a parasite

of deer, has also infested horses and presumably has the potential for CNS invasion.[8]

Halicephalobus Gingivalis

H. gingivalis (previously *Halicephalobus deletrix*, *Micronema deletrix*) is a free-living microbivorous tylenchid nematode that feeds on bacteria in rich organic environments such as decaying vegetation, compost, or manure.[9,10] Cases of meningoencephalomyelitis caused by *H. gingivalis* occur sporadically worldwide in equids (including zebras) and occasionally in humans and cattle.[11-17] The nematode opportunistically enters the body through breaks in the mucous membranes (and possibly skin) of the nose, mouth, prepuce, and mammary gland of horses and invades and proliferates locally to cause clinically apparent granulomas.[18-23] Such masses can be locally invasive and destructive, particularly in the jaws, nasal cavity, and paranasal sinuses.[18,24] In one case a foal was apparently infected by suckling from its dam, which had *H. gingivalis* mastitis.[25] From these superficial sites, larvae or adults may enter lymphatic or venous drainage and be distributed hematogenously to various organs and tissues.

H. gingivalis has a propensity to invade and proliferate in the kidneys (Fig. 35.20), CNS, and eyes, but lesions have also been found in long bones, the heart, the lungs, the liver, the uterus, the testes, lymph nodes, and the walls of the aorta and pulmonary arteries.[23,26-28] The brain is the usual site of CNS infection, with lesser involvement of the spinal cord or, in one instance, the cauda equina.[29] The typical severe progressive neurologic signs are due to massive proliferation of nematodes adjacent to blood vessels and the associated florid perivascular granulomatous inflammation.[9] Only female nematodes are present in lesions, and reproduction is by parthenogenesis.[9]

Clinical signs of *H. gingivalis* infection of the CNS depend on the location of the lesions and include asymmetric ataxia, hypermetria in the thoracic limbs, obtundation, behavioral changes, compulsive walking, head pressing, head tilt, circling, nystagmus, recumbency, convulsions, and coma.[12-17,30-32] *H. gingivalis* meningoencephalitis is invariably fatal, regardless of treatment; affected horses die or are euthanized within several days of onset.[26,33] CSF analysis in affected horses ranges from normal to xanthochromic appearance with increased protein and mild to moderate pleocytosis of nucleated cells. Differential analyses reveal mostly mononuclear cells with lesser numbers of neutrophils and occasional eosinophils. In many (possibly most) cases of *H. gingivalis* meningoencephalitis, the animals also exhibit characteristic renal lesions.[26] The latter are usually multifocal large nodules in the renal parenchyma of one or both kidneys.[26,34] Of potential diagnostic significance in such cases are a history of weight loss, hematuria, or polyuria, or a combination of these, and findings at initial examination of nematodes in the urinary sediment, high serum creatinine and calcium concentrations, and ultrasonographically evident renal masses.[35-38] Severe progressive, usually unilateral verminous chorioretinitis or panophthalmitis may precede or coincide with the onset of signs of encephalitis.[37,39,40] Efforts to eliminate subcutaneous or renal *H. gingivalis* infections by surgery and anthelmintics are occasionally successful[21] but, unfortunately and unpredictably, are often followed within several days to weeks by the onset of encephalitis.[19,39,41-43]

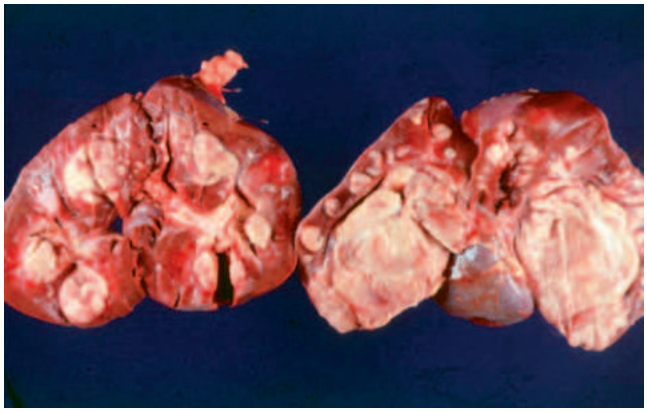

FIG. 35.20 Kidneys from a horse with disseminated *Halicephalobus gingivalis* infection, including fatal meningoencephalomyelitis.

Parelaphostrongylus Tenuis

P. tenuis (the meningeal worm) is a ubiquitous parasite of white-tailed deer in the eastern United States (north of a line through the middle of the states along the Gulf of Mexico[44]). Infective larvae are ingested within infested snails and slugs, exit through the abomasum, and then migrate to the dorsal horn of the gray matter of the spinal cord, where they mature into adults before traveling along the dorsal nerve roots to the venous sinuses and subarachnoid spaces over the cerebral hemispheres. *P. tenuis* is increasingly a cause of verminous meningoencephalomyelitis due to aberrant larval migration in the CNS of other cervids, goats, sheep, and New World camelids within the same geographic range. In 2003, six equine cases with cervical scoliosis were described.[45] In each case, a unilateral multisegment contiguous lesion involved the dorsal horn of the gray matter on the convex side of the neck. In one case, cross-sections of a metastrongylid nematode were associated with the characteristic lesion, and the presumption is that all cases were caused by aberrant migration of *P. tenuis*. Five of the horses were younger than 1 year, and each exhibited acute onset of severe scoliosis after a variable prodrome with degrees of hypalgesia of the neck and cranial thorax, limb weakness, and limb ataxia, all on the side of the cervical convexity. Treatment with anthelmintics and antiinflammatories had no effect, and all affected animals were euthanized for humane reasons. An additional case, also in a young horse, was reported in 2007, this time with signs of obtundation, head tilt, circling, quadriparesis, and ataxia in all four limbs.[46] Numerous larval stages, eggs, and occasional adults of both sexes were associated with granulomatous eosinophilic inflammation in the cerebellum and adjacent brainstem. Presence of *P. tenuis* has been confirmed by PCR in lesions from the brain and spinal cord.[47,48] A *P. tenuis* nematode was extracted from the anterior chamber of a horse with signs of anterior uveitis.[49]

Angiostrongylus Cantonensis

A. cantonensis is a neurotropic metastrongylid parasite with a life cycle in rats closely analogous to that of *P. tenuis* in white-tailed deer.[50] It has long been endemic in the Pacific islands and Southeast Asia, but its range has spread into Australia, the United States, and the Caribbean. It is now well established among the wildlife of Louisiana.[51] The definitive hosts are species of wild rats that become infected by ingesting the infective larvae in slugs or snails. The larvae migrate to the CNS to continue development before finishing the life cycle via the pulmonary vasculature. Inadvertent ingestion of infective larvae by atypical hosts such as humans, dogs, and horses may lead to aberrant migration in the CNS and signs of verminous meningomyeloencephalitis similar to those described earlier for *S. vulgaris*. Equine cases have been reported in two foals in Australia and an American Miniature Horse foal in Louisiana.[52,53] Larvae migrated in the gray and white matter of the spinal cord and brainstem. CSF analysis revealed mild pleocytosis with small numbers of neutrophils and eosinophils. Specific ELISA tests are available for testing of CSF in humans and dogs.[50]

VetBooks.ir

Draschia Megastoma

D. (Habronema) megastoma is a spirurid nematode that has been found in the brainstem of a horse from the southern United States.[54] The adult worm is normally embedded in benign pyogranulomatous masses in the equine stomach, but larvae can invade wounds to cause granulating summer sores and have been reported to cause pulmonary nodules. The two unusual features of the solitary report of encephalitis are, first, the parasite found at necropsy was an adult gravid female and, second, there was a quiescent period of 6 weeks during the clinical course when clinical signs improved before the horse's condition deteriorated again.

Setaria Species

Setaria spp. are long, threadlike filarid nematodes that live without causing adverse effect in the peritoneal cavities of animals worldwide.[55] Microfilariae are released into the blood of the host and acquired by feeding mosquitoes, in which they undergo development to infectious larvae. Bovids outside the Americas are hosts to several setarial nematodes, including *Setaria digitata*, *Setaria labiatopapillosa*, and *Setaria marshalli*.[56-58] When inserted by mosquitoes into atypical hosts such as horses, goats, and sheep, immature *S. digitata* nematodes may migrate aberrantly through the CNS and other organs of atypical hosts.[57,59] This parasite has also migrated aberrantly in the CNS of cattle.[60] Outbreaks of so-called epizootic cerebrospinal nematodiasis, lumbar paralysis, or kumri occur during the summer or autumn when mosquito intermediate hosts are active. Outbreaks have been reported in Japan, Taiwan, China, Korea, Sri Lanka, Burma, India, Nepal, Iran, Israel, and Saudi Arabia.[57,59,61,62] Cases in horses are sporadic and often involve older horses; in goats, young animals are usually affected, and morbidity and mortality rates are up to 100%.[57] *S. digitata* apparently does not occur in the United States[56]; however, a single case of verminous encephalomyelitis due to *S. labiatopapillosa* has been reported in this country.[63]

Clinical signs are variable and are related to mechanical and inflammatory destruction along the tracks left in the brain or spinal cord by one or more larvae.[59,64] In this regard, the pathologic features of setarial meningoencephalomyelitis are identical to those described earlier for *S. vulgaris*. Changes in the CSF associated with *Setaria* infestation include xanthochromia, pleocytosis (25 to 84 cells/μL), and a slightly increased protein concentration. The cells of one horse contained a small proportion of eosinophils and basophils, but this finding was inconsistent with other reports.

Treatment and Prevention When single or a few migrating larvae are involved, the use of combinations of anthelmintics and vigorous antiinflammatory treatment has yielded successful outcomes. The latter component is probably important to prevent the effects of strong inflammatory responses against killed parasites.[50] Because penetration of the blood-brain barrier by anthelmintics is limited, high-dose benzimidazoles are often used for this purpose. Typical protocols are fenbendazole, 10 to 60 mg/kg by mouth or nasogastric tube, one to five daily doses, with dexamethasone (or equivalent), 0.05 to 0.1 mg/kg IV or IM, once daily for 3 days. Ivermectin was effective in goats with early signs of setarial myeloencephalitis[57] but has not been effective in treatment of *P. tenuis* or *H. gingivalis* cases in horses, even when used against *H. gingivalis* at a potentially toxic dose of 1.2 mg/kg (six times the recommended dose).[35] Diethyl carbamazine citrate, 40 to 100 mg/kg daily, was effective in natural and experimental setarial cases in horses.[65] Most types of verminous encephalitis are unlikely to occur in horses on a regular deworming program; however, *H. gingivalis* cases regularly occur in horses on any of a variety of regular anthelmintic regimens.

Postanesthetic Myelopathy and Encephalopathy

Robert J. MacKay

A sudden-onset progressive myelopathy that is recognized during recovery from anesthesia has been described in horses and in a single calf.[1-6] Most of the horses initially described were large, young, and in dorsal recumbency under halothane anesthesia. There is a tendency for affected animals to be hypotensive during anesthesia. Paraparesis, ataxia, recumbency, or paraplegia is usually apparent during recovery from anesthesia but may be delayed as long as several days. Other reported signs include cutaneous hypalgesia and areflexia of the hindquarters and occasionally the thoracic limbs. Treatment is ineffective, and in all reported cases, the animals were been euthanized after a brief period during signs progressed rapidly. Lesions occur mainly in the lumbosacral spinal cord, although cervicothoracic segments also may be involved. There is malacia predominantly within gray matter (poliomyelomalacia), with associated mild to severe hemorrhage (hematomyelia) in most cases. Postanesthetic myelopathy is rare. CNS disease/myelomalacia contributed to 5% and 4% of anesthesia-related deaths in noncolic cases in the Confidential Enquiry of Perioperative Equine Fatalities (CEPEF), phases 2 and 3.[7]

Rare cases of postanesthetic encephalopathy have been described in horses.[5,8] Clinical signs include dementia, pacing and circling, cortical ("central") blindness, ataxia, hypermetria, and recumbency. In mild cases, blindness may be the only clinical sign. The onset of signs ranged from a few hours after recovery from anesthesia to several weeks later. The major pathologic finding in affected horses that did not survive was cerebrocortical necrosis, particularly in regions of the cortex supplied by terminal arterial branches ("watershed zones").

Although the pathogenesis of postanesthetic myelopathy is incompletely understood, it is proposed that compromise to the blood supply to the spinal cord is caused by hypotension or pressure from the abdominal viscera on the great veins (caudal vena cava, azygos vein). Systemic hypoxia, hypovolemia, and hypercapnia may underlie postanesthetic encephalopathy.[8] Factors suspected to increase the risk of postanesthetic encephalopathy include positioning in dorsal recumbency during anesthesia, use of multiple anesthetics, use of halothane for anesthesia, endotoxemia, and shock. Differential diagnoses for myelopathy include orthopedic conditions such as limb fractures, spinal fracture, myopathy, and peripheral neuropathy secondary to recumbency. The differential diagnosis for encephalopathy includes numerous metabolic, infectious, and toxic disorders. Prognosis for recovery in cases of myelopathy is poor or hopeless. In contrast, most horses with encephalopathy recover completely. The risk of these complications probably can be reduced by supporting adequate blood pressure and ventilation in patients under anesthesia, minimizing anesthesia duration, and preventing dorsal recumbency whenever possible.

Occipitoatlantoaxial Malformation

Robert J. MacKay • Mary O. Smith

Occipitoatlantoaxial malformations (OAAMs) are a heterogeneous group of developmental defects of the first two cervical vertebrae.[1,2] They have been reported to occur in cattle, sheep, goats, and horses.[3-6]

Equine OAAMs have been classified into six groups.[1] The first, a heritable condition in Arabian horses, is characterized by symmetric atlantooccipital fusion, atlantalization of the axis, and hypoplasia of the atlantal wings.[2,7-9] A similar disorder has been reported in an Arabian-cross colt.[10] The other groups are congenital asymmetric OAAMs,[11] asymmetric

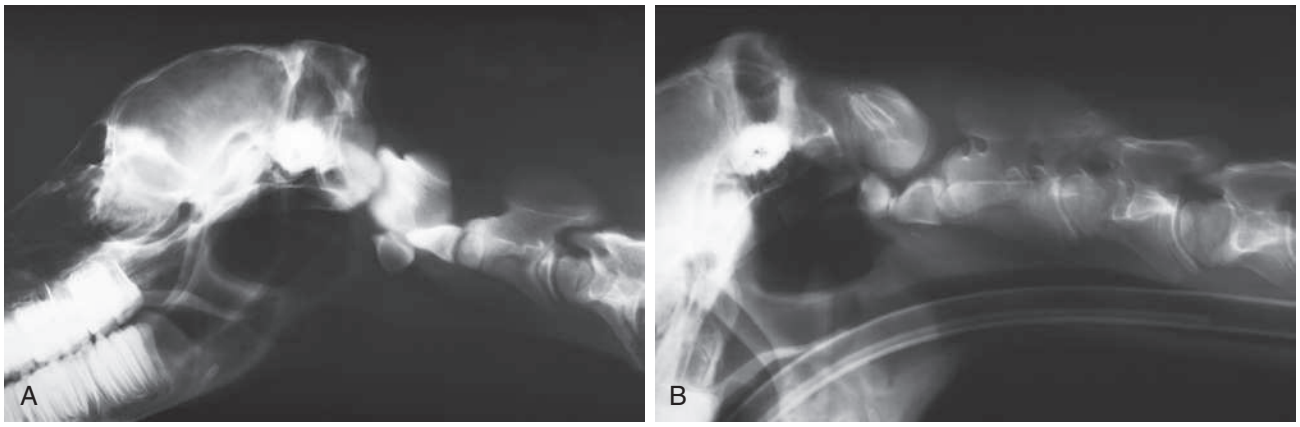

FIG. 35.21 Occipitoatlantoaxial malformation (OAAM). Radiographs of the craniocervical region of a normal neonatal foal **(A)** and a 3-week-old Arabian foal with OAAM **(B).** In the foal with OAAM, note slightly shortened dens, ventral luxation of the dens, cranioventral movement of the body of the atlas to encroach on the guttural pouch, and fusion of the atlas to the occiput with occipitalization of its caudal surface. *(Images courtesy Dr. I.G. Mayhew, Massey University.)*

atlantooccipitalfusion,[2] duplication of axis or atlas,[12] and symmetric OAAMs in non-Arabian horses.[13,14] A deletion mutation near the *HOXD3* gene was identified in one Arabian foal with OAAM but was not found in two others with atypical OAAM phenotypes.[9]

The clinical signs range from normal with or without abnormal head position to brainstem compression, sudden unexpected death, and stillbirth.[2] In typical familial cases, signs of tetraplegia or tetraparesis begin at or shortly after birth and progress at variable rates. Foals may become suddenly tetraplegic and appear to stabilize for several days but then die suddenly.[15] In rare cases, horses may not show nervous system signs until 3 years of age.[13] The signs are symmetric in most affected animals and include hyperreflexia, hypertonia, weakness, and ataxia in all four limbs. Affected animals may be reluctant to move the neck and head and show resistance to manipulation of the area. A click or crepitation may be palpated over the cranial cervical spine when the head is moved.[2,5] With asymmetric bone lesions, torticollis is common, whereas patients with symmetric lesions hold their heads in extension and frequently display the "weathervane posture." Neurologic deficits may not be apparent despite moderate torticollis.

The malformations are readily apparent radiographically (Fig. 35.21), and CT can further elucidate the anatomic abnormalities.[16] There may be subluxation of the atlantoaxial joint, ventral displacement of C2 in relation to C1, nonunited ossification center of the dens, shortened or elongated dens, shortened transverse process of the atlas, fusion of C1 with the occipital condyles, atlantal duplication, and deviation of the basioccipital bone.[2,17] In sheep, additional malformations of the cervical vertebrae have been present concomitantly.

Suggested approaches to treatment are surgical fusion of the atlantoaxial joints, with or without laminectomy.[13,18] Laminectomy alone has been used to alleviate spinal cord compression and clinical signs caused by occipitoatlantoaxial malformation.[19] However, long-term results of surgical intervention have been poor, with neurologic deficits persisting. Closed reduction of the luxated atlantoaxial joint has yielded similarly unsatisfactory results.[16,20] If treated, Arabian horses must not be bred because of the hereditary nature of the disease in that breed.

Congenital Vertebral Malformations

Robert J. MacKay

The vertebral column develops early in gestation via a highly orchestrated series of events comprising, sequentially, notochord formation, neural tube closure, segmentation, and vertebral formation.[1,2] Any disruption in this complex sequence by genetic defects, mechanical injury, teratogens, nutrient deficiencies, microbial infections, or maternal illness can lead to abnormalities in the structural anatomy of the spine. Most congenital vertebral malformations (CVMs) are simple and may go undetected or are discovered incidentally during imaging procedures or at necropsy. In rare cases, a CVM is complex and has serious structural or neurologic implications. CVMs may occur as discrete abnormalities or be part of multiorgan developmental malformations involving neurologic, musculoskeletal, cardiovascular, urinary, or reproductive systems or a combination of these. When symptomatic, CVM is often fatal or life-threatening. Milder presentations predispose affected animals to spinal instability, stenosis, and spinal cord injury.

The spine is subdivided into five distinctive series (cervical, thoracic, lumbar, sacral, and caudal).[3] Vertebral variants and anomalies are most common around the boundaries between series (i.e., craniocervical, cervicothoracic, thoracolumbar, lumbosacral, and sacrocaudal).[3] Patterns of variation reflect the segmental organization of vertebral development under the influence of *Hox* genes and various growth factors.[3]

Incidental

Between 13% and 38% of horses have transpositions from C6 to C7 (or occasionally C5) of part of all of one of both ventral processes (also known as *ventral laminae of transverse processes*).[4,5] Disproportionately high numbers of Thoroughbred and warmblood horses are affected. Although this commonplace homologous variation has been considered incidental, vertebral canal stenosis and cervical pain were found significantly more often in horses with C6 ventral process transposition than in those lacking this anomaly.[5] Variations in the dorsal spinous processes of C7 and T1 and malformations of the first rib were also found in only horses with C6 ventral process transpositions.[6-8] Of 36 Thoroughbred racehorses, 8 had transitional thoracolumbar (T18-L1) vertebrae and 13 had transitional sacrocaudal vertebrae.[9] Numerous other variations in lumbosacral vertebral anatomy were noted, including intertransverse joints and articular process asymmetries. Transrectal ultrasonography reveals 10% to 20% of horses with ankylosis of L5-L6 or L6-S1 probably have transitional vertebrae at those sites.[7]

Other malformed vertebrae that may be found incidentally can result from failure of sagittal fusion of the vertebral body (i.e., butterfly vertebra[10]) or dorsal arch (spina bifida occulta). Hemivertebrae (lacking one side of the developing vertebral

body) and wedge vertebrae (lacking either ventral or dorsal vertebral component) are more extreme malformations that are rarely asymptomatic.

Symptomatic

The most serious CVMs are disorders of notochord development. These commonly involve multiple different organs, in addition to potentially catastrophic CVMs, including caudal/sacral agenesis and segmental spinal dysgenesis (aplasia of vertebral bodies).[11,12] Perosomus elumbis is a sporadic lethal congenital defect of equids and livestock that includes arthrogryposis and organ malformations in addition to agenesis of vertebrae caudal to the thorax.[13-15]

CVM syndrome is an inherited condition of Holstein cattle and related breeds caused by a mutation in the gene *SLC35A3*.[16] This mutation manifests as multiple spinal deformities secondary to defective vertebral segmentation along with arthrogryposis, ventricular septal defect, and skull abnormalities. The trait was widely disseminated by the U.S. Holstein sire Carlin-M Ivanhoe Bell and resulted in tens of thousands of abortions and neonatal deaths worldwide before genetic testing was instituted.[17] There are numerous reports of congenital syndromes of calves and lambs that phenotypically are similar to CVM. In a few instances, especially when multiple animals were affected, a cause was identified. For example, gene mutations (*AGRN* gene in Angus cattle and *CHRNB1* in Danish Red cattle) that cause bovine arthrogryposis multiplex congenita syndromes have been identified.[18] Since 2011, fetal infection with Schmallenberg virus has been associated with multiple spinal deformities, arthrogryposis multiplex congenita, and multiorgan malformations in cattle and lambs in Europe.[19] Lesions are similar to those described for related bunyaviruses: Akabane virus, Aino virus, and Cache Valley virus. Other teratogenic viruses of ruminants, including bluetongue, BVD, and border disease, are not known to cause vertebral anomalies. The diagnosis of Schmallenberg viral infection can be supported by specific quantitative PCR, immunohistochemistry and serum neutralization tests on affected neonates. Arachnomelia is another similar autosomal recessive trait with multiorgan involvement and a component of defective segmentation.[20] This syndrome is found in Simmentals and Brown Swiss breeds. In addition to scoliosis and kyphosis, affected animals exhibit skull deformities and abnormally thin and elongated "spider" legs. The trait in Simmentals has been localized to a mutation in the *MOCS1* gene.[20]

Congenital scoliosis, kyphosis, lordosis, kyphoscoliosis, or torticollis are relatively common spinal deformities and, if mild, usually do not cause ataxia.[21] These deformities are caused by disorders of alignment or ossification of vertebral precursors (sclerotomes), which lead to asymmetric malformations of the vertebral bodies, articular processes, spinous processes, and ribs. Wedge vertebrae or hemivertebrae cause sharp-angle axial deviations that predispose to spinal cord compression.[22,23] Disordered sagittal fusion of the sclerotome dorsally or ventrally results in defects in the vertebral dorsal arch (spina bifida) or vertebral body (e.g., butterfly vertebrae). Protrusion of the meninges (meningocele), exposure of the spinal cord (myelocele), or both (myelomeningocele) are herniations through the dorsal vertebral defect (spina bifida cystica) and may be apparent as masses on the dorsal midline, either exposed or covered by skin.[24-28] Most spina bifida defects are in the lumbosacral spine, although thoracic and cervical examples occur. Spina bifida cystica is associated with neurologic and other abnormalities at and caudal to the lesion, which may be severe. It is hypothesized that chronic CSF leakage into the amnion via the vertebral defect predisposes the affected fetus to hydrocephalus and cerebellar herniations (Arnold-Chiari syndrome) that often accompany spina bifida.[29-31] An unusual case in a foal involved herniation of a myelomeningocele ventrally through a defect in the vertebral body.[32]

Interseries junctions are particularly prone to vertebral variances such as fused or transitional vertebrae (vertebrae with characteristics of adjacent segments). Many of the changes around cervicothoracic, thoracolumbar, and lumbosacral junctions appear to be asymptomatic, as described in the previous section. In contrast, many CVMs involving the craniocervical junction, including occipitoatlantoaxial malformations,[33] cause either stiffness of upper cervical joints ("weathervane posture") or spinal cord compression and ataxia.

Finally, congenitally reduced height of vertebral arches causes vertebral canal stenosis and vulnerability to spinal cord compression.[34] Although the vertebral malformations that characterize cervical stenotic myelopathy of horses occur largely after birth, a role for congenital vertebral variations in this condition has not been excluded.

Chapters 51 and 52 contain more information about CVMs.

Myelodysplasias

Mary O. Smith • Robert J. MacKay

The following types of myelodysplasia occur in livestock[1-15]:

1. *Spinal dysraphism.* Abnormal development of the spinal cord before complete differentiation of gray and white matter; the areas of agenesis form longitudinal cystic structures instead of differentiated nervous tissue. Most of these anomalies are neural tube defects.
2. *Syringomyelia.* Longitudinal fluid-filled cavitations of the spinal cord.
3. *Hydromyelia.* Abnormal fluid-filled dilation of the central canal.
4. *Diastematomyelia.* Duplication of the gray matter at one or more segments.
5. *Rachischisis.* Complete failure of the neural tube to close; the central canal remains exposed and communicates with the integument.
6. *Meningocele.* Herniation of the meninges through a vertebral defect (usually spina bifida).
7. *Meningomyelocele.* Herniation of the meninges and dysplastic spinal cord through a spinal column defect.
8. *Myelodysplasia without vertebral defects.*

Associated abnormal neurologic signs are as described earlier for spina bifida.

Myelodysplasia has been related to genetic factors in Charolais and Hereford calves, although the mode of inheritance is unknown.[3,16] The condition has also been recognized in foals of several breeds.[15,17-19] In addition to genetic factors, causes include intrauterine bunyavirus (Schmallenberg, Akabane, Cache Valley, and Aino virus) infections, hypovitaminosis A or copper deficiency, maternal fever, or exposure to teratogens, including substances in species of *Solanum* and *Veratrum*.[15,20]

The neurologic deficits of myelodysplasia are difficult to differentiate from other spinal diseases unless the disorder is accompanied by spina bifida. Clinical recognition of myelodysplasia is usually based on the historical findings of paraplegia in a newborn calf without radiographic evidence of spinal fractures and with no myelographic evidence of spinal cord compression.

Acquired Torticollis

Robert J. MacKay • Mary O. Smith

Primary acquired torticollis with or without neurologic disease occurs in all species of domestic livestock. Causes include fracture or subluxation of the cervical vertebrae, basilar skull fractures, dystrophic muscle degeneration, unilateral cicatricial muscular contracture from injections, lupinosis, traumatic rupture of

the cervical muscles, parasitic migration through the cervical spinal cord, hydranencephaly, asymmetric neurodegeneration, and congenital vertebral deformity.[1-6] In one study, researchers hypothesized that physical constraint within the narrow tips of uterine horns caused acquired torticollis and a variety of other deformities such as head scoliosis and limb malformations in more than 200 foals.[7] Draft horses may be predisposed to this problem, which frequently results in severe dystocia in horses. If the spinal cord is intact, no neurologic deficits result. The current epizootic of fetal Schmallenberg virus infections has caused torticollis with other malformations in calves, kids, and lambs.[8]

Treatment of traumatic torticollis should be directed at reducing the edema, relieving pain, and immobilizing the damaged structures. Muscular tears may be treated by encasing the head, neck, and proximal thorax in a fiberglass cast. Ancillary supportive treatment may include dexamethasone (0.05 to 0.1 mg/kg IM or IV daily for 2 to 3 days), methocarbamol (8 mg/kg IV tid for 5 days), and NSAIDs (e.g., phenylbutazone 2 mg/kg bid PO or IV or flunixin meglumine 1.1 mg/kg IV bid for 3 to 5 days after injury). A method of surgical correction of cervical muscle contractures through a muscle-splitting procedure has been described[9]; however, this seems unnecessary because most animals recover with only medical treatment. When torticollis is the cause of equine dystocia, delivery of the foal by cesarean section is often followed by rapid and complete anatomic and functional recovery.[7]

Tetanus

Robert J. MacKay

Tetanus is characterized by muscular rigidity and spasms. Death is common and results from respiratory compromise or tetanic convulsions. Clinical signs are caused by tetanospasmin, an exotoxin produced by the anaerobic, spore-forming, Gram-positive bacterium *Clostridium tetani*. Horses are exceptionally sensitive to tetanospasmin; cattle are relatively resistant, and small ruminants have intermediate sensitivity to the toxin. Spores are long-lived and resistant to most disinfectants and environmental extremes. They are not completely destroyed by boiling but can be eliminated by autoclaving at 115° C (239° F) for 20 minutes.[1] *C. tetani* is a ubiquitous soil inhabitant and can be isolated from feces of herbivorous domestic animals, with highest frequency in horses.[2,3] Tetanus is usually a disease of individual animals, but herd outbreaks of tetanus in livestock have been described.[4-8]

Pathogenesis

The most common route of infection is inoculation of wounds with *C. tetani* spores. Deep puncture wounds contaminated by manure, soil, or rusty metal are especially likely to cause tetanus. In horses, such wounds are typically in the lower limb, although contaminated surgical sites, the postpartum uterus, injection abscesses, and infected umbilical structures are also potential sites for *C. tetani* infection.[9-11] Causative wounds are not found or reported in up to 50% of equine cases. Dairy cattle are infected most frequently after bacterial contamination of the uterus postpartum. Reestablishment of anaerobic conditions in the involuting uterus favors germination and proliferation of *C. tetani* spores. Other sites for growth of *C. tetani* in livestock include lesions caused by elastrator bands, sharp castration or tail docking, dehorning or disbudding, insertion of bull rings or ear tags, shearing, fly strike, intramuscular injection of anthelmintics or vaccines, and umbilical infections.[4,5,7,8] Outbreaks of "idiopathic tetanus" occur occasionally in young cattle, usually in association with the grazing on rough, fibrous feed, and it is likely that this is analogous to the pathogenesis of toxicoinfectious and forage poisoning forms of botulism wherein toxin is produced in wounds in the mouth or GI tract or is ingested preformed in contaminated feed.[12,13]

The crucial event in development of tetanus is germination of *C. tetani* spores, followed by vegetative growth and elaboration of exotoxins. Factors that enhance the germination and growth of *C. tetani* include necrotic tissue, pus, concomitant bacterial infection, and foreign bodies. Spores inoculated into the tissues are highly resistant to normal host defenses and may remain dormant for months or years before germinating. *C. tetani* produces at least two exotoxins: *tetanospasmin* and *tetanolysin*.[14] *Tetanolysin* damages viable tissue, thereby lowering the redox potential and creating favorable conditions for expansion of the anaerobic infection.[3] The neurotoxin tetanospasmin is a 150-kD polypeptide that is immediately cleaved by tissue proteases into active heavy and light chains connected by a single disulfide bond. It diffuses from the site of production into the vascular system and is distributed hematogenously to somatic neuromuscular junctions and autonomic ganglia, where it binds to nerve terminals. Once bound, the toxin is internalized and transported in a retrograde manner 75 to 250 mm/day in axons of both somatic and autonomic motor neurons.[15] After 1 to 14 days, the toxin enters the CNS, reaches the neuronal cell body, traverses the synaptic cleft, and binds irreversibly to presynaptic inhibitory interneurons. Intact toxin is internalized, and then toxin light chain is released into the cytosol, where it acts to inhibit membrane fusion and recycling, events crucial in the release of the inhibitory neurotransmitters glycine and GABA.[14] The resulting disinhibition of motor neurons is the proximate cause of muscle rigidity and spasms.[3]

Preganglionic autonomic motor neurons in the lateral column of the gray matter and parasympathetic centers in the brainstem are affected by a similar mechanism but with delayed kinetic action in comparison with somatic motor neurons.[16] Both a basal increase in sympathetic activity and episodes of intense hyperactivity ("autonomic storms") occur, involving α-adrenergic and β-adrenergic receptors. During autonomic storms, the concentration of circulating epinephrine increases up to 10-fold. The resulting sympathetic overactivity causes hemodynamic instability and is an important cause of death in ventilated human patients with tetanus.[17] Its significance in large animal patients is unclear, although horses with either bradycardia or extreme tachycardia were reported as part of a large recent European case series.[18]

Neuronal binding of toxin is thought to be irreversible.[19] Recovery requires sprouting and growth of new nerve terminals, a process that is completed in weeks to months.

Diagnosis

Routine blood work is unhelpful, and abnormalities found are nonspecific. Gram stain of wound exudates reveal the characteristic drumstick-shaped Gram-positive bacilli in approximately 30% of human patients with tetanus,[20] but Gram stain and culture are seldom attempted in large animals with tetanus.[18] With the development of a real-time PCR assay for the tetanospasmin gene,[21] timely confirmation of *C. tetani* wound infection is now theoretically possible, and this assay may have application to veterinary cases.

Necropsy findings of animals with tetanus are nonspecific; secondary signs of musculoskeletal trauma and pulmonary congestion, atelectasis, and edema are most common.[9,10] The diagnosis can theoretically be confirmed by detection of tetanospasmin antigen in spinal cord ventral or intermediate horn cells with immunohistochemical staining in which antibody ia directed against tetanus toxin.[22]

Clinical Signs

Signs occur 1 to 60 days after wound inoculation by *C. tetani* spores; most affected animals show signs between 7 and 21 days.[9,10,18,23] The incubation period varies, depending on the size of the wound, redox potential of the contaminated tissue, number of spores inoculated, and

VetBooks.ir

host's antitoxin titer. Probably because cranial somatic nerves are shorter than nerves to the limbs, the first signs of tetanus are associated with rigidity of muscles around the head and neck. These signs are commonly missed in livestock that are not closely watched but are usually recognized in horses. Increased tonus of the masticatory muscles (trismus), rigidity of facial expression (risus sardonicus), and neck stiffness are typical early signs.[9,24] Prolapse of the membrana nictitans begins during this phase and may be a prominent sign in the horse but is inconsistent in cattle and usually not observed in sheep.[12] The head and neck are held in an extended position, and the face has a fixed, anxious expression. The ears and commissures of the lips are retracted caudally, and the upper eyelids are elevated. Often the mouth is clamped shut and the jaws cannot be pried apart manually (lockjaw). Hyperthermia (usually <102.5° F) occurs in some animals during the early stages, and rectal temperature may rise further after tetanic convulsions.

In mildly affected animals, signs may be restricted to the head and neck; however, in most cases, generalized spasticity is evident within the first 2 days. The limbs, back, and neck are held in a characteristic rigid extended posture that resembles the legs of a sawhorse (i.e., "sawhorse" stance).[9] The tail is elevated from the ischiorectal fossa ("pump handle"). Affected animals display a stiff, toe-scuffing gait and an extended head posture. Gas bloat usually begins during the first 24 hours in ruminants and camelids, and colic is occasionally an early sign in horses.

In all cases of generalized tetanus, tonic muscle spasms develop shortly after the onset of rigidity. These can be initiated by external tactile, visual, emotional, or auditory stimuli or by voluntary movements such as posturing to acquire food or water, urinate, or defecate. The limbs and head are resistant to passive flexion, and dramatic responses to even minor stimuli manifest as hyperresponsiveness or hyperesthesia. When the face is touched, there is reflex retraction of the eye and prolapse of the nictitans.[12] This reaction is inconsistent in cattle and sheep. Attempts to chew or suckle set off rounds of masseter contractions that are easily visible under the skin. Unmasticated feed is lodged in the cheeks or between the teeth. Even if ingesta can be moved to the pharynx, reflex pharyngeal and laryngeal spasms result in nasal regurgitation, drooling of saliva, and stridor. Aspiration pneumonia may develop as a result of impaired swallowing.

Disturbances of autonomic function have not been well documented in large animals, but heart rate and blood pressure may be increased or dramatically fluctuant with profuse sweating in horses.[9,11,18] It is not clear whether these signs represent tetanospasmin-induced sympathetic overactivity or are physiologic responses to the pain of muscle rigidity and spasms and the anxiety they cause. Signs of sympathetic overactivity are usually overlooked until after muscle spasms have been controlled. It is reported in humans that hypersalivation, increased respiratory secretion, and late-onset hypotension occur because of parasympathetic overactivity.[25]

Severely affected animals are at high risk of falling to the ground, especially during spasms. Once recumbent, they lie in lateral recumbency with the head and legs in full extension and the ears held almost parallel to the back. Frothy saliva accumulates at the commissures of the lips because the animals are unable to swallow. Spontaneous deaths are usually due to respiratory failure because of laryngeal spasm and asphyxia; contractions of the chest wall, diaphragm, and abdomen; accumulation of excessive respiratory secretions; and aspiration pneumonia. Autonomic overactivity may cause fatal cardiac dysrhythmia or heart failure and death secondary to hypertension. In advanced tetanus of cattle, ventrolateral strabismus may occur, and pupils may become dilated and fixed. Many animals die during a tetanic convulsion.

Treatment

The general principles that guide tetanus treatment of large animals are as follows: provide muscle relaxation, ensure good footing, eliminate the infection, neutralize the unbound toxin, maintain hydration and nutritional status, and establish active antitoxic immunity.[26]

PROVIDE MUSCLE RELAXATION. All possible external stimuli, including light and noise, should be minimized. Packing the animal's ears with cotton to minimize auditory stimulation can also help reduce muscle spasms. Sedatives and muscle relaxers are administered for control of muscle spasms and rigidity.[27] The cornerstone of this approach is the combination of a phenothiazine-based ataractic sedative such as acepromazine with a GABA-ergic agent such as pentobarbital or diazepam.[19] An IV catheter should be placed to minimize treatment-associated stimulation.

In mildly to moderately affected animals, acepromazine (or chlorpromazine) produces obvious muscle relaxation within minutes that lasts for hours. Acepromazine also has α-adrenergic antagonist and anticholinergic actions that may help suppress autonomic overactivity.[28] Pentobarbital sodium provides additional muscle relaxation in cattle, but in horses it must be titrated carefully in order to prevent recumbency.[9,29] Phenobarbital, at a dose of 10 mg/kg IV and then by nasogastric tube q8h, provided effective muscle relaxation for a neonatal foal with tetanus whose spasms to that point had not been controlled by high and frequent doses of diazepam.[30] Large doses of diazepam or midazolam by repeated injection or constant-rate infusion are effective for control of muscle rigidity, but these drugs are expensive and impractical in many settings. The direct muscle relaxant dantrolene is used in horses for prevention of myopathy and might be useful in the treatment of tetanus. This drug has been used successfully in human tetanus.[31] Methocarbamol, glycerol guaiacolate, mephenesin, and d-tubocurarine have all been used for muscle relaxation in horses with tetanus but have been used widely.

Magnesium infusion has multiple potentially useful actions against spasms and autonomic dysfunction and is inexpensive. It blocks neuromuscular transmission, interferes with catecholamine release from nerves and the adrenal medulla, reduces receptor responsiveness to released catecholamines, antagonizes the actions of calcium, and is an anticonvulsant and vasodilator.[32,33] Magnesium has been shown to reduce the requirements for other drugs used to control muscle spasms and cardiovascular instability in human patients with tetanus.[32] Of interest is that electromyographic studies show that magnesium tends to spare the respiratory muscles, which is a marked advantage. Effective serum/plasma magnesium concentrations are 5 to 10 mg/dL. An electrocardiogram should be monitored continuously and infusion discontinued if the width of the QRS complex increases by more than 25%.

ENSURE GOOD FOOTING. The affected animal should be moved carefully to a large well-bedded stall. Feed and water should be hung so that the animal does not need to lower its head. Horses and, theoretically, cattle in danger of falling may be maintained in a body sling, tackle and girdle, stocks, or walking frame. Appropriate caution must be exercised to ensure that such procedures do not cause the patient to become frantic.

ELIMINATE THE INFECTION. Because *C. tetani* grows in nonvascularized sites, the infection is best eliminated by surgical debridement of the affected area. If a recent wound or other infection can be identified, it must be opened, cleaned, debrided, and flushed. Penicillin (procaine penicillin G, 22,000 IU/kg IM bid) traditionally has been given to kill remaining *C. tetani* organisms and remains the drug of choice for food animals; however, penicillin might have anti-GABA and proconvulsant activities.[34] Metronidazole is now the preferred antimicrobial[28] and has outperformed penicillin in two clinical trials in human patients. It can be given at 25 mg/kg PO every 12 hours (q12h)

for 3 to 5 days. If the horse's condition precludes oral medication, 50 mg/kg can be given rectally, or 10 to 20 mg/kg can be given IV, q6-8h (neonates). Use of metronidazole in food-producing animals, however, is illegal in the United States and Canada.

NEUTRALIZE THE UNBOUND TOXIN. Tetanus antitoxin can be infiltrated into the tissues around the lesion, although this procedure is not recommended in protocols for treatment of human tetanus.[3] Despite the lack of evidence for efficacy of large doses of tetanus antitoxin, it is prudent to ensure neutralization of any residual unbound toxin by administration of at least 20 IU/kg IV, IM, or SC, repeated daily for up to 5 days. The results of intrathecal therapy as reported in small case series in horses have been inconclusive but generally not positive.[9,10,18,35] Although the data from human studies before 1991 were not supportive, meta-analysis of 12 more recent studies of both neonatal and adult cases detected a statistical survival advantage for intrathecal tetanus antitoxin over intramuscular administration.[36] A suggested protocol is 400 to 1000 IU/kg by slow installation via the lumbosacral space, including frequent cycles of aspiration of CSF into the loaded installation syringe in order to dilute the biological before delivery. Alternatively, tetanus antitoxin can be infused into the atlantooccipital cistern, but this route requires general anesthesia.

Because of severe reactions to intrathecal equine serum in ruminants, intrathecal administration of equine-origin tetanus antitoxin is contraindicated.[26] Administration of tetanus antitoxin has been associated with acute hepatic necrosis in horses.[37,38] The first clinical sign of this potentially fatal adverse reaction may appear 4 to 10 weeks after administration of tetanus antitoxin and has been reported in horses that received this treatment for treatment of clinical tetanus (see Acute Hepatitis in Horses section, Chapter 33).

MAINTAIN HYDRATION AND NUTRITIONAL STATUS. The patient's hydration and food intake should be monitored daily. As mentioned, food should be placed off the ground, in an elevated feed bunk or hay net, to allow easier access. Intravenous fluids should be administered as needed to correct dehydration and electrolyte abnormalities. Alimentation via a nasogastric tube may be attempted in horses with tetanus, but because of adverse reactions, supplementation via an indwelling esophagotomy tube or IV may be necessary. A 5- to 10-cm-diameter rumenostomy should be created in affected cattle in which tetanus is worse than mild.[39] This has the dual advantage of relieving bloat and providing a portal for water and feed (usually alfalfa pellets).

ESTABLISH ACTIVE ANTI-TOXIC IMMUNITY. Clinical tetanus does not elicit a protective immune response. Affected animals should begin a primary toxoid series (see Prevention section).

Prognosis

The fatality rate for adult dairy cattle is up to 50% and, for horses, was between 65 and 75% in several published reports.[9,10,18,23,26] Outbreaks of tetanus associated with contaminated procedure wounds in small ruminants usually produce high mortality rates (>80%). Most affected animals that die are recumbent by 24 to 48 hours after admission to a clinic. In survivors, signs usually stabilize by 2 to 7 days, with gradual recovery over the next several weeks. However, one horse reportedly remained stiff at 6 months but was normal at 9 months after onset of signs.

On the basis of various prognostic scoring systems used for tetanus in humans[28] and the few large animal series published, negative prognostic indicators are an incubation period of less than 7 days, period of onset (time from first sign to first spasm) of less than 2 days, umbilical or uterine entry site, no vaccination within the previous year, and presence of comorbid disease. Severe signs at presentation, recumbency, or initial rapid progression of clinical signs are all predictive of poor outcome.

Prevention

Because cattle are more resistant to tetanus than horses and small ruminants, they are not routinely immunized against the disease unless outbreaks have occurred previously.[26] Adult horses not previously vaccinated should be given an initial series of tetanus toxoid in two doses administered 3 to 6 weeks apart. Protective responses are usually attained within 2 weeks after the second dose. Current recommendations are to give booster doses annually thereafter or in addition at the time of injury or surgical procedure.[40] Broodmares should be revaccinated 4 to 6 weeks before foaling to provide for colostral transfer of immunity to their foals. Passively transferred antibody suppresses the IgG response of foals to toxoid vaccination at 3 months but not 6 months of age[41]; therefore it is recommended that foals from vaccinated mares be given a three-dose initial series beginning at 4 to 6 months of age, with a second dose 4 to 6 weeks later and the third dose at 11 to 12 months. Foals from nonvaccinated mares are vaccinated three times at 4-week intervals beginning at 1 to 4 months of age. Pregnant ewes and does should receive boosters with trivalent vaccine (*C. perfringens* types C and D and tetanus toxoid) approximately 4 weeks before parturition to cover lambs and kids during the early high-risk period around common husbandry procedures.[42] Young replacement animals can be given a primary series of inoculations at 1 and 2 months of age and annual boosters thereafter.

Tetanus antitoxin is produced by hyperimmunization of donor horses with tetanus toxoid. Administration of one vial of antitoxin (1500 IU) to a nonvaccinated horse should provide immediate protection that lasts for 2 to 3 weeks. Antitoxin is indicated in foals from nonvaccinated mares and in any wounded horse that has not been vaccinated within the previous year. In these cases, antitoxin and toxoid should be administered concurrently, with separate syringes at separate sites. Because the use of antitoxin is associated with hepatic necrosis (serum hepatitis) in a small number of horses, antitoxin should not be given in horses that are adequately covered by toxoid vaccination. Also, occasional failures are reported for both passive and active immunization protocols. Two of 16 foals and 10 of 74 adults developed tetanus after they were given tetanus antitoxin at birth or after injury, respectively.[18] In this same series, there were four cases in adults that had been vaccinated appropriately.

Spinal Abscesses

Lisle W. George

Definition and Etiology

Most abscesses of the spinal cord originate from a preexisting osteomyelitis in a vertebral body. The bone is usually infected hematogenously. Extension of bacteria from the lungs, heart, or a septic injection site is common. Neonates frequently develop vertebral abscesses secondary to septicemia.[1,2] Ascending infections secondary to tail-docking in lambs may also occur. Some ewes chew the tails of newborns; this can lead to ascending infections of the spinal column and spinal cord as well. Bone lesions may develop from sequestra broken from as a result of vertebral fracture. Epizootics of spinal abscesses can result from injection of contaminated vaccines or mineral supplements near the spinal column. Similarly, spinal abscesses may occur along with other diseases in groups of animals that are immunocompromised.[3] Infectious agents isolated from spinal abscesses of ruminants include *C. pseudotuberculosis*, *T. pyogenes*, *M. haemolytica*, *Staphylococcus aureus*, and *Fusobacterium necrophorum*.[1,4-6] Agents typically found in vertebral infections of foals include β-hemolytic streptococci, *Salmonella* spp., *Actinobacillus equuli*, *E. coli*,

Rhodococcus equi, and *Klebsiella pneumoniae*.[6-10] In rare cases, septic arthritis of the atlantooccipital joint may result from extension of a mycotic guttural pouch lesion.[11,12]

If the infectious agent remains localized in the vertebral body, the patient usually shows signs consistent with a transverse myelopathy. If the infection erodes through the dura mater, the animal develops signs of septic meningitis. If the bone infection is extensive, the vertebrae may fracture suddenly, which results in signs characteristic of spinal trauma.

Pathogenesis Hematogenously derived abscesses arise because of embolization of septic thrombi into the metaphyseal arteries. These vessels have a sluggish blood flow because they become tortuous as they approach the physis. The metaphyseal vessels communicate with the ventral vertebral plexus, which in turn drains into the postcava, portal vein, and pulmonary veins. The ventral vertebral plexus does not have valves; blood flow reverses with an increase in abdominal or pleural pressure. Regurgitated blood from infected sites in the body cavities may shower the vertebrae and spinal cord with bacteria.[4,13]

Clinical Signs The neurologic deficits of animals with vertebral body abscesses without pachymeningitis (inflammation of the dura mater) are similar to those described previously for spinal fractures.[5] Animals with mildly compressive cervical abscesses show a characteristic "weathervane posture," are stiff, and are reluctant to eat food from the ground.[5,7,8] Ruminants with this lesion hold the neck in extension and attempt to prehend food from the ground by using their tongue.[5] Additional signs of spinal abscess include heat, pain, swelling, or crepitus over the affected areas and associated signs of bacteremia. Abscesses in the thoracolumbar spine cause hindlimb weakness and ataxia of variable severity, from mild gait abnormalities to complete recumbency. Stud males may be unable to breed because of weakness and pain.[14] The differential diagnosis includes trauma, aberrant parasite migration, tumor-related and pathologic fractures, hemorrhage into or around the spinal cord (e.g., postanesthetic myelopathy), myopathies, caprine arthritis–encephalitis, and fibrocartilaginous embolism.[15] Spinal abscesses can be mistaken for other painful conditions such as orthopedic disorders or traumatic reticuloperitonitis.[16]

Clinical Pathology and Radiographic Findings Radiographs are the best method for obtaining a definitive diagnosis of spinal abscess. Affected vertebrae exhibit a random pattern of lucency and increased bone density characteristic of osteomyelitis, with or without adjacent soft tissue mass lesions indicative of abscess formation.[17] Diskospondylitis usually results in detectable osteolysis in the intervertebral joints.[7] Nuclear scintigraphy can be used when the bone lesions are not well defined on plain radiographs.[13] In addition, myelography may be used to detect the specific site of the spinal cord compression.

A complete blood cell count may indicate the presence of a chronic inflammatory focus, including hyperfibrinogenemia, neutrophilia, monocytosis, nonresponsive anemia, and left shift. The plasma globulin levels are often increased in affected adults but may be increased or decreased in neonates, depending on the adequacy of colostral immunoglobulin transfer.

Changes in CSF depend on the location of the abscess in the CNS tissue and the meninges. In most cases the abscess does not infiltrate through the meninges, and the CSF is normal or shows xanthochromia and mild increases in the protein concentration (60 to 120 mg/dL), with mild to no increase in nucleated cell count.[18] If the infection infiltrates into the meninges, pachymeningitis or septic myelitis will result; in affected animals, the CSF contains high numbers of WBCs (>100 neutrophils/μL) and a greatly increased protein concentration (>200 mg/dL). The CSF may clot after collection because of high concentrations of fibrinogen. Bacteria may be observed in a Gram-stained smear of CSF sediment. Spinal abscesses have been associated with *Brucella abortus* and *Mycobacterium bovis* infections in horses, and so affected horses should be tested for exposure to these organisms.[19,20]

Pathology The most common sites of involvement are the costovertebral and intervertebral articulations and the vertebral body epiphyses.[21] Lumbar vertebrae are frequently involved. The bone is uneven, deformed, and softened. The abscessed area is interspersed with calcified trabeculae and pockets of necrotic debris. Sequestration of necrotic bone may occur in some cases. The meninges may be adherent to the abscessed site, and occasionally a fistulous tract may extend from the center of the abscess pocket to the subarachnoid space. In other cases the abscess is compartmentalized away from the CSF, but the proliferating bone impinges on the spinal cord.

Treatment and Prevention If spinal abscessation is recognized early, prolonged antimicrobial therapy is generally effective. The results of cultures from the patient's blood, urine, feces, and CSF should guide selection of appropriate antimicrobial treatment. When bacteriologic culturing yields inconclusive results, a broad-spectrum antimicrobial should be chosen. NSAIDs may be administered for pain relief. Immobilization of the head and neck in a fiberglass cast extending from the thorax to the nose may provide support to smaller patients with a cervical abscess. Surgical drainage of the abscess and curettage of the necrotic bone may be feasible in animals with sufficient economic value to justify the procedure.[10,22] Surgical intervention in adult cattle and horses is usually difficult because of the size of the epaxial musculature and inaccessibility of the spine in large animals.

Triaryl Phosphate Poisoning (Chronic Organophosphate Poisoning; Dying-Back Axonopathy)

Definition and Etiology Ingestion of triaryl phosphates causes a neurologic disturbance of livestock characterized by a delayed neuropathy that results in incoordination and paralysis. Common sources of the triaryl phosphate esters include motor lubricants, hydraulic oils, industrial solvents, plasticizers, and automotive brake fluid. Chronic organophosphate poisoning also occurs in some families of sheep after treatment with organophosphorous anthelmintics.[1]

Triaryl phosphates have few effects on the glial cells,[2] but they have profound neurotoxic effects on the longest axons.[3] These fibers degenerate first at the distal, nonterminal areas. These degenerative lesions then spread proximally from the terminal nerve rootlets into the spinal cord until the cell body dies (dying-back axonopathy). Ingestion of 5 to 10 g/kg of triaryl phosphate causes paralysis by 19 to 36 days after exposure.[4]

Clinical Signs The onset of slowly progressive neurologic signs occurs approximately 10 days to a few months after exposure.[5-7] The clinical signs of chronic organophosphate intoxication are rough hair coat, bloat, dyspnea, muscular weakness, and incoordination of the rear legs. The animals may slip on their hindlimbs and assume a dog-sitting posture. The limbs are circumducted and lack normal conscious proprioceptive responses. Affected animals become recumbent. When they attempt to rise, they do so incompletely and fall. Muscular tone and flexor reflexes may be normal, or flaccid paralysis may be evident.[6] The tail, bladder, and rectum are often paralyzed, and affected animals show signs of incontinence, constipation, and perineal scalding. Slight ventrolateral strabismus has been described, and some affected animals have been reported to become mute.[7,8] Most animals retain

VetBooks.ir

VetBooks.ir

a normal appetite and sensorium during the development of the paralysis. Electromyographic changes in experimentally poisoned animals include increased insertional activity, positive sharp waves, and fibrillation potentials in the muscles of the hindlimb, which are consistent with denervation of affected muscles.[9] Organophosphate-induced neuropathy has also been reported in horses, in which the most striking clinical sign was bilateral laryngeal paralysis.[10,11] Degeneration similar to that caused by delayed organophosphate toxicity in other species was most severe in the recurrent laryngeal nerves, but changes present in other peripheral nerves were milder.

Clinical Pathology Clinical pathologic parameters are usually normal. The RBC cholinesterase level is low or undetectable at clinical onset but may return to normal concentrations by the time the animals display profound paralysis. The specific concentration of cholinesterase depends largely on the type of organophosphate and the patient's genetic ability to metabolize the toxic compounds. Whole-blood cholinesterase concentrations in esterase A–deficient animals remain significantly lower than in controls for at least 27 days after administration of haloxon (375 mg). In comparison, the enzyme concentrations in the plasma of normal sheep do not decrease after drug treatment.[12] Cholinesterase levels in exposed animals are not predictive of the delayed onset of neurotoxicity.[7]

Pathology Laboratory confirmation of the condition is usually based on histopathologic detection of a dying-back axonopathy. Macroscopic lesions are not usually observed. Microscopic lesions are found exclusively in the CNS, and their severity appears to be dose dependent. The lesions begin distally and progress retrograde along the long, unsynapsed proprioceptive and motor tracts. The dorsospinal, cerebellar, gracile, and cuneate tracts are most susceptible to the effects of the toxins.[9] Specific lesions include demyelination, internodal axonal swelling, and wallerian degeneration. There is also a vacuolation of the large neurons of the ventral motor nucleus of the spinal cord. The mechanism of neurotoxicity is unknown, but alteration of a cell membrane protein found in neurons and some other cells has been implicated.[12-14] This protein has been designated a "neuropathy target esterase" and is thought to be "aged" by phosphorylation induced by the toxicosis.

Newer compounds in the triaryl phosphate group are less capable of causing delayed neurotoxicity, which offers some hope that the incidence of this type of toxicity may decline in the future.[14]

Treatment and Prevention Delayed organophosphate toxicity is not treatable and is irreversible. Prevention is centered on eliminating access to potential sources triaryl phosphates and ensuring secure storage and disposal of automotive lubricants and fluids.

Motor Unit and Cauda Equina Diseases

Botulism

Robert J. MacKay

Botulism is a highly fatal disease characterized by muscle flaccidity and progressive generalized paralysis. Death results from euthanasia or respiratory failure. Clinical signs are caused by the potent botulinum neurotoxin (BoNT), an exotoxin produced by the anaerobic, spore-forming, Gram-positive bacterium *Clostridium botulinum*. Eight distinct antigenic types of BoNT and botulism have been identified: A to G, with C1 and C2 subgroups.[1,2] All but C2 are BoNT toxinotypes. Two other clostridial species, *Clostridium barati* and *Clostridium butyricum*, also produce BoNT. Mosaic recombinant toxins, with either type C or type D light chains (types CD and DC) have increasingly been identified in outbreaks of bovine botulism in Asia and Europe and probably are the dominant toxinotypes of animal botulism in Europe.[3,4]

C. botulinum spores are ubiquitous in the soil and marine sediments of most regions of the world. In general, soil-origin botulism in large domestic animals in the United States is caused by BoNT types A and B (and occasionally type C), whereas botulism caused by contamination of feed by animal carcasses is caused by BoNT types C and D. Botulism caused by *C. botulinum* type B is endemic among horses in Kentucky and in the mid-Atlantic states and accounts for most cases in the United States.[5] Almost all type A equine cases and outbreaks in the United States have occurred in western states, with Oregon and Idaho overrepresented.[6] Type C cases occur sporadically throughout the country, and type D botulism has rarely been reported in horses.[5] BoNT is acquired either by ingestion of preformed toxin (forage poisoning), germination of ingested spores in the GI tract (toxicoinfectious botulism), or contamination of wounds with spores and subsequent vegetative growth and toxin production (wound botulism).[6] Iatrogenic botulinum toxicity is an occasional cause of botulism in humans and is a potential side effect of the increasing use of BoNT for treatment of neurologic and muscular disorders in horses.[7] Forage poisoning is the most common route of infection, although shaker foal syndrome, a form of toxicoinfectious botulism caused by *C. botulinum* type B, is endemic in the United States.[5]

Horses are much more susceptible to the effects of BoNT than are cattle.[5] In fact, horses and humans are among the mammals most sensitive to the toxin.[1] Botulism in horses typically affects one or a few members of a group. In contrast, the disease in cattle is usually in the form of outbreaks.[5] These outbreaks in cattle have increasingly been associated with ingestion of poultry litter.[8-12]

Pathogenesis The seven authentic BoNTs, BoNT mosaic toxins, and tetanus neurotoxin (tetanospasmin) are closely related 150-kDa proteins that differ in receptor and substrate specificities.[1] Unlike tetanospasmin, which is released alone, BoNTs are associated with a variable number of accessory proteins. It is believed that these proteins stabilize BoNTs during transit through the stomach and then may facilitate transport across intestinal epithelial cells. BoNTs are distributed hematogenously to bind to presynaptic cholinergic nerve terminals, most consequentially at the somatic neuromuscular end plate. Tissue proteases activate the toxin by cleavage into light and heavy chains connected by a disulfide bridge. After receptor-mediated internalization of BoNT in endosomes, the light chain, which is a zinc endopeptidase, is released into the cytosol, where it inactivates the SNARE (soluble *N*-ethylmaleimide–sensitive factor [NSF] attachment protein [SNAP] receptor) complex and thereby prevents docking and fusion of synaptic vesicles.[1] Vesicles containing acetylcholine are thus prevented from undergoing exocytosis and release of neurotransmitter at the neuromuscular junction. Flaccid paralysis of striated muscle is the main clinical result; however, paralysis of smooth muscle occurs, and parasympathetic effector functions fail. Once toxin is bound at the motor end plate, recovery is possible only by the sprouting of new axons and formation of new motor end plates, a process that requires weeks to complete.

Soil contamination of forage (including pasture) is the usual cause of botulism affecting one to several animals in the United States. In endemic areas of the United States, this is almost always caused by BoNT type B; cases associated with type A are also reported.[5,6] In small outbreaks or individual cases involving types C and D (or mosaic toxins), it is often not clear whether the source is carrion or soil contamination. Birds

VetBooks.ir

may play a role in carrying spores from a carcass to feeding areas.[5,13-15] Large outbreaks of foodborne botulism are of two types: germination of *C. botulinum* spores and bacterial growth in spoiled or moldy forage and point contamination of feed (forage or concentrate) by animal carcasses. Spoiled forage can be in the form of hay (especially large bales) or chaff or even grass clippings stored improperly or left out to rot, but usually it involves some type of improperly fermented forage.[5,16-18] Conditions of high pH, low oxygen, and high water content favor spore germination and toxin production.[19]

Traditionally, small-grain silage (i.e., rye, wheat, oats, and barley) has been a common source of botulism for cattle,[20] but corn silage has also been implicated in several outbreaks.[15] The use of plastic film or bags to envelop (or encircle in the case of round bales) partially dried cut forage has become a popular way to produce and preserve silage and haylage for both cattle and horses. Unfortunately, plastic-wrapped forage has been the source of numerous outbreaks of botulism in both species.[5,20-22] These outbreaks have usually involved *C. botulinum* types B or A. In many cases, the plastic on the offending bale is found to be torn.[5] Accidental incorporation of an animal corpse into feed can have devastating consequences. For example, a single cat carcass that contaminated feed caused the deaths of 420 cattle.[5,23] Carcass-origin botulism is usually caused by BoNT type C, type D, or, perhaps more often, either of the mosaic variants type DC or type CD.[16,24] Rodents can be caught in a grain auger and contaminate cereal grain or be killed by hay mowers and incorporated into the center of bales.

Poultry litter has become by far the most important source of carrion-based botulism. Processed broiler litter is widely used as a cheap source of nonprotein nitrogen in feed for beef cattle and as a fertilizer for pastures and hayfields. Accidental incorporation of chicken or rodent carcasses into these litter products has resulted in botulism outbreaks all over the world, affecting up to 5500 steers and 378 sheep and goats in separate outbreaks.[8-11,25,26] For these reasons, feeding of poultry litter to cattle is now banned in Australia and Brazil and guidelines are provided for resting of pasture after litter fertilization. Even free-ranging poultry were suspected as a source of botulism in outbreaks in dairy herds in Germany and The Netherlands.[12,27-29] Type C and D botulism in cattle, including large outbreaks in Brazil, have been associated with osteophagia and sarcophagia (chewing on bones and soft tissues of decaying carcasses) by cattle with phosphorus deficiency.[19,30,31]

C. botulinum can colonize the GI tract of normal infants or adult humans whose intestinal microflora has been disrupted by intercurrent disease or antimicrobial treatment. Shaker foal syndrome, an endemic form of toxicoinfectious botulism caused by *C. botulinum* type B, is of this type.[32] The peak age at occurrence of shaker foal syndrome is 4 weeks; 70% of cases occurr between the ages of 2 and 6 weeks.[5] The juvenile equine GI tract, possibly influenced by putative risk factors such as high milk intake, gastric ulceration, and heightened stress, is relatively hospitable to colonization and toxin production by the organism.[33,34] Toxin is detectable in the feces of approximately 30% of shaker foals but only in the acute clinical phase of the condition.[5] Normal intestinal flora of mature horses presumably inhibit colonization by *C. botulinum*. Evidence has been offered that chronic "visceral" botulism of dairy cattle in Germany is associated with GI dysbiosis and colonization of the GI tract by *C. botulinum*[35,36]; results of studies have contradicted this claim.[37,38]

Diagnosis

Routine bloodwork is unhelpful, and abnormalities found are nonspecific.

BoNT or spores must be present for diagnosis. The level of diagnostic support ranges from definitive to presumptive for detection of the following: (1) botulinum toxin in serum, GI contents, tissues, or wounds; (2) antibodies against botulinum toxin in the serum of convalescent animals; or (3) *C. botulinum* spores in the GI contents or suspect feed materials. Toxin is detected by the sensitive mouse bioassay and typed by mouse protection tests. In 139 horses with a clinical diagnosis of botulism, sensitivity of the mouse bioassay for detection of toxin in feces or GI contents was 32%, and specificity was 97%. In 43 cases in foals, sensitivity and specificity were 53% and 100%, respectively.[39] With mosaic toxins, mice may be protected by both type C and type D antisera, which probably explains why many outbreaks are recorded as involving both toxinotypes.[40] Detection of toxin in serum is possible only in animals with peracute onset and rapidly progressive clinical signs; the toxin is more likely to be detected in cattle than in horses.[19] Spores are detected by inoculation of mice with culture filtrate after incubation of samples anaerobically for several days in enrichment media.[6] ELISA and real-time PCR have been used on enriched samples to detect and distinguish botulinum toxins or toxin genes, respectively.[3,41,42] Sensitive duplex (BoNT types A and B) and simplex (type C) quantitative PCR assays for toxin genes return results in 4 days, in comparison with 2 to 3 weeks for mouse bioassays, and do not require the sacrifice of laboratory animals.[43] Spores are found in the feces of approximately 34% of adult horses and 70% of foals affected with endemic type B botulism but are rarely detected in samples from normal foals or adult horses.[5] The presence of toxin antibodies in survivors has been used diagnostically in outbreaks of type C and D botulism in cattle in Australia[44] but lacked sensitivity when examined in similar outbreaks in England and Wales.[45]

Needle electromyography and decremental responses to repetitive nerve stimulation at low stimulus rates and incremental response at high stimulus rates can be used to support the diagnosis.[46-48] No obvious gross or histologic lesions are typically associated with botulism in most species.

Clinical Signs

The severity and rate of progression of clinical signs are dose dependent. Horses given low doses (e.g., 10^3 mouse lethal dose units) or very high doses (e.g., 10^8 units) of BoNT display the extremes of the clinical spectrum of botulism.[49] The low dose may cause only dysphagia with some progression over 5 to 7 days and then recovery with minimal treatment. In contrast, the high dose causes recumbency within 8 to 12 hours and death within 48 hours of the first detectable signs. After high experimental doses, signs may begin as soon as 12 hours after toxin challenge, whereas when low amounts of toxin have been ingested, cases may continue to develop for up to 14 days after removal of the suspect feed source.

Signs of dysphagia, lethargy, and generalized muscle weakness are the first indications of most naturally occurring cases.[50] In horses, an early sign that can be exploited diagnostically is slow, clumsy prehension and swallowing of concentrates. Normally, bright horses require less than 2 minutes to eat 250 mL of sweet feed from a shallow pan; horses with botulism might take at least twice as long. Efforts to swallow are made with the head extended and seem exaggerated and prolonged; mixtures of food and saliva are retained in the cheeks or between the teeth, or they drop out of the mouth. There are often thin trails of green-stained saliva from each nostril. Endoscopic examination of the nasopharynx usually reveals persistent displacement of the soft palate and aspiration of feed into the trachea. With progression, water runs freely from the nostrils during attempts to drink. For investigating suspected botulism in horses in areas endemic for equine grass sickness, it is important to remember that *both* these conditions interfere with grain ingestion, and both may result in "failure" of the grain test.[50] Drooling of saliva in affected cattle is continuous, although the volume is usually not great, perhaps because of inhibition of saliva production by BoNT. In foals, dysphagia

is evident as spillage of milk from the mouth and regurgitation through the external nares during attempts to suckle. Some horses present with colic, and most have reduced auscultable borborygmi. Affected cows have decreased strength and frequency of rumen contractions and firm feces.

Although animals showing the first signs of botulism may appear obtunded, it is facial muscle weakness and lack of facial expression that creates this impression. Even mildly affected animals tend to lie down more frequently than usual. With stimulation, such an animal may stand and initially walk quite normally before moving in a progressively more stilted and hypometric manner. When the patient is made to stand in one place, tremors may be apparent in the triceps muscles. As the disease progresses, tremor spreads to other antigravity muscles and increases in intensity until the animal collapses into recumbency. Prominent, generalized tremors of this type in foals in the United States with endemic toxicoinfectious botulism gave rise to the description "shaker foal syndrome."

Tongue weakness is an important and consistent early clinical sign and, at least for type B botulism, a reliable indicator of impending limb weakness in at-risk cattle and horses. Tongue tone is assessed for this purpose as the ability of the animal to withdraw its tongue back into the oral cavity after the tip has been pulled out several inches through the interdental space. Another sign of myasthenia around the head is jaw "looseness," evinced by cattle as lack of resistance to forced lateral movements of the lower jaw. Mydriasis and sluggish pupillary light reflexes are variable early signs; the prominence and persistence of these signs probably corresponds well with the dose and type of botulinum toxin ingested.

Between episodes of recumbency, moderately affected animals walk with a slow, shuffling, toe-scuffing gait and hold the head progressively lower.[24] Recumbent animals mount increasingly more ineffectual attempts to stand and often adopt unusual positions while recumbent; severely affected cattle often lie in sternal recumbency with both pelvic limbs extended caudally. Other animals lie in lateral recumbency with intermittent weak voluntary limb movements. Heart and respiratory rates rise during these struggles and, in some cases, respiratory efforts may seem labored, with a prolonged expiratory lift. Animals often die within 3 days of becoming recumbent. In survivors that remain standing, signs of limb weakness, dysphagia, and slow pupillary light reflexes completely reverse over several days to several weeks. Most persistently recumbent horses die, but in those that live and in the larger proportion of cattle that survive after becoming recumbent, efforts to stand typically resume after 1 to 4 weeks. Once such animals have successfully regained the ability to stand, they remain standing for increasingly longer periods until recovery is complete weeks to months later. Generalized but reversible muscle atrophy may be evident in long-standing cases.

The differential diagnosis for horses include any disease associated with muscular weakness and dysphagia, including infectious encephalomyelitis (EPM; EEE, WEE, and VEE; EHM; WNE); generalized myopathy (nutritional, seasonal pasture, polysaccharide storage myopathy); equine motor neuron disease (EMND); grass sickness; hyperkalemic periodic paralysis; and heavy metal toxicity. Diagnoses in cattle that should be ruled out include hypocalcemia, hypokalemia, sulfur toxicity, listeriosis, epidural lymphosarcoma, and organophosphate toxicity.

Treatment Treatment involves nursing care and the use of specific anti-BoNT. Early treatment with specific antitoxin is a critical determinant of survival in horses. Of 91 untreated horses of various ages, 89 died of presumptive type B botulism,[49] whereas 27 of 28 foals[32] and more than 70% of adults[49] treated early with antitoxin survived. Among 92 adult horses with botulism that were transported to a referral hospital for treatment, the survival rate among those given antitoxin was 59%, in comparison with 10% among horses not given antitoxin.[51] The trivalent antitoxin commercially available in the United States (*C. botulinum* A, B, C [Antigen Select, Lake Immunogenetics, Ontario, N.Y.) covers cases typically observed in this country. Only one dose of antitoxin is necessary because the half-life of botulinum antitoxin (equine origin) is approximately 12 days in normal horses.[5] Unfortunately, antitoxin has minimal efficacy if used after the onset of recumbency in adult horses. The doses of antitoxin are 200 mL (≈20,000 IU) for a foal and 500 mL (≈50,000 IU) for an adult horse.[49] Clinical signs may progress for 12 to 24 hours after antitoxin administration. Horses with mild, slowly progressive disease may survive without antitoxin, as long as they are confined to stalls to restrict activity as much as possible.

Recumbent animals need to be kept on deep, clean bedding and, if in lateral recumbency, need to be rolled to the opposite side several times daily. Bony prominences need to be padded with pillows or circular inflatable tubes in an effort to prevent decubital ulcers. Standing horses with prominent neck weakness may suffer life-threatening edema of the head and upper respiratory tract as a result of persistently hanging their heads near to the ground. This was noted to be a feature of the presentation during an outbreak of type C botulism in horses.[22] These horses need to have their heads supported above the level of the heart for several hours daily to allow mobilization of tissue fluid. Adults that are dysphagic can be fed and watered via an indwelling stomach tube. Thoroughly soaked and suspended complete pelleted feed (e.g., Equine Senior, Purina Mills, St. Louis) can be administered indefinitely by this route. It is important to establish the patient's tolerance for bolus feedings and adjust volume and frequency of feedings accordingly. A reasonable starting point is 50% maintenance caloric requirement in 50 mL/kg water divided over four to six feedings. Caloric intake is progressively increased, and feeding frequency decreased as the animal's GI motility allows. Foals are initially fed at least 100 mL/kg of milk daily via this route, in 6 to 12 feedings, increasing to 200 mL/kg if tolerated. All recumbent animals must be in sternal position during feeding and remain sternal for at least 30 minutes after feeding. Patients without auscultable or other evidence of GI motility may be hydrated intravenously and may also be given intravenous parenteral nutrition. Recumbent adults that are being fed by nasogastric tube are at increased risk for large intestinal impactions and should be given 1 to 2 L mineral oil daily with feedings (or the equivalent twice weekly) in an effort to lubricate digesta. Recumbent male horses, including foals, are prone to retention of urine and bladder distention and must be catheterized with meticulously clean technique at least twice daily to prevent pressure necrosis and failure of the bladder wall. Animals that are able to support their own weight when assisted to a standing position should be lifted several times daily by an abdominal sling and allowed to stand with sling support for brief periods (or simply helped to their feet in the case of small ruminants). Flotation tanks may be used intermittently for this purpose in recovering cattle, especially those that are limited by recumbency-associated peripheral neuropathies.

At minimum, laboratory monitoring in recumbent horses with botulism should include daily measurements of hematocrit and total solids for hydration status, twice-weekly urine dipstick and specific gravity measurements to detect urinary tract infections and monitor hydration, and twice-weekly chemistry panels to assess organ function and electrolyte homeostasis. Total CO_2 values should be accorded particular attention. Values below 18 mEq/L indicate metabolic acidosis, whereas values above 35 mEq/L indicate significant metabolic alkalosis. The latter finding suggests compensation for chronic respiratory acidosis caused by respiratory paralysis or aspiration pneumonia and may prompt management changes such as improved sternal

VetBooks.ir

body position, frequent monitoring of respiratory function via arterial blood gas testing, or even initiation of mechanical ventilation. Horses with partial pressure of arterial oxygen (PaO_2) persistently below 65 mm Hg should be given humidified oxygen by nasal insufflation; those with partial pressure of arterial carbon dioxide ($PaCO_2$) persistently above 60 mm Hg need to be mechanically ventilated. This is generally practicable only in foals, although successful ventilation, including weaning from the ventilator, of a 425-kg horse over a period of 14 days has been reported.[52] Of 30 foals with type B toxicoinfectious botulism admitted to a referral hospital and given antitoxin, 16 required nasal insufflation with oxygen, and 8 of those 16 foals also required mechanical ventilation.[32,53]

Antibiotics are generally used only to treat known infections (e.g., aspiration pneumonia or cystitis) or to prevent or treat bacterial sepsis in heavily instrumented foals. In cases in which wound botulism is suspected, the responsible wound must be opened, drained, cleaned, and debrided, in the same approach as is used for wounds associated with tetanus. Antibiotics such as metronidazole and penicillin G that are clostridiocidal are generally not recommended for treatment of wound or infant botulism in humans, out of concern that lysed organisms will release another pulse of BoNT into the circulation.[54] Pretreatment of large animal patients with antitoxin is presumed to remove this theoretical risk. Aminoglycosides should also be avoided if possible because they may potentiate the action of BoNT and were a significant risk factor for a subsequent requirement for ventilation in cases of infant botulism.[54] Because gastric ulcers were an important feature of the original postmortem descriptions of shaker foals,[33,34] such foals are usually on a regimen of acid suppression (e.g., omeprazole, 4 mg/kg PO once daily, or sucralfate, 40 mg/kg PO every 6 hours), although the importance of this approach is unknown.

The rate of recovery from botulism depends on the toxin type and dose, the species and body weight of the patient, and the dose and timing of antitoxin. Dysphagic horses that are able to stand and are given antitoxin will gradually regain the ability to swallow over 1 to 14 days, with most cases resolving within 7 days.[5,49] Mydriasis usually resolves within several days, but the pupillary light reflexes may remain sluggish for weeks. Return to full limb strength often takes more than 1 month.[5,49] Few adult horses that become persistently recumbent recover unless they are provided meticulous nursing care, and most such horses should be euthanized. Decubital ulcers and secondary respiratory problems are the major complications. Recumbent foals that were treated with antitoxin and intensive care at a referral hospital were able to stand in an average of 7 days if they did not need ventilation and in 10 days if they did.[32,53] There is a belief, based on small numbers of cases, that horses with type A botulism have a worse prognosis than those with type B; in fact, only one horse with type A botulism, a 10-day-old foal, has been reported to survive.[48] If the controversial category of chronic visceral botulism is excluded,[36] death rates among cattle and other livestock with botulism are close to 100%.[30,31] This relatively high death rate among livestock needs to be interpreted in view of the general implausibility of providing specific BoNT antitoxin and intensive nursing care to affected cattle.

Prevention BoNT type B toxoid (BotVax B, Neogen Corporation, Lexington, Ky.) is a safe and highly effective vaccine. The primary series is three inoculations, each 4 weeks apart, and then annual revaccination of broodmares 4 to 6 weeks before foaling to provide passive immunity to their foals. Although multivalent and BoNT type C toxoid vaccines for horses and cattle are available in many parts of the world, no vaccine of this type is licensed for horses or livestock in the United States.

Equine Motor Neuron Disease

Robert J. MacKay

EMND is an acquired neurodegenerative disorder of the ventral horns of the gray matter of the spinal cord and selected brainstem nuclei.

History and Epidemiology EMND was first reported in 1990 in 11 horses from four northeastern states.[1] Hundreds more cases occurred in the northeast section of the United States over the subsequent 20 years; fewer cases were scattered elsewhere across the country.[2,3] Additional solitary cases or outbreaks of EMND have been reported in many other countries, including Great Britain, Canada, Ireland, Switzerland, Korea, Belgium, Japan, Brazil, and The Netherlands.[2-6] The annual incidence of EMND cases in the United States peaked in 1997 and has since declined to low levels, with less than one new admission annually to Cornell University College of Veterinary Medicine's Equine Animal Hospital.[7]

The disease usually occurs sporadically, with only one case on a given premise at any time; however, one or more additional cases have occurred on the same premise within 2 years of the original diagnosis.[2] An unusual cluster of more than 80 cases occurred among horses in a city police cavalry in Brazil during the 1990s.[2] The age range of animals in reported cases is 2 to 27 years[3,8]; the mean age is 9 years, and the age at estimated maximal risk is 16 years.[9,10]

In the United States, Quarter Horse breed and age,[9] duration of residence, lack of recent rabies vaccination, exercising in a dirt paddock, a history of cribbing or coprophagia, use of pelleted feed (alone or with sweet feed), and frequent supplementation with vitamin/mineral supplements lacking vitamin E/selenium were significant nutritional risk factors in multivariate logistic regression models.[10] Of most importance is that after other significant risk factors were controlled, a strong negative association was demonstrated between serum/plasma α-tocopherol concentration and EMND risk.[11] In Europe, 13 of 32 horses with EMND had part- or full-time exposure to pasture, and yet all had low plasma levels of α-tocopherol, which suggests that bioavailability of ingested vitamin E was low in these horses.[8] A horse in Finland developed EMND despite supplementation with 300 mg α-tocopherol daily for the previous 10 years.[12] In that case, daily supplementation with excessive amounts of iron was suggested as a possible cause. In the United States, horses with EMND that had normal access to pasture had enteric or hepatic disease, which presumably resulted in malabsorption of vitamin E.[3,13] Eosinophilic enteritis associated with the presence of giant ciliated protozoa was described in five young Andalusian horses with EMND, which led the authors to speculate that these lesions either caused α-tocopherol deficiency or were the result of α-tocopherol deficiency.[14]

Although epidemiologic analyses of EMND data do not suggest a familial basis for the condition, histologic evidence of both NAD/EDM and EMND were found in two young Thoroughbreds and a Paint horse.[15] One horse had the NAD/EDM phenotype, one had the EMND phenotype, and one had clinical signs of both conditions. These horses had a common Thoroughbred ancestor within five to six generations.

Cause and Pathogenesis EMND is a spontaneous, progressive, sporadic, even solitary, condition that closely resembles progressive spinal muscular atrophy, a variant of amyotrophic lateral sclerosis (Lou Gehrig disease) of humans.[9] Although sporadic amyotrophic lateral sclerosis is probably multifactorial, it is widely believed that oxidative stress is involved in the final common pathways of neuronal injury. Evidence of systemic oxidant stress in horses with EMND includes the dominant involvement of oxidatively active type

VetBooks.ir

1 myofibers in atrophied skeletal muscles and the abundant deposits of ceroid lipofuscin found in the retinal pigmented epithelium and in the endothelium of spinal cord capillaries.[3,16] Such deposits are thought to be the end products of peroxidation of membrane polyunsaturated fatty acids.[17]

In addition to the epidemiologic evidence of an association between hypovitaminosis E and EMND, the disease has been reproduced experimentally by prolonged feeding of vitamin E–deficient diets. After 21 to 28 months on a diet deficient in vitamin E but high in the pro-oxidant transition elements iron and copper, 4 of 8 horses developed clinical signs of EMND that were confirmed histologically.[18] In a separate experiment, 4 of 10 horses on the vitamin E–deficient diet but with normal iron and copper levels developed clinical signs of EMND after 18 to 37 months, and in the remaining horses, the disease was confirmed histologically via peripheral nerve biopsy or necropsy.[19] Together, the results of these experiments and epidemiologic studies confirm that a diet low in vitamin E is a strong risk factor for EMND. Left unresolved is whether vitamin E intake is the *only* responsible nutritional or management factor influencing the development of EMND in these experimental horses and in other affected horses around the world.

Clinical Signs

The clinical signs of EMND reflect denervation of skeletal muscles. Signs of muscle weakness and atrophy dominate the clinical presentation.[2-4,13,18] Weakness commonly occurs acutely in affected horses with noticeable muscle wasting; it is uncommon in affected horses without such wasting. In four horses that developed EMND when fed a vitamin E–deficient diet, the mean weight loss was 92 kg at the time signs of limb weakness occurred.[2] In rare cases, the atrophy may advance insidiously without sudden weakness. Typically, there is acute onset of trembling in antigravity muscles and generalized sweating. Episodes of recumbency are frequent. When standing in one place, horses with EMND adopt a characteristic "horse-on-a-ball" stance with the limbs gathered close together under the body (Fig. 35.22).[20] Affected horses lack the strength necessary to engage the stay apparatus of the limbs when standing still; thus they constantly shift weight between limbs and have great difficulty standing in a confined area such as stocks. Acutely affected horses are more comfortable walking than standing, although even brief walking exercise may cause signs of distress such as sweating, tachypnea, and nasal flaring. Typically, at the walk, protraction phases appear somewhat short and hypometric. Horses with EMND do not have signs of ataxia such as interference between limbs or circumduction of the pelvic limbs.

In most horses with EMND, the head is carried below the shoulders, usually reflecting obvious wasting of the neck muscles.[2] The tail head is elevated in many cases because of atrophy and contracture of the dorsal coccygeal muscles.[2] Widespread muscle atrophy, if not present at presentation, develops quickly (days to weeks) and is most obvious in the quadriceps, triceps, and gluteal areas.

Despite the frequent occurrence of pathologic changes in the motor nuclei of cranial nerves V and XII, noticeable atrophy of the masseters or tongue is rarely reported.[21-23]

In approximately 40% of cases, fundoscopic examination reveals a horizontal band of pigment above the optic disk at the tapetal-nontapetal junction.[2,17] The pigment may be brown-black to yellow-brown and has a reticulated or mosaic appearance. Surprisingly, problems with vision have not been reported even in EMND horses with severe pigment retinopathy.[17]

FIG. 35.22 Equine motor neuron disease in a 13-year-old Quarter Horse mare whose feet are placed close together under the body in a characteristic "horse on a ball" stance. Also note the generalized muscle atrophy, extended tail, and flared nostrils (indicative of severe exercise intolerance).

Laboratory Findings

Typical cases have below-range plasma/serum α-tocopherol concentrations. However, as a stand-alone test, α-tocopherol concentration is quite nonspecific[20]: Normal pasturemates of horses with experimentally induced[18] or naturally occurring[13] EMND often also have low α-tocopherol concentrations. In healthy pasture-fed horses, α-tocopherol concentrations are variable during the day and often drop transiently below the normal range.[24] For this reason, it is recommended that plasma (or serum) from serial blood collections throughout the day be combined for the purpose of α-tocopherol assay.[24] Although CSF α-tocopherol concentrations in horses with EMND have not been published, they are presumed to be lower than the published normal range of 4.1 to 13.5 ng/mL.[25,26]

Mild to moderate increases in plasma or serum CK and AST activity are found during the initial rapid progression of clinical signs, but muscle enzyme activities may be normal in chronic stable cases.

Cytologic changes in CSF are not observed in EMND; however, there may be increased total protein concentration and CK activity.[3,18] The IgG index is high in many cases, which suggests the presence of intrathecally produced IgG.

Ancillary Tests

NEEDLE ELECTROMYOGRAPHY. Needle EMG can be performed in a standing or recumbent, anesthetized horse. Horses with EMND often have abnormal EMG findings, including prolonged insertional activity and pathologic spontaneous activity such as fibrillation potentials and trains of positive sharp waves.[20] Signs of denervation are found in facial muscles, as well as appendicular and epaxial muscles.[3] Standing EMG is preferred in order to avoid anesthesia in weak, compromised animals; however, interpretation of these studies is difficult because of movement artifacts associated with the reluctance of affected horses to stand in one place. The use of sedation and caudal epidural anesthesia (lidocaine, 0.2 mg/kg) was reported to facilitate the procedure in a horse with EMND.[21] Techniques for quantitative analysis of motor action potentials have been published, and results are abnormal in horses with EMND.[20,27,28] Regardless of the EMG technique used, abnormal results are nonspecific as to cause; they suggest only denervation or myopathy.[20]

GLUCOSE ABSORPTION/METABOLISM TESTING. Oral glucose tolerance tests in horses with EMND yielded abnormal results in approximately 50% of reported cases, whereas results of oral xylose absorption tests were normal or slightly low.[2,13,28] It appears that increased glucose metabolism, possibly in

association with increased glucose sensitivity, rather than reduced intestinal absorption, is the cause of abnormal oral glucose tolerance in horses with EMND. Euglycemic clamp results from one horse showed a 5.4-fold increase in insulin sensitivity in comparison with control horses.[29]

NERVE BIOPSY. Biopsy of the ventral branch of the spinal accessory nerve allows reliable antemortem diagnosis of EMND, at least in subacute and chronic cases.[3,30] A 5-cm section of the nerve is excised as it courses over and into the medial belly of the sternocephalicus muscle. The procedure can be performed when an anesthetized horse is either standing or recumbent and does not induce visible muscle atrophy at the surgical site. A positive histologic result is evidence of mild to severe wallerian degeneration of axons and Schwann cell proliferation. Chronic cases are marked by loss of myelinated fibers, presence of compact Büngner bands, and increased endoneurial collagen. The positive predictive value of nerve histologic findings for EMND was 77.4%, and the negative predictive value was 90%.[30] False-negative results appeared to be most likely to occur in acute cases (<2 weeks). Nerve biopsy has largely been supplanted as an initial test by evaluation of sacrocaudalis dorsalis muscle biopsies (see next section).

MUSCLE BIOPSY. The initial invasive procedure of choice is biopsy of the sacrocaudalis dorsalis tailhead muscle.[3] This muscle is rich in type I myofibers, a fiber type that is highly sensitive to the effects of denervation. With the animal under local anesthesia, the muscle sample is obtained, placed on a tongue depressor, and sent chilled or in 10% formalin for histologic examination. Neurogenic atrophy is characterized by variable numbers of angular atrophied fibers. Atrophied muscle fibers are of both types, but type I fibers predominate. The results of muscle biopsy have high sensitivity for EMND (>90%) but relatively low specificity.[3] In chronic EMND cases, histologic study of nerve biopsy samples may have higher sensitivity for diagnosis than that of muscle samples.[3]

Diagnosis

Antemortem diagnosis of EMND is suspected on the basis of typical clinical signs, patient's age of 2 years or older, and diet low in green forage and high in carbohydrates. Needle EMG findings of denervation, especially in the deep limb muscles, are technically difficult to obtain because of movement artifact in weak horses, but they do support the diagnosis, as do mild to moderate increases in plasma CK and AST activity and low plasma α-tocopherol concentration. Evidence of denervation in muscle or nerve biopsies in the context of the preceding clinical and laboratory findings is tantamount to a definitive diagnosis of EMND. In occasional cases of insidiously progressive EMND, especially in nonendemic areas, diagnosis is made only post mortem.

Necropsy Findings

Although horses with EMND exhibit obvious weight loss, fat deposits noted post mortem are usually within normal limits.[1,4,20,31] Acute cases are characterized by widespread degeneration and loss of somatic motor neurons in the ventral horns of the spinal cord, accompanied by degenerative axonal changes in the ventral roots and peripheral nerves. All brainstem cranial nerve somatic motor nuclei, except those of cranial nerves III, IV, and VI, are variably involved. Most affected neurons are swollen, markedly chromatolytic, and diffusely argyrophilic; severely affected neurons are shrunken or vacuolated. Horses with cases of disease burnout (described later) demonstrate glial scars consisting of astrocytes and lipofuscin-laden microglia. Additional deposits of ceroid lipofuscin are found in the retinal epithelium and occasionally in the liver and intestine. Relatively minor neurodegenerative changes may be found in dorsal root ganglia. In contrast with grass sickness, minimal or no lesions are present in the autonomic nervous system. In skeletal muscles, angular atrophy affects all myofiber types, with some selectivity for type I fibers. Atrophied fibers are intermingled among normal fibers and fascicles. Involvement of the deeper muscles of the limbs may be grossly evident as pale discoloration. Histologic signs of EMND concurrent with NAD/EDM were identified in three young horses.[15] A genetic basis for these cases is suspected.

Treatment

The only treatment recommended for horses with EMND is vitamin E. This can be supplied in good-quality grass and alfalfa hay or by vitamin E supplementation (at 10 to 20 IU/kg/day). The water-dispersed form of natural vitamin E (RRR-α-tocopherol) is five to six times more bioavailable than synthetic vitamin E (all-rac-α-tocopherol acetate or d,l-α-tocopherol), and its administration results in rapid rises in plasma and CSF concentrations of α-tocopherol. After an initial period of at least 2 weeks' supplementation with water-dispersed RRR-α-tocopherol designed to raise plasma and CSF α-tocopherol concentrations into the normal range, treatment can be transitioned to less expensive synthetic RRR-α-tocopherol acetate for subsequent maintenance therapy.[26]

The frequent clinical observation that many horses with EMND have increased appetite may be explained by an estimate that daily caloric requirement of horses could be doubled.[20] Thus as part of the convalescent program of surviving horses, high-quality pasture, hay, and concentrate are recommended in high quantities.

Clinical Course

Within 6 weeks after onset of signs, approximately 40% of horses progressively deteriorate and must be euthanized; a similar number undergo marked improvement in clinical signs (usually after relocation to another premise or administration of antioxidants).[2] Some of these "recovered" horses look normal but may show relapse under the pressure of intensive training or competition.[1] In the remaining 20%, the disease appears to "burn out"; such horses survive with permanent and obvious muscle wasting and emaciation.

Acquired Equine Polyneuropathy (Scandinavian Knuckling Syndrome)

Robert J. MacKay

Since 1995, a disease characterized by bilateral knuckling of the metatarsophalangeal joints has been observed in more than 400 horses in Sweden, Norway, and Finland. Originally known as *Scandinavian knuckling syndrome*, the condition was renamed *acquired equine polyneuropathy*.[1,2] Adult horses of any age, all breeds, and both sexes are affected. Large-fiber polyneuropathy with inflammatory demyelination-remyelination and conspicuous Schwann cell inclusions has been reported in affected horses.[2,3] The cause of the disease is unknown, although an ingested neurotoxin is considered the probable cause, possibly acting to trigger autoimmune demyelinating neuropathy.[3] Clinical signs appear mainly in late winter to spring, and almost all affected horses have been fed wrapped forage (haylage/silage). In Sweden and Norway, the disease has clustered within farms, and all cases on a particular farm occurred within 100 days of the index case on that farm.[1] The clinical signs are bilateral pelvic limb hyperflexion and collapse of the limb and knuckling of the metatarsophalangeal joints, so that the dorsum of the hooves contact the ground. Surprisingly, there is no or only slight atrophy of digital extensor muscles, and neurogenic atrophy is not found on histologic study.[3] It has been suggested that the affected nerves are type 1a and 1b sensory nerves from muscle spindles and that clinical signs of acquired equine polyneuropathy may be related to impaired reflex modulation of α motor neurons to the digital extensors of the pelvic limbs.[3] Mild and inconsistent thoracic limb weakness has been described in a few cases. The disease apparently has no cutaneous sensory

VetBooks.ir

or proprioceptive component, and cranial nerve abnormalities are not found clinically. In a longitudinal study of Norwegian horses with acquired equine polyneuropathy, 35% were euthanized within 6 months of diagnosis because of severe or persistent signs.[4] Of 57 surviving horses with long-term follow-up, all but 3 returned to a previous or higher level of performance. Those 3 horses experienced a relapse or new attack during the follow-up period. Possible disease-related clinical signs (intermittent pelvic limb weakness, fetlock knuckling) were reported in 14 of the surviving 57 affected horses. An apparently similar syndrome, termed *idiopathic peripheral polyneuropathy*, has been reported in horses in Japan[5]; however, this syndrome severely affects all limbs, and limb muscles show marked neurogenic atrophy.

Definition and Etiology

Robert J. MacKay

Polyneuritis Equi (Neuritis of Cauda Equina)

Polyneuritis equi is a progressive granulomatous polyganglioradiculoneuritis involving the cauda equina and, less commonly, cranial nerves and other spinal nerves.[1-4] The disease usually occurs in adult horses,[2] although it has been described in a yearling filly.[5] No breed or gender predilection has been noted.[6]

The cause of polyneuritis equi is unknown. The lesions are characterized by heavy infiltrations of cytotoxic T cells and macrophages with lesser populations of helper T cells, B cells, and plasma cells.[1,7] This pathologic process is similar to experimental allergic neuritis of rats, coonhound paralysis of dogs, and Guillain-Barré syndrome in humans, all of which are suspected of having an autoimmune basis.[1,8] Other proposed causes include a hypersensitivity reaction after systemic infection, aberrant migration of helminth larvae, and association with equine herpesvirus type 1, equine viral arteritis, or adenovirus infections.[5,6,9,10] However, conclusive evidence for any of these theories is lacking.

Clinical Signs The clinical signs of polyneuritis equi reflect destruction of somatic and autonomic lower motor neurons and sensory neurons at the level of the nerve roots and dorsal root ganglia. Vague signs of dysuria and tail rubbing may precede the neurologic syndrome.[1] The onset of acute signs is marked by cutaneous and muscular hyperesthesia around the hindquarters, focused on the tailhead. Rubbing and chewing of this area is characteristic. Over days to weeks, there is progressive desensitization of previously hyperesthetic areas until the skin over the caudal rump, tail, perineum, and caudal thighs becomes anesthetic. At least initially, there may be a zone of residual hypersensitivity around the margins of the desensitized skin. Paresis of the tail, bladder, rectum, anal sphincter, and penis progresses, with neurogenic atrophy of the muscles of the tail. Fecal retention and overflow urinary incontinence reflect paralysis of rectal and detrusor muscles, respectively. Urine dribbling causes scalding and staining of the perineum (in mares) and hindlimbs. In males, the penis may remain dropped out of the sheath, although penile and preputial sensation is preserved. Impotence resulting from incomplete erection and inability to achieve intromission was the presenting sign in one stallion with polyneuritis equi.[11] In some cases, involvement of the lumbosacral nerve roots causes variable weakness and ataxia of the pelvic limbs and atrophy of muscles of the rump or legs. Any spinal nerve root may be affected symmetrically or asymmetrically, and so discrete areas of muscle atrophy, cutaneous desensitization, and sweating are possible anywhere along the spine. Weakness and ataxia have been observed in all four limbs of a few affected horses.[12-14]

Cranial nerves can be involved. The signs depend on the individual nerves affected and the severity of the disease. The nerves most often affected are the motor division of the trigeminal nerve (cranial nerve V; atrophy of chewing muscles), the facial nerve (VII; facial paralysis), and the vestibular nerve (VIII; head tilt and ataxia), although signs due to involvement of cranial nerves XII (tongue weakness and atrophy), III (reduced pupillary light reflex), IX, and X (dysphagia) have also been reported.[9,12-14] Signs of cranial nerve involvement are usually asymmetric.

Any disorder that affects the cauda equina may cause similar signs. These include instabilities of the caudal spine caused by luxations or fractures, EHM, sorghum-sudangrass intoxication, rabies, and other infectious diseases that involve the cauda equina or sacrocaudal spinal cord segments, as well as some primary diseases of the lower urinary tract.

Diagnosis CSF may have a moderate mononuclear pleocytosis with lesser numbers of nondegenerate neutrophils and high protein concentration. Electromyographic abnormalities occur in polyneuritis equi as a result of denervation of affected muscles. Affected horses have high circulating antibodies to P2 myelin basic protein, but this test is not available commercially and is reported to be nonspecific.[15,16] The diagnosis was supported in one case by the finding of an intense mononuclear neuritis in a biopsy sample from the sacrocaudalis dorsalis muscle.[1] Thickened sacral nerves were also imaged by transrectal ultrasonography in that horse.

Necropsy Findings The cauda equina is thickened, discolored, and covered with edematous tissue and fibrous material. There may be adhesions of the nerve roots or the spinal cord to the meninges and the periosteum of the vertebral canal. Subdural or epidural petechiation and hemorrhage are sometimes present.

At the microscopic level, the major finding is granulomatous inflammation of the extradural and intradural parts of the nerve roots. The nerve sheaths are thickened and infiltrated to varying degrees by lymphocytes, plasma cells, lymphoblasts, macrophages, giant cells, eosinophils, and, in rare cases, neutrophils. Nerves are obliterated by intraneural inflammation, necrosis, and endoneurial thickening. Axonal degeneration and demyelination are present in surviving nerves. Nerve bundles are separated by large amounts of fibrous tissue. There is minimal to moderate evidence of nerve regeneration.

Treatment and Prognosis Treatment with corticosteroids at antiinflammatory doses early in the course of the disease may be palliative but is not curative. Immunosuppressive gold salts and cytotoxic drugs such as azathioprine have been used for the treatment of polyneuritis equi, but the efficacy of such approaches has not been reported. General supportive care should be given, including fluid therapy when necessary, and the rectum and bladder must be emptied manually and by catheter, respectively. With careful management, affected horses can be kept alive for months, but the prognosis for extended life is still regarded as hopeless; the usual cause of death is euthanasia for humane reasons.

Sorghum Toxicity

Robert J. MacKay • Mary O. Smith

Definition and Etiology A syndrome of ataxia and cystitis in horses, cattle, and sheep has been linked to the consumption of annual grasses of the genus *Sorghum*.[1-4] Incriminated species have included *Sorghum bicolor* (sorghum), *Sorghum sudanense* (sudangrass), sorghum-sudan hybrids, and *Sorghum halepense* (Johnson grass, oxgrass). The causative toxin is not known, although there is evidence that chronic cyanide toxicity has a role.[5] This disease does not appear to be linked to the breed, gender, or age of an animal.[3]

VetBooks.ir

Clinical Signs The first sign observed is usually ataxia of the pelvic limbs, followed by urinary incontinence. Affected animals have a swaying pelvic limb gait and a tendency to knuckle in the fetlocks. Occasional affected horses may walk with a hopping gait, in which both pelvic limbs are lifted off the ground simultaneously. Signs in horses tend to worsen on backing, and animals may fall or even become recumbent.[3] During an outbreak of the disease in cattle, 3 of 54 affected cows became recumbent, and 2 died.[6] The perineal muscles are relaxed, and urine dribbles from a flaccid, distended bladder.[4,6] In mares the vulva opens and closes repeatedly; in stallions and geldings the penis is relaxed and protrudes from the prepuce.[7] There may be paresis of the tail in affected horses and cattle. Loss of skin sensation over the hindquarters has been described in a cow, which suggests involvement of both sensory and motor nervous pathways.[6] Headshaking, ataxia, weakness, recumbency, opisthotonos, and death have been reported in affected sheep, and the rate of mortality can approach 50%.[8]

Cystitis in affected animals may be severe and occurs secondary to urine retention. Dribbling of urine onto the skin of the perineum and pelvic limbs results in scalding of the skin and dermatitis. Pyelonephritis is a common sequela to chronic cystitis and may be fatal.[2,3] Sometimes the clinical signs may be chronic; in one outbreak, horses had been showing signs for as long as 3 years.[3]

Abortion in mares, arthrogryposis as a congenital deformity of foals and lambs, and neurologic abnormalities in newborn lambs have also been linked to the feeding of *Sorghum* plants.[3,8]

Clinical Pathology Diagnosis of sorghum toxicity is based on the presence of typical clinical signs in association with a history of feeding on *Sorghum* plants. No specific diagnostic test is available. Cystitis and pyelonephritis are identified by typical findings on routine urinalysis, serum biochemistry, and urine culture.

Pathophysiology The precise nature of the toxic substance in *Sorghum* plants that causes this syndrome is unknown. Most *Sorghum* spp. are cyanogenic plants that contain the cyanogenic glycoside surrina, which, when hydrolyzed, releases hydrocyanic acid at potentially toxic concentrations.[1] Acute, sometime fatal cyanide toxicosis has been described in cattle that ingest large amounts of rapidly growing sorghum.[9,10] Chronic exposure to cyanide has been suggested as the cause of the neuropathologic changes found in animals with ataxia-cystitis syndrome.[3] Experimental long-term dosing of potassium cyanide to goats caused histologic changes in the CNS that were comparable with those of the natural disease.[5] It has also been suggested that the toxic principle in *Sorghum* plants may be a lathyrogen-like substance.[2]

Epidemiology The cyanide content of *Sorghum* plants is increased by rain after drought and higher in new shoots and wet plants.[1] In one survey of the disease in horses, most cases occurred during the wet season and involved young, growing plants.[3] The period of grazing before the onset of signs ranges from 1 week to many months.[3,6]

Necropsy Findings Wallerian degeneration, swelling of axons and myelin sheaths, and demyelination in a small number of nerve fibers throughout the length of the spinal cord and in the cerebellum, cerebellar peduncles, and pons have all been described, together with the presence of phagocytic gitter cells. In lambs grazing on sorghum, there were also lesions in the ventral horn gray matter of the spinal cord.[3,6,8] These changes are not associated with specific tracts. Ultrastructural studies of brains and spinal cords of affected sheep have revealed that the axonal swelling (spheroids) are composed of aggregates of neurofilaments, mitochondria, vesicular bodies, and dense bodies, enclosed within a thin myelin sheath.[8]

Treatment and Prognosis Withdrawal of *Sorghum* plants from the diet of affected animals results in a gradual improvement in the clinical signs over weeks to months, although recovery may not be complete.[6,8] Death is a potential outcome, however, and mortality rates can be high in some cases.[8] There is no specific treatment for affected animals. Supportive therapy includes antibiotics for treatment of bacterial urinary tract infections.

Control Avoidance of feeding *Sorghum* plants as a predominant part of the diet or the sole diet is the only method of control. This plant has considerable feed value and does not present a major hazard when used as part of a diversified feeding regimen.

Stringhalt

Robert J. MacKay

Stringhalt is a condition of horses characterized by sudden exaggerated flexion of one or both pelvic limbs during the swing phase of locomotion. Two distinct syndromes are recognized: *classical stringhalt*, a persistent condition of individual horses involving only one limb; and *pasture-associated* or *Australian stringhalt*, which involves both pelvic limbs and occurs in outbreaks in horses at pasture. Both forms occur worldwide, but pasture-associated stringhalt is most common in Australasia, South America, and the western United States.[1-6]

Clinical Signs The defining clinical sign of stringhalt is abrupt hyperflexion of the hock and stifle during attempted movement. In classical stringhalt, typically only one limb is affected; in contrast, Australian stringhalt is almost always bilateral, although signs may be asymmetric (Fig. 35.23). Stringhalt is most evident during backing, sharp turning, when the horse goes down a slope, after a sudden stop, and during the transition from standing still to walking forward.[2,7] Signs may be exacerbated by excitement, cold weather, or hard exercise.[2,8] During forward walking, the flexing limb snaps forward and upward in an adducted or sagittal plane; this feature of stringhalt distinguishes it from similar presentations of shivers, in which the limb is abducted during protraction.[9] The clinical presentation of stringhalt varies greatly, even among horses with

FIG. 35.23 Bilateral hyperflexion of the pelvic limbs in a horse with pasture-associated (Australian) stringhalt.

pasture-associated stringhalt grazing on the same pasture. In mild cases, flexion is only slightly exaggerated and pelvic limb action may be completely normal at gaits above the walk. Such horses are able to perform without impairment. At the other end of the spectrum, the upper joints of the limb flex so violently that the dorsum of the fetlock slaps against the horse's abdomen with each stride.[7] When the condition is bilateral, the result is a bouncing bunny-hopping gait in which "progression can only be accomplished with a series of bounds and plunges extremely painful to witness."[4,10] In the most severe cases, ambulation is impossible. An atypical pasture-associated stringhalt syndrome is described wherein the forelimbs are also involved and there are signs of generalized weakness.[1,2,4,11,12] Signs of obtundation, nervousness, hyperesthesia, or increased aggressiveness have occasionally been reported.[2,4,6,13] A variable proportion of horses with pasture-associated stringhalt have abnormal laryngeal movement, stridor, or abnormal vocalization.[4,5,13,14]

Onset of stringhalt is usually sudden. Signs may fluctuate but tend to worsen over several weeks in horses with pasture-associated stringhalt, before plateauing, often for several months; then they begin to improve.[2] Within 2 weeks after onset of severe pasture-associated stringhalt, atrophy of the muscles of the gaskin and, less obviously, the thigh and other parts of the body, becomes apparent.[2,15] Horses with severe or atypical pasture-associated stringhalt may develop profound generalized neurogenic muscle atrophy that results in marked weight loss despite normal appetite and food consumption.[12]

Clinical Pathology No abnormal clinical pathologic findings are associated with stringhalt. EMG of affected muscles reveals increased insertion activity and abnormal spontaneous activity such as fibrillation potentials and positive sharp waves consistent with denervation.[2,14] NCV is slowed in the peroneal nerves of affected limbs, which indicates demyelination, and improves as animals recover clinically.[2]

Pathophysiology The cause of classical stringhalt is unknown. Foot conditions and articular lesions of the hock or stifle are possible risk factors.[4,7,16] Trauma to the proximal dorsal metatarsus, particularly over the digital extensor tendons, often precedes classical stringhalt and probably is an important factor in the development of this form of the condition.[2,4] Months may elapse between injury and the onset of stringhalt.[17]

Since 1884,[10] most reports of pasture-associated stringhalt have implicated the common pasture weed *Hypochaeris radicata* (also known as flatweed, castear, cat's ear, or false dandelion).[1,3,4,8,12,13,16] Most outbreaks occur in late summer or autumn among horses grazing on drought-damaged pastures heavily infested with *H. radicata*. Cases often occur after weeks to months of grazing on suspect pastures.[10,13] Interestingly, some affected horses are thought to have developed a taste for flatweed, to the exclusion of other forage.[13] Several outbreaks have been associated with "true" dandelion *(Taraxacum officinale)*, and one has been associated with mallow *(Malva parviflora)*.[1,4,18] During pasture-associated stringhalt outbreaks, less than 50% of populations are usually affected, but attack rates vary widely.[2,8,13] Some attempts at producing pasture-associated stringhalt by feeding cut *H. radicata* to horses have been unsuccessful; however, stringhalt was induced in a 6-month-old colt fed a daily average amount of nearly 10 kg of *H. radicata* harvested from a pasture where the disease had occurred.[3]

Pasture-associated stringhalt is a distal neuropathy primarily affecting large myelinated axons of the peripheral nervous system.[15,19] The longest nerves in the body—namely, the recurrent laryngeal nerves and the peroneal and tibial branches of the sciatic nerve—appear to be most severely affected. This also explains why tall horses are more prone to the condition than young horses, ponies, or small native Chilean breeds.[18] Shetland ponies have been affected, however.[8] The lesions of pasture-associated stringhalt are consistent with ingestion of a neurotoxin produced by either pasture weeds such as *H. radicata* or, less probably, by associated fungi.

Pasture-associated stringhalt and some cases of classical stringhalt probably result from interference with myotatic reflexes.[17] The immediate cause of pelvic limb hyperflexion in pasture-associated stringhalt is presumably progressive degeneration of large myelinated axons in tibial and peroneal nerve branches, including α motor neurons to skeletal muscle, 1A and 1B sensory neurons from muscle spindles, and Golgi tendon organs. Classical stringhalt may be the final common sign of a variety of insults: besides interference with limb reflexes, mechanical effects of adhesions involving the muscles and tendons of the digital extensors of the pelvic limb may occur, as may painful conditions of the hock or distal limb.

Pathology In long-standing cases of pasture-associated stringhalt, affected animals exhibit variable, often severe atrophy of the muscles of the pelvic limbs, especially distally, and atrophy of the muscles of the larynx supplied by the recurrent laryngeal nerves.[1,12,19] Peripheral nerves demonstrate axonal degeneration of large diameter fibers acutely and decreased numbers of myelinated fibers in chronic cases, with perineural fibrosis and accumulation of myelin debris. Evidence of nerve regeneration, including regenerating nerve clusters, "onion bulb" formations, and Schwann cell proliferation, is usually found. Recurrent laryngeal nerves, branches of the sciatic nerves, and variably other nerves are affected with a proximal to distal gradient of increasing severity.

Treatment Care should be taken to identify sources of pain (e.g., arthritis, hoof abscess, recent hoof trimming) that might account for stringhalt-like signs. Signs of stringhalt were blocked in one horse by intraarticular anesthesia of the distal tarsal joints; use of intraarticular corticosteroids permanently resolved the problem.

Several skeletal muscle relaxants have been investigated in horses with pasture-associated stringhalt. Phenytoin, an inhibitor of voltage-gated sodium channels, gives partial to complete remission of signs in horses in a dosage of 10 to 15 mg/kg PO, once or twice daily.[2,12,14] Mephenesin, which acts in the spinal cord to specifically inhibit polysynaptic reflexes, suppressed signs in a horse with chronic pasture-associated stringhalt[7] but was ineffective in an outbreak of pasture-associated stringhalt.[1] Baclofen, an analog of the inhibitory neurotransmitter GABA, had no effect in a horse with severe stringhalt.[8,14] Taurine (10 mg PO q24h) may help with behavioral abnormalities.[13]

Although the results of the procedure are unpredictable, surgical removal of the distal muscle belly and tendon of insertion of the lateral digital extensor effects a clinical cure in a proportion of horses with either classical stringhalt or pasture-associated stringhalt.[3,4] Of four horses with classical stringhalt treated with lateral digital extensor myotenectomy, two resolved and the other two improved partially. The surgery was precluded in two other horses because of adhesions involving the tendon.[17] Responses to a survey of veterinarians in Australia indicated that more than 50% of over 100 lateral digital extensor operations had been successful in eliminating signs of stringhalt.[2] Even more impressive was that 11 of 13 horses with pasture-associated stringhalt were normal within 12 days of surgery.[5] The surgery can be performed with horses standing or in lateral or dorsal recumbency. An initial skin incision is made over the lateral digital extensor tendon immediately proximal to its junction with the long digital extensor, and the tendon is isolated and exposed. A second incision is made over the muscle belly proximal to the hock, and the muscle belly is dissected free of overlying fascia. The tendon is severed through the distal incision, and then the tendon is pulled through its sheath into the proximal incision

VetBooks.ir

by means of traction on the muscle. The muscle belly is then incised 2 cm proximal to the musculotendinous junction. In a modification of the technique, which may improve success rate, 7 to 10 cm of muscle is removed. After the fascial and skin layers have been closed, a bandage is applied over the surgical site and maintained, with box stall rest, for 2 to 3 weeks.

Prognosis There is almost no information on outcomes for horses with classical stringhalt; however, it is commonly supposed that most cases persist, although they may improve with time. Of one series of four cases that developed after proximal dorsal metatarsal trauma, one horse recovered, two improved, and one's condition was unchanged for at least 6 months after onset of signs.[17] Many cases of pasture-associated stringhalt recover normal gait and muscle mass if removed from toxic pasture. In a series of 70 cases monitored over several years in France, 36 recovered in an average of 8 months, 6 died, and 14 still had stringhalt signs at least 2 years after onset.[13] The few reported deaths were in horses that were either unable to stand or unable to move to sources of water and feed; they were euthanized for humane reasons. Recovery times of 3 days to 3 years have been recorded; most horses take 6 to 12 months.[2,7] It is unclear to what extent athletic performance returns after clinical recovery from severe pasture-associated stringhalt. There is evidence that laryngeal dysfunction may persist beyond the time of recovery from gait abnormalities.

Tick Paralysis

Robert J. MacKay

Definition and Etiology An ascending lower motor neuron paralysis has been described in horses, cattle, sheep, pigs, dogs, cats, and poultry in Australia, associated with feeding by ticks of the genus *Ixodes*, especially *Ixodes holocyclus*.[1-7] In the United States and Canada a similar disease occurs in dogs, humans, cattle, sheep, New World camelids, and wild animal species as a result of infestation with several *Dermacentor andersoni*.[8-10] A similar problem occurs in small ruminants in Africa, where *Ixodes rubicundus* and *Rhipicephalus evertsi* are the tick species implicated.[11-13]

Clinical Signs Progressive generalized flaccid paresis develops over one to several days, terminating in recumbency. Death from respiratory paralysis may occur in as little as 24 hours in severe cases.[6] Animals may be found recumbent or may be paraparetic and ataxic in the early stages of disease. When signs are mild to moderate, the differential diagnosis includes a variety of neurologic and nonneurologic diseases such as botulism, rabies, colic, uterine torsion, trauma, myelopathies, myopathies, and metabolic disorders. Of these, only botulism progresses to the profound muscular flaccidity characteristic of tick paralysis. Both reflex withdrawal from a noxious stimulus and the blink reflex are reduced or absent, although sensory function appears normal.

Tick paralysis may be fatal when caused by *I. holocyclus* even when the ticks have been removed. In contrast, paralysis caused by *Dermacentor* spp. is usually reversible if the ticks are removed before the animal is recumbent.[10] Paralysis in sheep does not occur when less than 0.2 *D. andersoni* ticks/kg are present but consistently occurs when more than than 0.8 ticks/kg are present.[10] One to five *I. holocyclus* ticks were found on 85% of horses with tick paralysis.[7]

Diagnosis Diagnosis is based on the clinical signs and finding ticks on the affected animal. There are no pathognomonic findings in affected animals except for the presence of ticks. EMG in tick paralysis in dogs in North America reveals minimal spontaneous activity and lack of evoked CMAPs in response to motor nerve stimulation.[14] Findings in large animals are expected to be similar. CSF is normal in tick paralysis, which helps differentiate it from some, but not all, myelopathies.

Pathophysiology The cause of tick paralysis is believed to be a neurotoxin in the saliva of female ticks that is inoculated into the host when the tick feeds. Nymphs and larvae in large numbers may also cause the disease. In the case of *I. holocyclus*, the toxin has been named *holocyclotoxin*.[15] The toxin or toxins elaborated by *Dermacentor* spp. have not been as well characterized. *Holocyclotoxin* acts by inhibiting release of acetylcholine from nerve terminals at the neuromuscular junction.

Epidemiology The disease occurs worldwide, in association with different tick species in different areas. In North America the region from the Pacific coastal range to the Continental Divide provides especially favorable conditions for the proliferation of *D. andersoni*.[9] Tick paralysis in the United States and Canada occurs mainly in the Pacific Northwest and the Rocky Mountains, although the geographic range of the responsible tick species is much larger. The disease tends to be seasonal in both North America and Australia; most cases occur in the spring, when ticks are most active. In North America, smaller animals such as sheep and New World camelids are more often affected than cattle.[16] In Australia, affected horses were of multiple different breeds, were between 1 week and 18 years of age, and weighed from from 9 to 450 kg.[7] Tick factors probably influence disease severity, and genetic variation within *I. holocyclus* may play a role in toxin potency.[17] A short-lived immunity has been demonstrated in dogs and sheep exposed to ticks.[10]

Necropsy Findings There is no pathognomonic finding at necropsy, although the presence of ticks should increase suspicion of this disease. Death usually results from respiratory paralysis.

Treatment and Prognosis Treatment is supportive after removal of every tick and topical application of an acaricide. Lack of improvement suggests that ticks remain on the animal, except in cases of *I. holocyclus* infestation, in which signs persist and may worsen for 1 to 2 days after removal of all ticks. In small animals, shaving the hair coat may be necessary to ensure detection and removal of all ticks. Areas such as the axillae and groin, in particular, provide good sites of attachment for ticks. The prognosis is good in the case of *Dermacentor*-induced paralysis when tick removal and supportive care are instituted before animals are recumbent. Fatalities occur in cases of *Ixodes*-induced paralysis despite removal of ticks. Cooling of the patient has been suggested in treatment of *I. holocyclus* toxicity, but this practice is controversial; a better approach may be to avoid warming the patient excessively.

Administration of a canine-origin hyperimmune serum has been shown to be beneficial in treatment of horses and a llama.[7,18] In horses, doses exceeding 0.5 mL/kg produced a higher odds ratio for survival than did a lower dose.[7] Adverse reactions such as anaphylaxis, bradycardia, and hypotension occur in a small number of dogs and cats treated with hyperimmune serum, but these can be avoided by of atropine.[19] Two of 95 horses given antiserum had reactions, one of which was fatal.[7]

Of 103 horses treated for tick paralysis in Australia, 27 (26%) died or were euthanized.[7] Paradoxically, the odds of survival were inversely related to the weight of the horse.

Control Environmental control to reduce tick populations and routine use of acaricides may decrease the incidence of tick paralysis.

VetBooks.ir

Equine Grass Sickness

Robert J. MacKay

VetBooks.ir

Grass sickness is a debilitating, often fatal, dysautonomia of equids associated with full-time access to pasture.[1] Because lesions are also found in the somatic lower motor neurons, it has been suggested that it is more accurate to describe grass sickness as a polyneuropathy rather than a dysautonomia.[2] A comparable fatal polyneuropathy has also long been recognized in the Patagonia region of South America, where it is known as *mal seco*.[3] Equine grass sickness (EGS) is endemic in Scotland, England, and Wales and has also been reported from many countries in northern Europe, Cyprus, the Falkland islands, and Colombia with isolated cases in Australia, Ethiopia, and the United States.[1,4-6]

Epidemiologic studies conducted since the early 1970s have identified high horse density, full-time grazing, a recent change in feed type or premises, previous occurrence of the disease on the premises, pasture disturbance, mechanical removal of horse manure from pastures, sandy or loamy soils, recent deworming with ivermectin, recent cool dry weather and irregular ground frosts, and good bodily condition as risk factors.[1,2,7-14] Concentrations of various herbage and soil minerals are associated with horses' risk of developing EGS.[2] Cases occur throughout the year with peak numbers in the spring and a smaller peak in the autumn. The risk of disease is highest in horses aged 2 to 7 years (peak, 5 to 6 years), although cases have been reported in horses from 2 months to 27 years of age. Horses of all breeds, ponies, donkeys, Przewalski's horses, and zebras are affected. Males and females are equally represented in surveillance data. Protective factors included contact with previous cases, daily feeding of hay or haylage, chalky soil, higher average maximal temperature, manual removal of feces from pastures, pasture grass mowing, and grazing together with ruminants.

Cause and Pathogenesis

Theories as to the cause of EGS have included mineral or vitamin deficiencies or exposure to toxic plants, secondary metabolites and trace minerals in pasture grass, insects, viruses, or bacterial or fungal toxins.[15,16] Although the cause of EGS is still unknown, considerable evidence has been adduced in support of roles either for *C. botulinum* toxins or mycotoxins.

The hypothesis that mycotoxicosis is the cause of EGS is attractive because it is consistent with the observed influences of pasture grazing and climate on disease risk.[2] Since the 1990s, a hypothesis has been developed that EGS is a toxicoinfectious form of botulism involving a type C strain commonly carried by birds.[17] Strong support for this hypothesis has been provided by (1) the demonstrated association between EGS and the presence in ileal contents of *C. botulinum* type C and type C1 neurotoxin (BoNT type C)[17]; (2) the observation that horses with EGS have significantly lower serum antibodies to *C. botulinum* and BoNT type C than do pasturemate controls[18,19]; and (3) the presence of rising titers of specific IgG antitoxin in cases of chronic EGS. *C. botulinum* type C is unique among clostridial organisms in that its major toxin, BoNT type C, possesses potent and nonspecific neurotoxicity in vitro, probably via action on cellular syntaxin.[17] It has been hypothesized that toxin production and absorption occur in the ileum as a result of either overgrowth from normal intestinal flora or spore germination in association with nutritional or environmental triggers involving factors such as parasite status and changes in feed, pasture, and weather conditions.[1,4] Set against this evidence are the many clinical, epidemiologic, and biological differences between EGS and neuroparalytic botulism of horses.[2] A survey of veterinarians in Great Britain confirmed the feasibility of conducting a controlled field trial of the efficacy of *C. botulinum* type C vaccination in preventing naturally occurring EGS.[20] A candidate vaccine was selected and shown to induce significant antitoxin responses and a longitudinal vaccine study has been ongoing since 2014.[21]

Clinical Signs

The major clinical signs of grass sickness principally reflect dysfunction of the enteric nervous system.[1,22] They include dysphagia, gastric and small intestinal dilation, nasogastric reflux, colonic impaction, and colic. Clinical presentations are classified as acute (course of <48 hours), subacute (2 to 7 days), and chronic (>7 days).[23] Two thirds of reported cases have been acute or subacute and one third was classified as chronic.[1] Acutely affected horses may be found dead or in abdominal crisis with signs of colic, tachycardia, generalized sweating, nasogastric reflux (including spontaneous nasal regurgitation of stomach contents), absence of intestinal borborygmi, and abdominal distention. Rectal palpation and transabdominal ultrasonography reveal distended loops of small intestine and gas-filled large bowel. Affected horses are unable to swallow food or water, and drool from the mouth may be in the form of thick, ropy saliva. Fine muscle fasciculations similar to those that occur with EMND may affect the triceps and quadriceps.

Horses with subacute EGS survive long enough to develop colonic impactions and secondary large intestinal tympany. Chronic EGS may develop insidiously, and only a minority of these cases show mild, intermittent colic. Patchy sweating or piloerection, or both, are evident on the neck, flanks, and behind the shoulders. Typically, the appetite is reduced, and affected animals have varying degrees of difficulty in chewing and swallowing; however, salivation, accumulation of fluid in the stomach, and impaction are not usual features. Bilateral ptosis with ventral deviation of the eyelashes are often secondary to loss of sympathetic eyelid tone. Because of suppression of normal nasal secretions, some horses with mild chronic EGS have a characteristic dry crusty nasal exudate (rhinitis sicca). Fecal production is reduced, and feces are unusually firm and small. Weight loss is rapid and severe.

Acute and subacute cases are invariably fatal. Death occurs from gastric rupture, circulatory compromise, or cardiopulmonary failure; most commonly, such animals are euthanized. With appropriate nursing case, many horses with chronic (mild) EGS survive and even completely recover.[2] EGS is unlikely to recur in recovered horses.[13]

Diagnosis

Definitive diagnosis requires demonstration of compatible neuropathologic features within the autonomic or enteric nervous systems.[1] The antemortem sample of choice is an ileal biopsy, which is processed for hematoxylin and eosin staining with or without synaptophysin immunostaining of myenteric and submucosal enteric plexuses.[2] Lingual and rectal biopsies have been undertaken for diagnostic accuracy, and preliminary results have been promising but require prospective validation.[2]

No confirmatory blood test for EGS is available. Nonspecific abnormalities are consistent with severe dehydration, systemic inflammatory response, hypovolemia, stress, loss of GI secretions, and anorexia.[2,24] Peritoneal fluid protein concentrations may be high, although nucleated and red blood cell counts are usually normal. Altered serum concentrations of numerous acute-phase proteins (including α_2 macroglobulin, serum amyloid A, ceruloplasmin, haptoglobin, and orosomucoid) have been recorded in horses with EGS but are nonspecific indicators of inflammation.[25]

In EGS cases with ptosis, topical application of 0.5 mL 0.5% phenylephrine eyedrops results in normalization of the eyelash angle within 30 minutes, and this result is supportive of the diagnosis.[26] Barium swallow contrast radiography, esophageal endoscopy, abdominal ultrasonography, and rectal

palpation are used to identify changes consistent with dysfunction of components of the enteric nervous system.[2]

Treatment and Prevention All cases of acute and subacute EGS are considered incurable and therefore necessitate euthanasia on humane grounds as soon as possible after diagnosis. For selected chronic cases, treatment involves excellent nursing care and provision of palatable, easily swallowed food and high energy concentrates. Clinical recovery occurs in approximately 70% of preselected treated cases.[1]

Current efforts at prevention involve minimization of known risk factors and introduction of suspected protective practices. Thus in endemic areas, horse owners are advised to avoid exposure to pastures where previous cases have occurred, minimize disturbance of pasture or soil, prevent overgrazing of pasture, and avoid the "overuse" of ivermectin dewormers. On the other hand, owners are encouraged to allow horses to graze with ruminants, mow pastures regularly, manually remove feces from pastures, and supplement pasture feeding with hay or haylage. These practices are particularly important during seasonal and climatic risk periods, as well as for young horses in good bodily condition, especially those recently imported.

Necropsy Findings Gross necropsy findings in horses with EGS include esophageal ulceration, fluid distention of the stomach and small intestines, impaction of the large colon or cecum (or both), and the presence of inspissated mucus within the small colon and rectum. Horses with subacute and chronic cases do not have gastric and small intestinal distention but do have variable degrees of large intestinal impaction and often rhinitis sicca.[22] Histologic lesions of neuronal degeneration are most evident in the autonomic ganglia, enteric nerve plexuses, brain, and spinal cord.[23,27] There is chromatolysis, nuclear eccentricity, nuclear degenerative changes, cell death and neuronophagia, cytoplasmic vacuolation, and spheroid formation.

Peripheral Nerve Disorders

Robert J. MacKay • Lisle W. George

Most peripheral nerve disorders of large animals are traumatically induced, but injections, abscesses, tumors, and parasitic invasion of the nerves occur in rare cases. Damage to nerves are classified into two major functional categories.[1] Type 1 injury involves loss of function without loss of axonal continuity. Type 2 injury involves damage to axonal structures in such a way that wallerian degeneration of the axon ensues distal to the site of injury; the proximal axonal segment and the cell body remain intact. Retrograde degeneration of the proximal nerve occurs if connectivity is not reestablished.

Type 1 *(neurapractic)* lesions are characterized by a failure of conduction of the action potential across the injured axonal segment. The pathologic basis for these reversible injuries could be nerve compression, damage to the myelin sheath, or alteration of the functions of the axonal cell membrane or its channel proteins. Type 2 injuries are characterized by axonal interruption *(axonotmesis)*. If there components of the connective tissue sheath and axon are also disrupted, the process is termed *neurotmesis*. Immediately after axonotmetic injury, the distal axonal segment is able to conduct action potentials; however, within 3 to 8 days after injury, the distal segment degenerates and no longer responds to electrical stimulation. In this way, neurapractic (type 1) and axonotmetic (type 2) injuries of longer than 8 days' duration can be theoretically distinguished. After axonotmesis of motor nerves, muscle reinnervation occurs by two separate mechanisms: collateral sprouting and axonal regrowth. If loss of axons to a muscle is incomplete, surviving motor axons generate sprouts from their nerve terminals, which can establish competent junctions with adjacent denervated muscle units. Reinnervation of muscle units by this process occurs within days to weeks. However, if the motor axons to a muscle are severed, reinnervation occurs by growth of collateral sprouts from the proximal stump. Axonal sprouts grow at a rate of 1 mm per day (≈1 inch per month). Because of progressive fibrous replacement of denervated muscle and retrograde degeneration of the proximal parts of affected motor neurons, reinnervation may not be possible if more than 12 months have elapsed since the original injury. However, reinnervation surgery has been successful when performed on human patients 20 years or more after denervation.[2]

Large-diameter myelinated fibers are most sensitive to compression forces. The largest axons (sensory axons), including afferent fibers conveying touch-pressure, vibration, and proprioception, are usually damaged first (which results in ataxia or inappropriate limb placement); second, the large myelinated motor axons are compromised; third, the smaller axons, which carry cutaneous and deep mechanoreceptor sensory information, are affected; last to be lost are the smallest-diameter fibers, which transmit pain sensation.

The following sections are discussions of the peripheral nerves most often damaged in large animals.

Suprascapular Nerve

Mechanical damage to the suprascapular nerve results in paralysis of the infraspinatus and supraspinatus muscles.[3] Such injuries occur most commonly when the animal collides at speed with gateposts, trees, or other objects.[4] Acute injury or local anesthesia of the suprascapular nerve is characterized by outward bowing or "popping" of the scapulohumeral joint, or both, as weight is placed on the limb. Neurogenic atrophy develops after 2 to 4 weeks, and the scapular spine becomes prominent (Fig. 35.24). The common name for this condition is "sweeney."

Brachial Plexus

Damage to the brachial plexus may result in any combination of dysfunction of the radial, pectoral, axillary, musculocutaneous, median, and ulnar nerves, although radial nerve signs usually dominate.[5,6]

Lesions of the brachial plexus are caused by trauma to the shoulder with or without scapular or rib fracture, deep penetrating axillary wounds, neoplasia or bacterial cellulitis, or forced extraction of a fetus to relieve dystocia.[7] Because of their

FIG. 35.24 Sweeney (neurogenic atrophy) of the left supraspinatus and infraspinatus muscles in a Quarter Horse gelding. The lesion was caused by trauma related to running into a fencepost 2 months previously.

tendency to move at high speeds, horses are most susceptible to brachial plexus injuries. The condition may occur in small ruminants after automobile accidents, carnivore attacks, or blows from larger animals.

Avulsion of the brachial plexus results in complete flaccidity, lack of reflexes, and desensitization of the affected thoracic limb. Disruption of the origins of the cervical sympathetic trunk in the caudal aspect of the plexus results in ipsilateral Horner syndrome. Lesser injuries may result in abduction of the elbow (pectoral nerve), dropped shoulder (subscapular), hyperextension of the elbow (musculocutaneous), or signs of radial paralysis (next section).[8]

Radial Nerve

The radial nerve provides motor input to a flexor of the shoulder and extensors of the elbow, carpal, and digital joints. The nerve courses over the lateral aspect of the elbow joint and is vulnerable to traumatic insult at that point. Radial nerve paralysis arises from injury to the T1 nerve root or nerve from vertebral or rib fracture, as part of a brachial plexus injury, as a result of humeral fracture, from direct trauma to the nerve over the elbow, as part of an ischemic myoneuropathy during prolonged anesthesia, or during restraint in lateral recumbency with inadequate padding of the forelimb.[7,9-11]

With radial paralysis, the limb position varies, depending on the location of the lesion in the radial nerve. Lesions at or near the elbow joint are characterized by dropped elbow, inability to protract the limb, scuffing of the toe, and flexion of all distal limb joints (Fig. 35.25). The foot is knuckled over at rest, and the animal is unable to bear weight on the leg. Lesions distal to the elbow cause knuckling of the carpus, fetlock, and pastern joints, but the animal can support weight on the affected limb if the metacarpus and distal limb are held in extension. The triceps reflex is depressed or absent. After weeks of radial denervation, the extensor muscles of the thoracic limb exhibit atrophy. Detectable sensory deficits resulting from radial nerve paralysis tend to be vague and probably vary from patient to patient.

FIG. 35.25 High radial nerve paralysis in a horse showing knuckling of the carpus and digit and dropped elbow.

KANGAROO GAIT IN SHEEP. A locomotor disorder predominantly involving the thoracic limbs of lactating ewes has been reported in New Zealand, Australia, Scotland, and northern England.[12,13] Knuckling and paresis of the thoracic limbs are suggestive of radial paresis, and a high-stepping forelimb gait is also present. In advanced cases, the pelvic limbs are also involved. Limited necropsy data suggest both CNS and peripheral nerve involvement.[14,15] Affected ewes are usually of large breeds and are nursing twins. Most recover after weaning their lambs. Affected sheep are usually grazing on mixed forage, often with some concentrate supplementation. A clinically identical condition has been reported in Israel and in Australia among sheep grazing on the legume fenugreek.[16] A causative toxin or nutritional deficiency is suspected for both kangaroo gait and fenugreek staggers, but no toxin has yet been identified.

Femoral Nerve

The femoral nerve is distributed to the quadriceps femoris muscles and the skin of the rear limb over the medial thigh. Traumatic overextension of the hip and stifle joints from a fall or other injury or forced posterior delivery of a fetus can damage one or both femoral nerves.[17] The nerve courses too deeply to be directly affected by an external blow to the pelvic limb; however, it can be damaged by ilial, femoral, or vertebral fractures. Ischemic injury caused by prolonged stretch or increased tissue pressure during anesthesia in dorsal recumbency may cause bilateral femoral neurapraxia.[18] A similar presentation, presumably caused by compression of lumbar spinal branches by the foal in the birth canal, occurs in mares after severe prolonged dystocia.

The clinical signs of femoral nerve paralysis are related to an inability to extend and fix the stifle.[3] The reciprocal apparatus is unable to fix the stifle and hock, which results in collapse of the limb during weight bearing and constant flexion of all distal digital joints. The hoof usually remains flat on the ground. Chronic femoral denervation causes atrophy of the quadriceps femoris muscles. The patellar reflex is absent or depressed, and the patella is often displaced laterally. Hypoesthesia or anesthesia of the medial part of the rear limb extends from the proximal thigh to the medial malleolus of the tibia.

Sciatic Nerve

The sciatic nerve is the largest nerve in the body and innervates the extensor muscles of the hip, flexor muscles of the stifle, and most of the muscles of the distal limb. Sciatic nerve paralysis occurs most often in postpartum cows after forced fetal extraction.[19] Injury to the sixth lumbar nerve proximal to the lumbosacral plexus is the usual cause of so-called calving or obturator paralysis syndrome. Injection of irritating drugs into the space between the greater trochanter and the ischial tuberosity may cause a sciatic neuritis.[20] This occurs most frequently in young animals, but rare cases occur in adult cattle and small ruminants. Other causes of sciatic nerve damage are pelvic fractures, sacroiliac or coxofemoral dislocations, tumors, or abscesses located along the course of the nerve. Sciatic neuropathy is a rare complication of sacroiliac joint injections in horses.

The sciatic nerve innervates most of the musculature of the rear limb, and so the motor deficits associated with denervation are profound. At rest, the limb hangs behind the animal. The stifle is dropped and extended, and the hoof rests on its dorsum (Fig. 35.26). If the limb is positioned properly, the animal usually can bear some weight on it because of the normal function of the quadriceps muscles and the action of the reciprocal apparatus. Chronic sciatic denervation results in neurogenic atrophy of the caudal thigh muscles and all of the muscles distal to the stifle.

The sciatic nerve divides into the tibial and the peroneal nerves in the distal limb. Therefore except for the medial

VetBooks.ir

FIG. 35.26 Characteristic posture of a foal with partial sciatic nerve paralysis. Note the flexion of the hocks, fetlocks, and stifle. The signs were the result of an intramuscular injection in the gluteal area.

part of the thigh and gaskin, sciatic denervation also results in hypoesthesia and anesthesia of the entire limb distal to the stifle.

Peroneal Nerve

The peroneal branch of the sciatic nerve is distributed to the flexor muscles of the hock joint and the extensor muscles of the digit. The nerve becomes superficial and is exposed to damage as it crosses over the lateral condyle of the fibula immediately distal to the stifle. Peroneal paralysis of this type occurs in all species of large animals and is common in postpartum dairy cattle that have been recumbent as a result of hypocalcemia or other causes and in horses because of postanesthetic ischemic myoneuropathy. The hock joint is hyperextended, the fetlock and pastern are flexed, and the dorsum of the hoof usually rests on the ground[3,21,22] (Fig. 35.27). Affected animals can bear weight when the limb is manually placed in the proper position. There is desensitization of the skin over the craniolateral aspect of the limb extending from the stifle to the hoof.

Tibial Nerve

The tibial nerve supplies the extensor muscles of the hock joint (i.e., the gastrocnemius) and the digital flexors. Tibial paralysis is most often observed in periparturient cattle or neonates that have been given an injection of an irritant drug in the caudal leg at the level of the stifle. Tibial paralysis also occurs in sheep and goats and is a common sequela to dog-bite injuries. The resting limb is held more flexed than is normal, and, although the foot contacts the ground in normal position, the metacarpophalangeal joint often partially collapses into a flexed position (i.e., "knuckles"). The limb moves in a stringhalt-like manner, with exaggerated flexion of the tarsus and stifle during protraction, followed by sudden extension to the weight-bearing phase of the stride. At rest the pelvis is asymmetric, with the affected side held lower than normal.[3] Chronic loss of tibial nerve function results in atrophy of the gastrocnemius and digital flexor muscles. The skin of the caudomedial aspect of the leg demonstrates anesthesia.

FIG. 35.27 Calf with peroneal nerve paralysis. Note the flexed fetlock and digit and the hyperextended carpus. This condition was caused by injection of antibiotics into the peroneal nerve on the caudolateral aspect of the leg.

Obturator Nerve

The obturator nerve supplies the adductor muscles of the pelvic limb. The nerve is well protected in horses and small ruminants, and so injury is rare in these species. In contrast, because the cow has a relatively shallow acetabulum and poorly developed round ligament, the obturator nerve and the lumbar branches that supply it are vulnerable to injury during forced extraction of a calf to relieve dystocia. Reports of obturator nerve paralysis of cattle accompanied by knuckling and inability to support weight on the rear limbs probably represent a combination of sciatic and obturator nerve dysfunction. Coxofemoral dislocation is a common complication of obturator paralysis in cattle housed in stalls with slippery flooring.

Obturator nerve paralysis is most common in cattle and is almost exclusively a result of dystocia. The nerve injury is located in the pelvis at the level of the obturator foramen. Of all dystocias in dairy cattle, 9.2% result in paraplegia.[23] The obturator nerve innervates the adductor, pectineus, and gracilis muscles. Effects are minimal if the cow is placed on a surface that has good traction. Clinical signs of an obturator nerve injury include a hopping pelvic limb gait when the animal attempts to run and severe pelvic limb abduction or splay-leggedness when the animal stands on a slippery surface (Fig. 35.28). In severe cases, the cow may be sternally recumbent with the pelvic limbs extending laterally to each side. Experimental studies have indicated that the so-called calving paralysis syndrome is actually a result of a combination of injuries to the obturator nerve and to the sixth lumbar spinal nerve (L6), a major contributor to the sciatic and obturator nerves. Experimental sectioning of the obturator nerve alone does not produce paralysis, if the animal has secure footing.[3,19,24] Obturator nerve paralysis does not result in a cutaneous sensory deficit.

Compression damage to one or more peripheral nerves during parturition or milk fever is a frequent factor in the so-called downer cow syndrome (discussed later). The condition occurs in 4 to 28% of all cases of milk fever and, before the advent of flotation tanks for treatment, was associated with a mortality rate of 20 to 67%.[25,26]

Peripheral Facial Nerve Paralysis

Facial paralysis is common in horses but uncommon in other large animals. Depending on the site of damage, some or all

VetBooks.ir

FIG. 35.28 Cow with obturator nerve paralysis caused by relief of a difficult dystocia. Note the basewide stance and yet the apparent ease with which the cow is able to stand on the deep bedding. Note also that rope hobbles are being applied to prevent further abduction and trauma.

of the facial muscles can be affected. Complete unilateral facial paralysis in horses is evident as deviation of the nose toward the normal side, reduced flaring of the ipsilateral nostril during inspiration, and ipsilateral drooping of the lip, eyelid, and ear. Reflexes involving cranial nerve VII, such as the lip, eyelid, and menace and ear reflexes, are reduced or absent. Inability to close the eyelid causes exposure keratitis, which may be particularly severe when there is damage to the secretomotor fibers of the facial nerve at or proximal to the geniculate ganglion (keratitis sicca). The tongue protrudes out of the paralyzed side of the mouth, which suggests, often erroneously, a problem with lingual function. Because of paralysis of the buccinator cheek muscle, boluses of feed accumulate between the cheek and teeth, from where they may be dropped from the mouth. With chronic facial denervation in horses, neurogenic atrophy of the parotidoauricularis muscle becomes apparent as a groove behind the vertical ramus of the mandible. In cattle, because of the rigid structure of the planum nasale, muzzle deviation is not observed. In small ruminants, subtle muzzle deviation can usually be appreciated.

Injury to the facial nerve proximal to the vertical ramus of the mandible causes full facial paresis. Proximal facial nerve trauma in horses is usually caused by fractures of the vertical ramus of the mandible, stylohyoid bone, or petrous temporal bone (after a blow to the head or as a complication of THO). Damage within the facial canal is often associated with concurrent signs of vestibular nerve damage such as head tilt, nystagmus, and circling. Tear production may also be reduced or absent. Hemorrhage into the middle/inner ear, otitis media/internal guttural pouch mycosis, and parotid lymph node abscessation each can involve the adjacent facial nerve, causing ipsilateral facial paralysis. Distal facial nerve damage is usually due to direct injury from a blow or lateral recumbency or strangulation by a tight-fitting halter. The nerve or its branches are often damaged as they cross the mandible, the zygomatic arch, or both. Facial paresis after recumbency during general anesthesia is common and usually involves only the nose, lips, or both. Similar conditions occur in goats and are caused by excessive pull on neck chains while the animal is being led onto the milk stand or tied with the neck chain. In cattle, facial nerve paresis is usually the result of space-occupying masses at the caudal aspect of the mandibular ramus.

Most animals with facial nerve paralysis caused by trauma have neurapractic (type 1) nerve injury and recover within 2 weeks; those with type 2 (axonotmetic) injuries regrow axons from the site of injury at the rate of approximately 1 inch per month, and so full resolution make take several months. The paralysis is occasionally permanent. In chronic cases, food should be removed from the cheek pouches twice daily, and the tongue and fauces should be routinely examined for ulcers. Oral ulcers, if present, should be treated by flushing of the mouth.

Treatment The objectives of medical treatment of peripheral nerve injury are (1) to reduce swelling and inflammation at the site of injury, (2) to support and stabilize the denervated area, and (3) to maintain of the general health of the animal.

In the case of lacerating trauma, the general principles of wound management apply. The wound should be cleaned, irrigated, debrided, and dressed, and ventral drainage should be established. If severed nerve ends are visible, they can be tagged for later identification and surgical repair. Medical therapy for inflammation and swelling should be initiated, especially if there is obvious tissue swelling. This may include any combination of a cyclooxygenase inhibitor (e.g., flunixin meglumine, 1.1 mg/kg IV, IM, or PO once or twice daily); DMSO (1 g/kg as a 10% solution IV or by nasogastric tube once or twice daily); and a glucocorticoid (e.g., dexamethasone, 0.05 mg/kg IV or IM once daily). An additional anti-inflammatory effect can be provided by cold water hydrotherapy or local application of skin-permeant drugs such as DMSO or diclofenac. In the presence of an open wound or other risk for bacterial infection, broad-spectrum antimicrobial therapy should be initiated. This can be directed by culture results, if available.

Fractured or dislocated bones that have the potential to further injure nerves must be reduced and stabilized. Stall rest helps prevent further injury. In the case of paralyzed limbs, a protective wrap may be necessary to prevent damage caused by dragging or improperly placing the limb. A support wrap, splint, or light cast should be maintained on a leg affected with radial paralysis so as to prevent limb contracture. A heavy support wrap, possibly with additional fetlock support, should also be placed on the opposite limb to protect against breakdown caused by prolonged increased weight bearing. If the horse has difficulty alternating between recumbency and standing, it should be supported as needed in an abdominal sling (horses and small ruminants) or flotation tank (cattle) until it is able to rise unassisted. Because of the buoyancy provided by water, affected animals (usually horses) may be able to exercise affected limbs in swimming pools. Skin over bony prominences should be padded to prevent decubital injury; such injuries must be treated aggressively if they occur.

If possible, passive range-of-motion exercises should be performed on paralyzed limbs in an attempt to preserve joint flexibility and prevent contracture. Faradic or galvanic electrical muscle stimulation, acupuncture, and hyperbaric oxygen therapy are other procedures advocated for treatment of peripheral nerve injury. Calcium gluconate can be given empirically to downer cows (500 mL SC daily), as may potassium chloride (100 g in 20 L of water given daily by stomach tube). Abduction of the rear limbs may be prevented in cattle by application of a hobble around the metatarsus. The distance between the legs should be approximately 35.6 to 50.8 cm (14 to 20 inches) when the legs are tied together and held abducted. It is important to apply the hobbles with a nontightening bowline knot to prevent strangulation of the foot.

Surgical procedures for repair of peripheral nerves are beyond the scope of this text but are described elsewhere. In external neurolysis, the nerve is dissected from a bed of scar tissue.[1] This is indicated if there is obvious compression from fibrous tissue, and it is performed routinely in horses with suprascapular neuropathy.

Downer Cows (Alert Downers)

John A. Angelos • Bradford P. Smith • John R. Middleton

Definition and Etiology Downer cows, down cows, or downers are cattle that are recumbent and cannot stand; those that can maintain sternal recumbency while continuing to eat and drink are classified as "alert downers." Common underlying causes of recumbency in cattle include severe mastitis, metritis, musculoskeletal disease (primary musculoskeletal injuries, including fractures and torn muscles/tendons), neuropathies secondary to pelvic trauma (calving paralysis), spinal cord compression (e.g., secondary to lymphosarcoma), and metabolic disease (hypocalcemia, hypokalemia, hypophosphatemia, hypomagnesemia).[1] After the initial episode of recumbency, secondary muscle and nerve injury caused by extended periods of recumbency on a firm surface may further exacerbate the recumbency. Heavy cattle down on concrete are particularly susceptible to pressure ischemia of the muscles and nerves and to muscle and ligament tearing secondary to repeated struggling and slipping. The severity of pressure damage depends on the nature of the surface on which the animal is recumbent and the duration of compression.

Identifying underlying causes of recumbency in downer cattle represents a diagnostic challenge for the practitioner. Assessing prognosis and determining reversibility of the underlying condition are necessary for practitioners to assist producers in making treatment decisions, as well as to conform to laws and abide by ethical norms surrounding humane handling of downer animals. In short, dragging of downer livestock is considered inhumane, and downer livestock that are in distress or that do not respond to treatment should be humanely euthanized.

Epidemiology and Pathogenesis It is reported that 3.8% to 28.2% of all cows with milk fever become alert downers,[2-5] and the mortality rate is 20 to 67%.[3-7] The incidence of the condition (24 hours or longer) was 21.4 cases per 1000 cow-years in Minnesota dairy herds, with a 33% recovery rate.[7] Fifty-eight percent of downer cases occurred within a day of calving, and 97% occurred within the first 100 days after calving.[7] Because the pressure damage done to muscles and nerves is aggravated by recumbency, it is desirable to have the animal on soft bedding (e.g., sand, grass) and to have the animal stand as soon as possible.

Clinical Pathology Laboratory testing for metabolic causes of recumbency would be ideal in all circumstances, but this is often not feasible or possible.

Of 16 normal cows anesthetized for 6 to 12 hours in sternal recumbency with the right hindlimb under the body, 8 were unable to stand on recovery and became alert downers.[8] Those that could stand exhibited swelling and stiffness and peroneal nerve deficits and paresis in the right hindlimb.[8] These signs typically appear in cows that have been recumbent for several hours on a hard surface. As pressure applied to a nerve increases, nerve conduction is impaired and eventually lost.[9] Serum CK values in experimental downer cows increased, starting at 12 hours and continued to increase up to 48 hours, and then decreased, even though the cow remained down.[8] The CK values at 12 and 24 hours did not differ statistically between the cows that could rise after anesthesia and the downers. After 48 hours and 96 hours, the downers had higher mean CK values than did the ambulatory cows, but the range in values was broad.[8] The clinical difference between cows that recovered and those that remained downers was attributed to damage to the sciatic nerve or its branches, particularly the peroneal nerve.[8] Peroneal nerve damage results in knuckling over at the fetlock. In another study of downers, AST levels were greatly elevated on days 4 to 7, even after CK levels fell.[10]

Serum levels of creatine phosphokinase, AST, and lactate dehydrogenase have been examined to determine whether these indices of muscle damage can help predict recovery of recumbent dairy cattle. Of the three enzymes, AST has been shown to be most useful in predicting nonrecovery. Dairy cattle with an AST level higher than 171 IU/L are 80% more likely not to recover than a dairy cow with an AST level lower than 171 IU/L.[11]

CSF collected from recumbent adult dairy cattle with spinal cord lesions (neoplasia, trauma, or infectious process) had significantly higher total protein concentrations and total nucleated cell counts than did recumbent adult dairy cattle without spinal cord lesions, which suggests that CSF analysis may be useful in differentiating alert downer cows with spinal lesions from those without.[12] Cows with CSF protein levels lower than 0.25 g/L and total nucleated cell counts of 4.5 or lower were predicted to not have a spinal cord lesion, whereas cows with total nucleated cell counts higher than 4.5 or a protein concentration exceeding 0.39 g/L were predicted to have a spinal cord lesion, according to the statistical modeling performed in the study.[12]

Treatment Many downer cattle are treated empirically for suspected metabolic abnormalities and response to treatment aids in establishing the diagnosis. Periparturient downer cows should be treated for hypocalcemia with one or more doses of calcium. Animals that become more alert but that are not standing after one or two doses of calcium are classified as alert downer cows.

Devices that aid and promote standing traditionally include hip lifters (hip clamps), slings, and inflatable bags. Although these devices help less severely affected animals stand temporarily, they do not allow the animal to stand comfortably for hours and may even cause further trauma in animals that struggle. For these reasons, the use of water flotation has been explored as a tool in the management of downer cows. Rasmussen[13] first reported on the use of a warm-water flotation system in Denmark in 1982. Commercial flotation systems practical for cows (Aqua Cow Rise System [http://www.aquacowsystem.com] and Aqua-Cow-Rise System [http://kirbymfg.com/aquacow.htm]) are marketed in the United States.

For flotation therapy to allow the best chances for recovery, the animal should first be examined to determine that it is a good candidate for flotation, by ruling out fractures, severe spinal cord compression, and severe systemic illness. Identifying and correcting electrolyte disturbances (e.g., hypocalcemia, hypophosphatemia, hypomagnesemia, hypokalemia) are required for successful application of flotation therapy. Once metabolic or systemic illnesses have been addressed and the cow is considered strong enough to stand once supported by water, the cow is placed in the flotation tank as follows: (1) the water tank is positioned near the downer cow; (2) the wheels and tongue are detached, and both ends of the tank are removed; (3) a mat is pulled from the tub to a position beside the downer cow, and the animal is rolled or slid onto the mat; (4) the mat is winched or otherwise pulled into the tub, and the ends of the tub are put in place; they seal with rubber gaskets and large turnbuckles; and (5) the cow's head is held up a few inches by a rope halter, and a hose is inserted into the tub, which is filled with water as quickly as possible; the water

VetBooks.ir

temperature should be 37.7° C to 38.7° C (100° F to 102° F). Cows in lateral recumbency on the mat become sternal when 12 to 24 inches of water fills the tub and usually attempt to stand beginning when the tub is half to two-thirds full.

If no hot water is available near the cow, or if the tub is not next to dirt or grass suitable for the cow to exit on, the wheels can be put back on and the cow easily transported by trailer to a better location. In addition, it is helpful to have an assistant support the tail or have a means to pull the tail once the cow attempts to rise. This helps the cow maintain a sternal position during early efforts at struggling before the cow is actually standing. Before flotation of lactating cattle at the University of California, Davis, cows are milked, and teat ends are sealed with a rubber teat sealant; this is removed once the cow is removed from the tank before milking. The sealant is reapplied after milking in preparation for the next flotation.

Once the cow is standing in warm water, it is possible to determine which limb or limbs are paretic or painful by observing which limbs the cow is using to support weight. Most cows calm down and relax in a standing position within 5 minutes. Most will eat hay, and even primiparous heifers that have not been handled much seem to be remarkably calmed by the warm water. Unlike horses, cattle do not panic or attempt to jump out. The cow can be left in the water for 12 to 24 hours. If the water temperature drops below 35° C (95° F), some water should be released from the discharge valve and replaced with hot water; this is especially recommended in cold weather. When the decision is made to remove the cow from the tub, the water is drained, and the end of the tub facing the dirt, sand, or grass is opened. The cow is encouraged to exit *slowly* into a pen with good footing. Some cows fall as the water is let out, and others collapse once they try to walk. By observing how a cow is ambulating on exit, it is possible to determine whether hobbles should be placed onto the cow before the next flotation. If cows are considered at risk for splaying out while exiting the tank, it is recommended that hobbles be applied before the cow is placed in the tank.

Careful observation as the cow moves can be helpful in trying to locate anatomic or functional problems. The animal that collapses can be pulled out on the mat and left on suitable bedding, dirt, sand, or grass until refloated after a period of rest. Advanced planning on location is important for successful use of flotation therapy. Cows that can walk out into a pen may or may not be able to stand by the next day and may need to be refloated. Cows may need to be floated for up to 10 consecutive days before they can arise by themselves. If cases are carefully selected to rule out fractures, severe traumatic stifle injuries, septic arthritis, and spinal cord compression, a recuperative success rate of 46% to 90% can be expected.[13,14]

Flotation is most effective if applied early, before a downer cow develops serious myopathy and neuropathy. Studies have shown that water flotation is practical and effective, even when cattle have been down for 24 hours or longer.[1] The sooner a postparturient alert downer cow can be floated after onset of recumbency, the sooner it can resume standing. In one study of postparturient alert downer cattle treated with flotation therapy, the mean time to resumption of standing was shorter for cattle floated within 1 day of going down (mean, 2.8 days to resumption of standing) than for cattle floated after being down for 2 days or longer (mean, 5.3 days to resumption of standing).[14]

Mammary Gland Health and Disorders

PAMELA L. RUEGG and RONALD J. ERSKINE, *Consulting Editors*

The presence of mammary glands is a defining characteristic of mammals. The original purpose of these specialized glands was to produce milk to feed progeny. However, milk has excellent nutritional qualities and several breeds of cattle, goats, and sheep are bred primarily to produce milk that is used for human consumption. Diseases of the mammary gland thus have important repercussions not only for animal health but also for the well-being of humans.

Mammary Gland Health of Dairy Cattle

The global dairy industry has dramatically changed in the past quarter century. Volatile milk prices, increasing herd size and reliance on hired labor, more complex feeding and housing systems, and increased pressure for environmental stewardship have fostered greater diversity among dairy enterprises. Bovine mastitis is the most common and economically important disease of dairy herds in developed countries[1,2] and hinders realization of optimum farm productivity, milk quality, and supply of dairy foods. Mastitis remains the most common cause of antimicrobial drug therapy for cows on U.S. dairy farms.[3] In addition, an important and often unrecognized obstacle to implementation of mastitis control practices is the behavior and attitude of farmers and employees.[4] Veterinarians can play a critical role in the control of this disease as part of a quality milk team that targets drug use, environment, milking practices, and the epidemiology of mastitis within each dairy herd. Implementation of quality milk programs within dairy herds will increase productivity for dairy producers, supply milk processors with superior raw milk, offer consumers better quality dairy foods, improve cow health and well-being, establish the dairy industry as an advocate for antimicrobial stewardship, and promote a sustainable market for U.S. dairy products globally.

Economic Impact of Mastitis of Dairy Cattle

Decreased milk production in affected mammary glands is the primary economic loss from mastitis. Inflammation causes pathologic changes in milk-secreting epithelial cells that decreases functional capacity. Depending on the type of pathogen, losses may continue into subsequent lactations. Most infections result in local inflammation or relatively mild clinical cases.[5,6] However, chronic infections can lead to agalactia in the affected quarter or, in the case of severe clinical cases, profound systemic involvement that occasionally results in death.

Somatic cell counts (SCCs) are indicators of leukocyte migration into milk that primarily occurs from infection of the mammary gland. Bulk tank somatic cell counts (BTSCCs) are strongly correlated with the proportion of infected cows within a dairy herd and are used as a measure of milk quality. Substantial economic loss may be incurred when regulatory or processor limits for BTSCCs are exceeded. Although the Pasteurized Milk Ordinance sets the BTSCC limit at 750,000 cells/mL for Grade A milk in the United States, in 2012 the U.S. Department of Agriculture (USDA) required that dairy exports to the European Union (EU) originate from farms with BTSCCs of 400,000 cells/mL or less. Because of this mandate and to be competitive for global dairy markets, 400,000 cells/mL has become the de facto limit for many milk processors, who may refuse milk from dairy operations that do not meet this standard. In addition, many producers are paid monetary premiums for low BTSCCs or are penalized for high BTSCCs. This may help explain why in 2015, BTSCCs in 96.0% of milk produced in the United States were less than 400,000 cells/mL; 68.8% of producers shipped milk below this limit for the entire year.[7] In addition, the percentage of total milk shipped with BTSCCs of less than 200,000 cells/mL during 2010 to 2016 increased from 40.6% to 52.5%.

Milk from cows with subclinical mastitis is not usually withheld from the bulk tank and thus contributes to increased BTSCCs and reduced milk quality. Proteolytic and other changes in milk due to subclinical mastitis adversely affect organoleptic qualities and the shelf life of milk and milk products. BTSCCs greater than 150,000 cells/mL are associated with decreased productivity per cow, shorter shelf life of fluid milk, and reduced yield of products such as cheese.[8,9] Overall, reduced milk production and quality associated with BTSCCs of 200,000 cells/mL or greater has been estimated to result in an annual economic loss of $3.1 billion to consumers.[10] Individual cow milk yield is estimated to decrease by 0.5 to 0.6 kg/day for each twofold increase in SCCs over 50,000 cells/mL.[2,11] However, the magnitude of the milk decrease relative to SCC increase has been reported to be higher in later lactation and older cows.[12] More recently, losses from subclinical mastitis have been determined to be a function of the milk production potential of the cow; cows that are higher milk producers have greater milk losses from subclinical mastitis than lower producing cows.[13] Thus milk yield losses for cows with a SCC of 800,000 cells/mL range from 1 to 3.3 kg/day, or 4.3% to 8.0%, relative to cows with SCCs of 100,000 cells/mL or less.[13] Losses from subclinical mastitis are even more substantial if accumulated over an entire lactation. Cows with chronic mastitis, measured by increased consecutive Dairy Herd Improvement Association (DHIA) test days with

SCCs of 100,000 cells/mL or greater, resulted in higher milk losses than cows with new infections.[14] In addition, DHIA records from more than 166,000 cow lactations in the western United States found that cows with a first test date SCC of 200,000 cells/mL or greater produced 718 kg less milk than cows with a first test date SCC less than 200,000 cells/mL.[15]

High-BTSCC milk also has a greater risk of condemnation because of violative antimicrobial residues.[16-18] In a retrospective study, the rate of antibiotic residue violations increased as herd SCC increased, and the relative risk of antibiotic residue violations (compared to herds with SCCs less than 250,000 cells/mL) was 2.4, 2.8, and 7.1 times greater for herds with SCCs of greater than 400,000, greater than 550,000, and greater than 700,000 cells/mL, respectively.[16]

Cows with chronically increased SCCs caused by intramammary infections (IMIs) are often culled prematurely as a consequence of decreased milk production. The cost of premature culling depends on the perceived value of the cow, the market prices for culled cows and replacement heifers, and the potential value of the replacement heifer.[19] Cows with an average SCC greater than 700,000 cells/mL were twice as likely to be culled as cows with an average SCC under 250,000 cells/mL, especially in herds with low BTSCCs.[20] Cows that are not culled may be segregated or require the use of milking procedures that increase labor costs. For example, cows with chronic IMIs caused by *Staphylococcus aureus* or *Mycoplasma* may need to be housed separately and milked last.

The incidence of clinical mastitis averages between 15% and 25% of lactations, although some herds may have rates greater than 45%.[21-25] Estimates of lost milk production from a case of clinical mastitis over an entire lactation range from 110 to 552 kg, depending on the parity and stage of lactation when the case occurred.[26-28] Further losses from clinical mastitis can result from subsequent repeated episodes during the same or later lactations. In a study of 7 New York dairies, milk losses in the first 50 days following onset of clinical mastitis were 304, 128, and 92 kg for cases caused by gram-negative, gram-positive, and other pathogens, respectively.[29] Clinical mastitis also results in additional economic losses beyond milk production. In a 1700-cow dairy, cows with clinical mastitis lost 341 kg of saleable milk, compared to projected yield, during the first 60 days after case onset.[30] Nearly 75% of the milk loss was discarded because of treatment, with the remainder accounted for by lost production. Cows in their second or greater lactation, or more than 150 days in milk, incurred greater losses, although the type of causative pathogen was not associated with differences in losses.[30] The average total costs per case (US$) of gram-positive, gram-negative, and other pathogens were estimated to be $133.73, $211.03, and $95.31, respectively.[31] Premature culling resulting from unresolved clinical mastitis cases or subsequent suboptimal milk yield of the affected cow may increase these costs to as much as $600.[32]

The occurrence of both subclinical and clinical mastitis has been associated with reduced reproductive performance. In a preliminary field study, cows were almost two times more likely to have altered interestrus intervals following an episode of clinical coliform mastitis compared to herdmates without clinical mastitis.[33] Conception rates for cows with clinical mastitis between 3 weeks before and 5 weeks after insemination have been reported to be lower compared to cows without clinical mastitis.[34,35] Clinical mastitis due to gram-negative bacteria has a more detrimental effect on the probability of conception than clinical mastitis caused by gram-positive bacteria or other organisms.[36] In addition, the days to first service, services per conception, and days to conception were all increased in cows with clinical mastitis as compared to nonmastitic cows.[37] Cows with a case of clinical mastitis in the first 45 days of gestation are nearly three times more likely to abort within the next 90 days than nonmastitic cows.[38] As well, cows with increased SCCs (>150,000 cells/mL) have decreased conception rates as compared to cows with lower SCCs, and as the SCC increases, the odds of pregnancy decrease.[39-41] It is likely that inflammatory mediators released in response to IMI play a role in oocyte and embryonic degradation. For example, lipopolysaccharide endotoxin in cattle induces a prolonged release of inflammatory mediators, including prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), leading to uterine smooth muscle contraction and luteolysis, a gradual decline in plasma progesterone, and thus abortion, especially in the first trimester of pregnancy.[40,42]

The total cost of mastitis is impossible to quantify accurately, varies over time, and is herd dependent. Nationally, the cost of mastitis has been estimated at $200/cow/year, or $1.5 to $2 billion.[19] Costs associated with implementation of mastitis control programs can be substantial. Return on investment in mastitis control is more important than the absolute cost and ranged from –$20 to $275/cow/year in a review of nine studies.[37,43] However, this return depends on the prevalence and type of mastitis in the herd, existing control measures, and producer compliance. In summary, although the costs incurred by producers to control mastitis are significant, the benefits of reducing mastitis include improved cow health and productivity, a superior raw milk supply for processors, better quality and safer dairy foods for consumers, and a more sustainable market for dairy products globally.

Anatomic Structures of the Bovine Mammary Gland

Cattle have a single udder that is composed of four independent mammary glands that are referred to as *quarters*. Suspensory ligaments attach the udder to the pelvic bone and abdominal muscles of the ventral body wall. The four quarters are anatomically independent with no direct physical connections,[44] but researchers have demonstrated mild inflammatory responses in apparently healthy quarters adjacent to quarters experiencing clinical mastitis indicative of some interdependence.[45] Each mammary gland consists of a teat with a single opening, small cisterns (also called sinuses) in the teat and base of the gland, a system of ducts, and secretory tissue. The secretory tissue is organized into lobes that are composed of lobules containing hundreds of microscopic alveoli lined by *mammary epithelial cells* that synthesize and secrete milk.[5] Nutrients required for milk synthesis are delivered to each mammary gland by the circulatory system and transported into epithelial cells or directly into the alveolar lumen. Milk components, including casein, lactose, and fat, are synthesized within epithelial cells and secreted into the alveolar lumen, where they combine with other constituents to form milk. Production of milk is continuous, and during the interval between milkings about 20% of the milk accumulates in the larger spaces of the udder such as the teat cistern, gland cistern, and large ducts *(cisternal fraction)*. However, about 80% of the milk remains fixed by capillary forces within the alveoli *(alveolar fraction)*, and removal of this fraction is dependent on achieving successful milk ejection *(milk letdown)*.[46]

Milk letdown occurs in response to tactile stimulation of teats, which triggers a neurohormonal reflex, causing the pituitary gland to release *oxytocin* into the bloodstream.[46] Milk is ejected from the alveoli into the cisterns when the surrounding myoepithelial cells contract after binding oxytocin. Milk flows through the teat orifice after resistance of the teat canal (also called the *streak canal*) is overcome due to the pressure of milk in the teat, suckling by offspring, or the process of milking. Activation of the sympathetic nervous system during periods of stress or excitement can inhibit the release of oxytocin from the pituitary gland or the binding of oxytocin to myoepithelial cells, thus preventing milk ejection.[47]

The teat canal and surrounding musculoelastic tissue are the primary physical barrier to microbial invasion and also

VetBooks.ir

prevent leakage of milk between milkings.[48,49] The teat canal is a narrow, longitudinally folded cylinder lined with stratified squamous epithelium. The tortuous shape of the canal provides physical protection against infection, as well as *keratin*, which lines the canal and is produced by the epithelial cells. Lack of keratin in the teat canal greatly increases the risk of IMI because keratin physically plugs the teat canal, traps invading microbes, and contains bacteriocidal fatty acids and proteins.[50-52] Hyperkeratosis of the teat end; trauma-associated abrasion of the teat orifice; or teat damage from ineffective pulsation, excessive milking vacuum, or poorly fitting teat cup liners can also increase the risk of IMI.[53-55]

Because of the importance of the teat in mammary gland defense, dairy producers should routinely monitor teat condition and use a combination of genetic selection and management practices to promote teat health and sound conformation of the udder. However, it must be emphasized that cows housed on wet or soiled bedding, or udders and teats exposed to excessive water during milking preparation, are at high risk for IMI, despite good teat end health.[56-58] In addition, lack of aseptic preparation of teat ends before cannula insertion or use of multiple-dose drug preparations that are not intended for intramammary infusion can result in outbreaks of infection caused by opportunistic pathogens.[59]

Immunologic Responses to Intramammary Infection

Reducing pathogen exposure is the foundation of prevention of infectious disease, including mastitis. When exposure to pathogens is sufficient to traverse the teat canal and multiply in the milk, the ensuing response on the part of the host immune system initiates inflammation of the mammary gland, which is recognized as subclinical or clinical mastitis. If the innate and acquired immune systems effectively eliminate the invading microbes, the mastitis will be mild and transient. However, when defense mechanisms are compromised (e.g., during the periparturient period, periods of heat stress, or after transportation and commingling of animals in the herd) or when the pathogen expresses virulence factors that resist phagocytosis or intracellular destruction, severe or chronic mastitis may develop. The intensity of the inflammatory response determines whether mastitis is subclinical or clinical.

With *subclinical mastitis*, the inflammatory process does not result in visible abnormalities in the milk, mammary gland, or cow, although leukocytosis and other soluble changes in milk occur. With *clinical mastitis*, milk from the affected quarter is visibly abnormal, the gland may undergo marked inflammation, and the cow may exhibit signs of systemic illness. Although mastitis can result from trauma, the vast majority of mastitis is caused by IMI via the teat canal. As stated earlier, limiting exposure to pathogens at the teat end remains the primary means to prevent infection. Mastitis occurs in all herds, but herds that manage pathogen exposure will endure less mastitis.

MAMMARY INFLAMMATION. If invading pathogens are able to overcome the teat canal barrier and gain entry into the gland, a series of innate host defenses help to limit bacterial growth. Because bovine mastitis is essentially a disease of bacterial and occasional mycotic or algal pathogens, the primary effectors of mammary immunity are polymorphonuclear neutrophils (PMNs). However, as in other tissues, these phagocytes rely on a complex system of soluble and cellular mediators that recognize pathogen presence and subsequently recruit and activate phagocytes to eliminate the microbes, termed the *innate immune system*. Soluble factors include complement, lactoferrin, and acute phase proteins (such as mannose-binding lectin and C-reactive protein). Lactoferrin is an iron-binding glycoprotein produced by mammary epithelial cells and found in PMN granules.[60] By sequestering iron, lactoferrin prevents multiplication of iron-dependent microorganisms, such as coliform bacteria.[61] Mannose-binding lectin and C-reactive protein will bind to molecules specific to pathogen cell walls and help to activate the complement cascade. Innate host defenses differentiate host tissue from pathogens by recognizing molecules that are universal to many microbes but not present on host cells. These pathogen-associated molecular patterns (PAMPs) are recognized and selectively bound by serum proteins and receptors in host cells, which are called *pathogen recognition receptors* (PRRs).[62]

Toll-like receptors (TLRs) are an important class of PRRs that reside both on cell surfaces and within host cells. These receptors invoke gene expression and release of inflammatory cytokines (e.g., interleukins, tumor necrosis factor [TNF]-α) from the host cells and act as the critical link between recognition of foreign agents and initiation of the host response.[62,63] Examples of specific pathogen targets bound by TLRs include peptidoglycan and lipoteichoic acid of gram-positive bacteria (TLR-2), gram-negative lipopolysaccharide (LPS; TLR-4), bacterial flagellin (TLR-5), and bacterial DNA as CpG oligonucleotides (TLR-9).[64] Much of the local inflammation and systemic signs (when they occur) associated with mastitis are attributable to this response. Numerous cell types, including epithelial and endothelial cells, macrophages, and other phagocytic cells possess TLRs, which can contribute to an inflammatory response.[65] The inflammatory response is further modulated by activation of eicosanoid (arachidonic acid) metabolites such as prostaglandins and leukotrienes, as well as by endocrine and adipose mediators.[66,67]

Milk from healthy mammary glands contains a low concentration of leukocytes. However, when microbial ligands (molecules) are detected by TLRs on macrophages and epithelial cells, these cells release proinflammatory cytokines, such as interleukin 1 (IL-1), IL-6, and TNF-α.[62] These mediators cause vasodilation and expression of adhesion molecules on endothelial cells, which in turn trigger an influx of neutrophils.[64] Circulating blood neutrophils must adhere to the vascular endothelium before migrating into the milk. Vascular neutrophils loosely bind and roll along the endothelium, using a surface adhesion molecule (CD62L or L-selectin).[68] L-selectin is highly expressed on the surface of normal circulating neutrophils, whereas similar molecules—E-selectin (CD62E) and P-selectin (CD62P)—are expressed on vascular endothelial cells at the site of inflammation.[68] Neutrophil CD62L is responsible for making initial contact between fast-flowing blood neutrophils and the vascular wall, which rapidly slows neutrophil movement in small postcapillary vessels, whereas endothelial CD62E and CD62P direct slow-moving neutrophils to the specific site of inflammation. Additional proinflammatory mediators, such as IL-8, leukotriene B4, and complement component 5a, serve as neutrophil chemotactic agents and promote expression of surface receptors on endothelial cells.[68] This in turn causes neutrophils to express the β_2-integrin adhesion complex CD11b/CD18. The CD11b/CD18 complex firmly anchors neutrophils to vascular and intercellular adhesion molecules.[68-70] Once bound, neutrophils migrate between the endothelial and mammary epithelial cells into the milk *(diapedesis)*, traveling along a chemotactic gradient to the site of infection.[68] During infection, neutrophils often exceed concentrations of 1 million cells/mL. Both the speed of recruitment and the extent of neutrophil influx into milk influence microbial clearance and are critical determinants of infection outcome.[64,71-73] Thus, compared to noninfected quarters, milk from infected quarters reflects the recruitment of PMNs and lymphocytes to eliminate the infection after initial signaling by antigen processing cells such as macrophages, and chemotactic modulators from endothelial and antigen processing cells. This leads to higher absolute numbers of neutrophils, lymphocytes, and macrophages but greater proportions of PMNs and lymphocytes relative to macrophages.[74,75]

VetBooks.ir

During migration and under the influence of proinflammatory cytokines (e.g., TNF-α and interferon gamma [IFN-γ], IL-17), neutrophils are further activated to become focused killer cells.[68] In this way, the leukocytes arrive at the infection site ready to recognize, phagocytose, and kill infecting pathogens. Phagocytosis is accomplished through a variety of specialized receptors on the surface of neutrophils, which are generally upregulated in response to the proinflammatory signals received during diapedesis and chemotaxis. Expression of CD14 receptors enables neutrophils to bind bacterial LPS in the presence of LPS-binding protein (LBP); this binding facilitates nonopsonic phagocytosis of gram-negative bacteria.[76] At the same time, soluble *CD14* is shed into the milk, where it neutralizes free LPS and binds to epithelial cells, enhancing chemoattractant release.[73] The most important neutrophil receptor for opsonic phagocytosis is the *Fc receptor*, which binds the Fc region of immunoglobulins (Ig), particularly IgG2 and IgM, enabling the phagocytosis of antibody-coated pathogens.[77,78] Complement component 3b is also opsonic for bovine neutrophils.[69]

Receptor binding stimulates the neutrophil to extend pseudopods and engulf the adhered pathogen into a phagosome. The phagosome fuses with cytoplasmic secretory granules to form an intracellular vesicle (phagolysosome), where degranulation and microbial killing take place. Neutrophil granules contain cationic peptides called *defensins*, which have broad-spectrum antibacterial and antifungal activities.[60,64] These proteins, along with lactoferrin, and hydrolytic enzymes contribute to oxygen-independent killing of engulfed pathogens.

To effectively respond to pathogen invasion, the lactating mammary gland of ruminants must overcome numerous deficits. The number of somatic cells (which in lactating dairy cattle are primarily leukocytes) in milk is typically less than 100,000 cells/mL in uninfected glands, which is approximately 100-fold lower than in blood. Concentrations of factors such as lactoferrin and complement are also lower in milk relative to plasma.[79] In addition, the ability of circulating macrophages in milk to re-enter tissue for antigen presentation remains speculative. As compared to blood, macrophages and neutrophils in milk have decreased phagocytic ability.[80,81] Neutrophils engulf fat globules and casein, which reduces subsequent pseudopod formation as well as intracellular killing capacity.[73] Host-adapted pathogens (such as *S. aureus*) often have numerous virulence factors to help evade recognition and phagocytosis, which further compromises the ability of host defenses to eliminate the infection.

As mentioned earlier, postpartum cows may be particularly susceptible to infections compared to cows later in lactation. $CD4^+$ (T-helper) lymphocytes are predominantly T_h2 (down-regulation of inflammation) compared with T_h1 (proinflammatory) within 3 days after calving. This alters the repertoire of cytokines produced and thus the effectiveness of phagocytic cells such as PMNs and macrophages.[82]

Specific Immune Responses. If a pathogen survives innate host defenses, the specific (also called *acquired*) immune system is triggered. This branch of the immune system recognizes specific antigens of pathogens, and if repeated exposure occurs, an immunologic "memory" initiates a faster and more intense response with longer duration. As with neutrophils, mammary macrophages ingest and kill microorganisms. In addition to initiating inflammation and killing pathogens, macrophages and dendritic cells play a key role in processing and presenting antigen to T lymphocytes. Antigen presentation is critical to activate T-helper cells ($CD4^+$), thus enabling secretion of cytokines, activation of B lymphocytes, as well as cytotoxic ($CD8^+$), suppressor, and memory functions.[83] To date, the role of the $CD4^+$ (helper), $CD8^+$ (cytotoxic and suppressor), and CD17 (phagocyte agonist) subsets in bovine mammary immunity are best understood.[84] B lymphocytes also are critical for antigen processing and serve as precursors to immunoglobulin-producing plasma cells.

Concentrations of immunoglobulin are low in normal milk but rise in response to IMI. This increase is partly a result of local Ig production but mostly from increased permeability of vascular endothelial cells and mammary epithelial cell tight junctions, which allows an influx of plasma Ig (and other plasma proteins) into milk. Influx of opsonizing Ig (IgM and IgG2) enables efficient phagocytosis of microorganisms by neutrophils.[77,78,85] Nonopsonizing Ig (IgG1 and IgA in cattle) have other beneficial functions, such as neutralization of bacterial toxins, agglutination of bacteria, and prevention of bacterial adherence to epithelial cells. Immunoglobulins in milk also mediate antibody-dependent cell-mediated cytotoxicity by leukocytes.[83,86]

DEFENSE MECHANISMS IN THE PERIPARTURIENT PERIOD. Mammary gland defense mechanisms are greatly reduced in the periparturient period, which increases vulnerability to IMI. Indeed, both the incidence and the severity of mastitis are greater in the periparturient period than during other periods of lactation.[68,87-89] Phagocyte diapedesis and killing and lymphocyte mitogenic responses are markedly decreased during the periparturient period.[84,86,90-92] Cows infected with *S. aureus* have a subpopulation of $CD8^+$ lymphocytes within the mammary gland that suppress proliferation of $CD4^+$ lymphocytes, and this class of $CD8^+$ cells is preferentially trafficked into the gland during the postpartum period.[93]

The immunosuppression accompanying parturition is partly caused by increased circulating cortisol concentration, which impairs neutrophil margination and recruitment.[64] Neutrophils of periparturient cows also undergo apoptosis more rapidly than do neutrophils of cows in later lactation, and early onset of apoptosis reduces phagocytic and intracellular killing activity.[73] Low circulating concentrations of insulin-like growth factor 1 (IGF-1) in periparturient cows may reduce neutrophil viability and impair cytokine secretion.[89]

Nutrition of the cows during the transition period can also play a critical role in mammary immunity. Non-esterified fatty acids (NEFAs) are released from adipose tissue in response to negative energy balances that are typical for cows in the transition period from late gestation to peak milk production. Particularly before calving, cows with excessive negative energy balances and high serum NEFAs are more at risk for culling and diseases during early lactation.[94,95] In addition, elevated serum NEFAs lead to undesirable expression of proinflammatory mediators, adhesion molecules, and reactive oxygen species.[67] The altered plasma fatty acid profile in cattle during periods of negative energy balance also changes the phospholipid content in membranes of endothelial and mononuclear cells.[96] Fatty acids from membrane phospholipids are the precursors for numerous arachidonic acid metabolites, the control of which is critical for the magnitude of inflammatory responses.

Oxidative stress resulting from high energy use by high-producing dairy cows further increases the expression of oxylipid (peroxylipid and other metabolites of polyunsaturated fats) pathways. Especially because of the dynamics of lipid metabolism in dairy cows around parturition, profound changes in the composition and concentration of oxylipids systemically and in the mammary gland may be responsible for dysfunctional inflammatory responses.[66] The key to modulating this potential problem is to manage the feeding of cows to mitigate excessive body condition loss, especially in transition cows.

Antioxidant supplementation has also been demonstrated to play an important role in mammary immune function. Antioxidants such as vitamin E, selenoenzymes, and zinc-dependent superoxide dismutase protect cells and membranes from oxidative damage that could result from expression of reactive oxygen species during phagocyte killing.[97] Phagocytosis and killing is reduced in neutrophils collected from selenium-deficient cows

as compared to those collected from selenium-supplemented cows.[98] In addition, selenium deficiency resulted in more severe outcomes in cows with coliform mastitis.[99] In one herd, vitamin E supplementation above National Research Council (NRC) guidelines (4000 IU/day) to dry cows in the last 14 days before calving was reported to decrease clinical mastitis in the first 7 days of lactation.[100] However, in a larger field study in five herds, feeding dry cows 3000 IU/day of vitamin E (which also exceeds NRC recommendations) was found to increase both subclinical and clinical mastitis in the first 3 months after lactation.[101] In this field study, antioxidant status in cows fed high levels of vitamin E varied, which may reflect the dependency of plasma α-tocopherol concentrations on lipid mobilization, which itself varies with individual cow energy balance.[102] Thus while antioxidant supplementation is critical for mammary health, there is no compelling evidence to feed selenium, vitamin E, or any other nutrient of this type above NRC guidelines.

Recently, recombinant bovine granulocyte colony-stimulating factor covalently bound to polyethylene glycol (PEG rbG-CSF) administered twice subcutaneously to cows before and within 24 hours after calving was found to increase circulating numbers of PMNs. This induced neutrophilia is hypothesized to permit a more robust and timely response for cows that may be prone to postpartum infectious diseases, including mastitis.[103] In a subsequent field trial conducted in four dairies in diverse geographic locations in the United States, administration of two doses of PEG rbG-CSF to cows before and after calving reduced the overall clinical mastitis rate during the first 30 days after calving by 35% compared to control cows.[104] However, the magnitude of the decrease in clinical mastitis varied by herd. This technology may help transition cows to overcome PMN-related immune dysfunction, although other pathways of postpartum immune dysfunction may not be affected by this approach. In addition, clinical benefits will rely on the incidence of postpartum clinical mastitis in a herd and should not be used as a substitute for other sound transition cow management practices.

Diagnosis and Detection of Mastitis

Definitions Technically, mastitis can be defined as any inflammation of the mammary gland (including inflammation caused by injury), but almost all mastitis occurring in dairy cows is caused by pathogenic organisms that are mostly of bacterial origin but can also include yeasts, fungi, and algae.[5] Like infections occurring in other tissues, mastitis begins with invasion by a pathogen, followed by a brief latent period and then progression to either subclinical or clinical states or resolution of the infection as a result of the cow's immune response.[105] Detection of mastitis is almost never based on identification of the precise moment of infection, but is based on observation of the resulting inflammation. Therefore recognition of mastitis is dependent on pathogen and cow characteristics that govern the magnitude of the immune response and the intensity and accuracy of the detection methods.

Subclinical mastitis is characterized by inflammation that is usually detected by enumeration of inflammatory cells in the milk. By definition, milk obtained from mammary gland quarters of cows experiencing subclinical mastitis appears visually normal but contains an abnormal number of somatic cells, with or without detectable presence of pathogenic bacteria.[5] In most instances, detection of subclinical mastitis is based on evaluation of the SCC in an appropriate milk sample. The SCC can be measured using milk collected from individual quarters or composite milk samples that are a mixture of milk from all functional glands of an individual cow. Composite milk samples are routinely used in DHIA programs for monitoring the SCC of individual cows. When composite SCC values are used, some subclinical infections will not be detected because the SCC of the composite milk will be reduced by dilution with milk from healthy quarters that contain few somatic cells.[106] When cows are not routinely tested for individual SCCs, veterinarians cannot determine important epidemiologic characteristics of subclinical infections (such as prevalence or incidence) that are necessary for implementing mastitis control programs.[107]

The distribution of cell types found in bovine milk varies depending on infection status and milk fraction.[108] The SCC of healthy quarters is quite low and usually remains well below 100,000 cells/mL.[5] However, based on detection of IMI (microbiologically positive milk samples), a threshold of less than 200,000 cells/mL is usually considered to be the optimal value to define a mammary quarter as healthy.[109-112] The selection of an appropriate threshold for defining subclinical mastitis is not fixed but rather is dependent on the goal of the control program. Use of a lower threshold will identify more animals with subclinical infections (increased sensitivity and fewer false negatives), whereas use of a higher threshold (increased specificity) will result in fewer false positives.[112] Regardless of threshold, review of the SCC history of a cow is much more informative as compared to observation of a single monthly value.

An SCC greater than 200,000 cells/mL does not always indicate that bacteria will be recovered from milk samples obtained from the affected gland.[113,114] The immune response indicated by the influx of leukocytes is often effective in reducing the number of bacterial colonies in milk, and about 10% to 25% of quarters that are above a threshold of 200,000 cells/mL will be apparently bacteriologically negative.[109,110,112] As the prevalence of infected quarters has declined, the predictive value of SCC relative to detection of IMI has declined. As the prevalence of pathogens that maintain long periods of subclinical IMI (such as *Streptococcus agalactiae* and *S. aureus*) has declined, the proportion of apparent "false negatives" (inability to recover bacteria from quarters that exceed the SCC threshold) has increased.[115] These culture-negative samples do not always indicate that the quarter is cured; they may indicate that the immune response has reduced the number of bacteria to below normal laboratory detection limits[114] and are essentially indicative of the chronic state of failed inflammation (inability to achieve bacteriologic cure). It is useful to educate clients that about 30% to 50% of milk samples collected from mammary glands with high SCCs will be culture negative, and thus sufficient samples should be collected to ensure meaningful diagnostic test results.

The duration of the subclinical phase of IMIs varies depending on etiology, as the magnitude of the inflammatory response is partially a function of virulence characteristics that vary among bacteria. In most herds, a greater proportion of subclinical mastitis is caused by gram-positive pathogens as compared to gram-negative pathogens (Table 36.1). Usually, gram-negative opportunistic pathogens such as *Escherichia coli* have a shorter subclinical phase as compared to gram-positive pathogens such as *S. aureus* or most IMIs caused by *Streptococcus* spp.[116] In general, approximately 25% to 35% of cows experiencing chronic subclinical mastitis caused by gram-positive pathogens may eventually exhibit clinical symptoms.[117] For opportunistic environmental pathogens, the likelihood of a clinical episode occurring in a cow with subclinical IMI varies among pathogens. For example, about 50% of IMIs caused by streptococci may progress to clinical signs, whereas more than 80% of coliform infections will exhibit clinical signs.[116]

It is important to diagnose both prevalence and incidence of subclinical infections within a dairy herd. Cows with IMIs that remain subclinical are known to produce considerably less milk, and they maintain a reservoir of pathogens that can result in increased exposure of otherwise healthy cows.[13,118] Subclinical infections that persist for long durations are

[b]NR indicates that the study did not report that outcome.

[c]Contaminated cases are included.

especially costly. For example, cows that maintain subclinical mastitis across the dry period (SCC >200,000 cells/mL at the last test of the completed lactation and first test of the subsequent lactation) have been shown to produce 9.1 kg (20 lb) less milk at their first DHIA test day.[112]

In diagnostic laboratories, the SCC of fresh or preserved milk is usually determined using automated methods that dye and enumerate cells.[119] Overall, about half of all U.S. dairy farmers and about 75% of dairy farms containing more than 500 cows subscribe to monthly DHIA testing, so it is possible for most cows in the United States to be monitored for subclinical mastitis using SCC values of composite milk samples.[120] SCC values of individual cows are not usually normally distributed, and many DHIA centers report the SCC using a linear score transformation, which is calculated using a simple formula ($LS = \log_2 [SCC/100] + 3$) that results in a normal distribution of values. At the herd level, increased linear somatic cell scores are associated with increasing prevalence of IMI.[121] At the cow level, SCC scores are the transformed representation of actual SCC, which are linearly correlated with milk yield loss, and thus serve as the basis to estimate economic losses from subclinical mastitis.[11,13] Reviewing monthly summarized SCC values at the herd level is a critical component of udder health programs and should be part of routine activities during scheduled veterinary visits to dairy farms.[122,123]

Laboratory-based methods for identification of subclinical mastitis are considered accurate, but because they are removed from the farm, they are sometimes criticized as too slow for making cow-side decisions. To overcome this hurdle, a number of indirect measures of SCC have been developed. The California Mastitis Test (CMT) is an example of an indirect test that has been used for more than 50 years to help guide mastitis control programs.[124,125] The CMT was developed to test milk from individual quarters but is also useful for composite milk and samples obtained from bulk tanks. The CMT reagent is a mixture of a detergent and bromocresol purple, which is used as an indicator of pH. The degree of reaction between the detergent and the DNA of cell nuclei is a measure of the number of somatic cells in milk. The CMT is generally read using a five-point scale that begins with "negative" (SCC range of 0 to 200,000 cells/mL) and "trace" scores (SCC range of 150,000 to 500,000 cells/mL) and ends with a maximum score of 3 (SCC >5,000,000 cells/mL). The CMT was developed during the period when many cows had very high SCCs as a result of chronic subclinical infections caused by *S. agalactiae* and *S. aureus*. Through the adoption of standardized best management practices, the prevalence of these pathogens has decreased,[115] and SCC values of IMI caused by minor pathogens are usually not as high.[126] While the CMT continues to have considerable utility, it is important to note that even "trace" scores indicate the presence of subclinical mastitis and the test may be difficult to read when used on milk obtained from cows in the first few days of lactation.[127]

In addition to an increased SCC, a number of changes in milk composition occur as a result of inflammation that is part of the immune response to infection.[45,128] Mild inflammatory changes can also be detected in apparently normal mammary gland quarters adjacent to quarters that are experiencing clinical mastitis.[45] Compositional changes include reduced casein, lactose, and α-lactalbumin concentrations; an influx of sodium, chloride, and plasma proteins; increased proteolytic and lipolytic activity; an increase in lactoferrin concentration and enzyme activities; and a rise in pH.[129] Many of these changes can be used as indicators of subclinical mastitis. Among the more common milk tests are those that detect albumin, sodium, chloride, lactose, or concentration of adenosine triphosphate; *N*-acetyl-β-D-glucosaminidase (NAGase) activity; antitrypsin activity; or pH. Plasma tests detect α-lactalbumin, casein, or lactose concentration.[130-133] Milk concentrations of acute phase proteins amyloid A and haptoglobin are able to distinguish healthy quarters from those with subclinical mastitis.[134] Although a variety of immunologic mediators are modified by IMI, measurement of SCC remains the most accurate method of identifying subclincally infected quarters.[132] With increases in diagnostic technology and increased emphasis on production of high-quality milk, considerable research has focused on producing tools for continuous in-line monitoring of milk quality, and these tools will increasingly be used in future dairy herds.[135] Increased use of automatic milking systems (robotic milking) has led to the search for automated methods that can consistently and accurately detect abnormal milk, but challenges remain to identify automated systems that are accurate throughout the lactation period.[136] While current testing technology generally gives accurate results, the ultimate value of any test depends on the value of the intervention that is chosen based on the test result, thus veterinary practitioners

should continuously review how such tests can be best used on dairy farms.

Clinical mastitis is usually defined as production of visually abnormal milk, with or without secondary clinical signs. Detection of clinical mastitis is based on observation of foremilk prior to attaching the milking unit, but the working definition of clinical mastitis varies greatly among farm workers. While the majority of workers on larger farms routinely remove foremilk, about one third of farms containing fewer than 500 cows do not routinely remove or observe foremilk of all cows, and in these instances detection of clinical mastitis is limited to cases with more severe signs.[21,137] To evaluate incidence of clinical mastitis, veterinarians should ask milking technicians to describe their definition and detection methods. Clinical signs of mastitis result from inflammation and may include abnormal appearance of milk (presence of clots or serum); swelling, redness, or edema of one or more quarters; and severe systemic signs such as anorexia, fever, or agalactia. As compared to subclinical mastitis, a much greater proportion of clinical cases are caused by gram-negative pathogens (Table 36.2). Like other bacterial diseases, many cases of mastitis occur as a syndrome with the infected quarters alternating between a clinical state and a subclinical state.[138] The disappearance of clinical signs indicates that inflammation has decreased and does not usually coincide with bacteriologic cure.[139] The ability to achieve a bacteriologic cure varies greatly among etiologic agents and is associated with variation in immune response among cows and the appropriateness of the therapeutic plan.[140]

Recording standardized severity scores can help veterinarians better define the pattern of clinical mastitis on individual farms.[139,140] One severity scoring system uses a three-point scale that combines the appearance of milk with the progression to additional clinical signs. A score of 1 (mild mastitis) = abnormal milk only; 2 (moderate mastitis) = abnormal milk and abnormal udder; 3 (severe mastitis) = systemic symptoms.[140] This system is practical and simply recorded and can be an important method to assess detection intensity. In most herds, distribution of severity of clinical mastitis is approximately 40% to 50% mild cases, 40% to 50% moderate cases, and 5% to 15% severe cases.[6,139] Veterinarians are rarely asked to treat mild and moderate cases of clinical mastitis and therefore may not understand the true incidence of clinical mastitis on many dairy farms.[141] Veterinarians need to promote the use of clinical mastitis records that allow them to monitor the occurrence of mild and moderate cases and to evaluate outcomes of mastitis treatments.

Identification of Etiologic Agents

Effective treatment and control of mastitis is based on knowledge of the etiology of the infection. As dairy farms increase in size, an increasingly diverse group of pathogens have been associated with the occurrence of mastitis.[6,142-144] Clinical signs may be suggestive of some pathogens, but it is impossible to diagnose the etiology based on the appearance of the milk, gland, or animal. Some practitioners erroneously believe that they can recognize coliform infections based on severity of the symptoms, but researchers have consistently shown that the majority of clinical cases caused by coliform bacteria present with only mild or moderate symptoms[6,145,146] and misdiagnosis of coliform infections is common.[147] Collection of an aseptically obtained milk sample and use of appropriate microbiological techniques is necessary to determine etiology.[5]

MILK SAMPLES COLLECTED FROM INDIVIDUAL ANIMALS. Milk samples may be individually collected from affected quarters (quarter milk samples) or combined from all four glands into a single vial (composite milk samples). Quarter milk samples collected from affected glands are more sensitive in detection of bacteria from subclinical infections as compared to composite milk samples, although the sensitivity of composite samples increases with the number of infected glands per cow.[148] Repeated sampling increases the likelihood of detecting glands that are intermittently shedding some pathogens.[5] The concentration of bacteria per milliliter of milk varies among pathogens. Some pathogens (such as most *Streptococcus* spp.) consistently shed large numbers of bacteria in milk. For these pathogens, the use of composite milk samples may be acceptable because concentrations of bacteria will likely consistently exceed the microbiological detection limit.[149] For many other pathogens (such as *S. aureus* and *Mycoplasma* spp.), composite samples will often result in apparently culture-negative results because these pathogens are often shed in fewer numbers and dilution with milk from healthy quarters will result in samples that contain less than the limit of detection in most laboratories (100 colony-forming units [CFU]/mL of milk).[150]

Microbiological culture or polymerase chain reaction (PCR) testing of composite milk samples is often used to reduce the cost of routine screening of high-risk animals for the presence of existing subclinical infections with potentially contagious mastitis pathogens. Pooling 5 to 10 aseptically collected composite or quarter milk samples is another strategy that is used in some herds to further reduce costs. When either of these strategies is used, it is important to recognize that the potential for false negative outcomes is increased. The sensitivity of composite milk samples for detection of *S. aureus* and *Streptococcus dysgalactiae* was estimated to be about 73% to 77% in contrast to about 60% to 62% for *Streptococcus uberis* and non-aureus staphylococci (NAS).[151] In all instances, sensitivities increase as the number of infected mammary gland quarters increases.[151] When using pooled or composite samples, veterinarians should routinely review cow histories to identify cows with increased SCCs that are typical of subclinical infections.

Mastitis is usually caused by a single type of bacteria, and the National Mastitis Council has developed standards that specify that recovery of more than two colony types of bacteria cultured from an aseptically collected milk sample is indicative of contamination.[5] Before collection of milk samples, technicians should be trained in techniques that ensure aseptic collection of the sample; adherence to aseptic sampling procedures is even more critical when DNA-based diagnostic tests are used. To maximize the possibility of recovering bacteria from the sample, milk should be collected after the teats have been prepared for milking (application of premilking disinfectant and drying) but before the units are attached.[152] Collection of samples before milking is usually easier because cows are more likely to stand still and there is less pressure from farm workers to release the cows. Before obtaining the sample, the udders should be clean, and dry-wiping the udder with a paper or cloth towel is often helpful in reducing the possibility of contamination. Milk should be collected in sterile vials by technicians who are wearing disposable nitrile or latex gloves and using a standardized process. After thoroughly drying the teat using a cloth or paper towel, the teat end should be vigorously scrubbed using 70% ethyl or isopropyl alcohol. If composite samples are collected, a separate alcohol swab must be used for each teat. Sanitation is not complete until the surface of the swab remains clean after it is used.

The cap should be removed from the sample vial without touching the inside and held so that the inner surface faces down. Milk from the teat to be sampled can be directed at an angle into the sampling vial. A sample size of 3 to 5 mL is usually adequate. The cap should be replaced immediately after the sample is obtained. When sampling multiple teats, the far teats should be scrubbed before the near teats and the near teats sampled first, to avoid contamination by the sampler's arm or hand. Samples must be cooled immediately, refrigerated at 4° C, held on ice, or frozen until cultured. Failure to use aseptic technique or mishandling after collection can produce

TABLE 36.2

Summary of Characteristics of Common Mastitis Pathogens

Pathogen	Most Common Point of Infection in Mammary Gland	Duration of Subclinical Phase	Clinical Cases That Develop Systemic Signs	Typical SCC Response (Cells/mL)	Common Source of Infection	Risk of Cow-to-Cow Transmission	Expected Rate of Spontaneous Bacteriologic Cure	Key Preventive Strategies
Gram-Positive Organisms								
Staphylococcus aureus	Adheres to and invades mammary parenchyma	Long	10%-20%	Variable, ranging from 250,000 to >1,000,000	Exposure to milk from infected cows	Moderate to high	Very low	Cull or segregate infected cows, five-point plan, good biosecurity
Non-aureus staphylococci (NAS); previously coagulase-negative staphylococci	Usually mucosal surfaces	Short to moderate	2%-10%	<500,000	Teat skin	Low to moderate	Moderate to high	Teat dipping and hygiene
Streptococcus agalactiae	Mucosal surfaces of ducts and cistern	Long	<1%	>800,000	Obligate udder pathogen	High	Negligible	Identify and treat infected cows, dry cow therapy, five-point plan, good biosecurity
Other *Streptococcus* spp. (*S. uberis*, *S. dysgalactiae*, and others)	Variable depending on species	Moderate to long	10%-20%	>500,000; varies by species	Environment and milk from infected cows	Varies by species	Low to moderate	Improve environmental hygiene
Corynebacterium bovis	Teat canal		<1%	<200,000	Exposure to milk from infected cows	Moderate	Moderate to high	Teat dipping and skin hygiene
Gram-Negative Organisms								
Escherichia coli	Mucosal surfaces	Short	25%-30%	>1,000,000	Environment	Low	Usually high	Improve hygiene, vaccination
Klebsiella spp.	Variable by strain	Moderate to long	25%-30%	>500,000	Environment and milk from infected cows	Varies by strain	Low to moderate	Improve hygiene, vaccination
Serratia spp. (*S. marcescens*, *S. liquefaciens*, and others)	Can invade mammary parenchyma	Moderate to long	<15%	>500,000	Environment and chlorhexidine teat dips	Moderate	Moderate	Change to iodine dip, cull or segregate infected cows
Other Commonly Isolated Organisms								
Mycoplasma bovis and spp. (*M. californicum*, *M. bovigenitalium*, and others)	Distributes throughout udder and other organs	Long, often multiple glands affected	Variable depending on herd	>500,000	Infected cows; aerosol transmission among cows infected with respiratory disease is common	High	Low	Cull or segregate infected cows, five-point plan, good biosecurity, control respiratory disease
Prototheca spp. (*P. zopfii*, *P. blaschakeae*, *P. wicherhamii*, and others)	Epithelial layer of mammary alveoli	Often long	Few	>500,000	Environment and milk from infected cows; poor hygiene during IMM treatments	Moderate	Low to moderate	Cull or segregate infected cows, five-point plan, reduce exposure to water, improve hygiene for IMM infusions

IMM, Intramammary; *SCC*, somatic cell count.

VetBooks.ir

erroneous results. If samples are to be submitted to a diagnostic laboratory, they should be submitted within 24 hours of collection. If samples cannot be processed within 24 hours, they should be frozen until transported to the lab. Freezing for periods of more than 2 weeks has minimal effects on recovery of most mastitis-causing bacteria but can reduce recovery of *Mycoplasma* spp.[153]

When proper sampling and laboratory techniques are used, the recovery of bacteria from bovine milk samples is highly specific for mastitis. However, microbiological examination of milk obtained from glands affected with clinical or subclinical mastitis is not very sensitive.[114] When a single milk sample is obtained from dairy cattle exhibiting clinical or subclinical mastitis, approximately 35% to 50% of milk samples will be culture negative (see Table 36.1).[5,6] Repeated sampling of affected quarters can increase the probability of reaching a diagnosis.[5,150]

Failure to recover bacteria from a milk sample can be a result of either a successful or a failed inflammatory response. For example, the inability to culture viable bacteria from milk samples collected from quarters with chronically high SCCs may be a result of suppression of bacterial growth caused by the chronic inflammatory response. In this instance, ongoing inflammation is likely caused by chronic bacterial infection and is indicative of failed inflammatory response. In contrast, failure to recover viable bacteria from milk samples obtained from cows with clinical mastitis is often due to spontaneous clearance of bacteria prior to onset of visible clinical signs. Many of these culture-negative clinical cases are the result of successful inflammation, and if the clinical signs are not severe, most of these cows have excellent prognoses without use of antimicrobial therapy.[140]

Laboratory Methods. Standardized laboratory methods for identification of mastitis pathogens have been well defined by the National Mastitis Council.[5] In general, laboratory technicians inoculate media that contain nutrients required for bacterial growth, and the inoculated media are placed in an incubator that contains the appropriate atmosphere and temperature to encourage growth of the target organisms. After 24 to 48 hours, the plates are examined for growth, and the bacteria are identified using a variety of specific test methods that depend on observable characteristics of the bacteria. In most mastitis laboratories, 10 to 100 μL of each milk sample are inoculated onto a portion of a blood agar plate (5%). The inoculum volume determines the lower limit of detection. For example, one colony observed on a plate inoculated with 0.01 mL (10 μL) is equivalent to approximately 100 CFU/mL of milk, whereas one colony observed using a 0.1-mL (100-μL) inoculum is equivalent to approximately 10 CFU/mL. The use of larger (0.05- or 0.10-mL) inocula increases recovery rates for pathogens shed in low concentrations, such as *E. coli* or *S. aureus*. Other ways to increase recovery are pre-culture centrifugation,[154] incubation,[155-157] or freezing[157] of the milk, or a combination of these methods. The optimal method is pathogen dependent. Augmented methods are most useful for detecting subclinical *S. aureus* infections and reducing false-negative results for clinical mastitis samples.

After inoculation, agar plates are incubated at 37° C and observed for growth at 24 and 48 hours.[5] Although there is no absolute definition of IMI,[158] the presence of at least 100 to 300 CFU/mL is usually required to define an infection.[5,114] Identification of bacteria is made based on phenotypic characteristics of the colonies and the result of additional laboratory tests. *S. aureus* is usually differentiated from other staphylococci based on a positive coagulase reaction and other typical phenotypic characteristics, such as hemolysis.[5] Streptococci are usually identified using the Christie–Atkins–Munch-Petersen (CAMP) test and esculin reactions. When milk samples originate from cases of clinical mastitis, MacConkey agar is usually also inoculated to facilitate the rapid identification of gram-negative, lactose-fermenting organisms (coliforms). Classic microbiological techniques use additional biochemical tests for final identification at the species level, but other techniques for identification of mastitis pathogens are increasingly used. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) has been shown to increase accuracy of diagnosis of NAS and streptococci.[159,160] Identification of *Mycoplasma* spp. requires the use of media containing specific nutrients not found in general media and incubation in a carbon dioxide–enhanced environment.

On-Farm Culture. As farm size has increased and specialized workers have become more common, on-farm culture (OFC) programs have been developed.[161] Methods used for OFC are not usually the same as those used in professional diagnostic laboratories and are often performed by farm personnel who may have some technical expertise but lack formal training in microbiological methods. On most farms, OFC methods are based on the use of laboratory shortcuts and have a goal of rapidly reaching a presumed diagnosis to guide treatment.[162-164] The most basic method of OFC is the use of biplates, triplates, or quadplates that contain selective[165] agars or chromogenic media.[154] Growth on a selective agar is used to differentiate cases caused by gram-positive or gram-negative bacteria, culture-negative cases, or in some instances specific pathogens. After 24 hours of incubation, culture plates are observed, and the treatment protocol is specified based on the culture outcome.[140,163,166] Typical agars that are used include MacConkey agar (selective for growth of gram-negative bacteria); TKT agar (selective for growth of streptococci), and Factor, Baird-Parker, or KLMB media (selective for growth and differentiation of some staphylococci). Studies have indicated that using selective media in OFC systems is about 80% accurate in differentiating gram-positive and gram-negative pathogens as compared to diagnostic laboratories.[165] The use of OFC to make more specific pathogen diagnoses is not as accurate and requires additional training of personnel.

Most smaller herds do not have sufficient cases of mastitis to develop the expertise needed for OFC, and one alternative is to offer in–veterinary clinic culturing (IVCC). In these instances farmers usually collect a milk sample and immediately initiate treatment, but they may stop or modify treatment duration or the drug after receiving a preliminary microbiological diagnosis from their veterinarian within 24 hours. Development and oversight of a culture program (either OFC or IVCC) is an ideal way for veterinarians to increase involvement in mastitis control programs. Using veterinary technicians to supervise these programs may also increase veterinary involvement and oversight of mastitis treatments. When OFC is used, veterinary technicians can visit farms to restock supplies, train farm personnel, and provide oversight and quality control.

MICROBIOLOGICAL ANALYSIS OF BULK TANK MILK. Microbiological examination of bulk tank milk samples is performed using a variety of laboratory techniques depending on the objective of the testing.[5,106] Enumeration of the total number of aerobic bacteria in bulk milk is routinely performed by milk processors as part of the regulatory requirements for milk production. Standardized methods for counting bacteria may be based on culture or performed using automated counting of stained bacterial cells.[119] Processors also commonly perform additional laboratory tests to assess hygienic conditions of milk harvest and storage and may use results of these tests to determine premium payments. Comparison of the number of psychotrophic, thermoduric, or coliform bacteria from various milk samples can be used to identify problems with dirty udders, inadequate premilking preparation, cleanliness of milking equipment, or cooling stored milk.[5] Methods used

for these tests are simply quantitative and do not result in identification of specific microorganisms.

Qualitative bulk tank cultures (BTCs) are usually performed to identify specific pathogens shed by cows that are being milked while affected with subclinical mastitis.[5,106] Methods of sampling, laboratory techniques, and reporting formats have not been standardized, thus it is difficult to compare results of BTCs among laboratories. Because of the variation in laboratory methods, it is best to submit bulk tank milk samples to a specialized laboratory that tests several dilutions using selective media for isolating and counting colonies. The laboratory should be informed if identification of *Mycoplasma* spp. is of interest so that the proper media and incubator conditions are used.

The interpretation of results of BTCs can be confusing, as bacteria can originate from teat skin, subclinical mastitis infections, failure of milking technicians to exclude milk from cows that have clinical mastitis, poor hygienic conditions, failure to adequately cool milk, and use of inadequately cleaned milking equipment. Because there are numerous opportunities for bacteria to contaminate bulk milk, interpretation of BTCs is based on knowledge of reservoirs of the organisms found in the milk.[5,167] Although few scientific studies have been performed to validate criteria for interpretation of BTCs, suggested interpretive criteria have been published.[5] A few organisms (*S. agalactiae*, *S. aureus*, and *Mycoplasma bovis*) are known to originate primarily from infected cows, but many organisms have multiple potential sources. Organisms such as NAS may originate from IMI or from poorly disinfected teat skin and udders that have been contaminated by bedding sources. Non-agalactiae streptococci are commonly found in the dairy farm environment and are associated with dirty udders, but these organisms can also cause subclinical mastitis. The natural duration of subclinical IMI caused by *E. coli* is short, and there are multiple environmental sources of this organism.[116] Thus when many *E. coli* are found in bulk milk, the most likely source is contamination during the milking process.[168] When organisms that have environmental niches are found in bulk tank milk, sources other than IMI should be investigated before assuming that infected cows are the source.

The sensitivity of a single BTC for detection of herds with infected cows is generally considered to be low, and results should not be used to estimate prevalence of infected cows.[5] Positive predictive values of BTCs (detection of at least one positive cow when the organism was found in a BTC) are estimated to be more than 97% for *S. agalactiae* and *S. aureus* and more than 80% for *Mycoplasma* spp.[169] Due to low sensitivity, the inability to isolate selected mastitis pathogens from bulk milk does not indicate the absence of subclinically infected cows, and negative BTCs routinely occur in large herds that contain infected cows. The relatively low sensitivity of a single BTC for screening herds for contagious pathogens can be improved by using enhanced laboratory techniques or by increasing the frequency of sampling. The use of commingled samples that have been independently collected for 3 to 5 consecutive days is recommended to reduce false-negative results that occur as a result of variation in bacterial shedding.[167]

MOLECULAR TESTING. The continued development of molecular techniques has the potential to improve diagnosis of mastitis; however, a full review of these technologies is beyond the scope of this chapter. A variety of molecular methods are used to diagnose mastitis pathogens, identify potential zoonotic agents in milk, identify genetic diversity of resistance genes, and investigate mastitis outbreaks and milk quality problems.[170-173] Some molecular methods are used to identify specific strains of bacteria to determine the likely source or transmission of mastitis pathogens.[174,175] Other methods are used to improve diagnosis of pathogens for which biochemical methods for identification of species are known to be inaccurate[176] or to more rapidly arrive at a diagnosis.[177] In general, genotypic methods of identifying bacteria are based on identification of unique sections of DNA that are compared to characteristics of known library strains. Several PCR-based methods of identifying bacteria have been developed,[172,178,179] and real-time PCR tests are widely available. One commercially available test is able to accurately detect the presence of bacterial DNA of up to 16 mastitis pathogens and the β-lactamase gene but requires the use of aseptically collected milk samples to limit the number of false-positive results.[180] In one study, use of this test resulted in identification of bacterial DNA of potential mastitis pathogens in 43% of culture-negative milk samples.[181] However, research has indicated that teat skin and teat canal flora may be the source of many minor pathogens identified in milk samples using PCR testing.[182]

The use of the commercially available reverse transcription PCR (RT-PCR) test to evaluate quality of bulk tank milk has also been investigated.[183-185] As expected, PCR testing is useful to detect the presence of obligate udder pathogens (such as *S. agalactiae*) in bulk milk, but a single PCR test of bulk tank milk is not reliable for diagnosis of mastitis pathogens.[183] Interpretation of PCR test results of bulk tank milk for bacteria that have possible environmental origins in bulk milk is difficult and not always more sensitive than bacteriologic culture.[185] PCR test results are interpreted relative to the cycling threshold (Ct) values, which indicate the number of cycles required to reach a signaling threshold. In general, the lower the Ct value, the greater the amount of the specified DNA in the sample, but similar to BTC results, PCR tests are not accurate to estimate the prevalence of infected cows within a herd.[183]

Decision making for management of milk quality based on PCR results is complicated because DNA from both live and dead bacteria is detected. Just as the occurrence of a few colonies of environmental pathogens on a blood agar plate would not be sufficient evidence to indicate that a treatment is indicated, identification of bacterial DNA from milk is not always sufficient evidence on which to base a treatment protocol. To improve the utility of diagnostic methods based on DNA, aseptic samples should be collected[180] and the medical history and SCC of the cow should be reviewed before making treatment or culling decisions. For some pathogens, such as *Mycoplasma* spp., *S. agalactiae*, or *S. aureus*, the cow history will generally support the presumed diagnosis; for other pathogens the relationship may be less apparent. It is clear that the cost of using molecular methods will decrease, and therefore the use of these methods will increase. However, continued research is needed to help define practical ways of best using these methodologies.

Milk was long considered sterile, but researchers have been exploring the potential presence of a microbiota in milk from apparently healthy mammary quarters.[186,187] The presence of a commensal microbiota in the teat canal is well accepted,[188-190] but the mammary gland itself has long been considered to be a sterile environment.[191] Based on a limited number of studies, some researchers[192] have hypothesized that the bovine milk microbiota is composed of a complex and diverse community that includes both culturable and nonculturable organisms that are linked to intestinal flora and contribute to homeostasis and mammary gland health. Others have challenged this view,[191] describing anatomic, immunologic, and practical research suggesting that while there is considerable evidence for the existence of a teat apex microbiota, the concept of a mammary gland microbiota is incompatible with known mammary gland immunobiology and warrants critical examination. This subject is an area of very active research, and clinical applications of these techniques in udder health programs have not yet been developed.

VetBooks.ir

Epidemiology of Mastitis Pathogens

TRANSMISSION AND RESERVOIRS. Mastitis is an infectious disease that occurs when udders become infected with pathogens, most of which are bacteria. With the exception of infections caused by a few unique microorganisms (such as *Mycoplasma* spp.), exposure of the teat sphincter to bacteria is the primary route of almost all mammary gland infections. Microorganisms that can potentially cause mastitis are typically categorized as either environmental or contagious based on the likely reservoir on the farm and the most probable source of the initial exposure.

Opportunistic organisms from the cow's surroundings are generally considered to be primarily environmental pathogens. Transmission occurs when teats are exposed to bacteria found in environmental sources such as fecal material, bedding, soil, and contaminated water.[58] Contamination of teat skin with environmental pathogens increases the probability of IMI, especially when defense mechanisms (such as the patency of the teat sphincter) are compromised. IMI with environmental pathogens can also occur when teat ends are not sufficiently disinfected before infusing antibiotics or when a contaminated infusion preparation or cannula is used.[58,193] Gram-negative bacteria, such as *E. coli* and *Klebsiella* spp., are the most commonly isolated environmental pathogens.[6] However, many gram-positive organisms, such as *S. uberis* and *S. dysgalactiae* can be found in the cow's surroundings, and the initial infection with these pathogens is often from an environmental source. Although coliforms and streptococci are commonly isolated, many other organisms are found in the environment of cows and are capable of causing mastitis. The diversity of environmental mastitis pathogens is increasing as management of dairy farms intensifies and as a variety of bedding sources are used.[58,194] Reducing exposure to environmental pathogens is based on improving hygiene of cows, housing areas, and the milking process.[195]

Mammary glands with chronic subclinical infections are the primary reservoir of contagious mastitis pathogens. Transmission occurs when teats are exposed to bacteria found in milk that came from an infected gland. In many instances, exposure to infected milk occurs during the milking process. Infected milk droplets can be found in teat cup liners, hands of milking technicians, towels used to wash or dry teats, or milk droplets that leak onto bedding surfaces. The presence of these organisms on teat skin increases the probability of infection. In some cases, abrupt vacuum fluctuations within the milking cluster (reverse pressure gradients) can propel contagious pathogens from the milk of an infected gland into the teat canal of a healthy gland.[196] The most common contagious mastitis pathogens are host-adapted bacteria that cause long-term subclinical infections. Historically, *S. agalactiae* was considered to be one of the most important causes of contagious mastitis[197]; however, this obligate udder pathogen is controlled in most developed dairy regions and is not commonly isolated from milk samples of cows located in developed regions.[115,198,199] In recent years, *S. aureus*, and *M. bovis* have been the most prevalent contagious mastitis pathogens found in U.S. dairy herds.[200] It is important to recognize that most organisms that establish chronic subclinical IMI can be transmitted in a contagious manner. Successful control programs for contagious pathogens are based on reducing the prevalence of subclinically infected cows, thus reducing the probability that healthy cows are exposed to milk that originated from infected udders.

The classification of organisms as contagious or environmental is a broad characterization of the most common sources of initial exposure to pathogens and does not preclude other potential routes of transmission[146] (see Table 36.2). Historically, contagious pathogens were considered to be caused by highly contagious identical clones that were transmitted only among cows, whereas environmental bacteria were often considered to consist of diverse strains that were found only in the environment.[201] However, use of DNA fingerprinting has demonstrated that it is not uncommon to find several different strains of contagious organisms such as *S. aureus* occurring in cows on a single farm.[202] Similarly, a single dominant strain of *Klebsiella* spp. isolated from multiple cases of mastitis has been reported as evidence of contagious transmission of a supposedly environmental pathogen.[203] The use of molecular methods has demonstrated that microbes are continually evolving in response to control measures and changes in farm management. While characterization of pathogens as "contagious" or "environmental" still provides a reasonable basis for initiating control programs, veterinarians should be aware of the possibilities of additional routes of transmission and the need for comprehensive control programs that may exceed the typical recommendations.

PREVALENCE OF MASTITIS PATHOGENS. More than 130 organisms, including bacteria and some algae, yeasts, and fungi, have been documented to cause mastitis.[5,204] Although some regional differences in prevalence have been demonstrated, the distribution of pathogens that cause clinical and subclinical mastitis on modern dairy farms is remarkably consistent (see Table 36.1). In recent years, widespread adoption of standardized mastitis control procedures in developed dairy regions has resulted in a decreased prevalence of mastitis caused by contagious pathogens such as *S. aureus* and *S. agalactiae* (see Table 36.1).[115,142,143] Herds that fail to control these pathogens typically have failed to effectively implement well-known mastitis control procedures such as postmilking teat dipping and comprehensive use of antimicrobial dry cow therapy.[199] On most dairy farms, about 25% to 30% of milk samples obtained from cows secreting abnormal milk result in no significant growth of bacteria (see Table 36.1), usually because of an effective immune response to infection by opportunistic environmental pathogens. Coliform bacteria and environmental *Streptococcus* spp. are usually the most common pathogens identified from milk samples collected from cases of clinical mastitis on modern U.S. dairy farms (see Table 36.1).[6,28,205,206] In contrast, when milk samples are collected from cows with subclinical infections, few coliform bacteria are identified, indicating the short duration and clinical nature of most of these infections.[116,207-210] In regions that have controlled *S. aureus* and *S. agalactiae*, NAS are often the most prevalent pathogen group associated with subclinical infections (see Table 36.1). While epidemiological studies of mastitis pathogens within regions have resulted in consistent recovery of typical groups of pathogens, the distribution of pathogens often varies among farms based on individual risk factors. The implementation of effective control programs and correct treatments is based on understanding the etiology of mastitis, and sufficient diagnostic testing should be used routinely by veterinary practitioners who are working to control mastitis.

CHARACTERISTICS OF PATHOGENS. Pathogenesis, virulence, and prognosis of IMI are each influenced by important characteristics that vary among pathogens. General characteristics of the most common mastitis pathogens are described in Table 36.2. Depending on specific virulence factors, organisms infect different locations in the mammary gland, have differing abilities to cause systemic symptoms, vary in the expected duration of subclinical phases of infection, and differ in the expected rate of spontaneous bacteriologic cure (see Table 36.2). Understanding these differences is fundamental to the development of effective control programs.

MASTITIS CAUSED BY *STAPHYLOCOCCUS* SPECIES

Staphylococcus aureus. The genus *Staphylococcus* contains at least 50 species, and initial differentiation among species is

based on their ability to coagulate plasma.[5] Historically, staphylococci that do not coagulate plasma have been referred to as coagulase-negative staphylococci (CNS), but non-aureus staphylococci (NAS) is now the preferred terminology, as the group includes some species that coagulate plasma. Among staphylococci associated with bovine mastitis, *S. aureus* and *Staphylococcus hyicus* are coagulase positive, but *S. hyicus* is usually considered to be a minor mastitis pathogen. *S. aureus* is considered a major pathogen because of its impact on SCC and widespread prevalence. *S. aureus* has been isolated from bulk tank milk of about 40% of U.S. dairy herds,[200] and about two thirds of producers who culture milk samples have reported its isolation,[21] but the prevalence and economic impact vary tremendously among herds. Most IMIs caused by *S. aureus* are chronic and subclinical, with periodic bouts of mild clinical mastitis. However, clinical mastitis caused by *S. aureus* can result in systemic signs, or the affected mammary gland may become gangrenous. Herds with a large proportion of cows with mastitis caused by *S. aureus* tend to have higher BTSCCs and many cows with chronically increased SCCs (see Table 36.2).

IMI caused by *S. aureus* is diagnosed by isolating coagulase-positive staphylococci from milk samples of cows. When grown on appropriate media, colonies usually demonstrate hemolysis and other typical phenotypic characteristics.[5] Occasionally some *S. aureus* strains are coagulase negative, thus definitive identification requires additional diagnostic testing. There are many different strains of *S. aureus;* some herds may have a predominant strain, whereas other herds may harbor diverse strains.[202,211] Some researchers have reported that variation among strains of *S. aureus* results in differences in transmission, virulence, and antibiotic susceptibility,[212,213] whereas others have reported similar outcomes independent of strain.[214,215]

Although much is known about *S. aureus*, considerable knowledge gaps about pathogenesis still exist.[216,217] Some strains of *S. aureus* can adhere to and invade mammary epithelial cells and interstitial tissue,[213,218,219] but variation in invasive potential among strains has been noted.[220] A variety of mechanisms to avoid the immune response have been noted for *S. aureus*. The organism can resist phagocytosis by neutrophils with antiphagocytic mechanisms such as a capsule that inhibits opsonization and a surface protein (protein A) that binds the Fc portion of host Ig. Leukotoxin production enables some *S. aureus* strains to kill phagocytes[221] while other mechanisms allow *S. aureus* to survive within leukocytes and epithelial cells and induce apoptosis.[219] Some strains of *S. aureus* produce enzymes and exotoxins that damage mammary cells and result in fibrosis and abscess formation.[222] Many strains produce β-lactamase, conveying resistance to antibiotics such as penicillin and amoxicillin. Others convert to L-form or small colony variants, which can persist even after antibiotic therapy.[215,223] Certain *S. aureus* strains form biofilms, making them inaccessible to phagocytes and antibiotics,[224-226] and some but not all biofilm-associated proteins have been associated with chronic infections.[220,227] For these reasons, *S. aureus* IMIs seldom resolve spontaneously and usually respond poorly to antimicrobial therapy.[223]

Farmers who purchase replacement heifers or lactating cows without screening the animals or source herds often have herds with greater prevalence of *S. aureus* as compared to closed herds, illustrating the importance of biosecurity in mastitis control. The prevalence of infected cows within a herd is an important risk factor for new infections. Cows with chronic *S. aureus* infections or with characteristics that predict a low likelihood of cure should be culled as soon as economically feasible or segregated and milked last. Alternatives are simply to stop milking the infected gland or to induce cessation of lactation in an individual gland.

Non-aureus Staphylococci (Previously Referred to as Coagulase-Negative Staphylococci). In most studies, NAS are the most prevalent bacteria isolated from milk samples obtained from cows with subclinical infections and from the mammary secretions of dry cows and prepartum heifers (see Table 36.1). Based on use of traditional microbiological methods of identification, there are at least 50 species of NAS, and many have been isolated from IMIs of dairy cows.[5,228,229] Epidemiological differences among various species have not been well defined. While researchers have demonstrated some variation in SCCs and persistency of IMI among NAS species, these differences have not been shown to affect milk yield,[230,231] and control programs are generally nonspecific. Historically, a thorough understanding of epidemiologic characteristics and differences in pathogenesis among NAS species has been limited by the relatively poor discriminatory ability of phenotypic or biochemical diagnostic tests.[232] The accuracy of identification of NAS associated with bovine mastitis has been improved by the use of genotypic methods (such as sequencing), and the use of MALDI-TOF MS by diagnostic laboratories has allowed for improved discrimination among species.[159,233]

Most recent surveys using modern discriminatory methods indicate that *Staphylococcus chromogenes*, *Staphylococcus epidermidis*, *Staphylococcus haemolyticus*, and *Staphylococcus simulans* are the most prevalent species associated with bovine mastitis, but variation among studies has been noted.[231,234,235] Staphylococci are the most common organisms recovered from mastitis in heifers, and a variety of NAS species have been recovered from teat skin, the streak canal, and precalving udder secretion obtained from heifers.[21,236]

IMI caused by NAS typically results in subclinical infection that is associated with only modest increases in SCC[237]; thus despite the widespread prevalence, NAS are often referred to as "minor" mastitis pathogens.[229] Most infections caused by NAS remain subclinical, with SCCs lower than 500,000 cells/mL. However, when NAS infections persist they may be characterized by greater increases in SCCs.[238]

Although NAS account for about 15% to 20% of subclinical IMI, they are recovered from a relatively small proportion of cases of clinical mastitis, and clinical signs are usually mild (Table 36.1).[146,239] The rate of spontaneous cure is often high,[240] but intramammary treatment used for cases of clinical mastitis caused by NAS usually results in bacteriologic cure rates that exceed 80%.[229,237] The use of β-lactam–based intramammary antibiotics at dry-off is often successful in treating subclinical IMI caused by NAS. Treatment of subclinical IMI caused by NAS during lactation is unlikely to be profitable because a potential increase in milk yield after treatment has not been documented. There are no specific control measures for NAS mastitis. Effective premilking and postmilking teat dipping, comprehensive antibiotic treatment of cows at dry-off, and attention to udder and milking hygiene are recommended.

MASTITIS CAUSED BY *STREPTOCOCCUS* SPECIES

***Streptococcus agalactiae*.** *S. agalactiae* is generally considered to be an obligate udder pathogen, and control measures that focus on reducing the prevalence of infected cows have been highly effective.[241] Historically, IMI caused by *S. agalactiae* was the most common cause of bovine subclinical mastitis, and most preventive practices used on modern dairy farms were developed to aid in reducing transmission of this highly contagious organism.[197] On modern North American dairy farms, control of *S. agalactiae* has been successful, and this organism is rarely isolated from individual cow milk samples (see Table 36.1) or bulk tank milk obtained from U.S.[200] or Canadian dairy farms.[143] However, without proper attention to biosecurity and milking procedures, *S. agalactiae* can be introduced and spread rapidly through a herd, resulting in substantial economic loss. Mastitis caused by *S. agalactiae* is usually subclinical and if not treated can persist for months or years (see Table 36.2). Subclinical infection may be interspersed

with bouts of mild clinical mastitis, but only rarely will cows exhibit systemic signs.

S. agalactiae adheres to epithelial cells in the mammary gland and localizes primarily in the ducts. Milk production declines when ducts become blocked with cells and debris and the associated alveoli involute. Early treatment can result in increased milk production because the superficial nature of the infection results in minimal damage to the milk secretory cells. However, tissue damage, fibrosis, and a permanent decrease in milk production can occur if infection becomes chronic. *S. agalactiae*–infected glands tend to shed high concentrations of bacteria and somatic cells in milk. and this organism should be suspected in the rare instances when a BTSCC exceeds regulatory limits.[24]

S. agalactiae is easily isolated from milk samples and is diagnosed when esculin-negative, CAMP-positive streptococci are identified in milk samples obtained from bulk tanks or from individual cows. *S. agalactiae* is usually an obligate udder pathogen so RT-PCR is useful for rapid diagnosis of infected cows.[176] In some regions that have not successfully controlled this organism, there is evidence of adaptation to environmental niches[242]; however, this is not common. When the organism is found in bulk milk or milk samples of affected cows, a sampling plan should be developed to screen the herd to identify and treat all infected cows. Antibiotic treatment has formed the basis for control of *S. agalactiae*, and intramammary antibiotics have been found to be more efficacious as compared to intramuscular treatment using penethemate.[243] In instances where use of antibiotics is not an option (e.g., organic dairy farms in the United States), it is especially important to identify and cull infected cows. Control programs for *S. agalactiae* are based on eradication through identification, treatment, culling, and biosecurity.

Environmental *Streptococcus* Species. A number of streptococci and closely related organisms are frequently isolated from milk samples collected from cows with clinical and subclinical mastitis (see Table 36.1). *S. uberis* and *S. dysgalactiae* are the most common streptococcal species recovered from IMI, but other species such as *Streptococcus parauberis*, *Streptococcus equinus*, *Streptococcus saccharolyticus*, *Streptococcus salivarius*, and *Streptococcus canis* have also been associated with mastitis.[244] In addition, there are a number of gram-positive, catalase-negative cocci such as *Enterococcus faecalis*, *Enterococcus faecium*, *Aerococcus viridans*, and several species of *Lactococcus* that have similar reservoirs and are often grouped with streptococci.[245] These streptococcal-like organisms are collectively referred to as environmental streptococci because the primary exposure is often in cow housing areas. Streptococcal organisms can be cultured from many materials commonly used for bedding, including contaminated sand.[194] Many of the IMIs caused by environmental streptococci result in subclinical infections, and strains that become chronic may be transmissible among cows in a contagious manner.[246-248]

Environmental streptococci are shed in the feces of cattle and are often ubiquitous in the dairy farm environment.[249] Infected dogs and cats can carry *S. canis* in their respiratory and urogenital tracts and serve as potential sources of infection for cows.[246,248] *S. uberis* is found in the vagina of cows,[249] but genital tract secretions probably play little role in the transmission of infection. Teats are often exposed to environmental streptococci that are present in bedding contaminated with feces[194]; straw is well known to support growth of *S. uberis*. *S. uberis* is also well known to affect cows on pastures and is the most frequent cause of mastitis in New Zealand dairy herds.[250,251] High-traffic cow lanes and areas of pastures or lots where cows congregate and defecate harbor *S. uberis* and serve as reservoirs.[249]

Approximately 50% of IMI caused by environmental streptococci are initiated during the dry period.[252] The mammary gland is highly susceptible to environmental streptococcal infection during the early and late stages of the dry period, when mammary secretions accumulate and host defense mechanisms are compromised.[116,253,254] Risk factors for IMI caused by *S. uberis* are similar to those for IMI caused by *S. aureus*.[255] IMI is accompanied by a rapid influx of neutrophils into the mammary gland and a resultant increase in SCC. Based on experimental inoculation studies with *S. uberis*, the recruited neutrophils are unable to fully prevent bacterial multiplication. Ineffective host response probably explains the prolonged infections and persistently high SCCs seen in some cases.

Although many IMIs caused by environmental streptococci spontaneously cure within 30 days, about one third of infections persist for long periods, sometimes longer than a lactation. Up to 50% of IMIs caused by environmental streptococci may result in clinical signs,[252] but only about 10% to 20% of those cases will become systemically ill.[6,256] Recurrent episodes of clinical mastitis are common.[257] Control of IMI caused by environmental streptococci is based on reducing exposure in housing areas and ensuring that cows remain healthy, clean, and dry.

MASTITIS CAUSED BY COLIFORMS

Characteristics Shared Among Coliform Bacteria. Coliform bacteria are defined as gram-negative, rod-shaped organisms that can ferment lactose.[3] These organisms are fairly easy to identify because growth on MacConkey agar results in a characteristic pink colony. *E. coli* and several other genera such as *Klebsiella*, *Enterobacter*, and *Serratia* (some of which are non-lactose fermenting) are commonly associated with bovine mastitis (see Table 36.1), whereas other coliforms such as *Citrobacter* spp. only rarely cause mastitis. Coliform organisms include both pathogenic and nonpathogenic strains that are ubiquitous in the dairy farm environment and frequently shed in feces. Within individual bacterial species, a wide variety of strains are capable of causing mastitis.[258] Teats are initially exposed to these organisms in housing or pasture areas, thus coliforms are considered to be primary environmental pathogens. Organic bedding materials, such as straw, wood chips, sawdust, recycled manure or solids from methane digesters, pelleted corncobs, and newspaper, support the growth of coliform bacteria.[259] Environmental conditions such as increased ambient temperatures and increased rainfall influence the growth of bacteria and thus the extent of teat end exposure and risk of intramammary infection. Large numbers of gram-negative organisms are present in bedding that is based on use of manure.[194,208] As compared to sand bedding, manure-based bedding materials have been associated with increased clinical and subclinical mastitis and reduced milk yield.[260] Likewise, management decisions such as increased housing density, poor stall design, failure to use sufficient bedding materials, or poor pasture management can increase the probability that teats will be exposed to coliform bacteria in manure.

In early lactation, clinical mastitis caused by coliforms may be the result of IMI acquired during the dry period.[116,261,262] However, coliform infections can be acquired at any time during lactation, particularly if the exposure is great and primary defense mechanisms, such as the patency of the teat sphincter, are compromised.

After coliform bacteria infect the mammary gland, they multiply rapidly but most do not adhere to or invade the epithelial cells.[263] If the cow's immune response is rapid and efficient, infection will be quickly eliminated and there will be little long-term impact on cow health or productivity. Although the majority of clinical cases of mastitis caused by coliform bacteria are mild, up to 30% of cases may result in systemic signs such as anorexia, fever, or a marked drop in milk production.[6,256] On most farms, IMI caused by coliform mastitis accounts for the majority of mastitis cases accompanied by systemic signs.[264] Development of systemic signs and severe

disease are primarily associated with characteristics of the cow that influence its ability to respond to the infection.[263] When influx of neutrophils is delayed or phagocytosis or intracellular killing mechanisms of neutrophils are impaired, bacterial multiplication continues, resulting in greater concentrations of inflammatory mediators and more severe clinical disease. Severe cases occur most frequently in the periparturient period and during early lactation.[72,265,266]

The outcome of clinical mastitis caused by coliform bacteria depends on the severity of the case, which usually depends on the balance between the dose (magnitude of of exposure) and the ability of the cow to response immunologically. Increased or subnormal rectal temperature, reduced rumen contraction rate and amplitude, marked dehydration, and marked depression are associated with increased risk of death, culling, or poor return to milk production.[145,267] Severe neutropenia and high bacterial concentration in the milk[145] are also indicative of a poor prognosis. Cows in early lactation do not develop neutropenia to the extent observed in later lactation; therefore the leukogram is not a good indicator of mastitis severity in early lactation.[268]

In contrast to environmental streptococcal mastitis, intramammary antibiotic treatment at dry-off is considered to be less effective in preventing coliform infections during the dry period.[269,270] The spectrum of activity of many antibiotics (β-lactams and macrolides) used for dry cows in the United States is primarily directed toward gram-positive pathogens. Infusion of internal teat sealant at dry-off reduced the incidence of new *E. coli* infections compared with infusion of antibiotics (cephalonium) in one study.[271] However, the risks of new gram-negative IMIs during the dry period and of clinical mastitis during early lactation were similar when quarters were treated with teat sealant plus antibiotics (cloxacillin) or antibiotics alone.[272] The use of internal teat sealant combined with appropriate intramammary antibiotics has been shown to result in reduced frequency of new IMI caused by coliform bacteria.[273]

Control of mastitis caused by coliform bacteria is based on reducing teat end exposure to these organisms. This is especially true for periparturient cows that may have compromised immune responses. Improving the hygienic conditions of the cows' surroundings and during the milking routine, reducing cow density, and ensuring that cows have access to an adequate diet are fundamental steps used to reduce the incidence of coliform infections. Although coliforms are often referred to as a group, there are some important differences in pathogenicity and expected outcomes of IMI among the coliform genera.

***Escherichia coli*.** Most IMI caused by *E. coli* has a short duration, and these organisms are rarely isolated from cases of subclinical mastitis.[274] While many producers may believe that *E. coli* typically causes severe mastitis, research demonstrates that about one third of cases present with mild symptoms (only abnormal milk), one third present with moderate symptoms (abnormal milk accompanied by local signs in the udder), and one third present with systemic signs.[6,256] Most cases of clinical mastitis caused by *E. coli* are preceded by low SCCs, and the transient nature of most *E. coli* infection is evidenced by the rapid return of SCCs to relatively normal levels within weeks of occurrence of a clinical case.[275] Although some researchers have proposed that specific strains of *E. coli* are more pathogenic in cows,[276] genomic studies indicate that virulence traits are highly diverse among strains[277,278] and *E. coli* is considered to be a facultative opportunistic pathogen that typically originates from the gastrointestinal tract.[277] However, about 5% of *E. coli* cases can result in persistent infections that may lead to recurrent clinical mastitis in the same or another quarter.[279,280] Differences in gene expression between *E. coli* strains that cause transient versus persistent infection have been identified, and transient strains have been reported to be more sensitive to complement-mediated killing as compared to persistent strains, suggesting that both host and pathogen factors may influence response to IMI.[281]

***Klebsiella* Species.** *Klebsiella oxytoca* and *Klebsiella pneumoniae* are the two most common species associated with bovine mastitis, and molecular studies have indicated that some organisms previously identified as *Klebsiella* spp. are actually *Raoultella* spp.[282] The clinical presentation and management of mastitis caused by *Raoultella* spp. are identical to recommendations for control of mastitis caused by *Klebsiella* spp.[282] Although the distribution of severity of symptoms is similar for clinical mastitis caused by both *Klebsiella* and *E. coli*,[283] the impact of *Klebsiella* mastitis on milk yield is significant and long lasting.[28,205] In contrast to IMI caused by *E. coli*, IMIs caused by *Klebsiella* spp. are often of much longer duration and accompanied by long duration of increased SCCs.[282] While the origin of initial IMI may be environmental, between-cow transmission can occur during periods of subclinical infection. Sawdust bedding has been implicated in outbreaks of *Klebsiella* mastitis, but *Klebsiella* species can proliferate rapidly in other bedding materials, and fecal shedding from healthy dairy cows has been documented.[284]

***Serratia* Species.** *Serratia marcescens* and *Serratia liquefaciens* are the species that are most commonly associated with bovine mastitis. Many *Serratia* species produce bright-red colonies on blood agar, but they are easily outcompeted by other pathogens and prevalence may be underestimated unless special media and cultural conditions (e.g., incubation at 20° C) are used.[285,286]

In contrast to mastitis caused by other coliforms, IMI caused by *Serratia* spp. often persists in a subclinical form for many months. Field observations and experimental infections have demonstrated that *Serratia* spp. are less pathogenic than most other coliform infections, probably because they stimulate less of an immune response.[287] In contrast to mastitis caused by other coliform bacteria, few cases of mastitis caused by *Serratia* result in severe clinical signs.[288,289] However, *Serratia* infection persists longer than *E. coli* infection. A mean duration of 55 days has been reported,[276,288] but many infections persist for 6 to 10 months.[285,289] Substantial SCC increases in cows and bulk milk are often associated with herd outbreaks of mastitis caused by *Serratia* spp.[289,290]

Serratia IMI can originate during lactation or the dry period. In one longitudinal study, 48% of *Serratia* infections were acquired during the first half of the dry period and 31% during the second half, with only 21% initiated during lactation.[288] IMI caused by *Serratia* can originate from environmental reservoirs such as organic bedding material.[285,286] However, mastitis caused by *Serratia* is frequency associated with contaminated chlorhexidine teat dips or teat dip cups.[282,291] In one outbreak that used molecular analysis to identify a source, the diversity of *Serratia* strains identified indicated that the chlorhexidine teat dips became contaminated with unique strains at each farm.[270,282] Antibiotic therapy is usually ineffective,[276,277] but up to 50% of infected quarters may eventually self-cure.[288,289] Segregation of chronically infected cows may help to contain an outbreak.[290] Culling is recommended for cows with recurrent cases of clinical mastitis or persistently high SCCs.

MASTITIS CAUSED BY OTHER ORGANISMS

***Mycoplasma* Species.** *Mycoplasma* spp. are well known pathogens of dairy cows that infect a number of organs and cause a variety of cattle diseases.[292] *Mycoplasma* spp. are associated with otitis media in calves, infections of the urogenital tract, arthritis in calves and cows, pneumonia, and mastitis. Infections caused by *Mycoplasma* spp. can be recognized in disease outbreaks that present with a range of clinical signs, including death of adult cows,[293] and often result in significant economic losses for dairy farms.[294] *Mycoplasma* has been isolated from

the bulk tank milk of about 9.4% of U.S. dairy herds, but the prevalence is strongly associated with herd size and region. In 2014, the USDA's National Animal Health Monitoring System (NAHMS) reported that *Mycoplasma* was isolated from 25% of bulk tank milk samples obtained from herds that contained more than 500 cows, in contrast to 6% and 0% of herds containing 100 to 499 cows and 30 to 99 cows, respectively.[21] Risk factors for *Mycoplasma* mastitis include commingling of cattle from multiple herds, off-site rearing of calves, and stressors such as overcrowding, nonhygienic milking practices, and insufficient biosecurity programs.

Although a number of *Mycoplasma* spp. are considered pathogenic for cattle, the most common species associated with mastitis include *M. bovis*, *Mycoplasma californicum*, and *Mycoplasma bovigenitalum*.[292] *M. bovis* is the most common species associated with bovine mastitis. *Mycoplasma* species can be isolated from a variety of mucosal surfaces of both normal and ill cattle. However, there is increasing evidence that *M. bovis* is an important cause of chronic nonresponsive pneumonia in cattle.[295] While *Mycoplasma* spp. can be isolated from the nares of clinically normal cattle, several researchers have noted that the prevalence of nasal shedding is greater in herds that have problems with *Mycoplasma* mastitis as compared to herds that have not identified a *Mycoplasma* mastitis problem.[292] At the individual animal level, neither nasal nor vaginal swabs are consistently positive in clinically affected animals,[296] and use of serology to diagnose individual animals has not been shown to be sufficiently predictive to be used in control programs.[297] Colonized cattle may remain asymptomatic or develop bronchopneumonia, otitis, polyarthritis, or mastitis. Because of the unique nature of carriage and transmission of this organism, veterinarians should review detection, diagnosis, and treatment of bovine respiratory disease as part of an investigation into mastitis outbreaks associated with *Mycoplasma* spp. In dairy herds with *Mycoplasma* mastitis, otitis media and otitis interna, respiratory disease, or swollen joints may be seen in calves, especially if unpasteurized milk is ingested.[298,299]

Transmission of *Mycoplasma* spp. is unique in that multiple routes of infection of the mammary gland are possible. Asymptomatic carrier animals may infect herdmates by shedding the organisms in nasal or vaginal secretions, feces, or milk,[292] and infected semen can serve as a route of infection in naive herds.[300] Infection can occur at milking time when teats are exposed to fomites infected with *Mycoplasma* organisms that originated from the udder of another cow. However, IMIs can also occur when *Mycoplasma* spp. are spread from other infected body sites such as the respiratory tract. In one study, intramammary inoculation of *Mycoplasma* species into a single mammary gland was followed by detection of phenotypically identical *Mycoplasma* species in extramammary body sites, blood, and noninoculated mammary glands.[301,302] Biddle and colleagues[303] found that isolates of *Mycoplasma* species from the milk, mammary gland parenchyma, and supramammary lymph nodes of infected cows all had the same pulse-field gel electrophoresis pattern and that all cows had at least one extramammary isolate with the same pattern. These findings suggest that cows with *Mycoplasma* mastitis frequently have disseminated infections and that internal transmission may occur.

The presentation of mastitis outbreaks caused by *Mycoplasma* spp. is extremely variable among farms. On many farms, most IMIs caused by *Mycoplasma* result in persistent subclinical infections. However, clinical mastitis often affects multiple glands (as a result of internal transmission of infection) and will not respond to antibiotic therapy. Many outbreaks of disease caused by *Mycoplasma* are not recognized because diagnosis depends on the use of appropriate laboratory methods. *Mycoplasma* spp. have unique growth requirements and must be cultured using appropriate media and incubation under specific conditions such as 10% carbon dioxide.[304] Prolonged freezing of milk samples reduces the concentration of viable organisms[153,305] and may result in false-negative diagnoses, but broth enrichment before culturing can enhance detection of *Mycoplasma* species.[153] When culture is used for diagnosis, the plates must be allowed to incubate for up to 7 to 10 days, as some colonies will grow very slowly. The identification of *Mycoplasma* DNA in milk is indicative of IMI, so PCR testing is useful because a diagnosis can be achieved more rapidly.[172] PCR-based diagnostic methods have acceptable limits of detection (<100 CFU/mL) and use primers that differentiate among several *Mycoplasma* species.[172] Although PCR-based methods will be increasingly used, it is important to review the health and SCC history of PCR-positive cows to ensure that the identification based on DNA is indicative of active infection.

The recovery of *Mycoplasma* spp. from bulk tank milk is strongly suggestive of the occurrence of at least one infected animal in the milking herd.[150] However, the failure to find *Mycoplasma* in bulk milk does not indicate that the herd is free of infection. Infected cows may not be contributing to the bulk tank, they may be culled, or they may not be shedding sufficient numbers of bacteria to be detected using typical culture methods. After an infected herd is identified, the next step is to identify the infected animals by obtaining milk samples from high-risk cows. It is possible to collect samples of milk from each string during milking to narrow sampling of individual cows to groups that test positive. Individual milk samples can then be collected and pooled to identify individuals for further testing. Cows with clinical mastitis and those with high SCCs are good candidates for testing, but some infected animals may not exhibit clinical mastitis and may maintain relatively low SCC values, so diagnostic testing should continue until the bulk tank tests negative and the symptoms of an outbreak subside.

Mycoplasma organisms lack a cell wall, thus most antibiotics approved for use in dairy cattle are not effective. Antibiotic treatment during lactation or at dry-off is not useful for control of *Mycoplasma* mastitis. *Mycoplasma* spp. have the ability to inhibit the inmate immune response[306] and enhance neutrophil apoptosis,[307] thus enhancing dissemination and reducing the probability of spontaneous cure. Although some IMIs may resolve spontaneously, infected cows should be considered permanently infected. Even if repeated culturing of milk from an individual quarter yields negative results, infection might persist in an extramammary site and spread to the mammary gland. For this reason, the most common and least risky control strategy is based on an aggressive testing and culling program for all cows diagnosed with *Mycoplasma* mastitis.[308] However, even aggressive diagnosis and culling programs may not prevent periodic *Mycoplasma* mastitis incidents if infections persist asymptomatically in extramammary sites. Some herds are able to control *Mycoplasma* mastitis without aggressive culling by implementing within-herd segregation, effective biosecurity, and excellent milking techniques. This strategy is more risky as even with these practices, airborne transmission among cows may still occur. Vaccination against *M. bovis* is possible, as bacterins are available, but the efficacy of these vaccines for control of mastitis has not been demonstrated. Vaccination against *M. bovis* is hindered because of variable expression of a diverse and ever-changing set of genes encoding variable surface lipoproteins (Vsps).[309]

Overall, control of *M. bovis* is based on identification of infected cows, prevention of transmission by excellent biosecurity, and implementation of milking and management programs that prevent new infections. As with other pathogens that can be transmitted in a contagious manner, effective postmilking teat dipping is required. *Mycoplasma* species are susceptible to most germicides found in teat dips.[310] Effective premilking and postmilking teat dipping and other measures used to prevent the spread of contagious pathogens in the milking parlor help

to limit *Mycoplasma* mastitis transmission. Care must be taken to ensure that hospital pens do not become a source of transmission either through direct contact with infected cows or through fomites or airborne transmission.[311] Control of respiratory disease and provision of housing with excellent ventilation is also necessary. Pasteurization of waste milk reduces the risk of *Mycoplasma* transmission to milk-fed calves.[299]

Pasteurella multocida. *Pasteurella multocida* is found in the upper respiratory tract of cattle and can be considered both normal flora and a contributor to bovine respiratory disease complex. This organism is occasionally associated with bovine mastitis. Most episodes are sporadic, but herd outbreaks can occur.[312] Mastitis caused by *P. multocida* can be recognized by increased incidence of clinical mastitis and by an increase in BTSCCs that is indicative of cows with subclinical infections. Hematogenous or lymphatic spread of *P. multocida* from the respiratory tract to the mammary gland has been proposed, and *P. multocida* has been isolated from the blood of cows with severe coliform mastitis.[313] Contamination of teats by nasal secretions (e.g., from nursing calves or intersucking cows), cow-to-cow spread at milking time, or inappropriate infusion practices may contribute to outbreaks. Antibiotic treatment has historically been unrewarding, and infected cows are often culled. However, spontaneous resolution appears to occur in some cases. Control of herd outbreaks associated with *P. multocida* should be directed at reducing the possibility of cow-to-cow transmission at milking time and improving ventilation of cow housing areas.

***Prototheca* Species.** *Prototheca* species are unicellular algae that are widespread in nature and occur throughout the world in habitats that contain moisture and organic matter.[57] *Prototheca* spp. have been isolated frequently from feces of cows and other warm-blooded animals such as pigs and rodents.[314,315] On dairy farms, several different *Prototheca* species have been found in moist areas such as soil, mud, vegetation, and water.[314] Although *Prototheca blaschkeae* and *Prototheca zopfii* genotypes 1 and 2 have been associated with bovine mastitis,[316,317] *P. zopfii* genotype 2 is the main species associated with herd outbreaks of *Prototheca*-related mastitis.[318,319] Initial IMI is likely due to environmental reservoirs, but several risk factors for *Prototheca* mastitis have been identified.[59] Important risk factors include the use of intramammary infusions of nonapproved products and the use of internal teat sealants at dry-off. On many farms, *Prototheca* is ubiquitous in the environment, and these risk factors illustrate the importance of hygienic technique when performing intramammary infusions. When *Prototheca* is identified as a cause of mastitis, veterinarians should investigate treatment practices and ensure that teats are thoroughly cleaned before infusion and that intramammary products are not warmed by being placed in potentially contaminated farm water before infusion into the udder.

P. zopfii will grow on blood agar and can be detected by microscopic examination of Gram-stained colonies; however, the colonies are easily overgrown and may be underdiagnosed. Diagnosis can be improved by culturing milk on selective media. *Prototheca* isolation medium (PIM) contains inhibitory substances that facilitate identification of the organism and is often used in mastitis laboratories. Identification of specific genotypes is not routinely performed but can be done for research or epidemiologic purposes using several molecular techniques.[318,320]

IMI with pathogenic *Prototheca* can result in both subclinical and clinical symptoms, and the infections can occur sporadically, endemically, or acutely. Most clinical cases are of mild or moderate severity. Infected cows may become chronically infected and experience persistently increased SCCs. Shedding of *P. zopfii* in milk can be persistent or intermittent.[321] Most *Prototheca* IMIs are probably acquired from the environment, but the possibility of transmission among cows in a contagious fashion should be recognized and prevented as part of a control program.

Treatment of mastitis caused by *Prototheca* is not recommended. *P. zopfii* is resistant to antimicrobial therapy, and infection can persist through the dry period.[198] Therefore identification, segregation, and progressive culling of infected animals are required to control *Prototheca* mastitis. On most farms, searching for point sources of environmental contamination will not be useful; however, hygienic conditions in the environment should be improved. Culling of infected cows should be coupled with identification and avoidance of contaminated environmental sites, enhanced cleaning of feed bunks and watering devices, and use of milking procedures that ensure clean teats and minimize contagious spread of infection.

Corynebacterium bovis. *Corynebacterium bovis* is commonly found in the streak canal and can cause occasional IMI that results in mild increases in SCC and very little impact on milk yield.[322] It is rarely a cause of clinical mastitis. *C. bovis* can be cultured on routine media such as blood agar, but colonies may not be apparent until after 48 hours of incubation. *C. bovis* can be a frequent contaminant in milk samples, and DNA from this organism is frequently identified in association with other bacteria when PCR testing is used on milk samples.[178] This organism can be transmitted from cow to cow at milking time, but the use of premilking and postmilking teat germicides is effective in controlling transmission.

Trueperella pyogenes. *Trueperella pyogenes* is the current name assigned to an organism that previously was named *Arcanobacterium pyogenes* (formerly *Actinomyces pyogenes* or *Corynebacterium pyogenes*). IMI with this organism usually results in acute purulent symptoms of clinical mastitis. In most instances, treatments are not effective, and mastitis caused by this organism has a poor prognosis.[5] Few cases remain subclinical, and the identification of this organism in bulk tank milk usually results from failure to detect and divert milk from cows with clinical symptoms. The outcome of most cases occurring in lactating cows is loss of the quarter or culling of the cow.[323] Transmission among cows can occur by flies or through environmental exposure of teat skin, especially if teat ends are damaged.

Historically, this organism was considered one of the etiologic agents of "summer mastitis," a condition of prepartum heifers and nonlactating cows that has been recognized mainly in Europe and Japan during summer months.[324] In most cases, anaerobic bacteria (e.g., *Peptococcus indolicus*, *Bacteroides* spp., *Fusobacterium necrophorum*) and facultative anaerobes (e.g., *S. dysgalactiae*) are also involved.[324,325] Summer mastitis is characterized by a swollen, hard, painful mammary gland containing purulent, foul-smelling secretion. Acutely affected animals typically demonstrated systemic signs ranging from lethargy and reduced feed intake to high fever, severe depression, abortion, and death. Systemic administration of procaine penicillin G often resolves systemic illness, but neither systemic nor intramammary antibiotics are effective at eliminating IMI.[325] The outcome of most episodes of summer mastitis is chronic clinical mastitis or a nonfunctional quarter. Horn flies are believed to be responsible for transmitting summer mastitis. Because *T. pyogenes* is often found in the environment on farms and on body sites of cattle, teat skin contamination may predispose to infection, as occurs with coliform or environmental streptococcal mastitis, particularly if teat defenses are compromised.

Control of summer mastitis is accomplished by fly control, infusion of mammary glands with antibiotics at dry-off, appropriate environmental hygiene practices and stocking density, prevention and treatment of teat lesions, and prompt recognition and segregation of infected cows. Amputation of the teat, which facilitates drainage of secretions, increases environmental contamination and should not be done unless the cow can be segregated.

Yeast Mastitis. Yeast are microorganisms that are ubiquitous in the environment of dairy farms, and they can

VetBooks.ir

cause opportunistic IMIs. Sources of exposure of teats include contact with soil, plants, and water and feedstuffs such as total mixed rations.[326] *Candida* species, *Trichosporon beigelii*, and other yeast organisms are associated with mastitis in individual cows or herds.[5] Yeast infection usually follows intramammary antibiotic treatment or teat skin injury. Outbreaks often occur when homemade infusion products or associated equipment (e.g., needles, syringes, bottles, cannulas) are contaminated or when the teat is not adequately disinfected before infusion.[327,328] In one study, six cows treated with a homemade intramammary antibiotic solution contaminated with *T. beigelii* all developed fever, hypogalactia, and swollen mammary glands within 2 weeks, and two of the six died. When the producer continued to use homemade solutions, an additional 23 cows (over half the herd) became infected, and the herd was dispersed.[327] Yeast have been cultured from towels and teat cup liners used on infected cows, suggesting that contagious transmission may occur.[327,329]

On blood agar, yeast colonies appear similar to NAS colonies, so it is important to examine the colonies microscopically. Sabouraud dextrose agar with antibiotics is a common alternative medium that selects for yeasts. Yeast infections are not susceptible to antibiotic treatment, and infusion of antibiotics may potentiate infection. The use of antifungal agents is not allowed in the United States, but experimental use has not been demonstrated to be effective. Infection (especially with *Candida* species) often resolves spontaneously within 2 to 4 weeks,[326,329] but cows with severe or recurrent clinical mastitis, reduced milk production, or persistently high SCCs should be culled. Control of yeast mastitis includes aseptic intramammary infusion procedures; use of single-dose, commercially prepared antibiotic infusion products; segregation of infected cows at milking time; and use of individual rather than shared towels. Feeding contaminated silage or total mixed ration can promote fecal excretion of yeast and has been blamed for outbreaks of yeast mastitis in some instances.

***Pseudomonas* Species.** *Pseudomonas* spp. are considered to be environmental pathogens that are commonly isolated from water sources on dairy farms.[5] *Pseudomonas* spp. typically appear on blood agar as white or gray hemolytic colonies and may produce a grape-like odor. *Pseudomonas aeruginosa* is the most common species isolated from milk of mastitic cows. IMI with *Pseudomonas* spp. can result in severe clinical mastitis that may develop into gangrene.[330] However, chronic subclinical mastitis with periodic bouts of mild clinical mastitis is the more common presentation.

After IMI with *Pseudomonas* spp. is established, it usually persists, and antibiotic therapy is unsuccessful. This is caused in part by production of factors that inhibit host defenses and reduce antibiotic efficacy, such as biofilm.[73] Cows with persistently high SCCs or repeated bouts of clinical mastitis should be culled, or individual glands may be dried off.[311]

IMI in cows usually occurs when teats come in contact with contaminated water, and the use of water to wash teats before milking has frequently been implicated in outbreaks of mastitis caused by *Pseudomonas* spp. Water sources should always be investigated when *Pseudomonas* spp. are responsible for outbreaks of mastitis on dairy farms. Predipping for teat disinfection rather than washing with water reduces the risk of infections caused by contaminated water sources. Similar to IMI caused by *Prototheca*, mastitis caused by *Pseudomonas* has been attributed to use of contaminated intramammary infusion products[56] or teat cannulas, inadequate teat end sanitation before drug infusion, contaminated teat wipes,[331] and exposure of cows to stagnant water. Investigation of a herd problem should focus on hygienic practices for intramammary infusion practices and reduction of exposure to water in the environmental and milking process.

***Nocardia* and *Mycobacterium* Species.** *Nocardia* species and mastitis-causing *Mycobacterium* species are saprophytes and therefore may cause IMI when teats are exposed to unhygienic environmental conditions. However, both *Nocardia* spp. and *Mycobacterium* spp. are uncommon causes of mastitis that have typically been associated with unhygienic use of intramammary infusions or use of contaminated intramammary products.[5,332,333] Both of these organisms have been associated with sporadic cases or herd outbreaks of mastitis. Symptoms are variable and can range from greatly increased SCC[334] to death. A tentative diagnosis can be made by observing acid-fast rods or gram-positive rods with branching filaments in a milk smear, but culture of aseptically obtained milk samples is required to diagnose and differentiate *Nocardia* and *Mycobacterium* species. Prolonged freezing can reduce recovery of *Nocardia* from milk samples. Antibiotic therapy is futile. *Nocardia* is a potentially zoonotic pathogen, and affected animals should be segregated and culled. Control of mastitis caused by these organisms involves proper intramammary infusion practices and general environmental hygiene.

Prevention and Control of Mastitis

Prevention of Intramammary Infection

At the herd level, the prevalence of mastitis is a function of the incidence and the duration of IMI. Thus control programs are directed toward implementing management programs that can influence either duration of IMI or the development of new infections. After an infection is acquired, duration of IMI is influenced by inherent characteristics of the pathogens (see Table 36.2), treatment efficacy, and culling decisions. Management practices that focus on limiting duration of infection occur after financial losses attributable to infection have already been incurred. In contrast, control programs that focus on preventing the development of new infections are profitable because they reduce the losses caused by mastitis. Thus the emphasis on controlling mastitis should be directed toward implementation of management practices that prevent new infections.

Prevention is based on knowledge of where the exposure to pathogens is occurring. In general, contagious transmission occurs when teats of healthy cows are exposed to bacteria that originated from subclinically infected udders of other cows. Thus the primary principle of reducing exposure to pathogens that can be transmitted in a contagious manner is to reduce the possibility of contact with milk that came from subclinically infected cows. Successful implementation of the five-point plan is the basis for control of pathogens that can be transmitted in a contagious manner.[335] The components of the five-point plan are discussed throughout this chapter and include (1) postmilking teat dipping, (2) comprehensive use of intramammary antimicrobial therapy at the end of every lactation, (3) appropriate therapy of clinical cases, (4) proper maintenance and functioning of milking equipment, and (5) appropriate culling of chronically infected cows. The components of the five-point plan are now widely viewed as standard management procedures and are highly adopted in many developed dairy regions.[260,336,337] As a result, many regions have dramatically reduced the prevalence of IMI caused by organisms that are primarily transmitted in a contagious manner.

To address the increased incidence of mastitis caused by environmental pathogens, the National Mastitis Council has added five additional components focused on implementation of a comprehensive mastitis control program (http://www.dairyweb.ca/Resources/WDD82/WDD8212.pdf). The 10-point mastitis control program incorporates all components of the five-point plan and is organized in the following checklist:

Point 1: Establishment of Goals for Udder Health. As with management of reproduction, nutrition, and production, it is difficult to improve udder health without having clear goals. While the establishment of goals seems intuitive, few farmers

set aside sufficient time to develop an udder health plan that includes herd-specific goals. Surveys of veterinarians and other professionals who work with dairy producers indicate that barriers to improvement in milk quality are often related to motivation and implementation rather than lack of technical knowledge or skills.[4,137,338-340] Several studies have indicated that many dairy veterinarians are only marginally involved in mastitis control programs. Upon beginning a team-based milk quality improvement program, only 24% of dairy farmers (n = 180) indicated that they used their herd veterinarian to plan milk quality programs.[137] In a companion survey, most dairy veterinarians (n = 42) interested in participating in a mastitis control program indicated that they spent less than 10% of their professional time actively working to improve milk quality.[339] Increased involvement in the development of annual udder health plans is an area of opportunity for dairy veterinarians, and the initial step can be to begin a discussion of herd-specific goals.

Point 2: Maintenance of a Clean, Dry, Comfortable Environment. Exposure to pathogens that have environmental reservoirs is strongly associated with facility and animal hygiene. Numerous hygienic practices on dairy farms have been associated with the incidence of clinical mastitis.[341-344] The rate of clinical mastitis occurring in dairy cows has been shown to be strongly associated with the cleanliness of animal housing and bedding sources.[341] The number of bacteria on teat skin is associated with bacterial count in bedding,[194,345] and a linear relationship between the rate of clinical mastitis and the number of gram-negative bacteria in bedding has been demonstrated.[182,346] Nutritional management can have an indirect influence on hygiene, as the use of high-concentrate diets has been associated with looser feces and reduced facility cleanliness.[347] Cow cleanliness can be evaluted using several scoring systems.[344,348] A four-point udder hygiene scoring (UHS) system for assessing udder hygiene has been described by Schreiner and Ruegg.[349] Cows that are scored as having dirty udders were at increased risk of IMI and increased SCC.[344] Similarly, Reneau and colleagues[350] used hygiene scores to evaluate five body areas on dairy cows.[326] The udder and hind limb scores were significantly associated with SCC.[326] Research has demonstrated that neither UHS nor the rate of new IMIs is improved by the use of tail docking, and this practice should not be encouraged.[349,351]

Mastitis control programs should focus on reducing bacterial exposures by improving facility hygiene. In many herds, clean or recycled sand will be the recommended bedding material because it does not support as much growth of coliform bacteria as organic bedding materials do.[194,208,346,352,353] In some herds, bacterial counts can be reduced by adding lime or other bedding conditioners or by using other methods to reduce bacterial counts, but the effect is generally short lived.[354,355] The use of dried manure solids as bedding is a risky strategy because these substances are ideal to support growth of bacteria found in the intestinal tract of dairy cows.

Point 3: Proper Milking Procedures. Milking hygiene and the risk of new IMIs can be improved by ensuring that milking technicians wear disposable nitrile or latex gloves.[356-358] Essential aspects of an effective premilking routine include effective teat disinfection, examination of foremilk, sufficient stimulation to allow for effective milk letdown, complete drying of the teats, and timely attachment of the milking unit. Research has definitively established that the gold standard for premilking teat disinfection is application of an effective disinfectant for a sufficient contact time, followed by drying the teat using a single cloth or paper towel for each cow.[359-362] To ensure that clinical mastitis is detected and abnormal milk does not reach the human food chain, two or three streams of foremilk should be removed and examined before attaching milking units. Drying teats has been demonstrated to reduce bacterial counts of teat ends,[360] reduce the number of colonies of spore-forming bacteria in bulk milk,[363] and effectively reduce the risk of contaminating milk with iodine residues from predips.[359] Teats should be dried using one dry cloth or paper towel for each cow. Use of towels to dry teats on multiple cows has been associated with a greater monthly rate of clinical mastitis as compared to herds that use a single towel per cow.[137]

Modern dairy cows in high-producing herds have been selected to milk rapidly, and removal of foremilk is often sufficient stimulation to achieve milk letdown. The time between stimulation and attachment of the milking unit should be approximately 60 to 90 seconds, but disturbances in milk flow and yield have not been reported until lag times have exceeded 3 minutes.[364,365] To prevent bimodal milk flows, premature attachment of the milking unit should be avoided.[364] To minimize stress on teat ends, milking units should be removed when milk flow rates drop to a level that indicates that most milk has been harvested. On most high-producing herds, milking units are removed when milk flow rates fall below 0.5 to 1.0 L/min. The use of automatic take-off units is encouraged, as they increase consistency of milking and allow milking technicians to focus more on premilking preparation.

The purpose of postmilking teat disinfection is to reduce the transmission of pathogens that can be transmitted in a contagious manner.[335,366,367] The principle is based on killing pathogens deposited on the teat skin during the milking process before they colonize the teat orifice and invade the gland, and effective application of postmilking teat dips can result in more than a 50% reduction in new IMIs.[368] Postmilking teat dipping is a highly adopted practice,[21,120] but it is not always properly implemented. Milking technicians should be trained to use an application method (such as use of a dip cup) that ensures that at least 75% of the teat skin is covered with an approved, commercially formulated teat disinfectant. Efficacy of the postmilking teat dip should have been demonstrated through properly performed scientific trials.

Point 4: Proper Maintenance and Use of Milking Equipment. The impact of machine milking on development of new IMIs is well known, and veterinarians should be aware of how to evaluate key indicators of milking equipment function. Improper functioning of milking machines can result in reduced resistance of the teat canal to IMI; vacuum fluctuations and liner slips may provide forces that overcome the resistance of the teat canal to bacterial invasion or dispersion of bacteria within the udder, and milking equipment can serve as fomites to transfer bacteria among cows. Providing stable teat end vacuum is a central objective of a properly functioning milking system.[369,370] A high rate of liner slips has been demonstrated to be associated with increased rates of clinical mastitis and increased risk of IMI.[370] Improperly functioning machines may cause congestion in the teat wall, which can result in slower closure of the teat canal and development of IMI.[371,372]

Point 5: Good Record Keeping. Measuring outcomes is an integral part of effective management.[373] Mastitis is a bacterial disease that occurs in individual animals, but mastitis control programs must be implemented at the herd level. Successful mastitis control depends on effective detection, accurate diagnosis, evaluation of appropriate treatment options, and implementation of preventive practices that address herd-specific risk factors associated with exposure to mastitis pathogens. Veterinarians who wish to reduce mastitis should regularly review herd records for SCCs and clinical mastitis and evaluate key performance indicators relative to herd goals. The program should be structured to allow for the evaluation of cow factors, environmental factors, and milking machine factors that can contribute to exposure to mastitis pathogens. An effective surveillance system for mastitis includes clear case definitions and effective mechanisms to detect both clinical and subclinical mastitis, the use of recording systems that allow for timely evaluation of risk factors, and feedback mechanisms that allow

VetBooks.ir

management personnel and veterinarians to develop goals and evaluate actions.

Points 6 and 7: Appropriate Management of Clinical Mastitis During Lactation and Effective Dry Cow Management. Both of these topics are discussed later in the chapter.

Point 8: Maintenance of Biosecurity for Contagious Pathogens and Marketing of Chronically Infected Cows. Biosecurity programs are designed to reduce the risk that healthy cows will be exposed to bacteria originating from other animals. The goal of mastitis biosecurity programs is to reduce the probability that teats of healthy cows will be exposed to infected milk and to enable the cow to have an effective immunologic response if exposure occurs (see Prevention Through Immunization section later). Many farmers arrange the milking order so that lower risk animals (first lactation cows or cows with lower SCCs) are milked first to reduce the risk of transmission of mastitis pathogens during the milking process. Physical segregation of chronically infected cows has been shown to be an effective method of reducing the new infection rate,[374,375] but it is dependent on using diagnostic methods that can accurately detect infected cows. Automated backflush of liners with disinfectants between cows has reduced the risk of new IMIs caused by *S. aureus*,[376] but the cost effectiveness of these systems depends on the prevalence of of infections within the herd. The use of an automated teat dipping and backflush system was shown to result in reduced bulk tank SCC and decreased new increased SCC, but the effect became more significant after 6 to 18 months of use.[377]

The prevalence of chronically infected cows is a strong predictor of risk of new infection with pathogens that can be transmitted in a contagious manner. One study demonstrated that the odds of a cow becoming infected with *S. aureus* doubled with each 5% increase in the herd prevalence of existing infection.[357] Chronically infected cows must be identified through routine testing of individual cows' SCCs, and microbiological analysis should be performed to identify the causative pathogens. Cows that develop chronic infections with pathogens that are refractory to treatment should be culled to reduce the risk of transmission to healthy animals.

When animals from outside sources are purchased, they should be bought from recognized individual herds (rather than sale barns), and historical information such as bulk tank culture results and individual cow SCC histories should be reviewed. Animals should be screened for *Mycoplasma* spp., and a history of recent respiratory disease should be viewed as an important risk factor for this syndrome.

Point 9: Regular Monitoring of Udder Health Status. Udder health recording systems must include monitoring programs that allow assessment of both clinical and subclinical disease. Animal health recording systems for mastitis should consist of both temporary cow-side records that are used for day-to-day decision making and permanent records (such as cow cards or computerized records) that are used to summarize trends over time.[123,354,355] The recording system should be accessible and allow the veterinarian to determine important risk factors and epidemiologic trends. The first step in monitoring subclinical mastitis is to ensure that SCC values are routinely obtained from all cows. Generally all cows with SCC values greater than 200,000 cells/mL (linear somatic cell score of approximately 4.0) are considered to have subclinical mastitis. SCCs should be reviewed monthly at both the herd level and the cow level. At the herd level, evaluation of monthly SCC patterns can be highly diagnostic for troubleshooting subclinical mastitis problems. Recommendations for key performance indicators for monitoring udder health are available.[373]

Point 10: Periodic Review of Mastitis Control Program. Dairy farming is a complex process that involves interactions between animals, nature, and people. Like other research-based businesses, the growth in knowledge about dairy management practices is extraordinary. Dairy farmers acquire information about animal health from a variety of sources, including veterinarians, nutritionists, other producers, dairy magazines, and consultants. Veterinarians visit multiple farms, see results from a wide variety of management decisions, and bring an outside perspective to farm decisions. On-farm management teams can be formed to troubleshoot specific farm issues or to meet periodically and review farm performance. A properly formed management team can aid the farmer by bringing together advisors with a range of experiences. Management teams also allow for dialogue between consultants (such as veterinarians and dairy plant personnel) who have a shared interest in specific outcomes. The management team format is extremely successful in solving mastitis problems. Farms that participated in a team-based milk quality program in Wisconsin increased adoption of best management practices and improved mastitis control.[378]

Prevention Through Immunization

Understanding the principles of the immunologic response to immunization is helpful in successfully implementing an effective vaccination program. Lymphocytes will respond to a specific microbial antigen only if the antigen (protein) is combined with a major histocompatibility complex (MHC) molecule on the surface of host cells, a process referred to as antigen presentation.[65] Cells such as macrophages and dendritic cells are particularly efficient in antigen processing by phagocytizing, digesting, and presenting antigens on their membrane surface in conjunction with an MHC molecule. In response to antigen presentation, naive lymphocytes then undergo clonal expansion and differentiation. A specific antigen can only be presented to a lymphocyte that solely recognizes that antigen.[62] Thus successful immunization against a pathogen must link the invasion of the pathogen with recruitment of innate phagocytic cells that recognize and digest the microbe, and subsequently present one of potentially hundreds of different antigens from the pathogen on the cell surface in order to attract and activate a matching lymphocyte for that specific antigen. T-helper cells play a central role by (1) enhancing B-lymphocyte clonal expansion and differentiation to antibody-producing plasma cells, and (2) completing the inflammatory response loop by releasing cytokines such as IL-17 and IFN-γ that stimulate phagocytes to more efficiently phagocytize and kill ingested microbes. Antigen-specific antibodies that arise from the acquired immune response also enhance phagocyte function by opsonizing microbes, thus assisting in target recognition and ingestion.

The decision to use a vaccine as part of a mastitis control program should be founded on the practitioner's ability to access peer-reviewed studies and compare incidence and severity of natural infections between vaccinated animals and unvaccinated controls. Such studies should encompass a diversity of herd management practices and geographic regions. Unfortunately, such trials require large numbers of animals and long duration. Alternatively, challenge-exposure trials are often performed to assess vaccine efficacy. This type of trial requires fewer animals and less time, and many variables such as different strains of bacteria, challenge dose, and physiologic status of the animal can be uniformly standardized. In addition, more comprehensive outcomes, including shedding of bacteria in milk, physical examination of the cow, and changes in biochemical parameters of serum and milk can be reliably measured. However, these studies may have limited application in relation to the diversity of dairy farm management and environment, as well as among pathogens.

As with therapeutics, appraisal of vaccine efficacy should *not* be made on testimonials, especially herd-level impressions of "before-and-after" responses. Assertions are often made based on perceptions that initiating a vaccine program decreased

VetBooks.ir

the incidence and severity of mastitis cases, lowered SCCs, increased milk production, et cetera, without using a concurrent nonvaccinated control group for comparison. This is a frequent flaw in the evaluation of autogenous bacterins, in addition to a lack of the quality control standards rigorously followed in commercial production. Mastitis incidence and SCCs within a herd can rise and fall based on many factors, including weather, changes in the proportion of younger to older animals in the herd, history of herd additions, correction of milking techniques or deficiencies in equipment, and culling decisions.

IMMUNIZATION AGAINST SPECIFIC MASTITIS PATHOGENS

Gram-Negative Core-Antigen (*Escherichia coli* J5) Bacterins. Gram-negative core-antigen bacterins are used on many dairy herds. The variants studied most extensively are formulated with a mutant strain of *E. coli* O111:B4 (Rc mutant, commonly termed J5) lacking the "O" antigen capsule of the cell wall but with the core lipopolysaccharide, membrane proteins, and lipid A antigens intact. These core antigens are highly conserved among gram-negative bacteria[379,380] and elicit cross-reactive anti–gram-negative antibodies in J5-vaccinated cows.[381-383] Thus dairy cattle immunized with these bacterins develop immune resistance against a wide variety of gram-negative bacteria, including mastitis-causing coliforms.

Initial studies in California determined that higher serum anti–*E. coli* J5 immunoglobulin G (IgG) was correlated with a lower incidence of clinical coliform mastitis.[384] A subsequent field trial demonstrated that cows administered three immunizations (at drying off, 30 days after drying off, and in the postpartum period) had a fivefold decrease in the rate of clinical coliform mastitis in the first 100 days of lactation, as compared to unvaccinated cows.[385] A field trial in Ohio using a similar dose regimen reported that core-antigen immunization did not reduce the prevalence of gram-negative IMIs at calving; however, 67% of the infections present at calving in unvaccinated cows developed clinical mastitis, as compared to only 20% in the J5-vaccinated cows.[386] In addition, vaccination with J5 bacterin increased anti–*E. coli* J5 IgG in serum and milk as compared to unvaccinated controls,[386-388] although anti–*E. coli* J5 antibody titers in milk are orders of magnitude lower than in serum. Following intramammary challenge of *E. coli*, core-antigen immunization reduced the severity of infection but did not prevent infection.[386]

The pathogenesis of severe coliform mastitis is dependent on LPS-induced immune mediator responses, and a high proportion of severe coliform mastitis cases become bacteremic.[313] Thus J5 bacterins may have a greater impact on the systemic effects of coliform mastitis than on local mammary inflammation. This concept is supported by a field trial from New York that determined that two doses of J5 bacterin decreased the proportion of clinical mastitis cases that resulted in culling or death by threefold but did not reduce the overall incidence of clinical mastitis cases.[389] However, coliform mastitis cases contracted during the first 50 days of lactation resulted in less milk production loss among J5-vaccinated cattle.[390]

Gram-negative bacterins are regarded as weakly immunogenic in dairy cattle because they elicit poor amnestic IgG1 and IgG2 responses.[81] An Ontario study found that a substantial population of cows that were administered two J5 bacterin doses during the dry period had poor antibody responses and a higher incidence of mastitis in the subsequent lactation.[391] This relatively short duration of immune protection is supported by several trials.[392-394] A New York study determined that cows vaccinated with two doses of J5 bacterin lost less milk production following clinical mastitis and survived longer as compared to unvaccinated cows. However, this protection, as well as anti–J5 antibody titers, declined as lactation (and time since vaccination) progressed and did not exist by 75 days in milk.[392] In a Michigan study, hyperimmunization of cows with six doses of J5 bacterin resulted in a threefold decrease in severe clinical coliform mastitis from 42 to 126 days in milk, as compared to cows that received three doses. This suggested that supplemental immunizations extended protection beyond that offered by traditional vaccination regimens.[393] A subsequent Michigan study determined that cows immunized with five doses of J5 bacterin had elevated anti–*E. coli* J5 antibody IgG1 and IgG2 titers, relative to unvaccinated cows, for up to 60 to 90 days longer than cows administered three doses of J5 bacterin only.[394] In addition, the best response to immunization, in terms of intensity and duration of antibody response, was gained when multiple immunizations were given as a series in different anatomic locations on the cow.[394]

Use of J5-type bacterins relies on five principles: (1) Diagnose if coliform organisms cause a substantial portion of clinical mastitis within a herd, (2) determine the severity and incidence of clinical coliform mastitis cases, (3) describe the epidemiology of the problem in the herd, (4) decrease other herd risk factors that may contribute to clinical coliform mastitis, and (5) develop a vaccination protocol that best integrates immunology with herd needs and practical limitations (Table 36.3). Veterinarians should review these steps when developing a protocol for dairy herds and periodically review progress and changes in the herd that may lead to a re-evaluation of the immunization protocol.

Use of *Staphylococcus aureus* Bacterins. Considerable effort, encompassing numerous antigens, virulence factors, and

TABLE 36.3

Guidelines for Core-Antigen Gram-Negative Bacterin Use in Dairy Herds

1. Diagnose the cause of clinical mastitis	Does bacteriology of clinical mastitis cases frequently yield coliforms (gram-negative)?	Bacterin ineffective for gram-positive pathogens.
2. Determine the incidence of severe mastitis caused by coliforms	Are >1% clinical mastitis cases?	Bacterin reduces severity, not incidence of infection.
3. Describe affected animals	What are the risk factors associated with animals with severe coliform mastitis in the herd?	Identify if stage of lactation, age, or season is associated with the problem.
4. Decrease risk factors of exposure	Are there other critical risk factors for coliform mastitis prevention that need to be addressed?	Bacterin effects are diminished in herds with poor sanitation, cow comfort, intramammary infusion techniques, teat end health, or milking preparation.
5. Develop a protocol that best fits the herd	Will the protocol likely be followed? Is it likely to offer the best return on investment?	Immunization programs should be designed to reduce unnecessary doses and target the affected animals.

VetBooks.ir

bacterial strains, has been made to develop an efficacious and practical *S. aureus* vaccine. Much of the interest has focused on vaccination of primiparous heifers. A bacterin containing a lysed culture of polyvalent phage types, including a variety of capsular serotypes, is commercially available in many regions (Lysigin). This product originated from work in Louisiana that determined that two initial doses 2 weeks apart, followed by doses at 6-month intervals, reduced IMI at calving caused by both NAS and *S. aureus*. However, a subsequent challenge-infection study determined that this bacterin did not prevent IMI, accentuate clearance of IMI, affect SCC, or milk yield post challenge.[395] The Lysigin-vaccinated heifers did have improved clinical scores and shorter duration of clinical mastitis.[395] Although immunization with Lysigin increased serum anti–*S. aureus* IgG1 in heifers, milk concentrations of IgG1, IgG2, and IgM were not affected.[396] In a subsequent report in lactating cows, representing multiple parities, two doses of Lysigin administered 14 days apart did not reduce the number of mammary quarters that developed new *S. aureus* or NAS IMI, the time after vaccination to develop new IMI, SCC, or milk antibody isotype to positive ratio.[395] The authors speculated that the bacterin may have induced insufficient opsonizing antibodies in milk to promote phagocytosis.

S. aureus vaccines would likely have limited use in many dairies, especially in herds with low prevalences of IMI, as is typical for herds with SCCs less than 200,000 cells/mL. Thus it is unlikely that *S. auereus* bacterins will have a significant impact in herds that successfully control contagious mastitis by practicing excellent milking techniques and maintaining milking equipment. Conversely, herds that immunize in lieu of good management practices are likely to have disappointing results. Investigators have administered *S. aureus* bacterins in an attempt to augment antimicrobial therapy, with conflicting results.[395,397]

Mastitis Therapy: Antimicrobial Drugs

General Concepts

Mastitis remains the most common cause of antimicrobial drug therapy for cows on U.S. dairy farms. In 2014, 21.7% of cows were treated for mastitis using antimicrobial drugs.[21] If this use represents the majority of all U.S. dairy herds, with approximately 9 million dairy cows, then nearly 1.9 million mastitis cases are treated annually. Surveys from Wisconsin and Canada estimated that between two and four doses of intramammary infusions are used per cow per year; this means that on a 1000-cow dairy, an average of 5 to 10 doses of intramammary antimicrobials would be administered daily.[398,399] Antimicrobial therapy benefits animal health and well-being, but economic losses associated with antimicrobial therapy of mastitis include drug and veterinary expenses, extended labor, and most importantly, discarded milk.[400] Unwarranted antimicrobial use in dairy cattle can result in residue violations in milk and meat and erode consumer confidence in the safety of dairy foods.

To date, the risk of emerging antimicrobial resistance among bovine mastitis pathogens has been low, particularly for drugs with high therapeutic value in human medicine.[401-403] Nonetheless, prudent administration of antimicrobials is needed on dairy farms, similar to stewardship of antimicrobial resources as advocated in human medicine. Responsible antimicrobial stewardship minimizes the emergence and dissemination of antimicrobial resistance among pathogens and preserves the therapeutic integrity of the drugs.

Mastitis therapy is often initiated empirically, without consideration of case risk factors for efficacy, and as a substitute for an integrated mastitis control program.[140,404] Standardizing mastitis therapeutic protocols should diminish spontaneous "cow-side" biases and establish uniformity for therapeutic regimens. However, farmer therapeutic decisions often differ from veterinary recommendations.[405] In a Wisconsin study across 51 herds, nearly a quarter of cows treated received an additional secondary treatment because of perceived lack of response to the initial treatment.[404] The majority of intramammary treatments were administered to cows with a microbiological diagnosis of no growth or *E. coli*, two culture outcomes that are not likely to benefit from therapy. In addition, in a survey of more than 600 herds from Michigan, Pennsylvania, and Florida, only about half of the respondents stated that they "frequently or always" record treatments or review treatment records before administering mastitis therapy.[406] In addition, more than 80% of the herds reported that they rarely or never use bacteriologic results for mastitis therapy decisions.

Risk factors that decrease therapeutic efficacy include increasing (1) age of the cow, (2) preexisting SCC before treatment, (3) duration of infection, (4) number of quarters infected, and (5) *S. aureus* infections.[205,223,407] In particular, chronic infections have poor therapeutic outcomes and may require extended duration of antimicrobial therapy.[400] Thus to reduce antimicrobial use associated with mastitis, we need to change behaviors and attitudes of farm personnel to (1) use bacteriology to the best of herd labor abilities, (2) determine the history of the cow and identify cow-level risk factors that may affect the efficacy of therapy, and (3) apply standardized therapy protocols that are based on sound pharmacology.

A small proportion of cows can be responsible for a large proportion of clinical mastitis episodes in a herd. Thus antimicrobial therapy is unlikely to cure infections in glands with repeated bouts of clinical mastitis episodes. Many herds tend to unnecessarily lose time and money by treating "repeat offender" clinical mastitis cases. When coupled with the lack of bacteriologic culture, thus opening the door for treatment of unresponsive pathogens, most clinical mastitis may be treated unnecessarily on many dairy farms. Veterinarians should not only direct drug selection and protocols for mastitis therapy on dairy farms, but more importantly establish selection criteria for cows to be either included or excluded for treatment. In addition, it is critical to have not only a therapy protocol, but also a protocol to determine efficacy or a "cure" after therapy. Many clinical trials in the literature, or those done on farm, evaluate therapeutic outcome in relatively short periods after treatment is completed (less than 14 days). As many cases of mastitis relapse after this period (up to 30 days is common), practitioners should adopt a long-range view of therapeutic outcomes, including subesquent SCC testing, survival in herd, loss of quarter function, and milk production, in additon to relapses.

Alternatives to antibiotic treatment include (1) euthanizing or culling the cow, (2) drying off the cow or gland, (3) administering supportive treatment alone, or (4) doing nothing. The cow's welfare must be considered when choosing among these options, to minimize pain and suffering. If supportive treatment or no treatment is chosen, the cow should be milked after healthy cows and the milk withheld from sale for as long as it is visibly abnormal. If a single gland is dried off, antibiotics should not be infused because this may result in antibiotic residues in milk from the other glands.

LIMITATIONS OF ANTIMICROBIAL SUSCEPTIBILITY TESTING. Antimicrobial susceptibility test results should not be used as the main basis for antibiotic selection. In most cases, susceptibility cut-points for zone diameters (for the disk diffusion test) or minimum inhibitory concentration (MIC) values are based on antibiotic concentrations in serum or interstitial fluid of people after oral or intravenous (IV) dosing; these are not equivalent to concentrations achieved in milk or mammary tissue after intramammary or systemic dosing.[408] The absolute MIC value is more useful than a dichotomous result (susceptible

VetBooks.ir

or resistant) based on an irrelevant cut-point. However, the reported MIC value may not reflect the MIC in milk because MICs in milk are often higher than in blood, especially for non–β-lactam drugs.[393] More recently marketed intramammary antibiotics have MIC or disk diffusion cut-points that are relevant to treatment of mastitis, but the cut-points need to be validated in vivo. Recent studies have determined that susceptibility test results (susceptible versus resistant) had no impact on the outcome (clinical cure, bacteriologic cure) of clinical mastitis episodes.[240,409,410] Interestingly, *S. aureus* isolates that are penicillinase-producing strains are less responsive to treatment even if penicillinase-resistant antibiotics are used.[411]

Treatment of Mild and Moderate Cases of Clinical Mastitis

TREATMENT OF CLINICAL MASTITIS CAUSED BY STREPTOCOCCI AND STAPHYLOCOCCI. The effectiveness and selection of antibiotic therapy depend on the pathogen causing clinical mastitis. Cows with cases of mild (severity score 1) or moderate (severity score 2) clinical mastitis and no bacterial growth in the milk are unlikely to benefit from antibiotic therapy, as are cows with a low concentration of *E. coli* in the milk. Cows with *Mycoplasma* mastitis or mastitis caused by opportunistic pathogens such as *P. aeruginosa*, *S. marcescens*, *P. zopfii*, or *Candida* spp. are unlikely to respond to antibiotic therapy.[56,57,292,412] Thus the use of antimicrobial therapy for mastitis cases caused by these pathogens should be avoided and may lead to unnecessary risks for drug residues.

On the other hand, antimicrobial drugs can enhance resolution of many cases of streptococcal or staphylococcal mastitis episodes. The prototype for therapeutic success is treatment of IMI caused by *S. agalactiae*. This organism tends to be highly susceptible to intramammary therapy with β-lactam drugs, with cure rates of 85% to 90% often reported.[196,241] This organism is essentially an obligate udder pathogen in dairy cattle, remains superficial in mammary tissue, and has a high level of susceptibility to therapy. Thus *S. agalactiae* can essentially be eradicated from a herd by simultaneously treating all infected cows, including those with subclinical infections.[241,413] This can be economical for a dairy, but only if proper prevention programs (e.g., postmilking teat dipping, dry cow treatment) are in place to prevent new infections after herd treatment.[193] For this and other gram-positive pathogens, systemic administration of antimicrobial drugs is not likely to attain any better cure rates than intramammary infusions.

Therapeutic efficacy of other gram-positive cocci, with the exception of *S. aureus*, can also be efficacious in many cases. Only 10% to 20% of clinical mastitis caused by environmental streptococci is severe.[6] Similarly, the vast majority of clinical mastitis caused by NAS is mild to moderate. Intramammary infusion of commercial products is the treatment of choice, although some strains of streptococci have been reported to be resistant to cloxacillin and pirlimycin.[401,403] Likewise, studies of naturally occurring clinical streptococcal mastitis determined that intramammary pirlimycin or amoxicillin therapy attained bacterial cures of 70% to 75% of infected quarters as compared to cures of 29% to 39% in untreated quarters, respectively.[414] However, results can vary depending on the herd, and as mentioned earlier, the duration of infection at the time of treatment has a large impact on outcome. Cures following pirlimycin therapy for NAS did not differ from untreated controls in one study (about 45%).[415] Similarly, about 66% of subclinical quarters infected with streptococci or staphylococci cured whether treated with two doses of intramammary pirlimycin or not treated.[410]

Several studies have described the potential benefits of extended intramammary therapy (beyond the traditional two doses) for the treatment of mastitis caused by streptococci and *S. aureus*.[416-418] This may be appropriate from a pharmacodynamic standpoint as all antimicrobial drugs that are labeled for intramammary use in dairy cattle (U.S.) rely on time-dependent inhibition of bacterial growth. Thus inhibitory action of the drug is more likely to be efficacious if the concentration of the drug is maintained above the MIC for extended periods at the site of infection as opposed to at peak concentrations. Experimental *S. uberis* infections treated for 2, 5, or 8 days (q24h) with intramammary ceftiofur attained bacterial cures in 43%, 88%, and 100% of the infections, respectively.[419] Similar results were obtained for chronic streptococcal and *S. aureus* infections treated with intramammary pirlimycin.[416] In naturally occurring subclinical mastitis, two doses of intramammary ceftiofur cured 39% of infections that included all gram-positive cocci, as opposed to 66% for quarters treated with eight doses, but the sample was not sufficient to determine pathogen-specific effects.[420] However, other studies performed as noninferiority trials have found that a shorter duration of therapy (3 days) did not differ from a longer duration of therapy (5 days) relative to survival in the herd after therapy or rate of clinical cure.[206]

The decision to use extended therapy as part of a herd mastitis therapy protocol should be made carefully and when possible should be based on microbiological diagnosis (see the On-Farm Culture section earlier). The success of therapy with conventional dosing should first be considered. If deemed to be unsatisfactory, especially as indicated by high rates of relapses after therapy, extended therapy may be a viable choice. To date, the benefits of extended therapy have best been determined for infections caused by streptococci and *S. aureus*. One study has determined that extended treatment of mild cases of clinical mastitis caused by a variety of coliform bacteria increased bacteriologic cures and reduced culling but did not influence posttreatment milk yield or SCC, although the outcomes were highly herd dependent.[421] Furthermore, the ability of the herd personnel to perform aseptic infusions into the teat canal is critical. Extended therapy is associated with an increased risk of infection from opportunistic pathogens, and herds with poor infusion techniques are not good candidates for multiple doses of intramammary tubes.

S. aureus intramammary infections often result in deep-seated abscesses. Therapy is difficult, especially as resistance to antibacterials (particularly β-lactams) is more common as compared to streptococci, and *S. aureus* may survive intracellularly following phagocytosis where antibacterial concentrations are reduced.[400] In addition, *S. aureus* has numerous extracellular substances that impart an ability to survive in the presence of a hostile host immune system. Consequently, elimination of IMI caused by this pathogen is often not as successful as compared to IMI caused by other gram-positive pathogens.

Experimentally induced *S. aureus* IMI has a reported cure rate of 25% to 55% of infected quarters when evaluated 21 to 60 days after infection. However, natural infections are usually of longer duration before detection and subsequent therapy and thus more refractive to therapy. The importance of duration of infection was evident in a study that determined that intramammary penicillin and novobiocin cured 70% in quarters that had been infected for 14 days or less as compared to only 35% in chronically infected quarters.[422] Similarly, Barkema and colleagues[423] reported a wide variation in the success of therapy, near 60% in younger, newly infected animals as opposed to less than 5% in older animals with chronic infections. Even modest results of efficacy reported in the literature may be optimistic, as relapses occurring more than 30 days after treatment are common.[420] This not only reaffirms the difficulty in attaining successful therapy but also suggests a poor correlation between in vitro culture and susceptibility and therapeutic outcome in chronic IMI caused by this organism.[424]

Consequently, combinations of parenteral and intramammary treatment regimens have been advocated to eliminate a higher proportion of *S. aureus* infections. In experimental infections

VetBooks.ir

in lactating cows, the combined use of intramuscular procaine penicillin G and intramammary amoxicillin achieved a better cure rate (18 of 35 infected quarters) than intramammary amoxicillin did alone (10 of 40 infected quarters).[425] Dry cows with *S. aureus* IMI had improved cure rates when administered 11 mg/kg IM every 24 hours of oxytetracycline in addition to intramammary antibacterials as compared to cows administered intramammary infusions only.[426] Other studies have not found any benefit from systemic antimicrobial use to eliminate chronic infections caused by *S. aureus*.[427,428] In addition, systemic therapy for mastitis is extralabel drug use in the United States, and milk and meat withholding periods must be determined judiciously. Therapy should be administered for periods long enough (7 to 10 days) to allow effective elimination of the pathogen and would be more economical and less likely to result in residues in milk if this therapy is administered to dry cows. Depending on susceptibility testing, lipophilic antibacterial drugs that distribute well into mammary tissue, such as oxytetracycline, are the best candidates for systemic administration. Cure rates may not be much better than those attained from spontaneous cure, especially in chronic IMI, and as stated earlier, efficacy must be defined critically. Affected quarters should be monitored by culture or SCC for at least 60 days to encompass the refractory period when bacteria may not be isolated.

USING BACTERIOLOGY AS A CRITERION FOR THERAPY. Microbial culture of milk is a practical tool to identify causative agents and the foundation to better target therapeutic regimens for mastitis. A multistate study demonstrated that culture-based therapy of gram-positive and mixed isolates only, as compared to empirical therapy of all mild mastitis cases, reduced antimicrobial use by 50%.[155,163,166] Furthermore, no differences were found between mastitis cases that were assigned to the empirical therapy or culture-based treatment program in terms of recurrence of clinical mastitis (35% versus 43%), linear SCC (4.2 versus 4.4), daily milk production (30.0 kg versus 30.7 kg), and culling or death (28% versus 32%) for the rest of the lactation after the clinical mastitis case. This concept was further supported by a more recent study that found no significant differences existed between cows administered empirical therapy and culture-based therapy in days to clinical cure, milk production, survival in herd, or SCC.[429]

Thus selective treatment of mild clinical mastitis based on culture results does not affect long-term outcomes but does decrease antibiotic use. As mentioned earlier, most farms do not routinely culture milk from cows with clinical mastitis, but it is still important to determine the most frequent clinical mastitis pathogens in the herd to make appropriate treatment and prevention recommendations. It is also particularly important to determine if *Mycoplasma* species or opportunistic pathogens that are nonresponsive to antibiotic therapy are contributing to clinical mastitis.

TREATMENT OF SEVERE CLINICAL MASTITIS. Clinical mastitis cases that include systemic involvement are considered severe (severity score 3).[205] Coliform organisms are the most common cause of severe mastitis in most dairy herds and are the common cause of cases that result in the loss of a cow from death or agalactia (see Tables 36.1 and 36.2).[6,430] Thus primary therapy for severe clinical mastitis should be directed against coliform organisms, although secondary consideration must be given to other pathogens. From a cow-side appraisal, treatment of severe clinical mastitis is a forced decision (i.e., empirical treatment is indicated). Although the basis for antimicrobial therapy is knowledge of the causative pathogen, this is not attainable for some hours after initial case recognition, and thus the practical problem is to design a therapeutic regimen on clinical impression. In addition, systemic antimicrobial therapeutic regimens currently are not labeled by the U.S. Food and Drug Administration (FDA). As a result, veterinarians often formulate therapeutic management of severe mastitis using extralabel drugs.

Experimental challenge models have clarified much of the pathophysiology of mastitis resulting from infection with gram-negative organisms.[99,263,387] Following infection, bacterial numbers in milk rapidly increase, and depending on the size of the challenge, peak bacterial concentrations in milk often occur within a few hours. Typically, a subsequent rapid decline in bacterial concentration follows neutrophil migration into the gland. Though often severe, experimental IMI caused by *E. coli* usually clears spontaneously and rarely is more than 10 days in duration. The resulting inflammation and leukocytosis in the affected quarter may persist for several weeks, or the quarter may become agalactic, despite the inability to isolate bacteria on culture. Although useful for determining the pathogenesis of coliform IMI, experimental challenge models should not be universally applied for therapeutic decisions. Most challenge infections do not include recently calved cows, use strains of bacteria that may not be as virulent as some of the wild types of pathogens, and are generally not administered if other possible immune stressors (metabolic or heat) are present. All of these variables could reduce the severity of clinical outcome for experimental as compared to natural infections. In addition, herd factors such as nutrition and housing can affect the outcome of naturally occurring infections, and host-adapted strains that may persist in affected cows have been identified.[282]

Many of the inflammatory and systemic changes that occur during severe coliform mastitis result from the release of LPS from the bacteria, which is released from the bacterial cell wall following phagocytosis and killing by neutrophils. As mentioned in the Mammary Inflammation section, LPS is a potent stimulator of the inflammatory cytokine response through the action of TLRs.[431-434] This results in subsequent activation of the cyclooxygenase and lipoxygenase pathways, releasing prostaglandins, leukotrienes, and thromboxanes, compounds that are potent mediators of local inflammatory and systemic circulatory events.[67] Also, endotoxin-induced cytokines, such as IL-1 and TNF-α, initiate a wide range of systemic responses, including fever, leukocytosis, protein synthesis and release by hepatocytes, and serum iron sequestration, collectively termed the acute phase response.[433,435,436] Although LPS concentration in the milk may be high, LPS is usually nearly undetectable in plasma.[437] This suggests that the fever, tachycardia, reduced rumen motility, and signs of shock that accompany severe coliform mastitis are not a consequence of endotoxemia but production and absorption of inflammatory mediators, such as TNF-α. The concentration of TNF-α in milk is positively correlated with coliform mastitis severity, and a high concentration of TNF-α in blood is seen only in severe responders.[87,266,438] Hematologic and plasma biochemical changes that often accompany clinical coliform mastitis include leukopenia (neutropenia, lymphopenia, monocytopenia), hypocalcemia, and reductions in plasma concentrations of zinc, copper, and iron.[268]

Consequently, in order to reduce the severity of acute coliform mastitis, either bacterial growth must be inhibited to reduce exposure of the quarter and the cow to LPS or the effects of the LPS release must be neutralized. From a practical standpoint, therapy of severe coliform infections cannot begin until clinical signs appear. Clinical recognition of coliform mastitis usually occurs after peak bacterial numbers have been attained. Thus by the time therapy is initiated, maximal release of LPS has likely occurred. This raises concerns regarding the advantages of antibacterial therapy in alleviating the effects of acute coliform mastitis. Thus the primary therapeutic concern is the treatment of endotoxin-induced shock with fluids, and other supportive care.

VetBooks.ir

Antibacterial therapy may be of secondary importance relative to immediate supportive treatment of endotoxic shock, but it remains an integral part of a therapeutic regimen for severe mastitis. Because of low MIC for gram-negative rods relative to other antimicrobials, aminoglycosides were considered for many years to be a drug of choice for coliform mastitis. However, cows experimentally challenged with *E. coli* and dosed with 500 mg of intramammary gentamicin q12h did not have lower peak bacterial concentrations in milk, duration of infection, convalescent somatic cell or serum albumin concentrations in milk, or rectal temperatures as compared to untreated challenged cows.[439] In addition, gentamicin readily diffused through the milk-blood barrier as indicated by detectable concentrations in serum throughout the treatment period and the first 12 hours after the last dose. Consequently, urine gentamicin concentrations were detectable 14 days after the last infusion, and gentamicin concentrations of 1 μg/g in renal tissue were detected in cows 6 months after the trial.[439] As well, intramuscular gentamicin was not more efficacious in preventing agalactia or death resulting from severe coliform mastitis or in improving other clinical outcomes, as compared to cows receiving intramuscular erythromycin or no systemic antimicrobial therapy.[440]

Considering the lack of efficacy in controlled studies, increased sophistication of drug residue testing among regulatory agencies, zero tolerance for residues in renal tissue of culled cows, the 30- to 45-day half-life for clearance in the bovine kidney, and extended milk withdrawal periods after use of aminoglycosides, the use of this class of drugs in adult dairy cattle has little merit.

Seminal research from Colorado found that bacteremia occurs in nearly half of severe coliforms cases and increases with the severity of the clinical signs.[313,441] Numerous pathogens, in addition to mammary-derived coliforms, that are likely opportunistic invaders from the respiratory and gastrointestinal tract were also isolated from blood.[313] This is likely a consequence of the profound neutropenia that occurs in many severe coliform cases.[268] Cows that remain neutropenic for 4 or more days, or that have high metamyelocyte and myelocyte concentrations in their blood, are more likely to be bacteremic than cows with a normalizing leukon.[441] Bacteremia suggests a poor prognosis, and these cows are at greater risk of death or culling.[313] Thus a primary target of antimicrobial therapy for severe coliform mastitis should be highly perfused tissue and the selection of drugs that remain in the plasma compartment and have low MIC for gram-negative rods.

Three doses of parenteral sulfadiazine-trimethoprim failed to achieve clinical improvement in experimental *E. coli* infections.[442] However, three intramuscular doses of cefquinome, a fourth-generation cephalosporin that has better distribution into mammary tissue than sulfonamides, was found to improve clinical outcome of experimentally infected cows as compared to use of cloxacillin or ampicillin.[443] Further research confirmed the possible benefits of systemic antimicrobial administration; intravenous oxytetracycline improved the clinical outcome of cows with coliform mastitis (not necessarily severe) as compared to cows that did not receive systemic antibacterials.[444] Ceftiofur sodium, a third-generation cephalosporin, has been reported to have excellent activity against gram-negative pathogens, with a suggested MIC for *E. coli* of 0.25 to 1.0 μg/mL. Mammary tissue and milk concentrations of ceftiofur following systemic treatment remain below these concentrations, and treatment of mild clinical mastitis caused by coliform organisms with systemic ceftiofur did not affect clinical or bacteriologic outcome, probably due to the poor distribution of β-lactams into the mammary gland following systemic administration.[445,446]

However, in a study of naturally occurring cases in Michigan, cows with severe coliform mastitis that were administered intramuscular ceftiofur at a dose of 2.2 mg/kg once per day for 5 days were three times less likely to be lost from the herd and had significantly higher marketed milk than cows not receiving systemic antimicrobial therapy.[430] This strongly emphasizes the inclusion of bacteremia in therapeutic considerations for severe coliform mastitis.

Intramammary antimicrobial therapy should be administered for most severe mastitis cases, at least until bacterial culture results are determined. Numerous severe mastitis cases are caused by gram-positive cocci and can be difficult to distinguish from cases caused by coliforms at initial presentation. Chronic IMI caused by pathogens such as *S. aureus* can become acutely gangrenous at times of neutropenic dysfunction such as parturition.[86] Bacterial culture of cases can also help to identify other causative agents that are not likely to respond to antimicrobial therapy, including *M. bovis*, mycotic organisms, and *Prototheca* spp. Severe, overwhelming IMI that leads to bacteremia can occur from *S. marcescens*, *P. aeruginosa*, and *Bacillus cereus*.

Thus therapeutic regimens for severe clinical mastitis should (1) administer supportive care, especially for those cows displaying shock; (2) target antibacterial therapy to maintain effective concentrations in plasma with a drug that has a broad spectrum of activity; and (3) administer intramammary antibacterial drugs to reduce the effects of a gram-positive IMI, unless bacteriologic results suggest otherwise.

Summary of Antimicrobial Therapy

Judicious antibiotic use is necessary for successful mastitis treatment programs. Case selection is critically important to avoid unnecessary antibiotic use, which is costly to the producer and of concern to the public. When producers are unwilling or unable to use culture results as the basis for treatment determination, a decision may be necessary to avoid treatment completely or, alternatively, to treat all cows empirically. Antibiotic selection and the timing, dose, frequency, and duration of treatment affect the outcome. Therefore antibiotic treatment protocols should be designed with veterinary input and monitored for efficacy. Monitoring requires that farm personnel record the incidence, severity, and duration of clinical mastitis, as well as the treatments administered. The occurrence of relapses, SCCs, and targeted milk bacteriology also facilitate assessment of treatment efficacy.

MASTITIS THERAPY: SUPPORTIVE TREATMENT. A variety of supportive measures are used in cows with severe clinical mastitis, often in conjunction with antibiotic therapy. Fluids and electrolytes are administered to correct circulatory and electrolyte disturbances (also see Chapter 44). Steroidal and nonsteroidal antiinflammatory agents are used to reduce pain, inflammation, and fever. Dairy producers and veterinarians use many other systemic and local treatments, most of which have not been scientifically evaluated or shown to be effective. This section discusses the most frequently used supportive treatments.

Fluid and Electrolyte Therapy. Cows with severe clinical mastitis can develop fluid and electrolyte disturbances as a result of decreased feed and water intake, rumen stasis, ileus, and diarrhea. Severely affected cows, particularly those with coliform mastitis, may develop septic or endotoxic shock; death or organ damage can result from decreased effective circulating volume.

The hydration status of an adult cow is assessed subjectively by observing skin tent duration on the neck or eyelid and position of the globe in the orbit. Unfortunately, findings can be influenced by the body condition of the cow. Objective criteria for estimating the extent of dehydration have been reported for dairy calves but have not been established for adult cows.[447] Extrapolating from calves, a healthy cow should have cervical skin tenting of 2 seconds or less and no recession of the eyeball. Skin tent durations of 4, 6, or 8 seconds and

VetBooks.ir

eyeball recession of 2, 4, or 7 mm would correlate with 4%, 8%, and 12% dehydration, respectively. Indicators of reduced peripheral perfusion are cold extremities (ears, tail, fetlocks—only reliable at moderate ambient temperatures) and a dry muzzle or mouth.[448] Hematocrit and plasma protein concentration are not reliable indicators of hydration status in an individual cow because of the wide range of normal values and the effects of inflammation and stage of lactation on total protein concentration.

Most cows with clinical mastitis, even severe mastitis, have normal acid-base balance or metabolic alkalosis; metabolic acidosis is uncommon and associated with a poor prognosis.[441,449] Therefore there is no need for routine IV administration of alkalizing agents, such as bicarbonate or lactate. Also, oral products containing magnesium hydroxide or sodium bicarbonate should not be administered.

Fluids can be administered by the oral (intraruminal) or IV route. The oral route is least expensive and is often adequate for cows with mild to moderate dehydration. Oral fluids should be hypotonic or isotonic and should contain sodium, to create an osmotic gradient between rumen fluid and blood and enable sustained absorption of fluid and electrolytes; hypertonic oral fluids should be avoided.[450] A 600-kg cow that is 6% dehydrated needs to absorb 36 L of fluid to replace her deficit. This volume can be safely administered orally, but administration of larger volumes of hypotonic fluid may lead to intravascular hemolysis.[451] Oral fluids are not sufficient for cows with severe dehydration because they do not cause rapid resuscitation.

Ringer's solution, which is an isotonic (isosmotic), mildly acidifying solution that contains physiologic concentrations of sodium, chloride, potassium, and calcium, is the fluid of choice for rapid IV resuscitation of adult ruminants.[450] Isosmotic (0.9%) sodium chloride is an alternative that can easily be constituted using table salt and distilled water in a sterile carboy. However, administration of isosmotic crystalloid solutions is impractical in many situations because of the large volume of fluid required and the need for IV catheterization. A 600-kg cow that is 10% dehydrated requires 60 L of fluid to replace her deficit.

A more practical alternative for on-farm therapy to isosmotic IV fluid therapy is IV administration of hypertonic (7.2%, 2460 mOsm/L) saline. Hypertonic saline is administered through a large-bore needle at 4 to 5 mL/kg body weight over 4 to 5 minutes, in conjunction with oral administration of water (5 gal). Rapid administration of hypertonic saline is required to effectively create an osmotic gradient that draws fluid from the intercellular spaces and gastrointestinal tract (mainly rumen) into the vasculature. Although hypertonic saline does not have a sustained effect and will not completely correct a large fluid deficit, it rapidly increases plasma volume and improves cardiac output and tissue perfusion. Hypertonic saline has been shown to be safe in cows with endotoxic mastitis.[452,453]

Mild to moderate hypocalcemia often accompanies clinical mastitis, with the odds of hypocalcemia increasing with the severity of mastitis,[145] although other serum electrolytes are variable. Affected cows may show muscle tremors or weakness but are seldom recumbent. Calcium supplementation can be by the oral, subcutaneous (SC), or slow IV route, depending on the severity of clinical signs and the product used. Anorexic cows often become hypokalemic, especially if anorexia persists for several days. Hypertonic saline administration also causes a transient reduction in serum potassium concentration. Potassium chloride can be supplemented orally at a rate of up to 240 g divided two to three times daily, with lesser amounts (30 to 120 g) being satisfactory for mild to moderate hypokalemia.[454] Sodium and chloride derangements are usually mild and can be addressed by administering balanced oral or IV fluids or hypertonic saline. Blood glucose concentration is usually normal or high in cows with clinical mastitis, so dextrose should not be administered routinely. However, IV dextrose treatment may be warranted in cows with concurrent ketosis.

Anti-inflammatory Drugs. Most of the physiologic and pathologic changes associated with clinical mastitis are a result of the inflammatory response to infection. Therefore it is logical to administer anti-inflammatory agents. Also, anti-inflammatory agents can reduce the pain associated with clinical mastitis.[455] However, the inflammatory response is necessary for resolving intramammary infection, and anti-inflammatory agents can produce detrimental side effects. Many of the agents used in other countries are not labeled for use in lactating dairy cows in the United States. The choice of anti-inflammatory agents in the United States is limited to three approved drugs—dexamethasone, isoflupredone acetate, and flunixin meglumine—although none is approved for the treatment of severe clinical mastitis.

Dexamethasone and isoflupredone acetate are inexpensive steroidal anti-inflammatory agents that have no milk-withholding requirement. Glucocorticoid drugs inhibit the production of inflammatory molecules and the adhesion molecules that facilitate transport of inflammatory cells from the bloodstream to the site of inflammation. Glucocorticoids also help to maintain microcirculation and cell membrane integrity, interfere with dissolution and disruption of connective tissue, decrease formation of histamine by injured cells, and antagonize toxins and kinins. These actions of glucocorticoid drugs could be expected to benefit mastitic cows, particularly those with mastitis caused by endotoxin-producing coliform bacteria. Glucocorticoids prevent arachidonic acid release by stabilizing cell membranes and by inducing lipocortin production. Lipocortin prevents phospholipase A2 from contacting cell membrane–associated arachidonic acid and effectively limits the precursor needed for eicosanoid production.[456] In addition, endogenous cortisol release has been identified as playing an important role in downregulating neutrophil trafficking into the site of infection and production of inflammatory cytokines.[68]

Data on the efficacy of steroidal anti-inflammatory agents for treatment of clinical mastitis are limited to experimental mastitis trials. A single, 30-mg IM dose of dexamethasone given at the time of *E. coli* inoculation reduced local signs of inflammation, tachycardia, rumen motility impairment, and 14-day milk production loss, compared with untreated controls.[457,458] A large IV dose of dexamethasone (0.44 mg/kg) given to goats 12 hours after *E. coli* infusion reduced fever and appetite suppression but had no effect on heart rate, rumen contractions, serum biochemical parameters, SCCs, milk yield, or histopathologic changes.[459] Isoflupredone acetate (20 mg IV) administered to endotoxin-challenged cows after the onset of clinical mastitis had no beneficial effect on systemic parameters, mammary gland swelling, or milk production, compared with untreated controls.[460]

However, each of these agents has potential adverse effects. Dexamethasone can cause abortion in pregnant cows, especially after 5 months of gestation, although this would be less of a concern for cows in early lactation. Repeated dosing (0.04 mg/kg IM for 3 days) of cows with subclinical intramammary infections resulted in increased bacterial shedding and development of clinical mastitis.[461] Perhaps more problematic is the use of isoflupredone acetate because this drug reduces plasma potassium concentration and repeated doses can lead to severe hypokalemia and recumbency.[462-464]

The above studies suggest that the most likely benefit for corticosteroid treatment would be for severe coliform mastitis, and delays in therapy relative to the onset of infection may hamper efficacy. Nonetheless, dexamethasone is a potent anti-inflammatory agent, and it is difficult to extrapolate the benefit for cattle in terms of improved attitude and shock

VetBooks.ir

mitigation from experimental mastitis trials to naturally occurring clinical mastitis. Because of mineral corticoid effects on serum potassium, dexamethasone may be preferred over isoflupredone. In addition, corticosteroid use in chronic IMI should be contraindicated.

A variety of nonsteroidal antiinflammatory drugs (NSAIDs) are used to treat clinical mastitis worldwide.[455] However, only flunixin meglumine is approved for use in lactating dairy cows in the United States. Dipyrone and phenylbutazone are banned, and other NSAIDs can be used in an extralabel manner only if appropriately justified. The NSAIDs are not immunosuppressive but carry a risk of abomasal ulceration and renal damage. These complications are not well documented in cattle and presumably are minimized if treatment is of short duration, hydration is maintained, and appetite is restored. The primary mode of action of NSAIDs is to inhibit the synthesis of prostaglandins and thromboxanes by inhibition of cyclooxygenase. NSAIDs also inhibit the formation of prostaglandin E2 in the brain, which effectively reduces fever.[465]

Treatment of cows with flunixin meglumine at 0 and 3 to 5 hours after *E. coli* inoculation abolished fever and improved rumen motility, compared with untreated controls, but had no effect on gland or milk appearance, heart rate, or respiratory rate.[466] Similarly, administration of flunixin meglumine every 8 hours beginning 2 hours after endotoxin infusion reduced fever and improved gland appearance and attitude, compared with untreated controls, but had no effect on milk appearance, heart rate, rumen motility, SCC, or milk production.[467] When administered after the onset of fever and gland swelling, flunixin meglumine (2.2 mg/kg IV) reduced heart rate and rectal temperature and increased rumen motility in cows with endotoxic mastitis but had no effect on milk production or mammary gland inflammation.[468] As with the steroids, the relevance of these trial results to cows with naturally occurring clinical mastitis is uncertain. Meloxicam, administered at a dose of 0.5 mg/kg subcutaneously, was found to have a beneficial effect in relieving pain, decreasing udder edema, and reducing body temperature response following an LPS-induced clinical mastitis.[468a] Although not labelled for use in cattle in the United States, this drug may have potential in the future for analgesia and as an anti-inflammatory agent. It appears that NSAIDs can improve well-being and outcome in cows with clinical mastitis. However, specific criteria for instituting NSAID therapy, the timing of therapy relative to infection onset, and the optimal duration of treatment remain to be determined.

Oxytocin and Frequent Milking. Oxytocin is administered to stimulate milk ejection and facilitate removal of secretions from mastitic mammary glands. Frequent milk-out (stripping) reputedly augments the removal of pathogens, toxins, and inflammatory mediators from the mammary gland. Although these are seemingly logical practices, no solid evidence exists to support their routine use, and some data suggest they can be detrimental. Oxytocin (20 IU IM twice daily for 3 days) at milking time prevented development of clinical mastitis in only two of eight cows experimentally inoculated with *S. uberis*; once clinical mastitis developed, oxytocin was ineffective at resolving the *S. uberis* infections.[469] When initiated at the onset of clinical *S. uberis* mastitis, oxytocin (80 IU IM, followed by 20 IU IM twice daily) resulted in no clinical or bacteriologic cures by 3 or 6 days.[470] In contrast, clinical and bacteriologic cure rates of 91% and 64% were achieved by intramammary antibiotic administration by 3 and 6 days, respectively. When oxytocin was used in conjunction with intramammary antibiotics, clinical and bacteriologic cure rates at 6 days dropped to 10%, implying a significant adverse effect of oxytocin and stripping. Frequent milk-out (every 4 to 6 hours) in conjunction with oxytocin administration did not shorten the time to clinical or bacteriologic cure or resolution of systemic illness in cows with experimentally induced coliform mastitis, compared with no treatment.[471] When oxytocin administration (100 IU IM twice daily for 1 week) was compared with no treatment (udder massage only) in cows experimentally inoculated with *S. aureus*, oxytocin administration reduced bacterial concentrations in the milk but did not improve the bacteriologic cure rate or reduce SCCs.[472] Oxytocin administration increases the permeability of mammary epithelial tight cell junctions in a dose-dependent manner, which can alter milk composition in nonmastitic glands, particularly if high doses (100 IU) are administered repeatedly.[473]

Oxytocin and frequent milk-out have not been evaluated extensively in the field. In a California study, oxytocin (100 IU IM twice daily for three treatments) at milking time resulted in similar clinical and bacteriologic cure rates, as compared to intramammary antibiotics, although an untreated control group was not evaluated.[474] However, no overall benefit resulted because the oxytocin-treated cows had a higher recurrence rate of clinical mastitis, particularly environmental streptococcal mastitis.[475] In a Virginia study, frequent milk-out (six times daily) in conjunction with oxytocin administration (20 IU) did not improve clinical or bacteriologic cure rates, time to cure, or return to milk production compared with no treatment.[471] In an Illinois herd, cows treated with supportive therapy alone (oxytocin administration [all cases], frequent milk-out [moderate and severe cases], anti-inflammatory therapy [severe cases], and fluid therapy [severe cases]) had lower clinical and bacteriologic cure rates and a higher recurrence rate than cows given antibiotics in addition to the same supportive therapy.[444] Furthermore, two studies have cited that 50 IU of oxytocin administered q12h for 19 or 22 days increased residual (non-harvested) milk by 15% at each milking.[476,477] Bruckmaier[476] noted, "Cows increasingly refused to enter the milking parlor voluntarily and had to be fetched by the milker and cow entry into the parlor remained disturbed for up to one week after the end of injections."

In summary, oxytocin administration and frequent milk-out are not likely to be effective standalone treatments for clinical mastitis, particularly mastitis caused by streptococci, and may even be detrimental. In certain circumstances, when a cow clearly will not eject milk or when garget in the milk prevents effective milk removal, these practices may be of some benefit. Otherwise, unnecessary administration of oxytocin injections and frequent milking of painful teats should be avoided for welfare reasons. Sustained use of this drug as a routine therapy is a poor substitute for good milking preparation and will likely incite cows to be reluctant to enter the milking parlor and milk out effectively, which is the opposite of therapeutic intentions with this drug.

Prevention and Treatment of Mastitis During the Dry Period

The dry (nonlactating) period of the lactation cycle is a critical time for udder health in dairy animals. The major proportion of calf growth occurs during this time, and metabolically this is the most critical time for the cow to prepare for the next lactation. Prevention of new infections during the dry period hinges on prevention of teat end exposure to environmental pathogens. Rates of new IMI of coliforms are thought to be greater in the dry period than during lactation.[58] Thus the same management practices (i.e., maintaining cows in clean, dry, comfortable housing) that prevent infections from these organisms in lactating cows apply to dry cows. The importance of dry cow management is apparent from studies that found that nearly two thirds of clinical coliform mastitis cases in the first 2 months of lactation were newly acquired infections during the dry period.[261] The rate of environmental streptococcal IMI was 5.5-fold greater during the dry period as compared to during lactation.[261]

VetBooks.ir

During involution, the mammary gland undergoes marked biochemical, cellular, and immunologic changes. Involution of the mammary parenchyma begins 1 to 2 days after the end of lactation and continues for 10 to 14 days. During this time, the gland is particularly vulnerable to new IMI; in conjunction with the periparturient period, these times represent the greatest risk for new IMI in the lactation cycle of the cow.[478] The most important defense, as with lactating cows, remains the teat canal. When a cow is dried off at the end of lactation, the teat canal does not fully fill with keratin for days to months. This contributes to the risk of infection during mammary involution, and cows that have higher milk production at dry-off are more at risk to have teats remain open throughout the dry period.[479,480] Leukocytes increase to millions per milliliter as involution progresses and then decrease prepartum. Macrophages are predominate in lacteal secretions, followed by lymphocytes and neutrophils.[478] Lactoferrin is also associated with resistance to infection during the nonlactating period.[478] Lacteal immunoglobulins increase throughout involution and function by opsonizing bacteria, neutralizing toxins, and preventing bacterial adherence.[478] Consequently, the dry period is an ideal time to attain synergy between antibacterial therapy and immune function to eliminate pathogens from the gland and not incur the extensive costs of milk withholding typical of lactating cow therapy.

Intramammary administration of antibacterials at the end of lactation (dry cow therapy) has been a standard of dairy mastitis management for 40 years, particularly as a tool to help reduce the prevalence of contagious mastitis. Cure rates for IMI caused by all gram-positive cocci (those IMIs that existed prior to the dry period but were not detected following calving), as with lactational therapy, vary from farm to farm and are dependent on pathogen. A New Zealand study determined that dry cow therapy eliminated 85%, 90%, and 90% of IMIs caused by *S. aureus*, *S. uberis*, and *S. agalactiae*, respectively, as opposed to spontaneous cures of 31%, 50%, and 29% in untreated controls.[481,482] Cures for chronic *S. aureus* IMI or gram-negative organisms may be considerably less.[427] However, a ceftiofur dry cow therapy is now labeled for use in North America, and a previous study found that cows that were dry-cow treated with a product with significant activity against gram-negative bacteria (100 mg framycetin, 100 mg penethamates, and 300 mg procaine penicillin) had decreased clinical coliform mastitis during the dry period and early lactation as compared to cows treated with cloxacillin.[273]

Because of concern regarding overuse of antibacterial drugs and potential effects on antimicrobial resistance of bacteria, selective dry cow therapy (treatment of infected cows only) versus total or blanket dry cow therapy (treatment of all cows) is debated. Although this approach does have the potential to reduce antimicrobial drug use on a dairy farm, it must also be considered how historically successful blanket dry cow therapy has been in both eliminating and preventing IMI during the dry period. Decisions should be carefully made on an individual herd basis, and results should be monitored to determine the success of a dry cow mastitis program based on new IMI during the dry period, probably best monitored by changes in individual cow SCCs, cures of existing infections, and impact on the rate of clinical mastitis, particularly in early lactation. If herds are considering selective dry cow therapy, it is important to consider the ability of the herd to control mastitis (i.e., herds that have BTSCCs >200,000 cells/mL should be advised to reconsider this approach). In addition, not only metrics for outcomes following adoption of selective dry cow therapy should be monitored, but also the criteria for selection of cows that should be either included or excluded for dry cow therapy.[140] Herd-specific algorithms should be designed that include at the very least individual cow SCC status before dry-off and clinical mastitis history during the previous lactation, and preferentially bacterial culture status of cows with low SCCs that might be considered to exclude from treatment. Examples of outcomes and various models for selective dry cow therapy have been reported, but the emphasis must be placed on both protocols and outcomes, which will vary greatly depending on the herd.[483-485]

In addition to the role that dry cow therapy has in eliminating existing IMI, one dry cow therapy is also thought to prevent new IMI. Early studies suggested that dry cow therapy reduced new IMI during the dry period by 50%.[482] Overall rates from multi-institution studies reported new IMI rates during the dry period as 11% to 25% of quarters in herds that practiced blanket dry cow therapy.[486] Intramammary infusion of tilmicosin reduced new infection rates by more than 33% in a Canadian study.[486] In addition, selective dry cow therapy can result in more clinical mastitis in the dry period, more new IMI during the dry period, and subsequently more clinical mastitis in early lactation as compared to cows treated with blanket dry cow therapy.[487] An internal teat sealant consisting of a bismuth subnitrate paste in a paraffin base has gained wide acceptance on many dairies to create a barrier in the teat canal during the dry period following intramammary infusion. This is an inert product with no activity or food residue risks. Numerous field studies have confirmed the efficacy of this product to reduce new infection rates over the dry period, especially when used in conjunction with antimicrobial dry cow therapy. As an example, following intramammary cloxacillin at dry-off, the combined use of the teat sealant and antimicrobial infusions resulted in 30% fewer new IMIs during the dry period and 33% fewer clinical mastitis cases from drying off until 60 days in milk, as compared to quarters that were infused with cloxacillin only.[272]

As with lactational therapy, the use of systemic administration as an adjunct to intramammary administration has stimulated interest in potential alternative therapeutic regimens. Subcutaneous norfloxacin nicotinate administered at the start of the dry period achieved a better cure rate and lower new infection rate over the dry period for *S. aureus* infections, as compared to untreated cows and cows administered intramammary cephapirin benzathine preparations.[488] However, in a Michigan study, cows administered intramuscular oxytetracycline and intramammary cephapirin did not have better cure rates for quarters infected with *S. aureus* than cows treated with cephapirin only, although this study was performed in a herd that had 50% of the cows infected with *S. aureus* with a history of long duration of infection.[427] Systemic therapy should be reserved for use in dry cows for animals of exceptional value and for infections for which cures are deemed to be difficult to attain (i.e., chronic infections). However, success rates are likely to be low and in most cases will not be worth the injection and withholding time risks, especially if extralabel drugs are administered.

Epidemiology and Management of Mastitis in Heifers

Mastitis in heifers is rarely apparent prior to calving, but few farms actively look for mastitis before parturition. Although many farms raise healthy dairy heifers, in some studies bacteria have been isolated from more than 50% of quarters of prepartum heifers.[489-491] Reviews of heifer mastitis studies indicate that the prevalence of mastitis pathogens recovered from mammary secretions obtained before the first parturition ranged from 29% to 74%, whereas the prevalence of infection at first calving ranged from 12% to 57%.[227,492] Recovery of *Mycoplasma* organisms from milk samples was not included in these studies.

Staphylococci (primarily NAS but also *S. aureus*) are the most frequent isolates recovered from heifers, but environmental pathogens such as streptococci are also frequently recovered.[227]

VetBooks.ir

NAS are the most common pathogens recovered from heifers and a variety of NAS species have been recovered from teat skin, the streak canal, and precalving udder secretion obtained from heifers.[227] While NAS is the most common group of bacteria recovered from postpartum heifers, many of the apparent IMIs spontaneously disappear within the first week after calving. One study indicated that 41% of mammary quarters had NAS infections between days 1 and 4 post calving but 46% of those infections had spontaneously disappeared by days 5 to 8 post calving.[493] However, some herds may experience persistent infections with NAS in heifers, resulting in increased SCC values and potentially decreased milk production. These herds require interventions to limit long-term effects on milk quality and production.

Detection of *S. aureus* in dairy heifers usually indicates that a significant number of lactating cows are infected. Although many herds have controlled *S. aureus*, regional differences in the prevalence of infected dairy heifers have been reported.[492] The exact mechanism of how nonlactating heifers develop *S. aureus* infections is not known, but studies have demonstrated that teat canals of heifer calves can become colonized at very young ages.[494] *S. aureus* can spread to heifers when they are fed nonpasteurized milk or colostrum or when calves come in contact with objects contaminated with infected milk.[495] While ingested milk is not transmitted directly from the digestive tract to the mammary gland, it is possible that calves may lick their udder or legs and colonize the teat skin, eventually leading to increased risk of infection. *S. aureus* can also be transmitted to heifers during the immediate pre- or postpartum period. Commingling ill animals and periparturient heifers may result in exposure to infected secretions (milk, blood, feces, etc.) from sick animals. These secretions may remain infectious for variable periods of time (depending on the characteristics of the organism, the type of bedding, and the environmental conditions) and serve as a point of exposure. Milking heifers using equipment that previously has been used on infected cows is also a common route of exposure. Several studies have demonstrated that biting flies can play a role in the transmission of *S. aureus* between infected and healthy heifers.[496] It is thought that flies congregating on teat ends of infected cows can become contaminated with bacteria present in milk droplets and mechanically transfer the bacteria when they land on the teats of uninfected animals.

M. bovis is an important pathogen that often affects heifers. This organism is associated with respiratory disease, ear infections, joint infections, mastitis, and other diseases of dairy calves and cows.[497] *M. bovis* dwells primarily in the respiratory tract of cattle, often without causing apparent clinical disease in the host.[298] This organism is unique in that respiratory infections can spread through the lymphatic and blood streams to infect other mucosal tissue such as the udder. Animals colonized with *M. bovis* can develop long-term infections and infect other animals. *M. bovis* is usually introduced into herds by clinically healthy cattle that are carriers of the organism,[497] and bulls have been demonstrated to be carriers.[498] *M. bovis* has been demonstrated to colonize developing udders of prepubertal heifers and eventually cause mastitis.[499] The feeding of waste milk from infected cows has long been considered a primary route of infection with *M. bovis.* Commingling of calves from different sources has consistently been identified as a risk factor for infection with this organism. Control of *M. bovis* in heifers is based on reducing the potential for contact with potentially infected shedders of the organism and ensuring that calves never receive unpasteurized milk. The organism's ability to colonize the respiratory tract of cattle also requires strict attention to limiting the potential for airborne transmission, thus adequate ventilation, isolation of calves from older animals or ill calves, and reduced stocking densities are commonsense precautions.

RISK FACTORS FOR MASTITIS IN HEIFERS. Most risk factors that contribute to the development of mastitis in heifers are related to exposure of heifers to mastitis-causing organisms. The exception to this is the occurrence of udder edema. Calves that are group-housed have the opportunity for cross-suckling, leading to increased risk for transmission of contagious pathogens.[500] Several studies have shown that contact of heifers with older cows before calving (even housing in the same barn) increases the risk of clinical mastitis after calving, and separation of heifers from older cows is generally recommended.[501] The hygiene of the environment is also an important determinant of the risk of developing mastitis in heifers, and this is true for heifers raised on pasture as well as heifers raised in confinement.[502]

PREVENTION OF MASTITIS IN HEIFERS. Prevention of mastitis in heifers is based on reducing exposure to mastitis pathogens and enhancing the ability of the heifers' immune system to respond to exposure. Prevention of mastitis in heifers includes the following strategies: (1) Controlling the prevalence of mastitis in the existing adult herd—exposure to contagious mastitis is more likely to occur when many animals are infected as compared to when few animals are infected; (2) using individual stalls for preweaned calves; (3) culling calves that persist in suckling other calves; (4) feeding milk replacer or pasteurized milk from healthy, uninfected cows rather than waste milk; (5) controlling flies—especially important in the control of *S. aureus;* (6) milking fresh heifers first using clean milking equipment; (7) calving heifers in clean pens that have not been used to house sick cows; (8) housing growing and prepartum heifers in an adequately bedded area that is clean and dry and provides sufficient space for all animals; (9) feeding a well-balanced diet that enhances the immune systems of the heifers—recommended values include 1000 IU per day vitamin E during the prefresh period and adequate selenium; (10) boosting the immunity of heifers by using gram-negative J5 vaccines, which work to reduce the severity of infections caused by gram-negative bacteria such as *E. coli;* and (11) considering prepartum teat dipping several times a week for problem herds[503] or the use of internal teat sealants administered about 1 month before calving.[504]

PREPARTUM TREATMENT OF HEIFERS. Intramammary therapy with antibiotics is one of the tools used to control mastitis in heifers.[494] Intramammary treatment of prepartum heifers is generally considered efficacious in reducing the prevalence of infection, can result in a reduction of SCC, and in some cases has been shown to increase milk production in the subsequent lactation.[496,505-508] However, research shows that the production response is highly variable among herds and this strategy should be routinely recommended only for herds that have demonstrated problems with heifer mastitis.[509] Oliver and colleagues[510] reported cure rates of 84% and 97%, respectively, for heifers infected with NAS that received intramammary treatment using 200 mg of either sodiumcloxacillin or cephapirin sodium; the spontaneous cure rate was 27% for heifers in an untreated control group. Research has shown that administration of intramammary antimicrobial treatments during late gestation is generally highly effective and cure rates for staphylococcal infections frequently exceed 90%.[510] Intramammary products designed for both lactating and nonlactating cows (dry cow products) have been evaluated for use in precalving heifers.[494] In virtually all instances, high rates of bacteriologic cure have been reported. No significant difference in treatment efficacy was found based on treatments given during the first, second, or third trimester of pregnancy, but fewer new *S. aureus* infections were reported for animals treated in the third trimester.[506,511] However, to minimize the potential for residues after calving, treatments should be administered at least 60 days before the

VetBooks.ir

expected due date, and milk should be checked for residues after calving. Unlike intramammary treatments, systemic antibiotics administered to heifers have not been shown to be effective in reducing the incidence of mastitis.[512] The effect of precalving treatment on production of heifers appears to be variable among herds and is not performed without introducing the risk of infections caused by improper administration of the intramammary tubes. The administration of internal teat sealants or intramammary antibiotics should occur only under hygienic conditions and after effective sanitation of teat ends. This practice is generally recommended only for herds that have demonstrated problems with mastitis in heifers.

Other Conditions of the Mammary Gland

UDDER EDEMA. Dairy cattle frequently develop physiologic edema of the udder during the periparturient period, and heifers have increased incidence of this disorder. Physiologic udder edema must be differentiated from *pathologic* edema, which can accompany mastitis and diseases of other body systems. *Physiologic* udder edema is symmetric, is cool to the touch, and pits on palpation. It can be limited to the udder or extend cranially along the ventrum or into the perineal region. In contrast, the edema that accompanies mastitis is more focal, is asymmetric, and is accompanied by abnormal milk and an inflamed mammary gland. Intermandibular and brisket edema, which are often observed in cows with congestive heart failure or severe hypoproteinemia, do not occur in cows with physiologic udder edema.

In most cases, physiologic edema is of little consequence and resolves spontaneously after parturition. However, treatment is recommended if the udder becomes excessively large and heavy, because this threatens the integrity of the udder suspensory apparatus and predisposes to teat injury and mastitis. Severe edema also can hinder ambulation or impair milking or nursing of the teats. If the edematous udder impinges on the skin of the thigh, moist dermatitis and secondary infection may develop, and the skin may slough; this condition is referred to as *udder scald.*

The mechanism(s) of physiologic udder edema is uncertain. Supplementing the ration of prepartum dairy cows with high concentrations of sodium or potassium salts significantly increases the incidence and severity of edema.[513,509] However, serum biochemical values and fractional clearance of electrolytes are similar in affected and nonaffected cows.[514] Increased capillary hydrostatic pressure (resulting from changes in mammary blood flow and intramammary pressure that occur around parturition) might be involved, as might incompetent valves in the cranial superficial epigastric veins draining the udder. Cows with udder edema have higher blood pressure in the cranial superficial epigastric veins than do unaffected cows, and blood pressure is inversely related to mammary blood flow.[515] Poor udder suspension can also predispose to physiologic udder edema.

First-calf heifers and high-producing cows are at greatest risk of developing udder edema. Other risk factors are not well documented. In a case-control study of heifers in Florida, the risk of udder edema increased as height of the heifer increased, was higher if calving occurred in winter than in summer, and was higher if the fetus was male rather than female.[516] Heifers with udder edema in the first lactation were more likely than unaffected heifers to develop edema in subsequent lactations.[516]

Treatment of udder edema includes preventing excessive salt intake and administering a diuretic. In the United States, furosemide is labeled for use in dairy cows, has 48-hour milk-withholding and slaughter-withholding times, and is the diuretic of choice for treating udder edema. In one study, high cranial superficial epigastric venous pressure in cows with udder edema was reduced by IV administration of furosemide (500 mg) but not by hydrochlorothiazide (250 mg) or acetazolamide (500 mg).[507,515] Repeated administration of furosemide for several days should be avoided, but if repeated dosing is necessary, cows should be monitored for signs of electrolyte imbalance. Although corticosteroids have been recommended for treatment of udder edema, their efficacy is questionable. Prepartum milking reduces the severity of edema[517] but also decreases colostral immunoglobulin concentration at calving, so an alternative source of colostrum is needed. Prepartum milking of affected heifers has also been shown to reduce the risk of developing mastitis, but care should be taken to manage energy balance to prevent the development of ketosis.[500] Milking first lactation animals four times daily did not reduce or increase udder edema scores.[518] Increased milking frequency or other testimonial treatments such as exercise have not been demonstrated to reduce udder edema. Udder supports are available for cows with extremely pendulous or heavy udders.

BLOODY MILK. It is not uncommon to observe blood in postpartum mammary secretions. Small vessels may rupture as a result of trauma or in conjunction with udder edema. The milk is usually light pink to red or brown and may contain small blood clots. Antibiotic treatment is not indicated. Bloody milk can also accompany severe clinical mastitis or gangrenous mastitis, both of which have a poor prognosis, but physical examination of the animal will identify these conditions.

Bloody milk should be withheld from sale for human consumption. The milk usually returns to normal appearance within 1 week. However, because blood contains natural antimicrobial inhibitors, bloody milk may cause false-positive antibiotic residue test results. The IgG1 concentration of bloody colostrum is similar to that of normal-appearing colostrum, meaning that it is not necessary to discard colostrum simply because it contains blood.[519]

TEAT AND SKIN CONDITIONS. Several noninfectious diseases of teats are recognized to occur.[55] The color and condition of teats can be influenced by milking equipment, overmilking, use of caustic chemicals, or environmental conditions. The development of hyperkeratosis of the teat ends is not uncommon and occurs more commonly during winter months. Hyperkeratosis is a thickening of skin that lines the teat canal and is the result of a localized hyperplasia of the stratum corneum.[48,55,520] Mild hyperkeratosis is a normal physiologic response to forces applied to the teat during milking and does not increase the risk of IMI. However, moderate and severe hyperkeratosis can become a problem. Various scoring systems have been developed to assess teat end health. In general, teats are scored on a 1 (N = no ring) to 4 (VR = very rough ring) based on the teat end callosity observed. It is recommended that herds have less than 20% scores of 3 (R = rough ring) and 4 and less than 10% scores of 4.[55] Rough teat ends not only are difficult to clean but also provide a surface for pathogenic bacteria to harbor. Hyperkeratosis is a multifactorial problem, and risk factors must be determined and addressed for individual farms. Areas to investigate that may resolve a problem with hyperkeratosis include liner compression, excessive teat end vacuum or overmilking, environmental conditions, and use of teat dips that do not provide sufficient skin conditioning.

Infectious lesion of teats have been associated with several viruses. Pseudocowpox is caused by a paravaccinia virus that can cause acute infection in cattle. This disease results in lesions that include center vesicles that ulcerate to form scabs. As the lesions heal, they result in a characteristic ring or horseshoe-shaped scab. This virus can affect the hands of milking technicians. Diagnosis is based on observation of lesions on the hands of milking technicians and teats. The condition is generally self-limiting within 3 to 5 weeks.

VetBooks.ir

Bovine herpes mammillitis has been associated with both herpesvirus type II and herpesvirus type IV. The resulting lesions appear similar and can occur either sporadically or in an outbreak. These viruses can present with a wide range of symptoms ranging from mild edema to the development of vesicles that result in severe ulceration and the formation of painful scabs. This condition appears to be more common during winter months. Diagnosis is based on observation of clinical signs and can be confirmed by histopathology. There is no effective therapy, but teat dipping using an effective germicide is recommended. This virus can spread among animals, so affected animals should be segregated and milked with separate milking equipment.

Teat warts are not uncommon and can be caused by several different papillomaviruses. The appearance of the warts is variable, ranging from small, smooth lesions to large, frond-like protuberences. Younger animals are often more susceptible and will develop immunity. Warts are generally self-limiting and will resolve within several months. No therapy is recommended.

Mastitis in Beef Cows

Several surveys have demonstrated that about 15% to 40% of beef cows have IMI in at least one mammary gland.[521,522] Similar to heifers and small ruminants, NAS are the predominant bacteria isolated, but *S. aureus* has been recovered from 7% to 10% of milk samples. Milk from infected glands has significantly higher SCCs as compared to milk collected from healthy glands.[521,523,524] Clinical mastitis occurs rarely and is diagnosed and treated when economically feasible, but most mild cases of clinical mastitis are likely undetected.

Several modes of transmission of mastitis pathogens have been proposed for beef cattle. Flies are believed to serve as vectors for staphylococci, and fly-induced teat scabs of beef heifers have been shown to harbor staphylococci.[525] Calves may also serve as vectors by transmitting oropharyngeal organisms to the teats or carrying bacteria-laden milk from teat to teat. Unsanitary housing conditions probably increase the risk of infection with environmental pathogens.[521,525] As with dairy cows, poor udder conformation and teat injuries may predispose to mastitis.

Several studies have demonstrated numeric or significant decreases (up to 40 kg) in weaning weights of calves from beef cows with subclinical mastitis,[521,522,524] probably as a result of reduced milk production.[523] The adverse effect on weaning weight appears to increase with the number of infected glands.[521] Use of dry cow antimicrobial therapy has been associated with decreased IMI in the subsequent calving and increased body weight gain of calves.[526] However, the economic justification for the routine use of antibiotic treatment at dry-off is lacking. Selective intramammary antibiotic treatment at weaning based on CMT reaction has been suggested, but CMT score is unlikely to be an accurate predictor of infection. Sanitary housing conditions, appropriate stocking density, and good fly control should help to minimize mastitis risk in beef cattle.

Mastitis in Small Ruminants

General Concepts

The udders of sheep and goats differ from those of cows in that they have only two mammary glands, which are logically referred to as halves. With the exception of the relative proportion of the cisternal cavities, anatomic structures, milk secretion, and milk letdown of small ruminants are similar to cattle. Both goats and sheep have much larger cisterns as compared to dairy cows, and the cisternal fraction of milk may approach 50% to 75% for these species.[527]

Just as in dairy cows, mastitis of small ruminants is a bacterial disease that occurs in either a subclinical or a clinical state. Subclinical mastitis is an important and underrecognized disease in small ruminants. In two separate studies, an Israeli research group compared milk production and composition of healthy and NAS-infected half-udders in ewes.[528] These studies demonstrated large increases in SCCs and 30% to 50% reductions in milk yield of infected half-udders. Subclinical mastitis is generally defined by the migration of neutrophils into the mammary gland in response to bacterial infection. This response occurs in all dairy species, but the magnitude of the response and the distribution of cell types in the healthy mammary gland differ considerably among species.[529] In both sheep and cows, a significant increase in somatic cells occurs almost exclusively in response to bacterial infection of the mammary gland. The SCC response in dairy goats is not as specific to infection, and thus different interpretation criteria are necessary. The proportion of neutrophils (PMNs) and the number of cytoplasmic particles present in milk are very different in milk produced by goats as compared to milk produced by ewes or cows. Part of this difference is generally attributed to different milk secretion mechanisms. Both goats and sheep are thought to produce milk using a largely apocrine process, where the apical portion of the secretory cell is excreted into the milk. Despite similar secretory processes, the number of cytoplasmic particles found in milk obtained from both healthy and infected glands is approximately ten- to twentyfold greater for goats (about 70,000 to 300,000 cells/mL) as compared to cytoplasmic particles found in sheep milk (about 15,000 cells/mL). The large number of cytoplasmic particles necessitates the use of DNA-specific counting mechanisms to accurately enumerate somatic cells in goat milk. Similar to dairy cows, microbiological analysis of milk samples obtained from affected glands is the only way to determine the etiology of mastitis.

Enumeration of SCC of goat milk must be performed using DNA-specific methods.[530] The CMT is based on reaction of the detergent with DNA in cells and is also considered accurate. When enumeration of SCC in goat milk is properly performed, IMI is a well-known cause of increased SCC, but the threshold used to determine infection must be determined relative to stage of lactation.[531] Milk samples obtained from infected udder-halves of goats generally exhibit SCC values greater than 500,000 cells/mL (first 90 days in milk) and greater than 1,000,000 cells/mL (later stages of lactation).[531] Important factors that must be considered when evaluating SCCs of goats include parity, stage of lactation, breed, and estrus.[532,533] In does, the ability of estrus to stimulate increased SCCs in the absence of IMI has been demonstrated in a controlled study using induced estrus.[534] In one part of the trial, the day after inducing estrus, SCC values were 1,778,000 cells/mL for does in estrus versus 363,000 cells/mL for does in the control group; both values have been converted from the reported log values. These physiologic increases were not associated with IMI or with decreased milk production, but the mechanism behind the increase was not elucidated. Overall, while several noninfectious causes for increased SCC are observed in goats, IMI remains an important cause of increased SCC. Although it is more complex to use SCC values to investigate mastitis problems in goats, the large variation observed among herds indicates that control of mastitis can result in lower bulk tank SCC, and veterinarians should work with producers to understand the factors that influence SCC in their herds.

The types and proportions of cells present in sheep milk are more similar to dairy cows than goats, and standard methods used to count somatic cells in cows' milk are considered accurate for counting somatic cells in ewes' milk. Evaluation of SCC data is considered an effective tool for diagnosing IMIs in dairy sheep.[535,536] In an uninfected half-udder, the SCC is generally lower than 200,000 to 400,000 cells/mL.[531,536] Higher

counts are almost always associated with bacterial infections and indicate the presence of subclinical mastitis.[537] Individual gland SCC values increase in response to IMI in ewes, and thus bulk tank SCC values are an indication of the quality of milk and increase when the prevalence of subclinical mastitis increases.[537] Dairy sheep producers should monitor bulk tank SCC and manage the flock to maintain a SCC of less than 300,000 cells/mL.

Mastitis in Dairy Sheep

In North America, most sheep are kept for production of meat, and most research literature discusses symptoms of mastitis occurring in ewes that are nursing lambs. In this population, only severe clinical mastitis is likely to be diagnosed. A longitudinal study of meat sheep conducted in Great Britain reported that acute mastitis affected 2% to 3% of ewes per year, but there was tremendous variability among flocks.[538] These researchers also reported that IMI occurred in 11% of lactating ewes and resulted in reduced weight gain of suckling lambs.[538] Udder conformation is a known risk factor associated with increased risk of mastitis in ewes.[539]

A lack of emphasis on milking ewes has led to an overemphasis on the occurrence of clinical mastitis and a lack of appreciation for subclinical mastitis. Although there are no national studies assessing the incidence of clinical mastitis in dairy ewes milked in the United States, based on research in other regions, clinical mastitis is thought to occur in less than 5% of ewes per year.[531,540] While few U.S. data are available to define the prevalence of subclinical mastitis, researchers believe that up to 30% of ewes in some flocks may be affected.

In almost all instances, mastitis is caused by a bacterial infection. While most bacteria can cause both clinical and subclinical mastitis, *S. aureus*, *Pasteurella haemolytica*, and various yeasts and molds are organisms frequently reported to be recovered from milk samples of ewes affected with clinical signs.[540] Bluebag (clinical mastitis with a hard, cold, swollen udder) is typically caused by either *P. haemolytica* or *S. aureus*. NAS are considered to be minor pathogens in dairy cows but behave as major pathogens in dairy sheep and have been frequently reported to be the most commonly isolated pathogens recovered from cases of subclinical mastitis in dairy ewes.[535,541] Subclinical infection caused by NAS and other mammary pathogens has been associated with increased SCC.[535,536] Other pathogens typically recovered from subclinical mastitis infections in ewes include *Corynebacterium* spp., yeast, *Streptococcus* spp., *Enterobacteriaceae* spp., and *S. aureus*. Yeast and mold infections in ewes are often associated with nonhygienic administration of intramammary treatments, and great care must be taken when these treatments are used.[542]

In rare instances, the lentivirus that causes ovine progressive pneumonia (OPP) has been associated with mastitis in sheep,[543] but there is no evidence that this virus has influence on the SCC of sheep milk.[531] Mammary gland symptoms are associated with lesions in secretory tissue. While it is known that this virus has an affinity for mammary glands, the disease is slowly progressive and results in weight loss, greatly reduced milk production, and other clinical signs that make it unlikely to become widespread in flocks used for dairy production.

Risk factors for subclinical mastitis are not well defined for intensively managed milking sheep in North America. European research in Mediterranean countries has indicated that most of the variation in mastitis is associated with differences in herd management.[544] In the same study, higher producing breeds were at greater risk of mastitis, and the use of dry-off treatment resulted in less mastitis.[545-547] Practices that improve udder hygiene and reduce teat exposure to bacteria are likely to result in less mastitis.

Ewes that develop clinical mastitis are often seriously ill and should be treated immediately according to protocols that have been developed in consultation with the flock veterinarian. Most treatments for severe clinical mastitis are administered systemically, and the ewe may require supportive therapy. There are no antibiotic compounds approved for treatment or prevention of mastitis in milking sheep. Drugs used for these purposes are considered by the FDA to be administered in an "extralabel" manner, and this usage must be prescribed and supervised by a licensed veterinarian. Administration of a drug that is approved for treatment of another sheep disease, such as ceftiofur for treatment of pneumonia, to treat mastitis is also considered extralabel usage. It is important to recognize that systemic administration of ceftiofur will not achieve effective inhibitory levels in the mammary glands of cows, sheep, or goats.

The use of intramammary dry-off treatment has been shown to positively influence milk yield and SCC in the subsequent lactation and is recommended.[542,547] However, administration of intramammary treatments does increase the risk of mastitis caused by yeast bacteria, and selective dry-off treatment can be recommended in flocks that have a relatively low prevalence of subclinically affected ewes. Milk samples obtained from ewes with three or more monthly SCCs of 400,000 cells/mL or greater in the previous lactation were six to eight times more likely to be positive for mastitis pathogens in the next lactation, as compared to milk samples obtained from ewes with SCCs below that threshold. That threshold may be appropriate to identify ewes that should receive dry-off treatment.

Mastitis in Dairy Goats

Similar to ewes, the incidence of clinical mastitis is generally reported to be less than 5% of lactating does per year.[531] A study that surveyed about 300 goat dairy farms in Holland reported an incidence of clinical mastitis of 2% per year, and about two thirds of the farms culled the majority of affected does rather than treat them.[548] One interesting study conducted in Spain linked the incidence of clinical mastitis to selenium deficiency.[549] Spanish researchers reported that for does consuming a deficient diet, the incidence of clinical mastitis was 3.8% and 15.4%, respectively, for does that had been treated with slow-release barium selenite or were enrolled in a nonsupplemented control group.[549]

There are neither national surveys nor comprehensive reviews that describe the prevalence of subclinical mastitis in dairy goats in the United States or Canada. Review of existing data about the prevalence of subclinical infection is further complicated by the lack of a uniform SCC threshold and the influence of intervening factors (such as estrus) on SCC. When recovery of bacteria from milk samples is used as the gold standard to identify subclinical mastitis, several studies have indicated that half-udder prevalence of subclinical mastitis varies between about 15% and 40%.[550,551] When using a SCC threshold of 500,000 cells/mL for defining subclinical mastitis, researchers have estimated sensitivity (probability of recovery of pathogens when the SCC is higher than the threshold) as ranging from 0.69 to 0.90 and specificity (probability of not recovering pathogens when the SCC is higher than the threshold) of about 0.35 to 0.77.[550] Although some high SCC values are likely associated with physiologic changes, some reflect IMI, and it is likely that the prevalence of subclinical mastitis in many goat herds is greater than commonly recognized.

Similar to dairy sheep, researchers have consistently reported that NAS are responsible for the greatest proportion of subclinical mastitis infections occurring in this species.[531,551,552] Infections with NAS are especially prevalent in goats at parturition, with recovery of NAS from up to 17% of goats reported.[531] Similar to ewes, the early lactation spontaneous cure rate is only about 50% for IMIs caused by NAS, and up to 25% of does may remain infected 6 weeks after parturition.[531] SCC values of infected half-udders of does are always significantly greater

VetBooks.ir

than SCC values of healthy half-udders. Other pathogens frequently recovered from goats with subclinical mastitis include *Corynebacterium* spp., *Streptococcus* spp., and *S. aureus*. The relationship between lentiviral infections (caprine arthritis encephalitis virus [CAEV]) and SCC has been reviewed,[531] and herds with greater prevalence of seropositive does have been shown to have greater SCC values. However, this relationship is considered weak and may have been a result of immunosuppression caused by CAEV infection.

Clinical mastitis in goats is often associated with infection by *S. aureus*, *Streptococcus* spp., *Pseudomonas*,[553] or miscellaneous pathogens such as yeast. In many regions of the world, IMIs are associated with infection by a variety of *Mycoplasma* spp., and milk samples obtained from goats with chronically increased SCCs should be submitted for *Mycoplasma* culture. When clinical mastitis cannot be explained by bacterial or fungal infection, *Mycoplasma* infection should be suspected. A variety of *Mycoplasma* species can cause clinical mastitis outbreaks in small ruminants. *Mycoplasma mycoides* subsp. *mycoides* (large-colony type) is an important mastitis pathogen in goats in the United States, especially in California.[554-557] *Mycoplasma putrefaciens* is involved in some outbreaks,[464] and *Mycoplasma agalactiae* is isolated on rare occasions.[556] Does with *Mycoplasma* mastitis often exhibit severe clinical illness and reduced milk yield, in addition to an inflamed udder and visibly abnormal milk; however, subclinical IMIs can occur. Adult goats and kids in herds with *Mycoplasma* mastitis may experience polyarthritis and pneumonia, and pregnant does may abort. Morbidity and mortality can be very high, with more than 90% of goats dying or euthanized in some herds.[556]

Because all mastitis treatments involve extralabel drug usage, treatment of clinical mastitis should be performed using protocols developed by a veterinary practitioner who has a valid veterinary-client-patient relationship. Treatment of systemically ill animals should focus on supportive care and appropriate antimicrobial therapy. Treatment of animals with local signs of clinical mastitis generally involves administration of commercial intramammary products and should be accompanied by microbiological assessments of at least some cases. Treatment of subclinical mastitis is unlikely to be pursued by most farms, and aggressive culling of affected animals has been shown to be associated with herds that have lower bulk tank SCCs.[548] At least one study has demonstrated that treatment of subclinical mastitis in early lactation based on CMT reaction resulted in increased bacteriologic cure but was not economically beneficial.[548] Thus treatment of subclinical infections during lactation is not currently recommended. However, the use of dry-off therapy has been shown to effectively cure NAS infections and result in lower SCCs in early lactation.[558] As with sheep, producers should be taught to use extreme care when disinfecting teat ends to prevent the iatrogenic development of IMI caused by yeast.

Mastitis is an important disease of small ruminants used in dairy production, and its prevalence varies with management. Most mastitis occurs in a subclinical form, and producers who do not routinely measure individual animal SCCs will be unable to determine the impact of subclinical mastitis on production and milk quality. Most subclinical mastitis in small ruminants is caused by NAS, which should be considered as major mastitis pathogens in these species. Prevention of infection is the key to control of mastitis, and good hygienic housing and milking practices are a necessity to minimize the impact of this disease. As in all dairy species, exposure of the teat end to bacteria is the mechanism for development of mastitis, and control programs are based on principles that improve hygiene and reduce exposure to potential pathogens. The prevalence of subclinical mastitis has been shown to be decreased in goat herds that practice good teat dipping and premilking teat sanitation.[559]

Mastitis in Horses

Mares have a uniquely different anatomic structure of the udder. Similar to the bovine udder, the equine udder is composed of four independent glands; however, the pairs of glands on each side of the midline share a single teat and are referred to as halves.[560] Mastitis occurs uncommonly in horses, in part because of the relatively small size and inguinal location of the udder, which minimizes exposure to potential pathogens. Little research has been done on the prevalence of subclinical mastitis in horses, but it is not recognized to be a serious problem and a longitudinal study estimated the prevalence to be 5% to 10%.[561] SCCs in uninfected glands have been reported to be relatively low (<250,000 cells/mL), whereas SCCs of microbiologically infected glands exceed 10^6 cells/mL.[562]

Clinical mastitis occurs sporadically in lactating and nonlactating mares; signs range from mild to severe. The most common clinical mastitis pathogen is *Streptococcus zooepidemicus*, but a variety of aerobic bacteria have been isolated from the milk of affected mares.[562-564] In a retrospective study of 28 cases, gram-negative bacteria (coliform bacteria, *Pseudomonas*, *Actinobacillus*, *Pasteurella*) were isolated from 42% of milk samples.[563] Streptococci and staphylococci constituted most of the gram-positive isolates. Rarely, mastitis is caused by nonbacterial pathogens. For example, one mare developed unilateral mastitis as a component of disseminated coccidioidomycosis.[565] Verminous mastitis has even been reported.[566]

Clinical signs of mastitis in horses include an enlarged, firm, warm, painful mammary gland and edema of the udder and surrounding tissues. The mare resists milking, and secretions are abnormal in appearance (color, viscosity, consistency). About half of all mares with clinical mastitis are systemically ill, with signs such as fever, tachycardia, tachypnea, anorexia, depression, or agalactia. The mare may be reluctant to move or may adopt an abnormal gait to minimize contact between the hindlimb and the painful gland. Sedation or anesthesia is necessary to achieve a thorough examination of the udder and collection of milk in some horses.[567]

Culturing milk is required to identify definitively the causative pathogen of equine mastitis and to confirm that antibiotic selection is appropriate. However, bacteria can often be observed on cytologic examination of the milk.[563] A differential diagnosis for a firm, enlarged, painful mammary gland is adenocarcinoma, particularly if the udder skin is ulcerated and the secretion is serosanguineous.[568-570] With adenocarcinoma, neoplastic cells may be seen during cytologic examination of the secretion, or a mammary biopsy may be required. Because bacterial mastitis and adenocarcinoma can occur simultaneously, it is important to reevaluate mares that do not respond as expected to antibiotic treatment. Fescue toxicosis should be included in the differential diagnosis for agalactia. With fescue toxicosis, the udder is not inflamed, and mares may sweat profusely, have prolonged gestation, or give birth to weak or dysmature foals.[571]

Treatment of bacterial mastitis in horses consists of intramammary and systemic antibiotics to combat infection; NSAIDs to reduce pain, inflammation, and fever; and fluids to correct dehydration. Hot packing, hydrotherapy, and frequent stripping of the affected gland are empirically justified supportive measures but may be difficult to accomplish. Furosemide can be administered if edema is substantial.

Broad-spectrum antibiotics should be given until results of cytologic examination or culture of the milk are available. Potentiated sulfonamides, or a combination of penicillin and an aminoglycoside, are reasonable systemic antibiotic choices. Because no antibiotics are labeled for intramammary administration in horses in the United States, intramammary infusion products for cattle are used. Infusion products containing ceftiofur, cephapirin, amoxicillin, or hetacillin are appropriate

VetBooks.ir

until the cause of the mastitis is determined. A commercial intramammary infusion product is preferable to a homemade solution because the latter carries a greater risk of unintentional contamination. Intramammary infusion of antibiotics can be difficult to accomplish in horses because of the small size of the teat orifice and the presence of two distinct lobes within each udder half. One or both lobes can be infected, so antibiotics must be directed appropriately. Antibiotic treatment should be continued for at least 5 days to avoid relapse.

The prognosis for survival of horses with bacterial mastitis is good; however, milk production may be transiently or permanently reduced. Fortunately, mastitis is usually unilateral, and recurrence is rare.[563] Most mares respond rapidly to antibiotic treatment. Although spontaneous recovery is possible, it is unethical to withhold treatment from a mare that is ill or in discomfort. The prognosis for mammary adenocarcinoma is poor, even with surgical removal of the affected mammary gland(s) and local lymph nodes, because of the high rate of metastasis.[570]

Diseases of the Hematopoietic and Hemolymphatic Systems

JOHANNA L. WATSON, *Consulting Editor*

JOHN A. ANGELOS, KRISTIN A. CLOTHIER, KRISTA E. ESTELL, JOHN E. MADIGAN, BRADFORD P. SMITH, SHARON JANE SPIER, BRETT A. SPONSELLER, JEFFREY W. NORRIS, and FERN TABIN

Diseases Associated With Blood Loss or Hemostatic Dysfunction

Johanna L. Watson • Debra Deem Morris

Blood loss may be acute or chronic, and the clinical and laboratory manifestations are widely different because physiologic adaptation occurs in the chronic state.

Acute Blood Loss

Common causes for acute blood loss include trauma (e.g., severe lacerations), surgical procedures (e.g., dehorning, castration), and erosion of the carotid artery by guttural pouch mycosis in horses. External hemorrhage is immediately obvious, but hemorrhage into a major body cavity may be occult (e.g., spontaneous rupture of the middle uterine artery, splenic rupture resulting from trauma or erosion of a major vessel by abscess, aneurysm, or neoplasia). Hemoperitoneum may induce signs of colic, and hemothorax is generally attended by dyspnea. Acute massive blood loss induces hypovolemic shock characterized by tachycardia, tachypnea, cold extremities, pale mucous membranes, muscle weakness, and eventual death resulting from cardiovascular collapse.

Acute blood loss does not initially cause a change in the packed cell volume (PCV) or total plasma protein, although rapid mobilization of extracellular fluid to maintain circulating blood volume causes PCV and total plasma protein to decline within 12 to 24 hours. The severity of blood loss may be partially masked by splenic contraction because shock causes activation of the sympathetic nervous system. Icterus is absent, and bone marrow erythroid hyperplasia is delayed by 3 to 4 days. Peripheral signs of erythroid regeneration in horses are limited to mild anisocytosis with a variable increase in mean corpuscular volume. Ruminants show erythrocyte polychromasia, basophilic stippling, Howell-Jolly bodies, and occasionally nucleated erythrocytes within 4 days of hemorrhage onset.

Diagnosis

Diagnosis of acute blood loss is based on clinical signs, evidence of recent hemorrhage, and anemia accompanied by hypoproteinemia. Hemoperitoneum and hemothorax may be suggested by ultrasound and abdominocentesis and thoracocentesis, respectively.

TREATMENT. Treatment of acute blood loss should initially be aimed at stopping the hemorrhage. External hemorrhage may be managed by pressure wraps or appropriately placed ligatures, but attempting to control internal hemorrhage when the patient is a poor risk for general anesthesia may be inadvisable and the source of hemorrhage may not be found. Hypovolemic shock should be treated by prompt intravenous (IV) administration of 40 to 80 mL/kg of sodium-containing crystalloid solutions. Studies indicate that a small volume of hypertonic saline (2 to 4 mL/kg 7.2% sodium chloride) may temporarily reverse the pathophysiologic sequelae of severe hemorrhagic shock.[1-3] The total volume of crystalloid solution required is usually much greater than the volume of blood lost because crystalloid solutions distribute throughout the extracellular space. The clinical response to fluid administration should be evaluated in light of ongoing losses to determine the necessary replacement volume.

If anemia becomes life threatening, whole blood transfusion must be considered. A PCV less than 20% in an animal with acute blood loss suggests depletion of erythrocyte reserves, and persistent reduction of the PCV over a period of 24 to 48 hours to 12% or less indicates the need for blood transfusion. A low but stable PCV (12% to 20%) does not necessitate transfusion, because transfusion should be reserved for instances in which oxygen delivery to the tissues is inadequate to support life. Blood transfusion can only be viewed as a temporary therapeutic procedure because even crossmatch-compatible allogeneic erythrocytes are removed from the circulation by the mononuclear phagocyte system (MPS) within 2 to 4 days of transfusion.[4] Horses and cattle display a high degree of blood type polymorphism, and minor antigenic incompatibilities are only delineated by blood typing.[5] Serum antibodies against nonhost erythrocyte antigens (erythrocyte alloantibodies) probably mediate the short life span of transfused erythrocytes. Compatibility testing is used to avert life-threatening antigen-antibody reactions caused by major blood group mismatching.

The routine crossmatch involves incubating washed erythrocytes from donor (major) and recipient (minor) with serum from the other. Gross and microscopic examination for clumping demonstrates serum agglutinins in horses. Sensitized cattle erythrocytes do not become clumped in saline solution but do lyse in the presence of rabbit complement, so only a hemolytic crossmatch can be performed in this species. Not all equine erythrocyte alloantibodies act as agglutinins, and hemolysins must be detected by adding complement to the reaction mixture. Pooled rabbit serum must first be absorbed

VetBooks.ir

with equine erythrocytes to remove naturally occurring antibodies. The necessity for special handling and storage of rabbit serum makes hemolytic crossmatch procedures impractical for most veterinarians. These tests are best performed by veterinary hematology laboratories (e.g., Veterinary Genetics Laboratory, School of Veterinary Medicine, University of California, Davis), which usually require serum and whole blood in sodium citrate or acid-citrate-dextrose (ACD) to crossmatch.

The first transfusion of whole blood to a horse or ruminant not previously transfused or sensitized by immunization or pregnancy is usually well tolerated because natural alloantibodies are of low concentration and weak activity. After incompatible transfusions, alloantibodies develop rapidly, making subsequent transfusions more hazardous.

Blood for transfusion should be collected aseptically into sterile containers of sodium citrate (2.5% to 4%) or ACD solution and used immediately. The necessary dosage can only be estimated, but in most instances replacing 20% to 40% of the calculated blood loss is sufficient to maintain life until the bone marrow can respond. A drop in PCV from 36% to 12% in a 500-kg animal (8% body weight blood) represents a loss of 27 L of blood. In this case, 6 to 8 L of whole blood would be therapeutic and easily donated by another 500-kg individual. Blood warmed to 37° C (98.6° F) should be administered through an in-line filter to remove clots. After pretransfusion vital parameters have been recorded, 0.1 mL of blood/kg body weight is given over 5 to 10 minutes and the evaluation is repeated. If parameters and attitude are unchanged, the transfusion can be continued at a rate not to exceed 20 mL/kg/h. The recipient should be continuously monitored so that the transfusion can be stopped if adverse reactions like tachypnea, dyspnea, restlessness, defecation, tachycardia, piloerection, muscle fasciculations, or sudden collapse occur. Although these signs may not indicate anaphylaxis, severe reactions should be treated with epinephrine (0.01 to 0.02 mg/kg). Mild signs may respond to a slowed transfusion rate or administration of corticosteroids or flunixin meglumine. Because it is often impossible to delineate the cause of transfusion reactions, the safest approach is to discontinue the blood and administer isotonic crystalloid solutions.

The prognosis is good for most cases of acute blood loss if hypovolemic shock is quickly treated and bleeding stops. Myocardial damage as indicated by elevated cardiac troponin I (cTnI) and arrhythmia has been reported with acute hemorrhage in the horse.[6] Normal bone marrow begins to replace lost cells within 5 days. Sequential PCV analysis will be necessary to determine whether blood loss is controlled. Examples of specific disorders follow.

Guttural Pouch Mycosis. See Chapter 31 for an in-depth discussion of this and other respiratory diseases.

Hemoperitoneum in Horses

Monica Aleman • Johanna L. Watson

Hemoperitoneum is accumulation of blood in the abdominal cavity and can be a life-threatening problem. In the horse, associated causes are trauma; postoperative abdominal hemorrhage; neoplasia; complications from pregnancy and foaling (utero-ovarian, middle uterine, and external iliac artery rupture); organ rupture; mesenteric injury; coagulopathies; ovarian hematoma; systemic amyloidosis; and idiopathic hemoperitoneum.[7-13] The underlying cause is identified in the majority of cases (78%).[13] Trauma (spleen and in mares, reproductive tract with associated vessels) and neoplasia are the most common causes of hemoperitoneum.[9,13]

A recent retrospective study of 67 horses with hemoperitoneum revealed that Thoroughbreds and Arabians were overrepresented breeds.[13] Middle-aged and older horses (>13 years of age) and females may be overrepresented.[12,13] The most common clinical signs include abdominal discomfort, lethargy, hypovolemic shock, pale mucous membranes, prolonged capillary refill time, tachycardia, and tachypnea.[12,13] Other clinical signs are anorexia, reluctance to move, weakness, trembling, cool extremities, and abdominal distention.[12]

Clinicopathologic abnormalities include anemia, neutrophilia, lymphopenia, thrombocytopenia, hypoproteinemia, hypocalcemia, and azotemia.[12] Abnormalities in clotting parameters may be observed, depending on the cause. Hemorrhagic abdominal effusion is characterized by high red blood cell (RBC) count (>2,400,000 RBC/μL), PCV (≥18%), and total protein (≥3.2 g/dL), with a normal to high leukocyte count.[12] Central venous pressure and blood lactate concentration appear to be early indicators of hypovolemia due to acute blood loss.[14] Fluid swirling and site of hemorrhage may be evident on abdominal ultrasound.

Primary goals of therapy are treating hypovolemic shock, restoring perfusion and oxygen delivery to tissues, correcting fluid deficits, stopping further blood loss, and preventing complications. Blood transfusion should be considered if anemia becomes life threatening. The use of antifibrinolytic and procoagulant agents has been reported in the literature, but controlled studies on efficacy and safety in the horse with acute blood loss are lacking. Physical activity must be restricted in affected patients.

The short-term outcome is strongly associated with the underlying cause.[13] Horses with neoplasia, uterine artery rupture, mesenteric injury, or disseminated intravascular coagulation (DIC) have a greater risk of not surviving. The survival rate has been reported to range from 51% to 74%.[12,13] Poor short-term outcome was significantly associated with high respiratory rate in one study.[13] Prepartum hemorrhage appears to be associated with a poorer prognosis than postpartum hemorrhage (100% vs. 20% mortality, respectively).[13]

Hemothorax

Hemothorax may occur secondary to trauma (including lung biopsy), neoplasia, and strenuous exercise (see Chapter 31).[15] Hemothorax in neonatal foals may be the result of lacerated lungs and vessels from fractured ribs (see Chapter 20).[16]

Exercise-Induced Pulmonary Hemorrhage

Exercise-induced pulmonary hemorrhage (EIPH) has not been identified as a major cause of blood loss. EIPH is associated with high-intensity exercise in horses. An estimated 14% to 75% of racehorses examined by endoscopy have EIPH.[17] On the basis of a bronchoalveolar lavage analysis, a study suggested that 100% of horses performing strenuous exercise have EIPH.[18] EIPH has been reported in various breeds. A recent study reported that the frequency of EIPH is associated with race type, distance, gender, and age. In one study, epistaxis was more common in females, older horses (vs. <2 years of age), following steeplechase races (vs. flat races), and at shorter distances (≤1600 m long).[19] Recurrence rate in that study was reported to be 4.64%. The pathophysiology of EIPH is not completely known. For a complete description of this disorder, see Chapter 31.

Chronic Blood Loss

Johanna L. Watson • Debra Deem Morris

A number of diseases can result in chronic loss of blood that is insidious until clinical signs of anemia develop. Physiologic

VetBooks.ir

adaptation to gradually developing tissue hypoxia generally masks signs of anemia until the PCV is less than 15%. Causes for chronic blood loss include bleeding gastrointestinal (GI) lesions, certain renal diseases, hemostatic dysfunction, blood-sucking external parasites, and haemonchosis (especially in goats and sheep).

GI hemorrhage is usually caused by neoplasia (especially gastric squamous cell carcinoma in horses and abomasal lymphoma in cattle), parasitism, or mucosal ulceration (e.g., abomasal ulcers in cattle and nonsteroidal antiinflammatory drug [NSAID] toxicity in horses). Significant hemorrhage may occur in ruminants heavily infested with *Haemonchus contortus* shortly after they are treated with an anthelmintic. Generally, GI hemorrhage is best detected by chemical determination of fecal occult blood, because melena rarely occurs in horses, and bleeding abomasal ulcers cannot be excluded in cattle when melena is absent. Because of the low specificity of tests for fecal occult blood, the diagnosis of chronic GI blood loss is usually supported by strong clinical suspicion and ruling out other sources of hemorrhage.

Although both renal calculi and renal papillary necrosis due to NSAID therapy cause hematuria, anemia rarely results. Renal neoplasia and congenital renal vascular anomalies are rare causes of chronic blood loss anemia. Other causes of blood loss include idiopathic hematuria and idiopathic recurrent hematuria of Arabian horses.

Disorders of hemostasis can cause internal or external hemorrhage that leads to anemia if enough blood is lost. Qualitative or quantitative abnormalities of blood vessels, platelets, or coagulation factors result in hemostatic dysfunction (see next section). Loss of erythrocyte iron secondary to chronic severe blood loss may result in iron deficiency anemia. Hypoferremia or reduced serum ferritin develops with increased total iron-binding capacity and reduction in marrow iron.

The key to managing chronic blood loss is determining the primary cause; treatment of the anemia per se is rarely indicated. Iron deficiency may be alleviated by oral (PO) supplementation with ferrous sulfate, although good-quality forages contain more than adequate amounts of iron. Parenteral iron supplementation as iron dextran should be avoided because it has been associated with anaphylactoid reactions in large animals. Examples of specific disorders follow.

Gastric Ulceration

Monica Aleman • Johanna L. Watson

Gastric ulceration is also known as *equine gastric ulceration syndrome* (EGUS). Although EGUS is not an important cause of blood loss, it has a high prevalence among adult horses. Thoroughbred racehorses have the greatest prevalence (range, 82% to 93%), followed by endurance horses (67%), show horses (58%), hospitalized horses (49%), and geriatric patients with abdominal pain (18%).[20-24] Gastric ulcers were found in 66.6% of pregnant and 75.9% of nonpregnant mares on a Thoroughbred breeding farm.[25] Clinical signs may include poor hair coat, decreased appetite, poor performance, nervous disposition, abdominal pain, teeth grinding, and salivation among others. Proposed causes of gastric ulceration include exercise, transportation, grazing deprivation, alternating periods of feeding and fasting, diets with high-concentrate content, and confinement. For a complete description of gastric ulceration see Chapter 32.

Right Dorsal Colitis

Right dorsal colitis (RDC) is an enteropathy associated with NSAID administration, most commonly phenylbutazone.[26,27] Other factors that may predispose to RDC are infection, immune-mediated response, genetics, and stress; pathogenesis is unknown. NSAIDs act by inhibiting cyclooxygenase (more inhibition of constitutively expressed COX-1 than inducible COX-2 expression during states of inflammation), which will cause inhibition of prostaglandin E production, resulting in hypoxic or ischemic GI mucosal damage and delayed mucosal healing.[27]

Ponies and young performance horses appear to be predisposed. Clinical signs include inappetence, lethargy, intermittent or episodic colic, diarrhea, and weight loss. Clinicopathologic abnormalities may include mild anemia, moderate to severe hypoproteinemia with hypoalbuminemia, hypocalcemia, and in some cases azotemia. Although mild anemia is seen in most cases, horses occasionally present with severe anemia and hematochezia. RDC often develops over a period of days or a few weeks. The complete discussion of diagnosis and treatment is included in Chapter 32.

Hemostatic Dysfunction

Johanna L. Watson • Debra Deem Morris

Basic Physiology of Normal Hemostasis

The basis for understanding the pathogenesis and manifestations of hemostatic disorders is a thorough understanding of the normal physiologic mechanism of hemostasis. Hemostasis can be viewed as two interrelated components—coagulation and fibrinolysis (both with their respective inhibitors)—which function to arrest bleeding from a damaged blood vessel and maintain nutrient blood flow.

Coagulation is mediated by blood vessels, platelets, and blood procoagulant proteins. When a blood vessel is damaged, vasoconstriction occurs, followed by rapid adherence of platelets to subendothelial collagen. Platelet adhesion causes membrane conformational changes that trigger aggregation, contraction, and granule secretion (the basic platelet reaction). Platelet phospholipoprotein (platelet factor 3) provides the necessary surface to catalyze interactions among the activated coagulation proteins that result in thrombin formation. Coagulant proteins are localized to this hemostatic plug because the platelet surface protects them from plasma anticoagulants. Through an incompletely understood mechanism, platelets also prevent spontaneous hemorrhage into the skin and mucous membranes by maintaining vascular integrity.

Procoagulant proteins circulate in the blood as precursor forms (zymogens) that must be altered during coagulation to become active. Numerous communications exist between the traditional extrinsic and intrinsic pathways, although initiating mechanisms remain distinct.[26] The extrinsic system is initiated when lipoprotein tissue factor (TF) gains access to the bloodstream. TF is widely distributed in most tissues, including endothelial cells and monocytes, and it may be increased or secreted in response to numerous pathologic stimuli like bacterial endotoxin. Intrinsic coagulation is initiated when blood is exposed to a negatively charged surface (e.g., activated platelets). Because of reciprocal activation between factor XII and prekallikrein, the intrinsic coagulation pathway stimulates formation of numerous inflammatory mediators such as kinins and complement. Both coagulation pathways culminate in the formation of activated factor X (Xa) by which thrombin is generated. In addition to catalyzing the conversion of fibrinogen to fibrin, thrombin promotes platelet aggregation, enhances cofactor activities of factors V and VIII, and activates factor XIII and protein C.[27] Mechanisms to localize coagulation to the site of vascular injury are critical to protect against generalized thrombosis.[28] Plasma anticoagulant proteins include the

VetBooks.ir

serpins, which inhibit activated coagulation factors, and the protein C system, which is directed against cofactors V and VIII.[29] Antithrombin III (AT III), the main physiologic inhibitor of thrombin and Xa, normally provides 70% of the anticoagulant activity of plasma. Although not absolutely necessary, heparin accelerates AT III action by 2000-fold.[30] Activated protein C destroys factors V and VIII, ultimately limiting its own activation, which depends on thrombin and endothelial cofactor, thrombomodulin. Protein S enhances the anticoagulant ability of protein C.

The fibrinolytic system is activated at the same time as coagulation and functions to prevent tissue ischemia by limiting the extent of fibrin clot formation. Plasmin, primarily responsible for degradation of fibrin, exists in the plasma as the zymogen plasminogen. Plasminogen has a high affinity for fibrin, as does tissue plasminogen activator (tPA); because clots contain the necessary components to allow lysis from within, systemic plasmin formation is avoided. α_2-Antiplasmin (α_2-AP), the main physiologic inhibitor of plasmin, competes with the binding of plasminogen to fibrin, and the clot contains equal amounts of both glycoproteins. Because of this molar balance between α_2-AP and plasminogen, a normal blood clot does not lyse spontaneously, despite fixation of tPA. Physiologic plasminogen activator inhibitors (PAIs) are found in plasma, platelets, and endothelial cells; platelet-derived PAI protects a blood clot against premature lysis. Clot lysis is initiated if additional tPA is taken up from the surrounding tissues, and stasis upstream from the occluded vessel is a potent stimulus for release of endothelial tPA. Conversion of plasminogen to plasmin allows partial digestion of fibrin and exposure of additional plasminogen binding sites. When this additional plasminogen is converted to plasmin, the inhibitory effect of α_2-AP is overcome and clot lysis is accelerated. Plasmin hydrolyzes fibrinogen and fibrin with equal affinity, as well as numerous other procoagulants, and it can activate complement and kininogen. The physiologic actions of plasmin are limited to the fibrin clot by the affinity between the latter and plasminogen and the presence of α_2-AP in blood. Because of multiple interactions between the coagulation and fibrinolytic systems, the most important factor that determines the rate of fibrinolysis is the rate of fibrin formation.[31]

Inherited Coagulation Disorders

Jeffrey W. Norris

Reductions in protein levels and/or activities associated with coagulation pathways have been documented in all species of domestic herd animals. These deficiencies arise either as the result of genetic transmission or are acquired secondary to intoxication or an underlying disease process. In domestic herd animals, inherited coagulation defects have been associated with proteins in the intrinsic pathway of coagulation, specifically prekallikrein, factor XI, and factor VIII. Defects in von Willebrand factor (vWF), vitamin K–dependent coagulation proteins, and fibrinogen have also been reported. Here, attention is given to the underlying genetics associated with these deficiencies, as improvement of breeding programs is an important aspect of overall management when patients with inherited coagulation disorders are encountered.

Prekallikrein Deficiency

Deficiency of prekallikrein, which is involved in initiation of the intrinsic pathway of coagulation, has been described in families of both miniature horses in the United States and Belgian horses in Canada.[1,2] In the family of miniature horses, a 4-year-old intact male and his female sibling were identified as having approximately fivefold decreases in circulating prekallikrein activity but no history of inappropriate bleeding.[1] The family of Belgian horses was first identified when a 7-year-old stallion had inappropriate hemorrhage for 7 days following an otherwise uncomplicated castration surgery.[2] Despite packing the incision sites with gauze sponges, the horse's hematocrit decreased by 19% over this period of time.

During initiation of the intrinsic pathway of coagulation, prekallikrein and factor XII are thought to undergo coordinated activation in a reciprocal manner. Recent studies have demonstrated that these two factors play critical roles in thrombosis but not hemostasis.[3,4] This subtle role of prekallikrein in the coagulation system is consistent with observations that many patients with prekallikrein deficiency are asymptomatic, but bleeding in response to trauma (e.g., surgery) is possible.

Blood from the affected horses in these studies had prolonged activated partial thromboplastin times (aPTTs) but normal prothrombin times (PTs).[1,2] Prekallikrein activities in plasma from the two affected miniature horses were less than 20% that of normal horses, but insufficient data were available to determine if suspected carriers had significantly reduced circulating prekallikrein activity compared with clinically normal horses.[1] In addition to the Belgian stallion with a history of inappropriate bleeding, 13 members of his family had circulating prekallikrein levels below the reference range, including two full siblings with activities <3% of normal.[2] The sire of the affected stallion was found to have 19% of normal plasma prekallikrein activity, while levels in the mare were not determined. Therefore the reliability of prekallikrein activity testing to segregate unaffected carriers from normal horses is unclear. It is also unclear whether reduced prekallikrein activity found in these horses is due to reduced levels of circulating protein. The mode of inheritanceof prekallikrein deficiency in horses, although likely autosomal recessive, and the underlying genetic mutation have not been determined.

Factor XI Deficiency

Activation of factor XI is the second step of the intrinsic pathway of coagulation, and measurable deficiencies in factor XI activity have been reported in Holstein cattle in the United States, Canada, and the United Kingdom, as well as Japanese Black cattle.[5-8] The degree of inappropriate bleeding described in cattle with this deficiency ranges from absent to severe. Where reported, inappropriate bleeding incidents have included excessive bleeding from injection sites, petechial hemorrhage, hematoma formation, gastrointestinal hemorrhage, blood in the milk, and anemia.[5,7]

Clinical laboratory tests of the coagulation system yield expected results for a patient with a defect in the intrinsic pathway. Affected cattle have normal platelet counts and PTs.[5-7] In Holstein cattle, aPTTs are prolonged and inversely correlated with plasma factor XI activity.[9] The level of factor XI antigen in these cattle is proportionate to the factor XI activity present.[10] The use of these tests for screening affected cattle is limited because of the occurrence of false negatives in the heterozygote carrier population.[8-12]

Factor XI deficiency in cattle is transmitted as an autosomal recessive trait. Two mutations in the gene encoding factor XI, *F11*, have been associated with the deficiency of this coagulation factor and can be used to discriminate heterozygote carriers in herds.The first of these mutations to be discovered was a 76–base pair (bp) insertional mutation in exon 12 of *F11* that occurs in Holstein cattle.[13] This mutation has been reported in cattle as widely distributed geographically as the United States, Japan, Poland, and Turkey.[13-16] More recently, this mutation

has been identified in frozen semen used for breeding from two Indian Sahiwal *(Bos indicus)* cattle sires.[17] In Japanese Black cattle, factor XI deficiency is associated with a 15-bp insertional mutation in exon 9 of *F11*.[8]

Factor VIII Deficiency (Hemophilia A)

Factor VIII deficiency has been reported in a range of species, including horses, cattle, and sheep. The affected breeds of horses include Thoroughbreds, Standardbreds, Quarter Horses, and Tennessee Walking horses.[18-22] In cattle, this deficiency has been found in Herefords and Japanese Brown cattle.[23,24] In sheep, affected animals were originally restricted to a specific lineage of Alpine White sheep, but more recently this lineage has been expanded to establish a laboratory model of hemophilia A in human patients.[25,26] Inappropriate bleeding incidents described in these animals include epistaxis; petechial hemorrhage; formation of intramuscular hematomas, hemoarthroses, hemopericardium, and hemoperitoneum; as well as prolonged, life-threatening bleeding at sites of invasive procedures, umbilical cords, and following castration. Icterus, pale mucous membranes, and ventral edema are additional physical examination abnormalities that have been reported in these animals. Signs relating to factor VIII deficiency present at a young age ranging between immediately after birth to time of castration.

Patients with factor VIII deficiency have marked abnormalities in both standard clinical laboratory tests and coagulation tests. The results of standard clinical laboratory testing in these animals may include anemia, hypoproteinemia, neutropenia, the presence of reticulated platelets, hyponatremia, hypekalemia, and hypochloremia. Blood from these animals invariably has prolonged aPPTs and normal PTs. In one case, hypofibrinogenemia was reported coincident with increased D-dimer levels.[21] Inappropriate bleeding has been reported in animals with factor VIII activity levels that are approximately 15% of normal and lower.[21] Female parents of affected animals may have factor VIII activity within normal limits, but in many cases they are found to have moderate decreases in circulating factor VIII activity.[21,22,24,25,27] In cattle, marked decreases in factors IX and XI have also been reported in animals with factor VIII deficiency, although the converse has not been shown in cattle with factor XI deficiency.[22,23] The half-life of factor VIII is extended in circulation via noncovalent association with vWF, and animals with true deficiencies in factor VIII should also have normal levels of vWF.[20,27] It has not been reported if decreased circulating factor VIII activity correlates with a decrease in circulating factor VIII antigen levels in animals.

Congenital factor VIII deficiency is X-linked and recessive, with clinical disease only having been reported in male horses and cattle. In sheep, affected females have also been reported, which is consistent with reports in humans of affected females with homozygous mutations in the gene encoding factor VIII (*F8*) or heterozygous for an inactivating mutation in *F8* combined with inactivation of the X chromosome carrying the normal *F8* allele.[25,28,29] A T-to-A substitution at nucleotide 6459 in *F8* occurs in Japanese Brown cattle with factor VIII deficiency and results in the mutation of a highly conserved leucine to histidine in the C1 domain of factor VIII.[30] In the Tennessee Walking Horse with factor VIII deficiency, cDNA made from factor VIII mRNA was found to be missing the sequence encoded by exons 1 and 2.[22] Analysis of genomic DNA revealed a deletion and two single nucleotide polymorphisms (SNPs) in intron 1, which separates the two exons that were missing in the mRNA. All three of these mutations had the expected allelic variation for a maternally transmitted deficiency (i.e., homozygous in the colt and heterozygous in the mare).

Although factor replacement therapy is the most common approach to managing factor VIII deficiency in humans, experience with this approach in veterinary patients is limited. A newborn Standardbred colt with factor VIII deficiency survived for 7 months with transfusions of 1 to 3 pints of whole blood or plasma from donor horses being given at 2- to 3-day intervals over the first 3 months of life.[20] In contrast, a growing hematoma in a 9-day-old Thoroughbred colt with factor VIII deficiency improved for only 36 hours following whole blood and plasma transfusions from normal horses in conjunction with administration of antifibrinolytic therapy.[27] Overall, the prognosis for animals with factor VIII deficiency is poor, and historically most owners have chosen euthanasia.

Von Willebrand Factor Deficiency

In addition to stabilizing factor VIII in circulation, vWF promotes platelet-endothelial adhesion at sites of vascular injury. vWF deficiency was reported in a Quarter Horse filly that had multiple instances of inappropriate bleeding from mucous membranes, conjunctiva, and injection sites during the first 6 months of life.[31]

Clinical tests of the filly's coagulation function gave subtly altered results compared with normal horses. She had a normal platelet count, normal PT, and slightly prolonged aPTT. Plasma factor VIII clotting activity measured at the low end of the normal range. vWF antigen was reduced to 18% of normal and activity was less than 10% of normal in plasma from the filly.

Coagulation function, including factor VIII and vWF activities, was normal in the filly's dam, while the stallion was unavailable for study. Evidence that the vWF deficiency was heritable was obtained by protein electrophoresis that showed abnormal vWF structures in both the filly and the mare. Several types of vWF defects are recognized in human medicine with structural abnormalities being characteristic of type 2 vWF disease. The underlying mutation that led to vWF deficiency in the filly is unknown.

In Simmental cattle, vWF deficiency was first reported in a 10-month-old heifer with epistaxis and hematoma formation.[32] Despite observations that platelet counts and clinical coagulation tests were all within normal limits, inappropriate bleeding in this cow was corrected with administration of fresh-frozen, platelet-poor plasma. vWF antigen levels were normal in the heifer, but vWF activity was 25% of normal. Consistent with a heritable disease, two siblings of the cow were reported to have decreased vWF activities (52% and 30%). However, inappropriate bleeding episodes were not reported in these siblings. Similarly, in a separate study of the genetics underlying Simmental hereditary thrombopathy, a calf with vWF deficiency that had not suffered inappropriate bleeding episodes was identified.[33] In human patients, there is poor correlation between vWF levels and bleeding symptoms.[34]

The 10-month-old heifer and one of its siblings also had platelets with markedly reduced aggregation in response to the physiologic agonist ADP.[32] This has also been observed in human patients with platelet-type von Willebrand disease, as well as in a transgenic mouse model of this form of the disease.[35,36] However, the mutation leading to vWF deficiency in Simmental cattle is unknown, and additional testing is necessary to discriminate platelet-type von Willebrand disease from other types of vWF deficiency in these cattle.

Deficiency of Vitamin K–Dependent Factors

A combined deficiency of the vitamin K–dependent coagulation factors (factors II, VII, IX, and X) was reported in five lambs from a flock of Rambouillet sheep.[37] Signs became apparent in affected lambs at birth and included excessive subcutaneous

VetBooks.ir

bleeding, hemoarthroses, tissue pallor, and bleeding from the umbilicus in newborn lambs following parturition.

Extensive testing of the coagulation cascade provided evidence for a defect associated with vitamin K–dependent coagulation factors in these lambs.[37] Standard clinical coagulation tests (aPPT and PT) were prolonged in affected lambs. In plasma from these lambs, activities of factor X and protein C were undetectable, while the activities of factors II, VII, and IX were markedly decreased. However, no abnormalities in either clinical coagulation test or any of the activities from the aforementioned individual factors were detected in the sire or ewes from which the affected lambs were bred. A study of liver samples collected at necropsy from the affected lambs showed no evidence for the presence of 10 vitamin K antagonists, including warfarin. Subsequent studies found that γ-glutamyl carboxylase activities were reduced in liver samples from affected lambs compared with age-matched control lambs.[38]

The affected lambs were produced following breeding of three ewes to a single sire across multiple years. This observation combined with the reduced γ-glutamyl carboxylase activities in liver samples from the lambs suggested the deficiency was inherited.[37,38] Breeding data from the original study also supported an autosomal recessive mode of transmission.[37] Genetic analysis of the flock revealed a single nucleotide polymorphismin exon 4 of the gene encoding γ-glutamyl carboxylase, *GGCX*, with the expected allelic frequencies in the affected lambs and their parents.[38] This mutation creates a STOP codon leading to premature termination of the protein.

Fibrinogen Deficiency

Fibrinogen, factor I, deficiency can be associated with an absolute loss of total circulating fibrinogen, afibrinogenemia, or a loss of clotting capacity, dysfibrinogenemia. Afibrinogenemia has been reported in a Saanen kid.[39] Although the underlying genomic mutation is unknown, heritability of the afibrinogenemia was demonstrated through a backcross to the doe, which led to the hypothesis that transmission was autosomal and had incomplete dominance. A likely case of dysfibrinogenemia was reported for a Border Leicester lamb; however, heritability was not determined.[40]

Signs associated with fibrinogen deficiency are severe. The Saanen kid was reported to have experienced prolonged umbilical bleeding, hematomas, hemarthroses, anemia, and prolonged bleeding from venipuncture sites.[39] Inappropriate bleeding episodes occurred with increasing frequency in this patient, and she survived for approximately 14 months. Similar signs were reported in the Border Leicester lamb, which was euthanized after diagnosis.[40]

Clinical coagulation tests will show prolongation of both aPTT and PT in cases of fibrinogen deficiency but are not capable of discriminating fibrinogen deficiency from inherited or acquired deficiencies in vitamin K–dependent coagulation factors. Antigen amount and functional tests for fibrinogen should be used together when assessing possible cases of fibrinogen deficiency as no one test can discriminate afibrinogenemia from dysfibringenemia.[41]

Thrombasthenias

Jeffrey W. Norris • Monica Aleman • Fern Tablin

Thrombasthenias, which are rare, often inherited, defects in platelet function, result in spontaneous or excessive bleeding. Unlike common clinical tests for specific coagulation factors, aPTT, PT, and platelet counts are unremarkable. However, prolongation of template or buccal mucosal bleeding times are common. Diagnosis frequently requires platelet-specific and genetic testing.

Glanzmann Thrombasthenia

Glanzmann thrombasthenia (GT) results from either quantitative or qualitative deficiencies of the platelet membrane integrin $\alpha_{IIb}\beta_3$ (glycoprotein IIb-IIIa). α_{IIb} and β_3 proteins, expressed by separate genes, form heterodimers that bind fibrinogen and mediate platelet aggregation.

Clinical signs are spontaneous bleeding episodes including chronic, intermittent epistaxis unrelated to exercise; petechial and ecchymotic hemorrhages; hematomas; and prolonged bleeding following surgical procedures or venipuncture. GT platelets have normal morphology, coagulation parameters, and fibrin degradation products.[1-5] GT platelets are unable to aggregate in response to collagen or ADP and blood from GT horses forms loose clots, with limited serum separation and decreased tensile strength.[1-5] Flow cytometry has documented marked decreases in $\alpha_{IIb}\beta_3$ integrin on the platelet surface.[3]

Genetic analyses of horses with GT have documented mutations in the gene encoding α_{IIb} *(ITGA2B)*. Currently, there are three documented mutations in this gene associated with GT. The first mutation to be identified in a Thoroughbred-cross gelding was a homozygous mutation in exon 2.[5] A Quarter Horse mare that was found to be heterozygous for this exon 2 missense mutation also had a 10-base pair deletion in the second *ITGA2B* allele associated with a splice site for exon 11.[6] This deletion was subsequently found to occur with homozygosity in a Peruvian Paso horse as well.[7] The third mutation in *ITGA2B* associated with GT was in an Oldenburg filly, which was homozygous for a distinct missense mutation in exon 2.[8]

Owners of GT horses should be alert for signs of bleeding requiring supportive care and regularly monitor for anemia.[7]

Atypical Equine Thrombasthenia

Another platelet defect was identified in a Thoroughbred filly with excessive prolonged bleeding following pin-firing.[9] In addition to this index case, the Tablin laboratory identified five other Thoroughbreds with atypical equine thrombasthenia (AET).[9-11]

AET platelets form normal clots, have normal expression of the $\alpha_{IIb}\beta_3$ integrin, and aggregate normally in response to ADP.[9,10,12] However, AET platelets simulated with low-dose thrombin have significantly reduced fibrinogen binding.[10,11] AET platelets have limited prothrombinase activity and reduced factor V released from AET platelet alpha granules.[11,12]

Treatment of bleeding has been managed with the antifibrinolytic agent ε-aminocaproic acid. Thoroughbred horses with characteristics of AET should be considered at risk for excessive bleeding during surgery.

Simmental Hereditary Thrombopathy

Spontaneous bleeding in Simmental cattle, Simmental hereditary thrombopathy (SHT), was first described in animals from Canada and the United States.[13,14] Cattle present with spontaneous hemorrhage, resultant anemia, and superficial hematomas. Prolonged bleeding secondary to tattooing or ear-tagging is commonly reported by owners.

Blood from SHT cattle has diminished clot retraction and reduced aggregation in response to ADP or collagen.[14-16] SHT platelets have normal morphology and normal calcium-dependent shape change in response to ADP.[14,17] However, SHT platelets fail to aggregate in response to the calcium ionophore A23187.[14,16,17]

The genetic transmission of SHT was investigated in Canadian Simmental cattle, and a homozygous missense mutation in exon 7 of the gene encoding calcium diacylglycerol guanine nucleotide exchange factor I (CalDAG-GEFI), *RASGRP2*, was identified in a heifer. A number of clinically normal calves in this study were heterozygous for the mutation.[18,19] The mutation leads to a change in a conserved region of the catalytic domain of CalDAG-GEFI, a protein necessary for calcium-dependent activation of the integrin $\alpha_{IIb}\beta_3$.[19] SHT platelets have delayed calcium signaling resulting in delayed integrin activation.[20]

Bovine Chediak-Higashi Syndrome

Chediak-Higashi syndrome (CHS), characterized by abnormal secretory granules in platelets, leukocytes, and melanocytes, has been identified in Holstein, Brangus, and Japanese Black cattle.[21-23] A marked reduction of CHS platelet dense granules leads to excessive bleeding.[25-27] Dense granules have markedly reduced ADP content and release disproportionately less ADP, yet platelets aggregate normally in response to ADP.[24,28,29] Importantly, CHS platelets have a slow and transient aggregation in response to collagen.[24,29] A missense mutation was identified in the gene encoding the protein lysosomal trafficking regulator, *LYST*.[30,31] The mutation is autosomal recessive, and one study found that 8.8% of Japanese Black cattle were carriers.[32]

Additional signs of CHS include hypopigmentation of skin, hair, and eyes; photophobia; and increased susceptibility to infection. Breed information combined with coat color dilution in cattle presenting with infections or inappropriate bleeding suggests CHS. However, coat color dilution in CHS Japanese Black cattle is mild and insufficient to discriminate affected from normal cattle.[27]

Acquired Hemostatic Disorders

Johanna L. Watson

Acquired defects of hemostasis may be divided into those involving blood vessels, platelets, and coagulation factors, although some diseases affect more than one component.

Vasculitis

Vasculitis is a clinicopathologic process that involves inflammation and necrosis of blood vessel walls, regardless of size, location, or cause.[1] Vasculitis in large animals is generally a secondary manifestation of a primary infectious, toxic, or neoplastic disorder and has characteristics of hypersensitivity vasculitis in humans. The predominant involvement of small vessels in the skin (e.g., venules, arterioles) is the hallmark of hypersensitivity vasculitis.

Clinical manifestations of vasculitis include demarcated areas of dermal or subcutaneous edema that may progress to skin infarction, necrosis, and exudation.[2] Hyperemia, petechial and ecchymotic hemorrhages, and ulceration of mucous membranes are common. Although the skin and mucous membranes are predominantly involved, hemorrhage and necrosis may occur in any organ system, resulting in lameness, colic, dyspnea, and/or ataxia. Subclinical renal disease is not uncommon. Vasculitis is often associated with adverse sequelae such as cellulitis, thrombophlebitis, laminitis, and pneumonia. Characterized vasculitis syndromes with predominant cutaneous involvement include equine purpura hemorrhagica (EPH), equine viral arteritis (EVA), equine infectious anemia (EIA), and *equine granulocytic* anaplasmosis (EGA). There are also a number of vasculitis syndromes in horses for which cause, pathogenesis, and clinical course are poorly defined.[3,4] Vasculitis is apparently uncommon in ruminants but may accompany certain septicemic diseases (e.g., malignant catarrhal fever of cattle, bluetongue of sheep).[5] Hematologic and serum biochemical findings in vasculitis are determined by the underlying disease, length of illness, organ involvement, and secondary complications. Chronic inflammation may be attended by neutrophilia, mild anemia, hyperglobulinemia, and hyperfibrinogenemia. Some horses with EPH develop a moderate anemia (PCV 20% to 25%) that is thought to be caused by increased erythrocyte destruction.[6] The platelet count is generally normal. Muscle damage may be reflected by increased serum concentrations of creatine phosphokinase (CPK) and aspartate aminotransferase (AST). The creatinine may be elevated, and urinalysis may rarely show trace hematuria or proteinuria if there is glomerulonephritis.

Definitive diagnosis of vasculitis is made by demonstration of the characteristic histopathology of involved vessels. Full-thickness punch biopsies (at least 6 mm in diameter) of skin in an affected area should be obtained and preserved in 10% formalin and Michel's transport medium. Multiple biopsies from different sites may be necessary to reach the diagnosis. The most common inflammatory pattern is neutrophilic infiltration of venules in the dermis and subcutaneous tissue, with nuclear debris in and around involved vessels (leukocytoclasis) and fibrinoid necrosis. Considerable evidence suggests that most vasculitis syndromes are mediated by immunologic mechanisms—that is, a hypersensitivity reaction to a microbe, drug, toxin, or protein.[1] In some instances, an exogenous stimulus cannot be identified and an autoimmune pathogenesis is suspected. Immune complex deposition in vessel walls, with subsequent complement activation and chemoattractant production, seems to be the major pathogenic mechanism. Immunofluorescence on biopsies preserved in Michel's medium may reveal immune complexes. Infiltrating neutrophils and macrophages release proteolytic enzymes that cause vessel wall necrosis with subsequent edema, hemorrhage, and infarction of supplied tissues. Size and physiochemical properties of immune complexes, blood flow turbulence in sites of vessel bifurcation, and hydrostatic forces in dependent areas account for preferential formation of lesions in certain disease states and anatomic locations. Horses and cattle with idiopathic vasculitis may have incomplete response to therapy with an unpredictable poor prognosis.[5,6]

Equine Purpura Hemorrhagica

Purpura hemorrhagica (PH) is a noncontagious disease of horses characterized by vasculitis leading to extensive edema and hemorrhage of the mucosa and subcutaneous tissue. The disease has been recognized as a sequela to infection with or exposure to *Streptococcus equi*, *Streptococcus zooepidemicus*, *Rhodococcus equi*, *Corynebacterium pseudotuberculosis*, and others, as well as vaccination against *S. equi*.[2,7]

Young to middle-aged horses are commonly affected (mean, 8.4 years of age; range, 6 months to 19 years).[7] Clinical signs usually develop acutely within 2 to 4 weeks of a respiratory infection.[8] Predominant signs are well-demarcated subcutaneous edema of all four limbs, lethargy, anorexia, hemorrhages on mucous membranes, fever, and tachycardia. Other signs are tachypnea, reluctance to move, serum exudation from the skin, colic, and epistaxis.

The predominant laboratory abnormalities include anemia, neutrophilia, hyperproteinemia, hyperfibrinogenemia, hyperglobulinemia, and elevated muscle enzymes. Thrombocytopenia is rarely detected in horses with PH.

Skin biopsy shows evidence of acute leukocytoclastic or nonleukocytoclastic vasculitis with necrosis of blood vessels. The lesions are marked dermal and subcutaneous hemorrhage, protein-rich edema, and multifocal areas of dermal infarction.

VetBooks.ir

VetBooks.ir

Small arteries and capillaries are swollen and infiltrated by degenerate or nondegenerate neutrophils. Hyaline thrombi may be observed.[7] Immune complexes have been demonstrated to be primarily composed of immunoglobulin (Ig)M or IgA and streptococcal M protein and may be present in capillaries and small blood vessels of horses with PH, leading to a type III hypersensitivity reaction.[9] Deposition of immune complexes in vessel walls and subsequent complement activation may result in cell death. Extensive hemorrhages in the dermis, subcutis, skeletal muscles, lungs, kidneys, spleen, intestinal walls, and blood vessels have been observed in postmortem examination.

Horses with infarctive PH can present with colic, lameness, muscle swelling, and stiffness.[10] Extensive GI infarction results in severe colic signs. Significant findings in these horses include leukocytoclastic vasculitis and necrosis of various tissues, neutrophilia with a left shift, hypoalbuminemia, and high serum creatine kinase.[10]

Treatment should aim to address the primary cause if identified, reduce the immune and inflammatory response, initiate antimicrobial therapy in cases of active infection or prevent infection if indicated, provide supportive care, and prevent complications. Horses with known streptococcal infection should receive penicillin (22,000 IU/kg of intramuscular [IM] procaine penicillin G twice daily, or IV potassium penicillin G q6h) or other antibiotic with excellent efficacy against streptococcal organisms for at least 2 weeks. Hydrotherapy, limb bandages, and light exercise (hand walk) have been helpful in reducing limb edema. Fluids administered IV or via nasogastric tube may be necessary for animals that become severely lethargic and fail to drink or those that develop dysphagia from laryngeal edema. Stridor and dyspnea may indicate the need for tracheostomy. Prolonged treatment with corticosteroids (2 to 4 weeks) has resulted in favorable outcome and low relapse rate. However, some horses may require a longer course of therapy than 4 weeks. Depending on severity of clinical signs, proposed dosages are 0.04 to 0.2 mg/kg of dexamethasone (IV, IM, or PO) once (morning) or twice a day, or 0.5 to 1 mg/kg of prednisolone PO once (morning) or twice a day, with gradual reduction of the dosage.[7] It has been suggested that antimicrobials be used throughout the course of corticosteroid therapy to reduce the occurrence of secondary sepsis.[2]

Outcomes will depend on early detection, early aggressive treatment, and extent of organ involvement. Skin sloughing, laminitis, cellulitis, pneumonia, and diarrhea are common and may significantly prolong convalescence. The prognosis is fair with early aggressive therapy and supportive care; a retrospective study of 53 horses with purpura hemorrhagica reported a mortality rate of 7.5%.[7]

Equine Viral Arteritis

Equine viral arteritis (EVA) is an infectious disease characterized by panvasculitis, edema, hemorrhage, and abortion in pregnant mares. EVA is caused by an enveloped, spherical, positive-stranded RNA virus with a diameter of 50 to 70 nm. Equine arteritis virus (EAV) is a nonarthropod-borne virus classified as a member of the new order Nidovirales within the family Arteriviridae.[11] EAV was first isolated from fetal lung collected during an epizootic of abortion in Bucyrus, Ohio.[12] Clinical signs may be absent or may develop 1 to 10 days after infection and include pyrexia, lethargy, anorexia, limb edema, stiffness, rhinorrhea, epiphora, conjunctivitis, rhinitis, and abortion. Edema of several regions can be observed, including periorbital, supraorbital, ventrum, mammary gland, scrotum, and limbs.[13] Other signs include urticarial rash, abortion, respiratory signs, ataxia, mucosal eruptions, submaxillary lymphadenopathy, and intermandibular and shoulder edema. EAV can present as epidemic abortion, with occasional fatalities in foals and adults. With natural exposure, abortion rate varies widely (<10% to >60%) and can occur from 3 to 10 months of gestation.[14] Infected mares do not become EAV carriers or chronic shedders and do not appear to have fertility problems.

Laboratory abnormalities are variable and not diagnostic for EVA. Experimentally infected mature horses had a consistent leukopenia due to neutropenia and lymphopenia.[15] After infection, EAV can be localized in macrophages and lymph nodes within 24 and 48 hours, respectively. Various tissues are affected, but blood vessels are the principal target of EAV. Within vessels, EAV localizes in endothelium, medial myocytes, and pericytes. The virus causes vasculitis with fibrinoid necrosis of the tunica media, abundant vascular and perivascular lymphocytic and lesser granulocytic infiltration with karyorrhexis, loss of endothelium, and formation of large fibrinocellular stratified thrombi.[13] Body cavity effusion is common.

The virus is mainly transmitted through aerosols from respiratory, urinary, or reproductive tract secretions of acutely infected animals. The other route of transmission is via semen from persistently infected stallions; the virus remains viable in fresh, chilled, and frozen semen.[14] Horizontal transmission via fomites is possible.[16] Natural EAV exposure results in long-term immunity to the disease. Mares and geldings eliminate virus within 60 days, but 30% to 60% of acutely infected stallions will become persistently infected, temporarily or permanently shedding virus in semen.[13] The virus is maintained in the accessory organs of the male reproductive tract (ampullae, vasa deferentia).[14] Seroprevalence for EAV is common in the Standardbred and warmblood breeds and, more recently, EAV infection has been established within some Quarter Horse populations.[17]

Laboratory diagnosis of EVA can be based on virus isolation, viral nucleic acid detection (polymerase chain reaction [PCR] assay), or serology. In the case of serology, a fourfold or more increase in serum neutralizing antibodies between acute and convalescent samples (3 weeks apart) is required for diagnosis. Stallions with positive titers of 1:4 should be tested for persistent infection by virus isolation from sperm-rich ejaculate.[14] Viral isolation and PCR can be attempted from respiratory secretions or fetal and placental tissues. Semen can be tested for viral shedding by culture, isolation, or PCR. Identification of carrier stallions is crucial in preventing dissemination of EAV. A modified live (ML) vaccine is commercially available (ARVAC [Zoetis Animal Health Inc, Kalamazoo, Mich., USA]). Vaccination will result in development of a serum titer that will be detected on EVA testing and cannot be distinguished from active infection. Horses vaccinated for the first time should have serum submitted to a U.S. Department of Agriculture (USDA)-approved laboratory to confirm seronegative status. After vaccination, these animals should be isolated for 28 days because they may temporarily shed the modified virus; however, there is no evidence that stallions vaccinated with the ML vaccine develop the carrier state.[18]

Equine Infectious Anemia

See section on hemolytic anemia.

Anaplasma Phagocytophila Infection in Horses

John E. Madigan

Definition and Etiology

Equine granulocytic ehrlichiosis (EGE) was first reported in the late 1960s in the foothills of northern California.[1] The

VetBooks.ir

disease is caused by *Anaplasma phagocytophila*. This organism was formerly known as *Ehrlichia equi*, but it was reclassified in the *Anaplasma* genus on the basis of genetic analysis.[2] Recently, the agents of human granulocytic ehrlichiosis (HGE), *Ehrlichia phagocytophila* and *E. equi*, were grouped into a single species and named *A. phagocytophila*.[2] These organisms are identical based on 16S rRNA gene sequences, and they have similar morphology, host cell tropism, and indirect fluorescent antibody (IFA) response.[3]

The organism is found within vacuoles (1.5 to 5 µm in diameter) in the cytoplasm of infected granulocytes, primarily neutrophils and eosinophils. These vacuoles or inclusion bodies are pleomorphic and contain one or more coccobacillus or large granular aggregates called *morulae*. The organisms are visible under light microscopy as deep blue to pale blue gray with Giemsa or Wright-Leishman stains.

Epidemiology

Since the disease was first reported in California,[4] cases have been diagnosed in Colorado, Connecticut,[5] Florida, Illinois, Minnesota, New Jersey, New York, Oregon, Washington, Wisconsin, Canada, Brazil, northern Europe, Poland, Italy, Pakistan, South Korea, Ukraine, and Israel.[6] Equine cases occur most commonly during late fall, winter, and spring. There is no apparent gender or age predilection, but the disease appears to be less severe in younger horses. Persistent, chronic, or latent infections or carrier status have not been demonstrated and are unlikely to occur, since the presence of *A. phagocytophila* is limited to the acute phase. Therefore it is also unlikely that infected horses could serve as reservoirs. Anaplasma phagocytophilum is a zoonotic infection with human infection occurring via tick bite. The disease is not contagious but could be readily transmitted through the administration of infected blood. The vectors of granulocytic ehrlichiosis are *Ixodes pacificus* in California, *Ixodes scapularis* in the eastern and midwestern United States, and *Ixodes ricinus* in Europe.[7-10] Potential or proposed reservoirs are white-footed mice, chipmunks, white-tailed deer, dusky-footed wood rats, cervids, lizards, and birds.[10]

Pathogenesis

The pathogenesis of the disease is unknown. Entry of the organism occurs after inoculation from a biting tick and is presumed to be spread via blood and/or lymph. The organism has cell tropism toward neutrophils and eosinophils, where it replicates within vacuoles, forming characteristic morulae. Presumed cytolysis, induction of inflammation, cell sequestration, consumption, or destruction result in the observed clinical signs and pancytopenia.[11] Modulation of clinical signs in experimental infection in horses occurs with dexamethasone treatment.[12] This indicates that the proinflammatory response plays a role in worsening disease severity and that disease severity can be decreased by modulating proinflammatory response.[12]

Cell- and humoral-mediated immune responses develop in affected animals. Antibody titers peak at 19 to 81 days after the onset of clinical signs, and immunity likely persists for a long period of time (>2 years).[13]

Clinical Signs

Clinical signs vary depending on the stage of infection. Early signs are fever of unknown origin and partial anorexia. Further signs develop over 24 to 48 hours and include reluctance to move, fever ranging from 39.4° to 41.3° C (102.9° to 106.3° F), mild to moderate tachycardia (50 to 60 beats per minute [bpm]), lethargy, decreased appetite, limb edema, petechiation, icterus, weakness, ataxia, and recumbency (reported in one case). Secondary trauma may result from falling in severely ataxic horses. Additional presentations besides the classic signs described may occur. Several reports of cardiac arrhythmias in clinical cases have been noted with premature ventricular contractions observed. Severe rhabdomyoliss may be the presenting clinical presentation in some cases.[14,15] The clinical signs appear to be less profound in younger horses. The incubation period after natural infection is believed to be fewer than 14 days. The prepatent period after experimental exposure to infected ticks or inoculation with infected blood is 8 to 12 days and 3 to 10 days, respectively. The disease is self-limiting and nonfatal provided no complications develop. However, affected horses may be predisposed to secondary bacterial, fungal, and viral infections.[1] Abortions and laminitis have not been reported in affected horses.

Clinical Pathology

Laboratory alterations include anemia, leukopenia characterized by granulocytopenia and lymphopenia, and thrombocytopenia. Morulae will be observed within the cytoplasm of neutrophils and eosinophils during the infection.

Diagnosis

Definitive diagnosis is based on the presence of characteristic morulae within the cytoplasm of neutrophils and eosinophils, or positive PCR assay for *A. phagocytophila* in peripheral blood (buffy coat).[16] Morulae may be observed in less than 1% of cells in the initial stages of the infection, rising to 20% to 50% of cells a few days later. False-positive morulae identification can occur when Dohle bodies in toxic neutrophils are mistaken for morulae. Therefore careful screening of a blood film and identification of several morulae is suggested. The history of Ixodes sp tick exposure should be a critical part of the history in suspected cases. A fourfold or greater increase in IFA titer of paired samples confirms recent exposure.[17]

Pathologic Findings

Petechiae and ecchymosis of subcutaneous tissues, as well as edema of the ventral abdomen, limbs, and prepuce, are characteristic in infected animals. Proliferative and necrotizing vasculitis, thromboses, and perivascular cuffing in subcutaneous tissue, fascia, kidneys, heart, brain, lungs, ovaries, and testes have been reported.[1,11]

Treatment, Prognosis, and Prevention

The treatment of choice is IV administration of oxytetracycline at 7 mg/kg, or oral administration of doxycycline at 20 mg/kg of body weight once a day for 5 to 7 days. Prompt response to treatment is seen within the first 24 hours. Supportive therapy may be necessary in some cases. In cases with severe ataxia, use of dexamethasone may hasten resolution of clinical signs. The disease can be self-limiting in 2 to 3 weeks if untreated. Prognosis is excellent provided no secondary complications develop. In experimental cases and reports of natural infection, there are no reports of laminitis associated with the infection. At present, prevention is limited to tick control.

Thrombocytopenia

Johanna L. Watson • Debra Deem Morris

Thrombocytopenia (platelet count <100,000/µL) can result from one or more of three basic mechanisms: (1) decreased or ineffective platelet production; (2) abnormal sequestration

VetBooks.ir

(usually in the spleen); or (3) increased platelet consumption or destruction. Thrombocytopenia causes a hemorrhagic diathesis characterized by multiple sites of small vessel bleeding. Petechial hemorrhages with or without ecchymotic hemorrhages can be found on the oral, nasal, or vaginal mucous membranes, as well as on the nictitans and sclera. Epistaxis, melena, hyphema, or microscopic hematuria may occur, but spontaneous hemorrhage is uncommon unless the platelet count is less than 10,000/μL. Prolonged bleeding from wounds, injections, or surgical procedures and the propensity to form hematomas after minor trauma are common when the platelet count is below 40,000/μL. Severe thrombocytopenia produces prolonged bleeding time and abnormal clot retraction without affecting clotting times or plasma fibrinogen.

Persistent life-threatening hemorrhage caused by thrombocytopenia may be treated with a transfusion of compatible fresh whole blood or, preferably, platelet-rich plasma. The latter may be produced by centrifugation of freshly collected blood, 3 to 5 minutes at 250 *g*.[1] Blood or plasma must be used immediately, and contact with glass must be prevented to avoid platelet adhesion and activation. Platelet transfusion is a transient life-saving measure, and the ultimate prognosis for thrombocytopenia depends on the cause.

Decreased production of platelets may occur secondary to replacement of the normal marrow architecture by neoplastic or inflammatory tissue (myelophthisic disease) or bone marrow aplasia. Both conditions are characterized by peripheral pancytopenia of variable severity and are extremely unusual in large animals. Myelophthisic disease with thrombocytopenia has been described in horses with various forms of myelogenous neoplasia[2-4] and eosinophilic myeloproliferative disorder.[5]

Hypoplastic anemia with leukopenia and thrombocytopenia has been reported in horses and cattle and is discussed later in the chapter in the section on aplastic anemia. Shortened platelet life span is by far the most common cause of thrombocytopenia in large animals. Increased platelet consumption accompanies DIC (discussed in the next section) and rare cases of vasculitis. Immune-mediated mechanisms result in platelet destruction.

Immune-mediated thrombocytopenia (IMTP) may be primary (idiopathic) or secondary to drug administration, infections, neoplasia, or other immunologic disorders. This disease is most common in horses and has been reported secondary to EIA,[6] lymphoma,[7] and autoimmune hemolytic anemia.[8] The clinical signs of IMTP include mucosal hemorrhages and the propensity to bleed from small blood vessels. Horses with idiopathic IMTP are usually bright, afebrile, and without overt hemorrhage despite severely reduced platelet numbers. Thrombocytopenia in a horse with obvious primary disease should prompt a thorough hemostatic workup to rule out DIC.

Alloimmune thrombocytopenia of neonates has been recognized as a spontaneous disease of human infants, piglets, foals, and mule foals.[9] Clinical signs include depression, loss of suckle, a bleeding tendency, blood loss, and rapidly developing anemia due to a profound thrombocytopenia. The condition occurs in multiparous dams, and immunoglobulins from the mare, found in her plasma, serum, and milk, bind to the foal's platelets. Alloimmune thrombocytopenia should be considered in neonates with severe thrombocytopenia when other causes can be excluded, and platelet antibody assays should be used to support this diagnosis. Differential considerations include neonatal sepsis, neonatal maladjustment syndrome, and neonatal isoerythrolysis. Laboratory findings of IMTP include severe thrombocytopenia (<40,000/μL), prolonged bleeding time, and abnormal clot retraction with normal thrombin time (TT), PT, APTT, and plasma fibrinogen. Fibrin(ogen) degradation products (FDPs) may be mildly increased, and anemia accompanied by hypoproteinemia develops if there is ongoing blood loss. In most cases of IMTP and other causes for shortened platelet life span, megakaryocytic hyperplasia is evident on examination of bone marrow aspirates or biopsies. The definitive diagnosis of IMTP requires demonstration of increased quantities of platelet-associated IgG or C3 or antiplatelet activity in the serum. Flow cytometric methods to detect platelet surface–associated IgG (PSAIgG) have been adapted for horses.[10] Without PSAIgG testing, the diagnosis of IMTP must be based on small-vessel hemorrhagic diathesis and severe thrombocytopenia in a horse with normal coagulation times and no other evidence of DIC. Response to therapy (see next section) supports the diagnosis. A tentative diagnosis of IMTP in the horse should prompt a thorough search for an underlying disorder, especially lymphoma.

Platelet destruction in IMTP is mediated by antibodies coating the platelet surface that cause premature platelet removal from circulation by the MPS.[11] Autoantibodies may attach to megakaryocytes, but the latter are not necessarily destroyed because they do not circulate through the spleen or liver. In secondary IMTP the Ig bound to the platelet surface is part of an immune complex composed of antibody directed against a drug, microbe, or neoplastic antigen that is nonspecifically attached to the platelet Fc receptor. Drug-induced IMTP generally subsides within a few days of drug discontinuation, although thrombocytopenia secondary to chrysotherapy (gold therapy) may persist for weeks to years. Because gold is occasionally used to treat pemphigus foliaceus in horses, thrombocytopenia should be considered as a potential side effect. The spleen is the major site of platelet phagocytosis because (1) much antiplatelet antibody is secreted locally, (2) more than 30% of circulating platelets are normally stored there, and (3) the stagnant splenic blood flow allows sensitized platelets to pass slowly through a dense network of phagocytic cells.

When any unexplained case of thrombocytopenia is treated, all current medication should be stopped. If a drug is absolutely necessary, it must be replaced by the chemically most dissimilar substitute. Drug-induced IMTP usually responds within 14 days of drug withdrawal. Most animals with suspected IMTP improve when treated with corticosteroids. Although their precise mechanisms of action are speculative, corticosteroids improve capillary integrity, impair clearance by the MPS, decrease the number and avidity of macrophage Fc receptors, impair antiplatelet antibody production, impede platelet-antibody interactions, and increase thrombocytopoiesis.

Dexamethasone (0.04 to 0.2 mg/kg IV or IM) given once daily generally results in an elevation in the platelet count within 4 to 7 days. Once the platelet count is greater than 100,000/μL, the dose of dexamethasone can be reduced by 10% to 20% daily while the platelet count is monitored for a relapse. Occasionally, animals with IMTP are refractory to dexamethasone, in which case prednisolone (0.5 to 1 mg/kg IM twice daily) may be tried. Treatment with corticosteroids can usually be discontinued after a period of 10 to 21 days, provided the platelet count has been normal for at least 5 days. Most horses with IMTP have a favorable prognosis, and the disease resolves within 14 to 21 days. This suggests that many cases may be secondary, yet the initiating cause is rarely found. Chronic or recurrent IMTP requiring prolonged corticosteroid therapy has been reported.[12] Alternative treatment modalities for IMTP are largely unproven in horses because most cases are responsive to corticosteroids.[13-15]

Disorders of Coagulation Factors

Johanna L. Watson • Debra Deem Morris

Normal blood coagulation proceeds in an integrated sequence that can be simplistically viewed as three key reactions:

formation of activated factor X, formation of thrombin, and formation of fibrin. Other protein interactions serve to accelerate or inhibit the reaction rates of coagulation factors. Excessive use or inhibition of these proteins produces a relative deficiency that causes hemorrhagic diathesis. Alterations in the coagulation cascade, including thrombocytopenia and procoagulant and anticoagulant effects, can be observed with snakebite (e.g., rattlesnake) envenomation (see Chapter 54).

Disseminated Intravascular Coagulation

The most common form of hemostatic dysfunction in large animals is a syndrome known variously as disseminated intravascular coagulation (DIC).[1,2] The pathologic process is characterized by widespread fibrin deposition in the microcirculationand development of a hemorrhagic diathesis caused by the consumption of procoagulants and hyperactivity of fibrinolysis. Never a primary disease entity, DIC represents an intermediary mechanism of underlying disease. In large animals, DIC has been described in association with localized or systemic septic processes,[2-5] neoplasia,[2] GI disorders,[6] renal disease,[6] and hemolytic anemia.[5,7] Diffuse activation of the hemostatic system is particularly prevalent in horses with acute GI disorders that cause colic[5,6] and is a likely initiating factor for laminitis.[8,9] Clinical manifestations of DIC may fall anywhere on the spectrum from diffuse thrombosis leading to ischemic organ failure to severe hemorrhagic diathesis. The most important determinants are the rate of thrombin generation, adequacy of fibrinolysis, and functional state of the MPS, which is largely determined by peripheral circulation. Coagulopathy usually occurs in a compensated form in horses and cattle and is rarely attended by overt hemorrhage; however, microvascular thrombosis and subsequent ischemia to vital tissues leads to organ malfunction (e.g., renal failure), which contributes to the morbidity and mortality of the primary disease process.

Renal involvement is common in DIC, which produces ischemic cortical necrosis followed by acute tubular necrosis. Renal disease may be manifested by oliguria, depression, and ileus caused by azotemia and electrolyte imbalances. GI microthrombosis may induce colic as a result of submucosal necrosis and superficial ulceration. Spontaneous GI hemorrhage caused by DIC may cause melena in ruminants and occult fecal blood loss in horses. Pulmonary function may rarely be compromised by microvascular thrombosis in DIC, causing tachypnea and variable hypoxemia. Altered consciousness, delirium, convulsions, or coma may follow cerebral microvascular thrombosis but is not common with DIC in large animals. Although reported in both horses[10] and cattle,[7] microangiopathic hemolysis is rare in large animals with DIC because of their small erythrocyte size.

Digital ischemia frequently accompanies DIC in horses and may play a role in the development of acute laminitis. Laboratory evidence of DIC has been documented during the developmental phase of equine laminitis,[9] and digital microvascular thrombosis occurs in horses that develop laminitis with colic or septic conditions.[8] The tendency for thrombosis of major peripheral veins is another prominent manifestation of coagulopathy in horses.

As the thrombotic stimulus continues or intensifies, the tendency for hemorrhage develops because of clotting factors and platelet depletion or generation of excessive fibrinolytic by-products (FDPs). Petechial or ecchymotic hemorrhages on mucosae and sclerae and a tendency to bleed from venipuncture or after minor trauma are the principal signs. Spontaneous life-threatening hemorrhage is rare, but trauma or surgery may induce uncontrollable hemorrhage. Diseases that must be differentiated from DIC include IMTP, warfarin toxicosis (horses), moldy sweet clover toxicosis, and inherited coagulation abnormalities.

Numerous laboratory tests of hemostasis may be abnormal during DIC, but no one test consistently or specifically provides a definitive diagnosis. The lack of test sensitivity is due to the dynamic nature of DIC, the laboratory reflection of which is determined by the balance between coagulation and fibrinolytic forces, as well as MPS integrity at the time of blood sampling.

The most widely used hemostatic function tests for DIC in large animals include platelet count, plasma fibrinogen, PT, APTT, antithrombin (AT), and serum FDPs/D-dimers.[11] Because clinical manifestations of DIC vary widely, clarification of the most frequent laboratory abnormalities in large animals with DIC is hindered by lack of a definitive diagnosis in most instances. Repeated hemostatic testing is advised when there is strong suspicion for DIC. Serum FDPs are most often elevated by DIC, but they are usually normal in the early or compensated form of the disease. Hypofibrinogenemia is an uncommon manifestation of DIC in large animals and, when present, should strongly suggest concomitant liver dysfunction. Hemostatic function tests are totally unreliable unless blood samples are collected and handled properly.

Criteria used for diagnosis of DIC are extremely arbitrary, and laboratory results must be interpreted in light of the patient's underlying disease. The combination of thrombocytopenia with mild to moderate PT or APTT prolongation strongly suggests DIC. The clinician should seek laboratory assistance when considering the diagnosis of DIC but appreciate that the findings are often not helpful. Clinical signs and specific situations suggest the possibility of DIC, and laboratory tests are only used to provide support.

Diseases initiate DIC by two major mechanisms: (1) generation of excessive procoagulant activity within the blood or (2) contact of blood with abnormal surfaces. Many diseases that produce DIC have the propensity to cause endotoxemia. The intestinal tract in large animals normally contains large quantities of endotoxins, only a small part of which is absorbed through the portal vein and removed by the liver. Conditions that cause intestinal mucosal edema or disruption allow endotoxins to gain access to the peripheral circulation and initiate many morbid sequelae, one of which is DIC. Intestinal strangulating obstruction, thromboembolic infarction, and severe colitis induce mucosal abnormalities, allowing endotoxemia to occur. The proliferation of gram-negative bacteria within tissues and the blood is also accompanied by endotoxemia.

Gram-negative endotoxins are capable of direct factor XII activation. However, most studies indicate that the procoagulant effects of endotoxin are primarily mediated by cytokine production by mononuclear phagocytes.[12] After endotoxin stimulation, phagocytes produce a platelet-activating factor (PAF), tissue factor, prostaglandins, interleukins (ILs), tumor necrosis factor (TNF), and other mediators with procoagulant activity.[13]

The net result of any triggering mechanism for DIC is exaggerated generation of systemic thrombin, which causes widespread microcirculatory thrombosis. In addition to the cleavage of fibrinogen to produce fibrin monomers, thrombin activates factor XIII to render fibrin more resistant to fibrinolysis, enhances the cofactor activity of factors V and VIII, and induces platelet aggregation and exposure of platelet phospholipid. Circulatory obstruction produces organ hypoperfusion, leading to ischemic necrosis.

The counterbalance fibrinolytic system is also activated by DIC, and plasmin contributes to factor consumption by destroying factors V, VIII, XIIa, IX, and XI, in addition to fibrin and fibrinogen. FDPs contribute greatly to the hemorrhagic manifestations of DIC because they have antithrombin activity, interfere with fibrin monomer polymerization, and cause platelet dysfunction. Paradoxically the combination of

consumption and anticoagulation predisposes to hemorrhage at the same time disseminated thromboses occur.

The MPS plays a vital role in the pathogenesis of DIC. The tissue-fixed macrophages of the spleen and liver normally remove FDPs and activated clotting factors from the peripheral circulation, and FDPs only increase when their rate of formation exceeds the ability of the MPS to clear them. Shock and hypoperfusion of the liver and spleen or diseases associated with excessive tissue debris that must be removed by the MPS (e.g., sepsis, metastatic neoplasia) reduce its ability to function effectively and predispose to or perpetuate DIC.

Therapy for DIC is highly controversial, and the only undisputed modalities are those directed toward identification and treatment of the primary disorder, along with general supportive measures to combat shock and maintain tissue perfusion.[14,15] Intravenous fluid administration helps prevent organ dysfunction after microvascular thrombosis and can correct existing acid-base or electrolyte imbalances. Septic conditions should be treated with appropriate antimicrobial agents, and necrotic tissue or purulent exudate should be removed whenever possible (e.g., immediate surgical intervention to resect nonviable bowel). Flunixin meglumine mitigates the deleterious effects of endotoxin caused by eicosanoids and is used in horses at a dosage of 0.25 mg/kg IV q8h). Corticosteroids may worsen DIC because they reduce the phagocytic action of the MPS and potentiate the vasoconstrictor effects of catecholamines.

Significant life-threatening hemorrhage is rare in large animals with DIC, but if it occurs, fresh plasma should be administered (15 to 30 mL/kg) to replace used coagulant and anticoagulant proteins. The use of low-molecular-weight heparin, over unfractionated heparin, in DIC has been recommended in various regimens to stall the disseminated microvascular thrombosis that precipitates organ failure.[11,16,17] In dogs, minidose heparin therapy (50 to 75 units/kg subcutaneously [SC] three times daily, or 5 to 10 units/kg/h) is commonly used with blood products to treat DIC.[14] Efficacy of heparin for DIC in horses is unproven. Heparin in all species can predispose to hemorrhage, thrombosis, and thrombocytopenia[16] and can cause anemia and erythrocyte agglutination in horses.[17] If heparin therapy is considered, one must ensure there is adequate plasma AT III, which is necessary for heparin action. Because AT III is often depleted by DIC, plasma may be necessary.

The prognosis for DIC in large animals depends largely on the nature and severity of the underlying disease and how effectively the latter is treated. Once DIC has progressed to the stage where signs of coagulation dysfunction predominate, the prognosis is generally poor.

Warfarin Toxicosis

Horses may develop a hemorrhagic diathesis due to warfarin toxicosis.[18] This coumarin-derivative anticoagulant has been used by some to treat horses with navicular disease.[19] Rarely, horses and other animals may be exposed to coumarins used as rodenticides in grains or other feedstuffs. The clinical signs of warfarin toxicosis include hematomas, ecchymoses of mucous membranes, epistaxis, and hematuria. The earliest laboratory indication of warfarin toxicosis is prolongation of the PT, because the plasma half-life of factor VII is shorter than the other clotting factors.[20] As the disease progresses, the APTT becomes prolonged and the animal may develop blood-loss anemia and hypoproteinemia. The diagnosis of warfarin toxicosis is based on a history of exposure, clinical signs of large-vessel hemorrhagic diathesis, and prolonged PT with or without APTT and with no other abnormalities of the clotting profile.

Warfarin acts through competitive inhibition of vitamin K, which is necessary for liver production of clotting factors II, VII, IX, and X.[19] Factor activity is reduced in the blood at a rate dependent on its individual half-life. In most species, factors VII, IX, X, and XI have increasingly greater half-lives, accounting for the greater sensitivity of PT for the early diagnosis of warfarin toxicosis. After GI absorption, warfarin is highly bound to plasma proteins. Drugs that are normally protein bound (e.g., phenylbutazone) can enhance warfarin's toxicity by allowing a greater proportion of the administered drug to be unbound and active.[21] In the same manner, hypoalbuminemia may increase the likelihood of warfarin toxicosis. Corticosteroids and thyroxin can lower the necessary therapeutic dose of warfarin by increasing both receptor affinity and clotting factor catabolism. Drugs that induce hepatic microsomal enzyme activity (e.g., barbiturates, rifampin, chloramphenicol) can accelerate warfarin metabolism and reduce therapeutic response to a given dose. Any reduction in hepatic function or content of vitamin K in the diet can also precipitate warfarin toxicosis.

Treatment of warfarin toxicosis depends on clinical signs. Warfarin therapy should be stopped if the PT exceeds twice the pretherapeutic value. Vitamin K_1 (0.5 to 1 mg/kg SC or IM) must be given every 6 hours until the PT is again normal and stable. Significant hemorrhage can be controlled by giving fresh plasma to provide necessary clotting factors. If the anemia is life threatening, whole blood transfusion should be considered. Although warfarin is eliminated rapidly, some potentiated coumarins have a prolonged half-life, requiring a longer course of vitamin K therapy. With early diagnosis and prompt vitamin K treatment, the prognosis for warfarin toxicosis is good. However, it is imperative that vitamin K_3 *not* be used because it has poor therapeutic action and is highly nephrotoxic for horses.[22]

Prevention of warfarin toxicosis is based on limiting access of livestock to rodenticides and carefully monitoring the therapeutic use of warfarin in horses. Warfarin's benefits for horses are highly controversial, and many question whether its advantages outweigh the risks.

Sweet Clover Toxicosis

Sweet clover (*Melilotus* spp.) toxicosis is caused by ingestion of moldy sweet clover hay or silage containing dicoumarol. Natural coumarins in sweet clover can be converted to dicoumarol when hay or silage is improperly cured and mold forms. The toxin persists in moldy hay or silage and is palatable. This disease can occur in all species but is most commonly seen in cattle fed sweet clover hay in the Northern Plains states. Early signs include epistaxis and melena, with the development of subcutaneous hematomas and periarticular swellings as the disease progresses. Visible swellings occur at points of trauma such as the brisket, tuber coxae, or carpi and are not hot or painful, although they may cause stiffness and disinclination to move. Accidental and surgical wounds cause severe hemorrhage and may precipitate fatal blood-loss anemia.

Clinical pathology is similar to that described for warfarin toxicosis, with prolonged PT being the earliest abnormality (detected before clinical evidence of hemorrhage). The platelet count remains normal, which differentiates this syndrome from DIC and bracken fern toxicosis. Other diagnostic ruleouts include mycotoxicosis and toxicosis from trichloroethylene-extracted soybean meal. In the absence of fever and anorexia, coagulopathy should make moldy sweet clover toxicosis a strong tentative diagnosis in animals with a history of access. Chemical analysis for dicoumarol in suspected feed or in the blood and liver of affected animals aids in the diagnosis,[23] but the disease cannot be excluded if dicoumarol is not detected.

The pathogenesis of moldy sweet clover toxicosis is identical to that of warfarin toxicosis. Dicoumarol interferes with hepatic

VetBooks.ir

synthesis of clotting factors II, VII, IX, and X by inhibiting vitamin K. Usually the syndrome appears in cattle 2 to 7 days after they ingest the moldy hay. Lower levels of dicoumarol (<70 mg/kg) in feed may prolong the onset of signs for up to 3 months.

Grazing sweet clover is not dangerous. Because of its high forage yield, sweet clover is usually harvested as silage, which should carry less danger of molding when properly cured. The toxic level of dicoumarol in sweet clover feed samples is 10 mg/kg of feed.[23]

Treatment of sweet clover toxicosis involves discontinuing the use of contaminated feed and administering vitamin K_1.[21] Dosages between 0.5 and 1 mg/kg of body weight should be administered SQ or IM every 6 hours; response occurs within 24 hours. Animals with severe blood-loss anemia or ongoing hemorrhage should be treated with plasma or whole fresh blood. Sweet clover toxicosis can be prevented by careful forage preparation, followed by the inspection of hay and silage before feeding. When the disease is suspected, questionable feed should be removed from the diet.

Diseases Associated With Increased Erythrocyte Destruction (Hemolytic Anemia)

Johanna L. Watson • Gary P. Carlson

Hemolytic disorders are characterized by an increased rate of red cell destruction, and anemia results when the rate of red cell destruction exceeds the bone marrow capacity for increased proliferative response. Although intravascular hemolysis occurs in some circumstances, these anemias are primarily due to an increased rate of extravascular erythrocyte destruction and shortened intravascular life span.

Hemolytic anemias are associated with a wide range of systemic disease processes. A list of differential considerations for possible causal factors of hemolytic anemia in large animals is presented in Box 37.1. Clinical manifestations of hemolytic anemia will vary with the degree of anemia, rate of red cell destruction, and primary or underlying disease process. However, several common clinical signs are seen in animals with severe hemolytic anemia, regardless of the cause: mucous membrane pallor, fatigue, depression, and anorexia. Clinical icterus can be quite variable depending on the rate of red cell destruction and the liver's ability to excrete bilirubin. Icterus is a characteristic feature in hemolytic anemia, but intense icterus is noted only after massive red cell destruction and is often transient. With continued low-level hemolytic processes, the liver may be able to excrete bilirubin at a rate sufficient to avoid clinical icterus. Hemolytic icterus must be differentiated from other potential causes like liver disease or anorexia in horses. If icterus is caused by hemolytic processes, clear clinical and hematologic evidence of anemia should exist. Massive intravascular hemolysis may result in an orange to reddish discoloration of the mucous membranes. Modest to marked and often variable febrile responses are frequently encountered in hemolytic anemias caused by infectious agents and during periods of active erythrocyte destruction. With advanced anemia the pulse and respiratory rates are elevated at rest. Death losses may occur, and neurologic abnormalities ranging from bizarre behavior to mania, collapse, and death may be associated with handling animals with severe anemia.

The hematologic manifestations of hemolytic anemia also vary with the rate of red cell destruction, time course of the anemia, and primary or underlying disease process. Anemia may be modest to severe, and after the first few days in all species except the horse, there is usually hematologic evidence of enhanced erythropoietic response seen as increased anisocytosis, polychromasia, reticulocytosis, and the presence of nucleated red blood cells in the circulation. Morphologic abnormalities of diagnostic significance (e.g., intracellular or epicellular parasites, granulocytic inclusion bodies, Heinz bodies, spherocytes, schistocytes, or poikilocytes) may be noted on examination of stained blood smears. Responsive anemias often are accompanied by neutrophilia and a regenerative left shift. Bone marrow usually shows an active erythropoietic response with a decreased myeloid/erythroid (M:E) ratio. The serum concentration of haptoglobin is decreased, and serum lactate dehydrogenase enzyme activity may be elevated during acute hemolytic episodes. An increase in serum bilirubin concentration caused primarily by an increase in indirect reacting bilirubin is a reflection of active red cell destruction. Specific serologic diagnostic procedures are available for many of the infectious causes of hemolytic anemia. Immunohematologic procedures like the direct and indirect Coombs test provide an indication that immune-mediated processes contribute to enhanced erythrocyte destruction. It should be noted that the principal mechanisms responsible for the increased rate of red cell destruction associated with many infectious causes of hemolytic anemia (parasitic, bacterial, viral) are immunologically mediated, and affected animals may be transiently Coombs positive.

BOX 37.1

Causes of Hemolytic Anemia

Infectious Causes

Parasitic

Anaplasmosis
Babesiosis
Hemobartonellosis
Eperythrozoonosis
Theileriasis
Trypanosomiasis

Bacterial

Leptospirosis
Bacillary hemoglobinuria

Viral

Equine infectious anemia (EIA)

Immune-Mediated Hemolytic Anemia

Autoimmune hemolytic anemia
Neonatal isoerythrolysis (NI)
Drug induced: penicillin, trimethoprim-sulfamethoxazole

Heinz Body Hemolytic Anemia

Phenothiazine toxicity
Wild onion poisoning
Red maple leaf poisoning

Other Causes

Severe cutaneous burns
L-Tryptophan-indole intoxication
Water intoxication
Postparturient hemoglobinuria
Copper poisoning
Hemolytic syndrome in horses with liver failure
Erythropoietic porphyria in Holstein cattle

Infectious Causes of Hemolytic Anemia

Bovine Anaplasmosis

Kristin A. Clothier

Etiology

Molecular characterization and genetic analysis of *Anaplasma* and *Ehrlichia* have resulted in identification of six species in the *Anaplasma* genus: *Anaplasma phagocytophilum* (formerly called both *Ehrlichia equi* and *Anaplasma equi*), which infects granulocytes in a wide range of mammalian species including dogs, horses, and humans; *A. marginale*, *A. ovis*, and *A. centrale*, which infect erythrocytes of wild and domestic ruminants; *Anaplasma bovis*, which infects monocytes of cattle and related species; and *Anaplasma platys*, which primarily affects platelets in small animal species.[1,2] Recently, a novel species has been identified in white-tailed deer and the name *Anaplasma odocolei* sp. nov. has been proposed.[1] Although many species become infected and demonstrate symptoms of disease due to *A. phagocytophilum* infection, there is no evidence that *A. marginale* or *A. ovis* is capable of infecting humans or any nonruminant mammalian species.

In livestock medicine, *anaplasmosis* traditionally refers to disease characterized by progressive anemia caused by intraerythrocytic infection with *A. marginale* in cattle and *A. ovis* in sheep and goats. In addition, *A. centrale* causes mild disease in cattle and has been used as a live vaccine to induce partial protection against *A. marginale*.[3] These organisms are obligate intracellular bacteria located either at the periphery (*A. marginale* and *A. ovis)* or center (*A. centrale)* of red blood cells (RBCs).[4,5] They reside and replicate inside parasitophorous vesicles and replicate by binary fission, with each vesicle containing four to eight organisms.[6]

Pathogenesis

Anaplasma spp. are naturally transmitted by ixodid species ticks, most commonly *Dermacentor* in the U.S. mainland and *Rhipicephalus* spp. (including tick species previously classified in the genus *Boophilus*) in tropical and subtropical regions worldwide.[1,3] When ingested by feeding ticks, *Anaplasma* spp. enter midgut epithelial cells, complete the first round of replication, migrate to salivary epithelial cells, undergo a second round of replication, and enter the saliva, where they can be passed to the next host. Organisms can be transmitted transstadially (from larvae to nymphs and nymphs to adults), indicating that ticks can become infective and transfer *Anaplasma* spp. to a new host after only a single molt. Transovarian transmission has not been demonstrated.[1,7]

In the host, sequential rounds of bacterial invasion of mature erythrocytes, replication, and egress result in a progressively increasing cell-associated bacteremia, with a doubling time of roughly 24 hours. Depending on the strain of *Anaplasma* spp. and host susceptibility, 10% to 90% of erythrocytes may become infected; clinical signs appear when more than 15% of erythrocytes are infected.[7,8] Bacteremia results in RBC membrane peroxidation with infected cells showing a 10-fold increase in membrane leakage over uninfected RBC.[6,8] Anemia is due to splenic and hepatic macrophage-mediated phagocytosis of infected erythrocytes.

A. marginale expresses a variety of major surface proteins (MSPs), which facilitate interactions with vertebrate and invertebrate host cells.[7,9] This plasticity facilitates development of different bacterial surface structures leading to immune evasion and persistent infection in the animal. Phylogenetic analyses of a variety of strains have demonstrated the coevolution of *A. marginale* with tick vectors.[1,7] In addition, cases have been documented in which individual animals are infected by more than one genotype of *A. marginale*.[6,7,10]

Protective immunity appears to require induction of both antibody against the outer membrane proteins and macrophage activation for enhanced phagocytosis and bacterial killing.[7] The regenerative response to anemia can be vigorous and begins by 20 days post infection. While the immune response controls the acute phase of infection, organisms are not completely cleared from the blood due to emergence of antigenic variants. Infected animals demonstrate cyclic subclinical peaks of rickettsemia and immune response with a 6- to 8-week period, establishing the chronic infection state.[6]

Epidemiology

A. marginale is the most prevalent of the tick-borne diseases of cattle worldwide and remains as a serious constraint to livestock production in tropical, subtropical, and even temperate regions.[11,12] In the United States, infection is endemic in much of the West, Midwest, and Southeast but occurs episodically in many states.[7] As of April 1, 2014, the disease is no longer federally reportable in Canada, and testing for entry into the country is not required. The expansion of anaplasmosis into previously nonendemic regions has been attributed to widespread movement of cattle and to the effects of global warming on vector expansion.[1,7,12]

Endemic regions are maintained by the prevalence of both competent tick vectors and persistently infected carrier cattle, which are typically asymptomatic but act as efficient reservoirs for tick-borne transmission to uninfected animals.[2,4] Vector activity varies by region, but outbreaks of anaplasmosis occur most frequently in the late spring and summer when arthropod activity is highest. Wild ruminants, including antelope, bighorn sheep, and elk have been experimentally infected with *A. marginale*, but the role they play in natural transmission is unknown. Male ticks can also remain persistently infected and a source for maintaining the bacteria in endemic regions.[4,11]

While tickborne transmission is perhaps the most investigated route of spread, with at least 20 different species of ticks identified as sources of infection, other activities in which blood transfer occurs can result in infection.[3,4] Fomites (surgical instruments, dehorning equipment, ear tagging devices) are important sources of risk, particularly in nonendemic regions where tick vectors are not present. Multiuse needles and other biting arthropods are implicated in mechanical dissemination for *A. marginale*.[1,3] Iatrogenic transmission can occur anytime and can be controlled by avoiding blood contamination during veterinary medical procedures.[3,11]

Clinical Presentation

Clinical signs are highly variable, from acute severe disease to subclinical infection, and reflect variation in virulence among pathogen strains, breed resistance, and age-related host susceptibility.[4,7] The incubation period is generally 10 to 30 days but can be as long as 60 days. Primary exposure in calf hood often produces asymptomatic or mild disease resulting in slight lethargy and anorexia for 24 to 48 hours.[6,7,10] Adult cattle are highly susceptible to acute disease characterized by a high fever ranging from 39.5° to 41° C (103° to 106° F), elevated heart rate, elevated respiratory rate, anorexia, lethargy, and in dairy cows, a dramatic decrease in milk production. Initial fever may be followed by subnormal temperatures, dry muzzle,

VetBooks.ir

and decreased rumination. Cattle may stagger or become aggressive as a result of cerebral hypoxia associated with anemia. Care must be taken not to stress severely anemic cattle because this may result in collapse and death. Mucous membranes are pallid or icteric if an animal has survived for 2 to 3 days past the acute crisis.[2,7] Additional clinical signs include constipation characterized by dark brown feces covered with mucus, pollakiuria with dark yellow urine, and abortion in late-gestation animals. Because hemolysis occurs extracellularly, hemoglobinuria is not present.[3,5] Differential diagnoses include diseases that can produce anemia and/or icterus (babesiosis, bacillary hemoglobinuria, leptospirosis); hepatotoxic plant poisonings *(Senecio)*, chemicals, and other causes of liver disease; and copper poisoning in sheep.

If an animal survives the acute crisis, the convalescent period is protracted (3 to 4 weeks) depending on the severity of the anemia, and icterus and weight loss are common. Recovered animals remain infected for life and serve as a reservoir for ongoing transmission. Although *A. ovis* infection in sheep and goats is often asymptomatic, anemia occasionally becomes severe enough to produce signs similar to those seen during *A. marginale* infection of cattle, particularly if they have conditions causing immunosuppression.[7,11]

Pathology

At necropsy, there are no pathognomonic lesions for the diagnosis of disease. In acute anaplasmosis the blood is thin, watery, and fails to clot readily. Mucous membranes, subcutaneous tissues, liver, and skeletal musculature are pale; in later stages of acute disease, the same tissues may be icteric. Splenomegaly is a consistent finding; hepatomegaly and gallbladder distention are commonly but less frequently observed.[7] Urine is deep yellow, but neither hemoglobinuria nor hematuria occurs, which helps differentiate anaplasmosis from other hemolytic diseases. Occasionally petechiae may be found in the subepicardium, subendocardium, and other serous membranes. Detection of *A. marginale*–infected erythrocytes within capillaries of Giemsa-stained histologic sections can be used to confirm a diagnosis of anaplasmosis. [5]

Diagnosis

Definitive diagnosis of acute anaplasmosis requires identification of *A. marginale*– or *A. ovis*–infected erythrocytes by microscopic examination or PCR in animals with severe anemia. *A. marginale* can best be detected in blood smears stained with Wright's, new methylene blue, or Giemsa stain.[3,5,7] The inclusion is composed of a small morula of 2 to 8 individual organisms and as little as 5% or as many as 70% of erythrocytes may be infected. Creating a blood smear from freshly collected blood in the field may increase the likelihood of detecting parasites over blood smears made from blood exposed to anticoagulants. PCR provides increased sensitivity over direct exam and can differentiate animals infected with *A. marginale*, *A.centrale*, and *A. phagocytophilum*.[13,14] A falling hematocrit provides an estimate of the severity of infection; PCV may drop precipitously within 24 to 48 hours and may decrease below 10% before death. Death can occur despite a PCV above 20% when the hemolytic crisis is acute. In protracted cases, serial monitoring of blood smears demonstrates a decrease in the percentage of infected erythrocytes and evidence of macrocytic, hypochromic red cell regeneration.[6]

Following recovery, cattle and sheep remain persistently infected with 0.000001% to 0.1% of erythrocytes affected, and detection of organisms in erythrocytes is unreliable. Serology can be used to identify persistently infected animals.[3,7] The competitive enzyme-linked immunosorbent assay (cELISA [VMRD Inc., Pullman, Wash.]) provides high sensitivity and specificity and is used for official testing by many regulatory agencies (USDA, the Office of International Epizootics, most if not all state diagnostic laboratories.)[7,11]

Treatment, Control, and Prevention

Therapy is aimed at minimizing or preventing the effects of *A. marginale* infection. Tetracyclines are the antibiotic of choice; however, once anemia is severe, treatment is often unsuccessful.[12] Short-acting oxytetracycline at 11 mg/kg IV q24h for 3 to 5 days or long-acting oxytetracycline at 20 mg/kg IM at 72-hour intervals may be effective.[2,7] Supportive therapy is important to maximize the chance of survival. If the PCV is 12% or below, whole blood transfusion (4 to 8 L) may be indicated to prevent death and shorten the convalescence period. A PCV of 8% or below indicates an unfavorable prognosis, and death often occurs despite appropriate antibiotic and supportive therapy. Antimicrobial therapy also neither eliminates persistent infection nor prevents disease, so alternative interventions are needed, especially in endemic areas.[7,11]

Control measures used vary depending on the geographic region and type of livestock production system. In endemic regions with high transmission rates, beef cattle are often allowed to become naturally infected at a young age and remain asymptomatic carriers with minimal risk of later acute disease.[2] In regions with lower transmission rates, live blood-based vaccines may be used to ensure infection of cattle at a young age, such as the trivalent *(A. marginale*, *Babesia bovis*, *Babesia bigemina)* live vaccine used in Australia. Similarly, live vaccines based on *A. centrale* or weakly virulent strains of *A. marginale* are commonly used in Africa, Asia, and Central and South America.[3,9] These vaccines are not licensed for use in the United States, largely because of the risk of transmitting known or newly emergent pathogens contaminating the blood-based vaccine. The exception to this is the licensing of a live vaccine for use in California (AnaVac [PHL Associates, Davis, Calif.]). Importantly, live vaccines should only be used in young animals and are contraindicated for pregnant and older animals. Killed vaccines are less efficacious and require multiple immunizations but can induce at least partial protection against severe morbidity and mortality. An experimental killed vaccine (Experimental Anaplasmosis Vaccine [University Products LLC, Baton Rouge, La.) has been licensed for use in 14 states and Puerto Rico.[11]

In the absence of immunoprophylaxis, anaplasmosis is usually controlled by preventing transmission. Advances in molecular characterization may provide additional targets for successful vaccine development.[12,15] Maintenance of an *A. marginale*–free herd in nonendemic areas can be accomplished by quarantine and serologic screening of all additions using the cELISA. In endemic regions, minimizing the exposure to vectors through strategic use of pastures, insecticides, and management of herd additions, as well as preventing iatrogenic transmission, can reduce the impacts of anaplasmosis.[2,7] Restricted use of antibiotics can also prevent elimination of the carrier status, which can protect from acute disease.[11] The risk of maintaining a fully susceptible herd within an endemic region should not be taken lightly.

Babesiosis

Johanna L. Watson • Jerry L. Zaugg

Babesiosis is a tick-borne intraerythrocytic disease of domestic and wild mammals and humans caused by protozoan parasites of the genera *Babesia* and *Theileria*. The acute disease is characterized by fever, hemolytic anemia, icterus, hemoglobinuria, and death. Although both morphologic and serologic

TABLE 37.1

***Babesia* Species (Babesiosis)**

Organism	Livestock Affected	Principal Geographic Distribution	Morphology of Organism	Tick Vectors
B. bigemina (B. bovis)	Cattle	Americas, Europe, Africa, Australia, Middle East	4.5 × 2.5 µm (large, round, and pyriform; acute angle)	*Boophilus annulatus*, *B. decoloratus*, *B. microplus* spp.
B. bovis (B. berbera, B. argentina)	Cattle	Americas, Europe, Russia, Africa, Asia, Australia	2.4 × 1.5 µm (small and more rounded; obtuse angle)	*B. annulatus*, *B. microplus*, *Ixodes* spp.[a]
B. divergens	Cattle	Europe	1.5 × 1.4 µm (small, narrow, and obtuse angle)	*Ixodes ricinus*
B. major	Cattle	Europe, Russia, North Africa, Middle East	2.6 × 1.5 µm (similar to *B. bigemina* but smaller)	*Haemaphysalis punctata*
B. jakimovi	Cattle	Asia	2-4.6 × 1.5-2.1 µm (large, round, and pyriform)	*I. ricinus*
B. ovate	Cattle	Japan	4.5 × 2.5 µm (large, round, and pyriform)	*Haemaphysalis longicornis*
B. caballi	Horses	Americas, Europe, Russia, Asia, Africa, Middle East	3 × 2 µm (large, pyriform; acute angle)	*Dermacentor*, *Hyalomma*, *Rhipicephalus* spp.
Theileria equi (B. equi)	Horses	Americas, Europe, Russia, Asia, Africa, Middle East	1-2 µm (small and rounded; Maltese cross is characteristic)	*Dermacentor*, *Hyalomma*, *Rhipicephalus* spp.
B. motasi	Sheep and goats	Europe, Russia, Asia, Middle East	3 × 2 µm (large, pyriform; acute angle)	*D. silvarum* (?), *Haemaphysalis* spp., *R. bursa*
B. ovis	Sheep and goats	Europe, Russia, Asia, Middle East	1.5 × 1 µm (small and more rounded; obtuse)	*I. ricinus* (?), *R. bursa*, *D. reticulatis* (?)
B. trautmanni	Swine	Europe, Africa, Russia	3.5 × 2 µm (large, narrow, and long; acute angle)	*R. sanguineus* (?), *Dermacentor* spp. (?) *Boophilus* spp. (?) *Hyalomma* spp. (?)
B. perroncitoi	Swine	Europe, Africa, Asia	0.7-2 µm (small and more rounded)	Vectors unknown

[a]Suspected vector.From Kuttler, KL: *Foreign animal diseases*, Richmond, VA, 1984, United States Animal Health Association, p 77.

differentiation is required for specific identification of the various disease-producing species, all can be categorized as being either "large" or "small" in size. A list of the commonly encountered *Babesia* spp., *Theileria equi*, their usual biological vectors, and livestock hosts is presented in Table 37.1. Babesiosis has a wide geographic distribution, particularly in the tropics and subtropics, largely related to the distribution of vector ticks. Of the different diseases, the economically most important infections of livestock are those of cattle and horses. Babesiosis must be reported immediately to state or federal authorities.

Babesiosis in the Bovine

Etiology

Known variably as *bovine babesiosis*, *piroplasmosis*, *Texas fever*, *redwater*, *tick fever*, and *tristeza*, the disease may be caused by at least six *Babesia* spp. (see Table 37.1). Animals other than cattle known to be susceptible to agents of bovine babesiosis include white-tailed deer, American bison, water buffalo, reindeer, and African buffalo. Infections in these species are nominal, and except under unusual conditions, such hosts are probably not significant reservoirs.

Of greatest concern in the western hemisphere are *Babesia bigemina* and *Babesia bovis*. *B. bigemina* is a large *Babesia* characteristically appearing within mature erythrocytes as nonpigmented, paired, pear-shaped bodies joined at an acute angle. Irregularly shaped, round, or amoeboid forms are also seen. *B. bovis* is a small, pleomorphic *Babesia* often identified as a single round body or as paired pear-shaped bodies joined at an obtuse angle within mature erythrocytes. Of the two species, *B. bovis* is usually considered the most virulent.

Natural transmission of both species occurs primarily by the feeding of various stages of the one-host ticks of the genus *Boophilus*. Ticks are most commonly infected transovarially (vertically). The female tick becomes infected by the ingestion of parasites during engorgement. After it drops off the host, the babesial organisms reproduce within the tick's tissues. Some of the reproducing organisms are incorporated within developing tick embryos, and the disease agents are transmitted to new vertebrate hosts by the feeding of ensuing tick larvae, nymphs, or adults. Larval ticks may transmit *B. bovis*, but *B. bigemina* is not transmitted until the larvae have molted into the nymphal or adult stages. Both *Babesia* spp. may also be transmitted iatrogenically through blood-contaminated fomites.

Clinical Signs

Clinical signs manifest 2 to 3 weeks after tick infestation. The incubation period following blood inoculation may be fewer than 5 days to more than 3 weeks, depending on the volume of inoculum. Clinical signs of fever (40° to 42° C [104° to 107.6° F]), depression, icterus, anorexia, tachycardia, tachypnea, anemia, hemoglobinemia, hemoglobinuria, abortion, and death are seen. Anemia is caused by intravascular destruction of erythrocytes by escaping merozoites following intraerythrocytic reproduction of the babesias by binary fission. In addition, the osmotic fragility of the whole erythrocyte population increases terminally, such that massive lysis occurs even though the parasitemia may be less than 1%.[1] In addition, an immune-mediated condition may result and the spleen will

VetBooks.ir

remove both damaged and healthy erythrocytes from circulation. Thus the degree of anemia may exceed that expected with a low parasitemia. Anemia may occur rapidly, with 75% or more of erythrocytes destroyed in just a few days. The exit of *B. bigemina* and *B. bovis* parasites from infected erythrocytes releases two or more parasite-associated proteolytic enzymes into the plasma. These enzymes and other parasite metabolic products are believed to interact with blood components and are responsible for such clinical signs as metabolic acidosis and anoxia. Tachycardia may be dramatic and heart sounds pronounced.

Cerebral babesiosis, characterized by hyperexcitability, convulsions, opisthotonos, coma, and death, may be observed in cattle infected with either *B. bigemina* or *B. bovis*, but especially with the latter. Central nervous system (CNS) signs are due to brain anoxia resulting from severe anemia and/or erythrocyte blockage of cerebral capillaries.

Death is caused by a shocklike syndrome associated with the accumulation of toxins, release of vasoactive substances, and anemic anoxia. Most cases with cerebral involvement are fatal, but mortality is extremely variable and depends on the *Babesia* strain, host susceptibility, and management and environmental stress factors. Many cattle that survive the acute phase recover but become chronic carriers. Other survivors often experience episodes of recrudescence, eventually succumbing to the disease, or they may die from secondary infections contracted during their debilitated state.

Cattle of all breeds are susceptible to babesiosis, but *Bos indicus* breeds exhibit a definite degree of resistance to both *B. bigemina* and *B. bovis* and the tick vectors.[2] Calves possess a natural immunity to babesiosis. Such immunity was believed to be reinforced by colostral antibodies for calves born to previously infected dams.[3] However, erythrocytes of young bovines may contain factor(s) independent of antibody that provide an innate resistance to severe babesiosis.[4] Thus calves infected up to the age of 9 months experience a minimum reaction to the disease, becoming asymptomatic carriers. Carriers remain resistant to clinical disease for at least 4 years.[5] The carrier state can be overcome, however, by such stresses as calving, malnutrition, or concurrent disease.[6]

Clinical Pathology

Clinical signs observed in cattle located in enzootic areas where *Boophilus* ticks occur may provide sufficient data for a presumptive diagnosis. Other conditions that may exhibit some of the same signs as babesiosis are anaplasmosis, trypanosomiasis, theileriosis, leptospirosis, chronic copper toxicity, and bacillary hemoglobinuria. The cerebral signs may be confused with rabies and other encephalitides. A positive diagnosis requires identification of *Babesia* on Giemsa-stained thin blood smears, positive serologic tests (IFA, ELISA, CF), or molecular diagnostics (PCR).[7] In acute infection, *Babesia* spp. can usually be detected in smears made from peripheral blood. In chronic cases the numbers of parasitized erythrocytes diminish, becoming so sparse as to make detection difficult. This is especially true with *B. bovis*, which shows a marked tendency to accumulate in capillaries, particularly those of the brain. *B. bovis* may favor capillaries in the brain and kidney, because the major energy-producing pathway of *Babesia* appears to be anaerobic glycolysis. The blockage of cerebral and renal capillaries by parasitized erythrocytes results in an anaerobic condition that enables the parasites to absorb preformed substrates by pinocytosis and diffusion through their surface membranes. PCV values drop rapidly from a normal of 35% to below 10% in less than a week after the onset of clinical signs.[8] Serum potassium levels decrease in some infected animals, whereas urine potassium levels increase in nearly all cases.[9]

Specific anti-*Babesia* antibodies are detectable in cattle sera in fewer than 7 days following infection.[10] Such antibodies also exist for at least 252 days after the disappearance of detectable parasites.[11] The CF and IFA tests are the most widely used.[10,12] The CF test follows the same basic procedure used in anaplasmosis CF testing,[11] but with a *Babesia* antigen.[12] The test is effective, but about 100 days after infection, CF antibodies drop below a reliable diagnostic level.[10] The IFA test uses the whole intraerythrocytic parasite as antigen rather than an extract and commercially prepared rabbit antibovine γ-globulin conjugated to fluorescein.[10] Other serologic tests include latex particle agglutination,[13] rapid card agglutination,[14] and enzyme-labeling immunoassay (EIA).[15] It should be noted that the immunologic assays are indirect methods and do not detect the causal organisms in samples obtained from a suspected infected animal. Recombinant DNA techniques using selected clones containing inserts of *Babesia* genomic DNA sequences are now available to be used as specific, highly sensitive DNA or RNA probes to detect the presence of the hemoparasite DNA in an infected animal or tick vector.[16]

Necropsy Findings

Postmortem findings in cattle that die peracutely are characteristic of an acute hemolytic crisis. Such findings include a generalized pallor or icterus throughout the carcass; an enlarged icteric liver; gallbladder distended with thick, dark green bile; and a markedly enlarged dark, soft spleen. Hydropericardium and subepicardial/subendocardial petechiation may be seen. The blood is thin and watery. The urinary bladder is frequently distended with dark red urine. There may be subserosal ecchymotic hemorrhages in abomasal and intestinal mucosa, and the lymph nodes are edematous. The carcass of an animal that dies after a prolonged illness is generally emaciated and icteric.

Treatment and Prognosis

After the onset of hemoglobinuria or cerebral signs, the prognosis is poor. Acute cases with PCV values above 12% usually respond well to treatment. The prognosis decreases for cases with PCV values below 10%. Successful treatment depends on early diagnosis and prompt therapy. In addition to specific treatment, supportive therapy such as blood transfusions (4 L of whole blood per 250 kg of body weight), fluids, hematinics, and prophylactic antibiotics are important. However, wild excitable cattle may best be left alone. With severe hemolytic anemias, any exertion associated with restraint and treatment may precipitate an anoxic crisis.

The small *Babesia* spp. are more resistant to chemotherapy and may require increased dosages or additional treatments. Chemotherapy with imidocarb can be both therapeutic and prophylactic, but there are concerns with milk and meat residue. In enzootic areas its use prevents clinical infection for as long as 2 months but at the same time allows mild subclinical infections to occur, resulting in premunition immunity.[17,18]

Prevention and Control

Eradication of *Boophilus* tick vectors has provided effective control in the United States. Most procedures aimed at reducing tick infestations (i.e., acaricide applications [on host or over environment], controlled range burning, cultivation, prolonged pasture rest, and use of repellents) are beneficial. Care should be taken to prevent accidental transfer of blood from one animal to another in routine surgery (e.g., dehorning, castration, ear marking, hormone implanting) and vaccination procedures.

The most common form of immunization consists of inoculating live organisms (virulent or attenuated) into susceptible calves to induce a state of premunition. Inoculation of older animals is followed by nonsterilizing chemotherapy as needed to modify clinical effects.[19] Although a premunition approach is useful in endemic areas, it is less desirable in areas

with low infection rates because the premunized carriers provide a large reservoir of infection. Subunit vaccines were proven effective in protecting against severe clinical disease.[20,21]

Babesiosis in the Horse

ETIOLOGY. Babesiosis/theileriosis of the horse (piroplasmosis) is a febrile tick-borne disease of equids caused by *Babesia caballi* and *Theileria equi*[22] (see Table 37.1). *B. caballi* is a large *Babesia* resembling *B. bigemina*, which affects cattle. A unique characteristic of *T. equi* is that the intraerythrocytic parasites divide into four cells to form a Maltese cross.[23]

Equine piroplasmosis is widely distributed throughout the tropics and subtropics and to a lesser extent in temperate regions. The distribution roughly corresponds to that of the tick vectors. Both species are naturally transmitted by ticks of the genera *Dermacentor*, *Hyalomma*, and *Rhipicephalus*. *B. caballi* is passed transovarially (vertically) from one tick generation to the next. Transmission of *T. equi* apparently only occurs transstadially (horizontally); that is, one tick stage (larvae or nymphs) becomes infected, and the disease agent is passed to the next vertebrate host in the next tick stage (nymph or adult). Because of the widespread prevalence of potential tick vectors in the United States *(Dermacentor albipictus*, *Dermacentor iteus*, *Dermacentor variablis)*, equine piroplasmosis could become a problem in the United States at any time.

CLINICAL SIGNS. Apparently, all equids are susceptible to both parasite species. The zebra in Africa is naturally infected with *T. equi* but not *B. caballi*. Once infected, survivors remain chronic carriers. At least *T. equi* can be transmitted transplacentally. Clinical features following an incubation period of 5 to 28 days are fever (39° to 42° C [102° to 107.6° F]), hemolytic anemia, jaundice, hemoglobinuria, and death. Generalized signs of depression, anorexia, incoordination, lacrimation, mucous nasal discharge, swelling of the eyelids, and frequent lying down are seen. *T. equi* is considered the most pathogenic of the two species and is responsible for a greater incidence of hemoglobinuria and death. *B. caballi* causes a more persistent fever and anemia. Differential diagnoses include equine monocytic ehrlichiosis, EIA, liver failure with hemolytic anemia, and other hemolytic anemias of the horse.

CLINICAL PATHOLOGY. A fever associated with anemia, jaundice, and hemoglobinuria, with the detection of parasite-infected erythrocytes in Geimsa-stained blood smears, is diagnostic. A significant increase in relative and absolute numbers of monocytes and absence of eosinophils may be observed in horses infected with *T. equi*. Hemoglobinuria is rare in animals infected with *B. caballi*, but urine is often dark yellow in color. The official testing method is the cELISA test. There is also a PCR test for both equine diseases. As with the bovine infections, both *B. caballi* and *T. equi* infections can be specifically detected with nucleic acid probes.[17]

NECROPSY. Postmortem features are similar to those seen in bovine babesiosis, but jaundice is even more prominent throughout the carcass. There is excessive fluid in the body cavities, especially the pericardial sac. Pulmonary edema is evident. The liver is swollen, and hepatic vessels contain large yellowish clots. The spleen is enlarged, with rounded edges.

TREATMENT AND PROGNOSIS. The drug of choice for eliminating the carrier state of infected animals is imidocarb. Imidocarb at the level of 2.2 mg/kg given two times in 24 hours is effective against *B. caballi*. A 4-mg/kg IM dose given every 72 hours for four doses is effective against *T. equi* of eastern hemisphere origin.[24] However, donkeys receiving similar treatment died from drug toxicosis.[24] The higher doses of imidocarb often produce transient colic in horses. To date, attempts to consistently eliminate the carrier state of *T. equi* of Eastern European origin have been unsuccessful.[25]

PREVENTION AND CONTROL. Control of tick infestations does much to reduce disease incidence, as does care to prevent blood transfer during such routine surgical procedures as castration. No vaccines effectively prevent equine babesiosis. Although premunition as used in bovine babesiosis is of limited value in some enzootic areas, it is not widely practiced. This is because early treatment without sterilization is effective, and the resulting chronic carriers resist further disease challenge. If a horse is diagnosed with *T. equi* in the United States, the veterinarian can enroll the horse in the USDA controlled treatment program to ensure appropriate quarantine, treatment, and subsequent release of cleared animals.

Haemobartonellosis (Eperythrozoonosis)

Johanna L. Watson • Gary P. Carlson

Haemobartonella bovis is an epicellular organism closely associated with the surface of erythrocytes. It may appear as a rod shape, an ovoid, or in chains with conventional stains. *Haemobartonella*, or hemotropic mycoplasma, infection is primarily of academic interest in North America; it is rarely a cause of anemia. The organism has been found in association with other rickettsial diseases and has been experimentally transmitted in splenectomized calves. The agent may be visualized as delicate ovoid, rod, or dumbbell forms arranged in chains or tight groups or randomly distributed epicellularly throughout appropriately stained blood smears.

Eperythrozoonosis in Cattle

The causal agent is *Eperythrozoon wenyonii (Mycoplasma wenyonii)*. Infection is usually latent, producing no clinical signs in normal cattle, but it may become apparent in animals that have been severely stressed by some other systemic disease. The disease can be produced experimentally if infected blood is administered to splenectomized calves. Even under experimental circumstances, clinical signs consist of mild depression, fever, and modest anemia. The disease in cattle is of little clinical consequence except for the potential for confusion should the organism be seen on stained blood films. Occasionally cattle may have swollen and tender teats and legs.[1]

Eperythrozoonosis in Sheep and Goats

The causal organism in sheep and goats is *Mycoplasma ovis (Eperythrozoon ovis)*, which appears to be similar morphologically and serologically to that found in cattle. The disease can produce more prominent clinical signs in sheep, with profound depression, anemia, and significant death losses in young lambs.[2] Red cell destruction is thought to be caused by intravascular hemolysis and erythrophagocytosis.

Theileriasis

Johanna L. Watson • Gary P. Carlson

Theileriasis is caused by a small hemoparasite of the genus *Theileria* that infects lymphocytes and erythrocytes of ruminants and is most common in tropical and subtropical climates. The organism is spread by bloodsucking arthropods, particularly ticks of the Ixodidae family. *Theileria parva* is the cause of East Coast Fever, a highly fatal disease of cattle in Africa. Other members of the genus *Theileria* (spp. *annulata*, *mutans*,

VetBooks.ir

hirci, and *ovis*) tend to be less pathogenic and produce diseases with a wider geographic distribution.[2] *Theileria cervi* has been seen in North American deer. *Theileria mutans* has been seen in erythrocytes of both cattle and deer in North America. Theileriosis due to an agent indistinguishable from *Theileria buffeli* has been described in cattle from Texas and North Carolina with parasitemia, but clinical signs were not reported.[3] *T. buffeli* was reported as the cause of hemolytic anemia in a 6-month-old Simmental calf.[4] There was serologic evidence of a high herd prevalence of *Theileria* infection, and the agent was transmitted to splenectomized calves that developed mild anemia. The organism produces a brief illness characterized by mild fever, anorexia, and modest anemia, followed by rapid recovery.

Trypanosomiasis

Johanna L. Watson • Gary P. Carlson

Trypanosomes are flagellated protozoal organisms that can produce a variety of serious diseases of humans and animals, although many are nonpathogenic. Nagana, a disease of cattle in Africa, is caused by *Trypanosoma congolensi*. *Trypanosoma evansi* is the cause of Surra, a disease of cattle in India, and *Trypanosoma equiperdium* is the cause of Dourine in horses. In North America, *Trypanosoma theileri (Trypanosoma americanum)* is the only agent reported and is principally of academic interest because it is relatively nonpathogenic. On stained blood films from cattle, small numbers of the organism can occasionally be seen free in plasma, appearing as large flagellated protozoa with undulating membranes. *Trypanosoma* is best visualized in buffy coat smears, which tend to concentrate it. *T. theileri* rarely produces clinical signs, but occasionally a fulminating parasitemia may develop, resulting in fever, depression, and decreased milk production.

Leptospirosis

Johanna L. Watson • Gary P. Carlson

Leptospira infections produce disease in several species including cattle, sheep, swine, horses, dogs, and humans, but the acute hemolytic syndrome associated with these infections is seen most commonly in calves and lambs. *Leptospira interrogans* serovars *pomona* and *icterohaemorrhagiae* are the serotypes usually involved in the hemolytic syndrome. Clinical signs of the hemolytic syndrome vary but generally include fever, lethargy, icterus, anemia, and petechial hemorrhages. The anemia is brought about at least in part by immune-mediated mechanisms. Cold-reacting IgM antibodies have been implicated in the hemolytic anemia seen in lambs. The degree of anemia is variable but can be severe, with evidence of bone marrow response apparent in the peripheral blood within 4 to 7 days. A moderate leukocytosis and elevation in plasma fibrinogen are often associated with the hemolytic anemia. The diagnosis is made on the basis of demonstration of the organism in the urine, PCR, and documenting an increase in serum antibody titer. Discussion of leptospirosis as a reproductive, renal, and ocular problem can be found in other chapters.

Bacillary Hemoglobinuria (Red Water)

Johanna L. Watson • Gary P. Carlson

Bacillary hemoglobinuria is an acute hemolytic disorder caused by *Clostridium haemolyticum* (*Clostridium novyi* type D). Also known as "Nevada red water," it has been reported as a naturally occurring disease in cattle and experimentally produced in sheep. Clinical signs develop rapidly, and death losses are often seen. Affected animals may manifest severe depression, anorexia, fever, hemoglobinemia, and hemoglobinuria. The disease is endemic in certain poorly drained areas of the western United States and is caused by ingestion of infectious spores. The organism finds a favorable environment for development in areas of preexisting liver damage that most often have been produced by migrating liver flukes. The hemolytic syndrome is produced by toxins elaborated by the organism, which also produce a characteristic focal liver lesion. The anemia produced may be marked, and both icterus and evidence of erythropoietic response may be seen in animals that survive for more than a few days. For a complete description of the disease, see Chapter 33.

Equine Infectious Anemia

Johanna L. Watson • Brett A. Sponseller

Equine infectious anemia virus (EIAV) is an RNA virus, a member of the Retroviridae family, belonging to the lentivirus genus. It has a structure and genome organization similar to other animal and human lentiviruses and uses virally encoded *reverse transcriptase* to convert the RNA genome to a DNA intermediate that is integrated into the host's genome by another virally encoded enzyme, *integrase*. The integrated DNA intermediate, or provirus, usurps the host cell to replicate its genome, manufacture viral proteins, and assemble the virally encoded proteins into virions that subsequently bud from the cell. Thus infection by a lentivirus results in lifelong persistent infection. EIAV causes equine infectious anemia, first described in 1843 by Lignée.[1] In 1904, Vallée and Carré determined that EIA was associated with a filterable agent, making it the first animal disease determined to be caused by a virus.[2]

Identification of Equids Seropositive for EIAV

EIA is a USDA-regulated disease. In 2003, the USDA estimated that serosurveillance of nearly 2 million samples cost U.S. horse owners in excess of $48 million. USDA-accredited laboratories use a testing scheme that detects the presence of serum antibody to the virus. The Coggins test, developed by Dr. Leroy Coggins in 1970, provided the first efficient serologic test for detection of EIAV-infected animals and remains a USDA-accepted test.[3,4] There are also four licensed ELISAs, one of which is a cELISA. These ELISAs detect antibody directed at the transmembrane glycoprotein (gp45) and/or the p26 antigen.[5] All U.S. states, Canada, and Mexico accept either the Coggins test or one of the licensed ELISAs when EIA testing is required for entry. Equids that cross state lines or attend many equestrian events (e.g., shows, races) have to be seronegative for EIA. The required period of seronegativity between tests varies state by state, however. No tests based on detection of viral nucleic acid are currently USDA approved for EIA diagnosis. It has been suggested that the use of a molecular test would help identify infected horses and assist with the eradication of the disease.[6]

Serosurveillance can lead to detection of horses infected with EIAV that otherwise appear healthy. Indeed, most horses infected with the virus are inapparent carriers. However, blood transferred from an inapparent carrier to another horse, either through instruments (needles, nasogastric tubes, dental equipment, etc.), blood products, or by insect vectors (primarily tabanids) can lead to infection and a fatal outcome.

VetBooks.ir

Equine Infectious Anemia

The clinical form of the disease is characterized by three defined temporal stages: acute, chronic, and inapparent. The acute stage occurs with the initial burst of viremia and is characterized by high fever, thrombocytopenia, and nonspecific signs of malaise including lethargy and inappetence. In experimentally infected horses, thrombocytopenia inversely correlates with virus load and occurs slightly in advance of onset of fever. Ecchymoses and petechiae may also be detected on mucous membranes. During the chronic stage, similar clinical features occur during recurrent episodes of viremia, which are interspersed with periods of clinical quiescence and low viremia. Throughout the chronic stage, clinical episodes tend to gradually diminish in severity and duration. The inapparent stage occurs once levels of viremia are immunologically contained and no clinical signs are detected. Horses experiencing clinical disease at any point may develop DIC and die. In addition, episodes of stress (e.g., transportation, racing, extreme temperatures) may precipitate clinical disease. Corticosteroids have been experimentally used to induce recrudescence of clinical disease.[7] Other chronic manifestations of EIA include development of dependent edema, weight loss, anemia, and other signs of ill thrift. Rare manifestations that may develop include leukoencephalitis and enterocolitis.[8] Expression of clinical disease, particularly during acute infection, likely involves multiple factors, including inoculating dose, virulence factors of the inoculating viral strain, immune status, and immunogenetics of the host, age, stress, and so forth. Indeed, clinical disease occurs concomitantly with high-titered viremia. Horses with high-titered viremia pose the biggest risk of transmission to uninfected horses.

Lentiviruses have a DNA-dependent RNA polymerase (reverse transcriptase) that misincorporates nucleotides, resulting in changes in the viral genome.[9] This mechanism allows for generation of viral variants that differ genetically from preexisting ones. As a result, genetic and antigenic variation of epitopes for neutralizing antibody and cytotoxic T lymphocytes allows viral escape from adaptive immune responses.[10,11] Antigenic variation plays a central role in clinical disease recurrence throughout the chronic stage of infection and thwarts attempts to develop an effective vaccine.[9]

EIAV can replicate effectively in monocytes, dendritic cells, and tissue macrophages[12-14] and has been shown to replicate in endothelial cells. EIAV replication in endothelial cells may play a role in the development of DIC by viral damage to endothelial cells, with subsequent exposure of subendothelium.[15] This in turn could lead to platelet aggregation and formation of thrombi.[16] In addition, damaged endothelium may lead to development of dependent tissue edema by transudation of fluid through compromised small vessels.[15]

Pathology and Clinical Pathology

Necropsy examination of horses that die of EIA may demonstrate splenomegaly, lymphadenopathy, hepatomegaly, pronounced hepatic lobular architecture, ecchymoses of the mucosa and viscera, dependent subcutaneous edema, and thrombotic disease of small vessels. Histologic findings may include a mononuclear cell infiltrate of periportal regions of the liver, adrenals, spleen, lymph nodes, meninges, and lungs. Hemosiderophages are frequently detected in the spleen, lymph nodes, liver, and bone marrow. Glomerulonephritis due to immune complex deposition is commonly observed.

Clinicopathologic abnormalities will vary depending on the stage and severity of infection. During clinical disease, a frequently profound thrombocytopenia develops concurrently with each successive episode of fever. Platelet dysfunction in EIAV-infected horses has been demonstrated, possibly exacerbating bleeding tendencies and the progression to DIC in clinically affected equids.[17] Anemia due to intravascular hemolysis, extravascular hemolysis, and depression of bone marrow erythropoiesis may progressively develop during the chronic stage of infection.[18] During the inapparent stage of infection, horses typically have increased plasma total solids and globulin concentrations, mild anemia, and decreased albumin concentration.[19] Polyclonal B-cell activation is also evident, suggesting chronic antigenic stimulation despite clinical quiescence.[19] Concomitant fever and thrombocytopenia should prompt immediate consideration of EIA. A history of recurring fever is also suggestive of EIA, particularly when other causes of fever have been ruled out.

Prevention, Control, and Regulatory Considerations

It is well recognized that seroprevalence varies with the region of the United States.[18] States considered at high risk include Texas, Oklahoma, Louisiana, and Arkansas, whereas the mid-Atlantic area, New England, Alaska, and Hawaii are considered low-risk regions. The remaining states are classified as being at intermediate risk. Despite regional differences in risk to noninfected horses, sporadic outbreaks do occur. Veterinarians should encourage all horse owners to test for EIAV, test new arrivals, and maintain good fly control.

Once a seroreactor is identified, all contact horses are quarantined and undergo testing until two negative test results at 30- to 60-day intervals are obtained for all individuals in the quarantined herd.[16] The required interval is based on the need to allow recently infected horses to seroconvert. Seroreactors may be either quarantined or euthanized, depending on state regulations. Quarantined horses must be at least 200 yards from seronegative animals, the distance shown to be sufficient to obviate viral spread by insect vectors. In addition, seroreactors remaining in permanent quarantine must be permanently identified. A USDA code number followed by the letter *A* is assigned to the quarantined horse and permanently applied to the horse in the form of a brand or lip tattoo.

Because an EIA eradication program has never been implemented in the United States, persistence of EIAV-infected horses can be expected. The vast majority of horses in the United States are not tested annually, so to encourage horse owners to voluntarily maintain vigorous surveillance testing, the veterinary community must educate them about the consequences of EIAV infection. Horse owners are often unprepared to deal with the financial and emotional losses associated with detection of a horse seropositive for EIAV.

Immune-Mediated Hemolytic Anemia

Autoimmune Hemolytic Anemia

Johanna L. Watson • Gary P. Carlson

Definition and Etiology

Autoimmune hemolytic anemia is associated with production of autologous antibodies directed against the patient's own red cells. These antibodies combine with complement and antigens on the red cell membrane, leading to rapid removal of affected red cells from the circulation and their accelerated destruction. Autoimmune hemolytic anemia occurs rarely as a primary idiopathic disorder[1,2] but more commonly is found secondarily associated with some other primary disease process.[1] Idiopathic immune-mediated hemolytic anemia (IMHA) has been reported in a calf[2] and pony.[3]

Clinical Signs and Differential Diagnosis

The presenting clinical signs of autoimmune hemolytic anemia are quite variable depending on the degree of anemia and the animal's primary disease. Marked anemia (PCV < 15%) manifests signs typical of those seen in any animal with a severe hemolytic anemia (i.e., depression, pale mucous membranes, variable icterus, elevated heart and respiratory rate, and variable to intermittent fever). Secondary autoimmune hemolytic anemia in horses has been associated most often with some other primary problem like purpura hemorrhagica, lymphoma, other neoplasms, protein-losing enteropathy, or chronic bacterial infections.[4,5] Clinical features are typical of the primary problem, with additional findings of hemolytic anemia. In humans, exposure to a wide variety of drugs has been causally associated with development of autoimmune hemolytic anemia. There are a number of reports of an association between procaine penicillin and autoimmune hemolytic anemia in horses,[6-10] as well as a single report in a 10-year-old horse that was treated with trimethoprim-sulfamethoxazole.[11] This apparently occurs rarely, perhaps only in specific individuals, but drug history should be ascertained in all animals with an otherwise unexplained hemolytic anemia.

It should be noted that the anemia in cattle with anaplasmosis and babesiosis or that in horses with equine infectious anemia, piroplasmosis, or anaplasmosis is largely the result of an immune-mediated hemolytic process.

Clinical Pathology

The hemolytic process is often rapid and persistent, leading to a pronounced anemia. Hematologic features are those typically expected for a responsive hemolytic anemia. The anemia is often progressive and may become severe, even life threatening (i.e., PCV < 10%). Erythrophagocytosis and autoagglutination may be noted on blood smears. If the process has gone on for 4 days or more, hematologic evidence of active erythropoietic response may be seen in the peripheral blood of all species except the horse. This evidence of bone marrow response is a favorable prognostic indicator, even when anemia is quite advanced. A moderate neutrophilic leukocytosis is a common feature, and thrombocytopenia may be noted in some individuals if the autoimmune process is directed at platelets and megakaryocytes in addition to erythrocytes.

Diagnosis

The direct Coombs test can detect the presence of antierythrocyte antibodies and/or complement on the red cell membrane, whereas the indirect Coombs test detects antierythrocyte antibody in the serum. It is important to remember that the Coombs test is based on species-specific reagents. These reagents are commercially available in the United States for small animals and horses, but not all diagnostic laboratories will have suitable Coombs reagents for other species. Multivalent Coombs reagent directed against IgG, IgM, and complement is most commonly used. The Coombs test is usually conducted at body temperature (37° C) and can also be run in the cold. Cold-reacting antibodies are primarily of the IgM class. Unfortunately, false-negative results to the Coombs test are possible and possibly occur because of low concentrations of antibody, low binding to the red cell membrane, or prior treatment with corticosteroids. The diagnosis in these cases is contingent on ruling out other causes of a responsive hemolytic anemia and on the response to corticosteroid therapy. Direct immunofluorescence flow cytometry can be used to determine the classes of antibody bound to erythrocytes in horses and dogs with IMHA.[12]

Pathophysiology

Autoimmune hemolytic anemia has rarely been reported as a primary or idiopathic process in large animals, but immune-mediated anemia occurs more commonly as a secondary problem (1) in association with certain types of neoplasia; (2) with a variety of viral, bacterial, rickettsial, and protozoal infections; (3) following exposure to certain drugs; or (4) in association with other immune-mediated disorders like systemic lupus erythematosus.[13] The initiating factors for this autoimmune disorder are not completely understood but may be related to alterations in the red cell membrane through direct or indirect injury, which elicits an abnormal response by the immune system. The red blood cell membrane is no longer recognized as self but is treated as a foreign antigen. Alternately, alterations in the immune system or stimulation by some other antigenic source may result in production of antibodies with a misdirected cross-reactivity with the patient's own normal red cells. Structural and functional changes in the red cell membrane are induced by the antigen-antibody reaction and complement fixation. The complement-fixing IgG or IgM antigen-antibody reaction may produce sufficient erythrocyte damage to result in intravascular lysis of erythrocytes, but more commonly, affected cells are removed from the circulation at a rapid rate by the reticuloendothelial system of the liver and spleen. Partial phagocytosis of affected cells may result in spherocyte formation. Although the presence of spherocytes on blood smears is a characteristic diagnostic feature in human and canine patients with autoimmune hemolytic anemia, the relatively small size of red cells of most large domestic animals may make it difficult to recognize spherocytes.

Treatment and Prognosis

The approach to treating autoimmune hemolytic anemia depends on causal factors. If the animal has a history of drug therapy, it is advisable to discontinue medication or change to another class of drug. Patients with primary or idiopathic autoimmune hemolytic anemia may be the best candidates for treatment. IMHAs that are secondary to other diseases can

VetBooks.ir

VetBooks.ir

only be managed if the primary problem is amenable to treatment. Thus treatment of an IMHA in a patient with extensive lymphoreticular neoplasia is likely to be unrewarding, and thorough diagnostic efforts should precede case selection for treatment. Although immune-mediated processes are responsible for hemolytic anemia in a number of infectious diseases, therapy must be directed at the primary agent and corticosteroids are contraindicated in these diseases. Corticosteroids can cause recrudescence of viremia in horses with EIA.

Treatment of autoimmune hemolytic anemia is directed at providing supportive care and interrupting the immune response responsible for antibody production. This is usually accomplished with systemic glucocorticoids. For a 450-kg horse, parenteral dexamethasone is recommended at an initial dosage of 30 to 40 mg/day. This dosage is continued for 3 to 5 days and then decreased gradually over a period of 7 to 14 days, depending on response to therapy. The hematologic response to therapy should be closely monitored. If there has been no response in 5 to 7 days, the diagnosis of autoimmune hemolytic anemia should be reviewed and potential causes of bone marrow suppression should be evaluated. Once the hemolytic process is well under control, treatment can be switched to oral prednisolone, 0.5 to 1 mg/kg daily. Human patients and small animals with IMHA that is unresponsive to corticosteroids are often treated with cyclophosphamide. One case of successful management of a horse with cyclophosphamide and azathioprine when anemia failed to respond to corticosteroids has been reported.[14] Supportive care consists of providing a quiet, restful environment and good nutrition, including vitamin supplementation. Iron- and copper-containing hematinics are generally of little benefit; neither of these elements is lost with hemolytic anemia. Blood transfusion is also of little benefit because it is often impossible to find a compatible donor, and transfused cells are rapidly removed from the circulation.

Neonatal Isoerythrolysis in Horse and Mule Foals

Johanna L. Watson • Monica Aleman

Neonatal isoerythrolysis (NI) is the most common alloimmune disease in neonatal foals (median age, 2.5 days).[15] NI is characterized by hemolytic anemia, icterus, and hemoglobinuria. Clinicopathologic abnormalities include anemia, high serum indirect and direct bilirubin concentrations, and sorbitol dehydrogenase (SDH) activity. NI is caused by a blood group incompatibility between the foal and dam. The foal inherits and expresses, from the sire, an erythrocyte antigen (alloantigen) that is not present in the mare. The hemolytic syndrome is mediated by maternal antibodies generated against foal erythrocytes (alloantibodies) absorbed from colostrum. Blood factors associated with NI in horse foals are Qa, Qb, Qc, Aa, Pa, and Dg and donkey factor in mule foals.[15] The most common antigens are Qa and Aa. Foals with NI may also present with alloimmune thrombocytopenia. For a complete description of NI, see Chapter 53.

Heinz Body Hemolytic Anemia

Johanna L. Watson • Gary P. Carlson • Monica Aleman

Definition and Etiology

Acute hemolytic anemia can develop following exposure to a variety of oxidizing agents. These include chemicals such as phenothiazine, methylene blue, acetylphenylhydrazine, or plants like wild or domestic onions, members of the *Brassica* family (rape or kale), and wilted or dried leaves of the red maple *(Acer rubrum)*.[1-7] Red maple toxicosis (RMT) has been reported in horses, zebras, and alpacas.[5,8-10] Heinz body hemolytic anemia also occurs in sheep on specially formulated diets that are low in molybdenum, which results in chronic copper toxicity; as herd problems in cattle grazing rye grass *(Secale cereale)*[11] or selenium-deficient pastures in Florida[12]; and in association with selenium deficiency as a contributing factor in postparturient hemoglobinuria in cattle in New Zealand.[13] These agents produce or allow oxidative denaturation of hemoglobin and resultant aggregation of the protein globin, which appears as Heinz body inclusions within the red blood cells. Heinz body anemia has been seen in association with lymphoma in a horse and was possibly due to failure of the reticuloendothelial system to remove Heinz bodies, as has been reported in horses with EIA.[14]

Clinical Signs and Differential Diagnosis

Clinical signs vary with the species involved, specific toxin or toxic metabolites, amount of toxin ingested, time course of the disease process, and occurrence of complicating secondary factors like hemoglobin nephrosis and acute renal failure. Weakness, lethargy, anorexia, and exercise intolerance are the usual presenting complaints, and death losses can occur. Mucous membranes are generally pale with variable to marked icterus. Heart and respiratory rates are generally elevated, but rectal temperature is usually within normal limits. Horses with RMT may be subclinical or may present with lethargy, muddy or cyanotic mucous membranes, tachycardia, inappetence, weakness, colic, icterus, brown discoloration of the blood, and pigmenturia. Rarely, sudden death occurs.[10] Most horses develop clinical RMT during summer and fall, and the high mortality rate may relate to the combination of a rapidly progressive hemolytic anemia and formation of methemoglobin. Urine output may be reduced, and the presence of hemoglobin, methemoglobin, or bilirubin may make urine appear dark.

It is not possible to differentiate Heinz body hemolytic anemia from other potential causes of hemolytic anemia without laboratory evaluation. The absence of fever may help differentiate these anemias from infectious causes of hemolytic anemia. History of exposure to potential oxidizing agents and the fact that these toxic plants may produce death losses or clinical signs in multiple animals at the same time should help differentiate these cases from autoimmune hemolytic anemia.

Clinical Pathology

Poisoning or intoxication resulting in Heinz body formation usually causes acute and profound anemia. In the early stages a high percentage of erythrocytes may have Heinz body inclusions. Later, as these cells are removed from the circulation and replaced by young cells from the bone marrow, the relative number of affected cells may decrease markedly. Heinz bodies are round, oval to serrated, refractile granules usually located near the cell margin or protruding from the cell. They are best visualized with vital stains like crystal violet or new methylene blue applied to unfixed blood smears. Heinz bodies appear as bluish-green inclusions with new methylene blue stain. Fixing blood smears with methanol in preparation for staining with the classic Wright stain interferes with stain uptake, and Heinz bodies appear as a pale area within or projecting from the cell margin and can easily be missed. After the first 3 or 4 days the anemia is usually associated with hematologic evidence of an active erythrogenic response in all species except the horse. Total plasma protein usually remains within normal limits, and the Coombs test is negative. Red maple poisoning also results in depletion of red cell mass, reduced glutathione, methemoglobinemia, increased osmotic fragility, and modest elevations of liver-derived serum enzyme activities.

VetBooks.ir

Rapid and profound erythrocyte destruction may lead to hemoglobinemia and hemoglobinuria. Development of renal failure secondary to hemoglobin nephrosis is a definite risk in these animals and is reflected by modest to marked increases in the blood urea nitrogen and creatinine, as well as changes in the urinalysis.[6,7] These parameters should be monitored in severely affected animals. As with other causes of hemolytic anemia, serum bilirubin, particularly indirect-reacting bilirubin, is elevated.

The clinicopathologic abnormalities of horses with RMT include anemia (PCV as low as 7.5%), eccentrocytes, Heinz bodies, and elevated plasma methemoglobin concentration.[10] Other significant findings are an inflammatory leukogram and renal insufficiency (75% and 40% of cases, respectively).[10] Mild serum total bilirubin elevation is observed in most cases, and hemoglobinuria is seen in all affected patients.

Pathophysiology

Heinz bodies are formed by precipitation of oxidatively denatured hemoglobin. The hemoglobin contained within the red blood cell is constantly undergoing mild oxidative stress associated with oxygen transport, as well as generation of superoxide radicals and hydrogen peroxide within the cell. There are a number of reducing mechanisms within the red cell to counteract these oxidative processes through production of the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) and reduced glutathione. The occurrence of Heinz body hemolytic anemia could be viewed as a consequence of exposure to oxidative stresses that simply overwhelmed the cells' reductive capacity. Selenium deficiency results in a decrease in glutathione peroxidase, a selenium-containing enzyme, and selenium deficiency may in special circumstances contribute to Heinz body formation by impeding the ability of the cells to respond to oxidative stress. There are substantial species variations in the rate of Heinz body formation that relate to the chemical structure of hemoglobin and efficacy of erythrocyte-reducing mechanisms in the face of oxidative stress.[1] Red cells with Heinz bodies are less deformable than normal cells and are rapidly removed from the circulation by the reticuloendothelial system in the spleen, where they are phagocytized and broken down. Splenectomy or corticosteroid therapy may alter Heinz body clearance mechanisms, allowing significant numbers of affected red cells to remain in the circulation of otherwise normal animals.

Gallic acid is a strong oxidant present in red maple leaves and has been implicated in the oxidation of hemoglobin, methemoglobin formation, and Heinz body anemia.[5,6,15] Methemoglobin results from the oxidative change of hemoglobin iron to the nonfunctional ferric state (see discussion of nitrate poisoning in Chapter 54). This is normally prevented by glutathione reductase, ascorbic acid, and reduced glutathione. Methemoglobin cannot load or transport oxygen and, when present in sufficient quantities, results in a brown color of peripheral blood and mucous membranes. An estimation of methemoglobin concentration in a blood sample can be made by comparing the hemoglobin concentration measured by the cyanmethemoglobin method, which measures all forms of hemoglobin, and the oxyhemoglobin method, which only measures oxyhemoglobin but not other forms (e.g., methemoglobin). Methemoglobinemia and hemolytic anemia have been reported in a mare and her dam in association with decreased levels of red cell glutathione and glutathione reductase, presumably as a result of an inherited enzymatic defect.[16]

Treatment

Treatment is largely a matter of removal from the source of toxicity and provision of supportive care. Blood transfusion can be beneficial in severely anemic patients, particularly when there is insufficient evidence of active erythropoietic response. Iron-containing hematinics are of little benefit. IV fluid therapy is indicated in animals with hemoglobinuria or azotemia to reduce the potential for further renal damage. High doses of vitamin C (ascorbic acid, 50 to 100 g IV daily), together with fluids and transfusion, were thought to aid recovery in two horses with red maple poisoning.[17] Another report suggests that vitamin C therapy may have little impact on survival of affected horses, and when methylene blue was used to treat the associated methemoglobinemia in two horses, both died.[18] Therapeutic goals should be to improve tissue oxygenation and perfusion and control inflammation and pain (e.g., with NSAIDs). Horses treated with corticosteroids have an increased likelihood of death.[10]

Prognosis

Prognosis in animals with modest anemia and evidence of response is good if the inciting factor can be controlled or eliminated. The mortality rate of experimental and naturally occurring cases of RMT in horses is said to be 60% to 65%.[18] In animals with rapidly progressive and profound anemia, prognosis is poor unless blood transfusion is undertaken. Complications are associated with hypoxia, hypoperfusion, and inflammation. Horses may develop acute renal failure, colic, pyrexia, and laminitis. A retrospective study of 32 horses reported a fatality rate of 59% but failed to show an association between mortality and severity of anemia.[10]

Other Causes of Hemolytic Anemia

Intravascular Hemolysis Following Cutaneous Burns

Johanna L. Watson • Monica Aleman

Intravascular hemolysis has been reported in horses following severe cutaneous burns affecting more than 25% of their body surface. Blood samples on admission showed hemolysis along with abnormal RBC morphology, increased osmotic fragility, hemoglobinuria, azotemia, and hemoglobin pigment nephropathy.[1] The pathophysiology of hemolysis is unclear but suspected to be associated with the production of hydroxyl radicals by complement-activated neutrophils. Abnormal findings reported in humans include intravascular hemolysis, increased RBC osmotic fragility, decreased membrane deformability, RBC crenation, eccentrocytosis, spherocytosis, bud formation, fragmentation, and vesiculation.[2] These abnormalities are dependent on severity of burn trauma.[2] Early fluid therapy and free radical scavengers have been beneficial for burn treatment in humans, along with supportive and wound care, control of pain and inflammation, and sepsis prophylaxis. A study in mice suggests that the level of plasma free hemoglobin is related to the size and depth of burn injury, which may be difficult to determine in some cases.[3]

L-Tryptophan-Indol Intoxication

Johanna L. Watson • Gary P. Carlson

Experimental studies in ponies have demonstrated an acute hemolytic process associated with orally administered L-tryptophan, which is converted to indol in the GI tract.[4] Intoxication was associated with an acute onset of restlessness, tachypnea, intravascular hemolysis, and hemoglobinuria. At necropsy there was evidence of hemoglobinuric nephrosis and bronchiolar degeneration in some ponies. Similar clinical signs were noted following oral administration of tryptophan at 0.35 to 0.60 g/kg, and indol at 0.1 to 0.2 g/kg.[4,5] Intravascular hemolysis was associated with increased osmotic fragility and with Heinz body formation in a few of the experimental ponies.

Water Intoxication

Johanna L. Watson • Gary P. Carlson

Massive water intake may produce marked hypotonicity of body fluids, with subsequent intravascular hemolysis of erythrocytes.[6] This problem has been described as a naturally occurring entity in milk-reared calves when they are first given access to unlimited quantities of water.[7,8] Severe neurologic signs may be seen (e.g., depression, convulsions, coma). Respiratory distress, hemoglobinuria, and death losses occur in some cases. Clinicopathologic features include hemolytic anemia, hypoproteinemia, hyponatremia, hypochloremia, hyposmolality, hemoglobinuria, and hyposthenuria. A sudden decrease in serum osmolality is believed to result in osmotic lysis of erythrocytes.[9] Erythrocytes are most susceptible to osmotic shock when calves are between 4 and 5 months of age. Treatment is primarily a matter of temporarily restricting water and providing supportive care. Calves with marked hyponatremia (sodium of 110 mmol/L) that are manifesting neurologic signs may benefit from hypertonic saline, mannitol, and corticosteroids. The goal of treatment is restoring serum sodium to 120 to 125 mmol/L without overcorrection. Death losses can occur in as little as 2 hours, but most calves recover without long-term adverse effects.

Postparturient Hemoglobinuria

Johanna L. Watson • Gary P. Carlson

A syndrome of intravascular hemolysis, hemoglobinuria, and anemia has been recognized in postparturient dairy cattle around the world.[10] The disease occurs sporadically, and the incidence is relatively low. Affected animals are most often high-producing multiparous cows that develop clinical signs during the first month after calving.[11] Depression, decreased feed consumption, and decreased milk production are associated with hemoglobinuria, anemia, and icterus. The anemia is often marked and after 4 or 5 days is associated with evidence of a marked erythropoietic response. The precise mechanism by which the intravascular hemolysis occurs has not been fully elucidated. The condition has been related to the marked hypophosphatemia commonly found in affected cows and moderately low phosphate levels in unaffected herdmates. Hypophosphatemia is brought about by inadequate dietary phosphorus intake in animals grazing phosphorus-deficient soils or fed fodder grown on such soils. Low intracellular phosphate concentration may interfere with energy metabolism, thus affecting cell viability and the ability of the red cells to deal with potential hemolysins (e.g., saponins from sugar beets or alfalfa). A postparturient hemolytic problem associated with copper deficiency and Heinz body formation has been described as a herd problem in New Zealand (see previous section).

Blood transfusion and supportive IV fluids are indicated in valuable cows with severe life-threatening anemia. Correcting hypophosphatemia consists of providing phosphate, initially as sodium acid phosphate ($NaH_2PO_4H_2O$), 60 g/300 mL of water IV, followed by oral supplementation with 200 to 300 g sodium phosphate salts every 12 hours. Correction of dietary imbalances is indicated.

Copper Toxicosis

Johanna L. Watson • Lisle W. George

Copper is an essential nutrient for domestic animals, but excessive supplementation can result in toxicity. Copper poisoning is a common intoxication in ruminants. Reviews of the toxicodynamics and clinical syndromes have been published.[1-3] Lambs are most susceptible to the toxic effects of copper, but poisonings have occurred in adult sheep, goats, and cattle; Merino sheep are more resistant than British breeds.[4] Cattle have been poisoned by ingesting diets containing 37 mg of copper/kg of feed for 2 years.[5] Cattle fed 12 mg or more of copper/kg of body weight have been reported to develop subclinical hepatic disease.[6]

Elemental copper is an essential trace mineral with a narrow therapeutic window. Dietary requirements for growing sheep range between 4 and 6 parts per million (ppm), yet toxicity can occur whenever sheep are exposed to diets containing as little as 10 to 20 ppm.[7-9] Phytogenous copper poisoning results from concomitant ingestion of copper at 20 ppm of food, molybdenum, and sulfate. Ingested salts of copper are absorbed through enterocytes by carrier proteins and transported to blood in loose complexes with albumin and amino acids.[10] Roughly 20% of total plasma copper is ionized copper. Between 70% and 90% of this ionic copper is internalized by hepatocytes, where it is redistributed to bile, packaged in lysosomes in protein complexes, or used for the formation of ceruloplasmin.[10] Accumulation of copper occurs because daily hepatic biliary copper excretion amounts to less than 1% of ingested copper in ruminants.[11] Hepatic storage can buffer high levels of copper intake until the sites become saturated. At that time, hepatocytes die spontaneously or in response to environmental stress or dietary changes. Hepatocyte death causes the release of large amounts of cuprous copper into the blood. Animals that have preexisting hepatitis from pyrrolizidine alkaloids store less copper and are more susceptible to the hemolytic crisis.[4,12]

Free inorganic copper is an oxidant and can participate in the Fenton reaction. Cellular damage is related to production of oxidative hydroxides and peroxides, not to copper oxidation. These reactive intermediates are thought to initiate lipid peroxidation and oxidative denaturation of proteins within erythrocytes. Oxidation of heme protein produces Heinz bodies, and oxidation of hemin produces methemoglobinemia. Vitamin E is also denatured. This latter reaction removes a potent antioxidative protective factor and enhances cellular susceptibility to additional oxidants.

The hemolytic phase of copper poisoning is often initiated by noxious stimuli that could include shipping, hierarchal change, administration of oxidative drugs, starvation, or change of housing.[13] High-protein diets have increased resistance to the hemolytic crisis in sheep, but the role of extra molybdenum intake in these supplemented animals was unclear.[9,14] The mechanistic relationship between stressful events and hepatocyte release of copper is unknown.

Sources of copper that have been responsible for copper accumulation in animals include trace mineralized salt, inappropriately formulated cereal grain mixtures, forages from pastures that have been fertilized by swine or chicken manure,[15]

VetBooks.ir

VetBooks.ir

orchard pastures that have been contaminated by copper-containing fungicides, rations containing more than 20% chicken litter, or diets that contain high concentrations of palm kernel oil. Other potential sources of copper include fencing and copper piping and overdoses of parenterally administered copper salts. Dairy goats have been poisoned by supplementation of trace minerals that were formulated for dairy cattle.

The toxic dose of copper for each species is variable and depends on duration of exposure, the animal's genetics, and the amount of molybdenum being fed. Diets with copper/molybdenum ratios over 6:1 are more likely to result in copper poisoning than diets with lower ratios. The interaction between the two minerals may occur in the solid phase of rumen ingesta, where insoluble and nonabsorbable complexes among copper, sulfur, molybdenum, and large-molecular-mass protein complexes are formed. The highly complexed copper is unabsorbed and hence not toxic. High dietary intake of zinc and iron also inhibit absorption of copper, and although the precise mechanism of antagonism is unknown, the elements share a competitive affinity for metallothionein.[16-18] Competition for this protein could alter the storage capacity for copper. Soil sulfates reduce molybdenum absorption by plants, increasing the potential for pathologic accumulation of copper in herbivores.

The respective single toxic doses of copper for sheep and cattle range between 20 and 110 mg/kg and 220 to 880 mg/kg of body weight. Most poisonings occur after long-term, low-dose ingestion of the element. Copper poisoning can occur in sheep after 2 months of daily dosing of 3.5 mg/kg of copper, feeding a ration that contains 20 ppm of copper for several months, or after a single SC injection of copper EDTA salt at a dose of 2 mg/kg.[19] Sheep have been poisoned by subcutaneous injection of 3 to 4 mg/kg of copper-calcium EDTA but remained normal after 6 mg/kg of copper methionate.[20] One study that fed 3.7 mg/kg of copper daily for 84 days reported peak hepatic copper levels that ranged between 258 and 375 mg/kg wet weight by 26 days after the final copper feed.[21] A single dose of 50 mg of copper caused acute hemolytic crisis in sheep when treated during midpregnancy. The largest incidence of hemolytic anemia occurred in Welsh sheep, and the lower cumulative incidence was in Cheviot sheep.[22] Single doses of copper calcium ETDA at 25 mg/animal have killed lambs.[23] Cumulative doses of copper ranging between 12.8 and 22 g have produced hemolytic anemia in Suffolk lambs by 42 days.

Goats may show signs of copper poisoning by 144 days after daily feeding of a ration that contains 80 mg copper/kg. Placental transfer of copper occurs, but concentrations in the tissues of lambs are not toxic even during the hemolytic phase in the dam. Adult cattle may be poisoned by feeding 5 g of copper sulfate daily for as long as 4 months. Calves may be poisoned after 6 to 8 weeks of feeding milk replacer containing 115 ppm of copper.[10,24] Horses are resistant to high dietary concentrations of copper and may remain clinically normal after prolonged feeding of diets containing levels as high as 791 ppm. In those horses, hepatic concentrations of copper at the end of the feeding period reached 4000 ppm. Adult ponies that were treated once with an oral dosage of copper of 40 mg/kg did not develop hemolytic anemia.

Clinical Signs

Animals exposed to high levels of copper are asymptomatic for weeks until the onset of hepatic necrosis.[25,26] Signs develop rapidly thereafter and are reflective of coexisting anemia, myopathy, and neurologic, renal, and hepatic disease. Clinical signs include inappetence, lethargy, weakness, recumbency, cool extremities, pallor, and grayish discoloration of the mucous membranes. Affected animals have a markedly increased pulse rate, poor pulse quality, tachypnea, hypotension, and hypothermia. Urine is dark red from the presence of free hemoglobin products. Feces are dark or have yellowish discoloration but are normally formed and do not contain hemoglobin unless secondary abomasal ulceration has occurred. Animals may have marked petechiation of the conjunctival mucosa. Pregnant animals often abort secondary to hypoxemia. Recumbent patients usually expire without struggling.

Pathology

The tissues of hemolyzing animals are pale and icteric, and serous surfaces are covered by petechial and ecchymotic hemorrhages. The liver is often pale and yellow, and the lungs are firm. Kidneys turn black and have a metallic sheen due to entrapped hemoglobin. The urinary bladder of copper-poisoned animals is filled with serosanguineous urine. Microscopic changes include hemoglobinuric and tubular nephrosis and necrosis of the splenic follicles and hepatocytes. There is also biliary ductular proliferation and pericholangitis.[21,27] Hepatic necrosis may be detectable by microscopic examination for as long as 412 days post poisoning. Microscopic brain changes in poisoned animals include spongy degeneration of the pons and brainstem.

Diagnosis

Normal hepatic concentrations in sheep have been reported as 173 ± 130 (mean ± SD) and 129 ± 59 ppm (wet matter) for adults and lambs, respectively.[28] Wet matter hepatic concentrations of copper in poisoned animals were 429 ± 249 (mean ± SD) ppm. Dry weight concentrations may be greater than 3000 ppm. Hepatic concentrations are usually high before and after the hemolytic episode, but normal hepatic copper concentrations in hemolyzing animals have been reported.[19] The correlation between plasma and hepatic copper concentrations in prehemolytic animals is poor.[29-30] Copper poisoning in animals with normal plasma concentrations and near-toxic liver levels have been reported.[31] Normal plasma copper concentrations range from 13 to 20 μmol/L (0.8 to 1.2 μg/mL).[21] Serum copper concentrations range between 0.60 and 1.50 μg/mL (0.6 to 1.5 ppm). Plasma copper concentrations that range between 2.4 and 20.0 μg/mL (2.4 to 20 ppm) are diagnostic for acute toxicosis.

Clinical Pathology

There are no consistent hematologic changes until 24 hours before the hemolytic crisis, when sudden concentrations of cytosolic hepatic enzymes rise coincidentally with a sharp rise in plasma copper concentration. Plasma copper concentrations fall rapidly following the hemolytic crisis and are often near normal by 4 days after hemolysis.[25] Copper concentrations within erythrocytes remain high.

Clinicopathologic changes that occur during the acute hemolytic crisis include Heinz body formation, intravascular hemolysis, methemoglobinemia (as much as 5%), decreased PCV, and increased concentrations of plasma bilirubin, AST, GGT, alkaline phosphatase, total bilirubin, creatine kinase, creatinine, plasma urea nitrogen, and plasma ceruloplasmin. Urine is dark brown to black and contains high concentrations of protein, blood, and hemoglobin casts. Microscopic examination of urine may detect erythrocytic casts and inflammatory cells.[32] Sheep that survive the hemolytic episode develop reticulocytosis by 4 days after the onset of clinical signs.[33]

Hepatic concentrations of 16 mmol copper/kg of dry matter are the threshold for development of hemolytic anemia. The half-life of copper in the liver of untreated poisoned sheep has been estimated to be 175 ± 91 days,[21] and high copper

concentrations in hepatic tissues can be found for as long as 100 days after initiation of the hemolytic episode.[29]

Kidney concentrations of copper in animals with hemolytic crisis are 15 and 50 ppm for dry and wet weight volumes, respectively. Sheep may have increased plasma concentrations of γ-glutamyltransferase (GGT) and AST for 3 days before the onset of hemolysis, and glutamate dehydrogenase may be increased for as long as 700 days after cessation of copper ingestion.[21] Fecal copper concentrations may exceed 10,000 ppm during the hemolytic episode.

Treatment

Animals with acute hemolytic syndrome should be insufflated with oxygen and treated with vitamin E (3 to 5 daily doses consisting of 3000 IU/dose). If PCV is below 8%, animals should be given packed washed homologous erythrocytes. Additional therapy should include D-penicillamine (Cuprimine [Merck Sharp & Dohme, Rahway, N.J.] at 52 mg/kg of body weight daily for 6 days), anhydrous sodium sulfate (1 g/sheep daily for 6 days), and ammonium molybdate (100 mg/sheep daily for 6 days). Treatment with D-penicillamine increases urinary copper excretion by 10- to 20-fold.[34] Single-dose therapy with D-penicillamine (28 mg/kg body weight) increases copper excretion, but the effect is transient and insignificant for reducing the total hepatic copper load.[35]

Dietary supplementation with 7.7 ppm ammonium molybdate also results in hepatic copper concentrations that are 40% lower than in unsupplemented controls. Addition of 7 or 15 mg molybdenum for 80 days to experimentally poisoned sheep has reduced hepatic copper concentration in sheep by 34% and 46%, respectively.[36] Copper-poisoned cattle have been successfully treated with oral sodium molybdate (3 g daily) and sodium thiosulfate (5 g daily). When introduced into the sulfur-rich rumen contents, molybdenum salts complex with high-molecular-weight proteins in the solid phase of the digesta.[37] The protein-bound thiomolybdate aggregates strongly chelate copper in insoluble and indigestible complexes. Molybdenum salts also enhance biliary copper excretion and selectively remove copper from hepatic metallothionein.[16,38,39] For poisoned cattle, top dressing food with 500 to 1000 mg ammonium molybdate daily for 18 days markedly reduced the amount of hepatic copper.[40]

Parenterally administered ammonium tetrathiomolybdate has been recommended for treatment of acute hemolytic crises due to copper poisoning. IV administration of ammonium tetrathiomolybdate reduces both lysosomal and cytosolic copper in hepatocytes. The drug has been given as a 5% solution in sterile saline with an IV dosing schedule of either 50 to 100 mg twice weekly for up to 11 weeks, or as 3 doses consisting of 3.4 mg/kg of body weight on alternate days and beginning at the onset of hemolytic crisis.[41-45] Concomitant administration of 36 mg of xylazine IV increased copper excretion in bile by as much as 2.25-fold over controls that were treated with thiomolybdate only.[46] Parenteral administration of thiomolybdate results in transient increases of copper concentrations in blood for as long as 24 hours. Because copper is acid insoluble, the effect is to protect copper-exposed animals from hemolytic crises and reduce tissue damage during a hemolytic event.[47,48] Biweekly injection of 100 mg molybdenum as tetrathiomolybdate increased daily hepatic biliary copper excretion by a factor that ranges between 150% and 300%.[49]

Prevention

Owing to the sporadic nature of copper poisoning and lack of signs during the accumulative phase, it can be difficult to prevent. Clients should be counseled to purchase concentrates with label claims for the species being supplemented. Copper-supplemented salts should be restricted, especially in sheep. Pastures heavily contaminated by copper can be top dressed with molybdenum phosphate (113 g molybdenum/acre). Fencing and plumbing that contain copper sulfate or metallic copper should be removed from the environment. One study in sheep receiving 36 mg copper/kg daily for 18 months controlled the hemolytic crisis and associated mortality due to copper poisoning by SC injection of sterile ammonium tetrathiomolybdate (containing 3 to 4 mg molybdenum) on alternate days for three injections.[44] Addition of ammonium molybdate at 7.7 ppm and sodium sulfate at 4200 ppm reduced liver copper and decreased plasma ceruloplasmin in experimentally exposed lambs.[30]

Feeding experimentally poisoned lambs sodium molybdate and sodium sulfate at respective daily dosages of 20 mg and 6 g reduced hepatic copper content after 90 days.[50] Addition of 3 mg/kg of food (dry matter) molybdenum in the form of tetrathiomolybdate reduced hepatic copper accumulation by as much as 33-fold.[43]

Hemolytic Syndrome in Horses With Liver Failure

Johanna L. Watson • Gary P. Carlson

A fulminant intravascular hemolytic syndrome has been reported as a near-terminal event in horses with either acute or chronic liver failure.[1] Marked hemoglobinemia and hemoglobinuria are associated with intense icterus, and the sclera and conjunctiva often take on a distinctive deep reddish-orange color. The onset of intravascular hemolysis is sudden and rapidly progressive. The prognosis is highly unfavorable; nearly all horses that develop this syndrome do not survive.[2]

The cause of this syndrome is unknown, but release of hepatic copper stores does not appear to be a factor. The hemolysis may be associated with increased erythrocyte osmotic fragility. Human patients with liver cirrhosis develop a hemolytic syndrome associated with alterations in the exchangeable lipoproteins of the red cell membrane. A similar mechanism has not been shown in horses, but morphologic alterations in these horses' red cells resemble the burr cells described in human patients.[3] Bile acids and their salts are markedly increased in liver failure and could play a contributing role in the hemolytic process. At necropsy, widespread hemorrhagic lesions that resemble those described for DIC are often present.[3]

Congenital Erythropoietic Porphyria

Gary P. Carlson

A rare congenital disorder of hemoglobin production that is inherited as an autosomal recessive has been recognized primarily in Holstein cattle, but it has also been reported in other breeds.[4-7] Commonly called "pink tooth," the disorder is characterized by slow growth rates in calves, photosensitization, and exfoliation of nonpigmented skin when exposed to sunlight, reddish-brown teeth, and modest anemia. The teeth and bones exhibit a pink fluorescence under ultraviolet light, and the presence of uroporphyrin turns urine a brownish-red color. The condition is present at birth, and the metabolic defect is a hereditary deficiency of the enzyme uroporphyrinogen III synthase (UROS), which catalyzes an essential step in the synthesis of the porphyrin structure of hemoglobin. This leads to accumulation of uroporphyrin and coproporphyrin, which deposit in the teeth, where they are concentrated in the dentin, bones, and other tissues. The anemia seen in these cattle is variable among individuals, and several factors contribute to

VetBooks.ir

it. Reduced intravascular red cell life span is related to the high concentration of uroporphyrin and coproporphyrin within the cells. Porphyrins may induce hemolysis and delay red cell series maturation in the bone marrow, although there is often evidence of active erythropoietic response in peripheral blood.[5]

There is no treatment for this inherited disorder, but genetic counseling is advisable. Substantial efforts have been made to reduce the incidence of this disease in the Holstein breed. Affected cattle have much lower levels of UROS than normal cattle, and carrier animals have intermediate levels of this enzyme. Despite their rather serious problems, these cattle do reasonably well if housed indoors out of direct sunlight. The principal differential consideration is chronic fluorosis, which also produces brown discoloration of the teeth, but they do not fluoresce under ultraviolet light.

Another form of altered porphyrin metabolism, erythropoietic porphyria, has been described in humans and cattle.[5] In humans the mode of inheritance is autosomal dominant, whereas in cattle the disorder appears to have a recessive pattern of inheritance and may be sex linked because it is only seen in females. The disease does not produce anemia, porphyrinuria, or teeth discoloration, but ferrochelatase (heme synthase) deficiency leads to high concentrations of erythrocyte and fecal protoporphyrins.

Porphyria has also been reported in swine, where it exhibits a dominant pattern of inheritance.[5] Health effects are minimal, and there is no photosensitivity, but the pigs' teeth have reddish-brown discoloration.

Finally, animals may develop acquired toxic porphyrias. This can occur with heavy metal poisonings, principally lead. Lead inhibits several key enzymes of heme synthesis. Inhibition of aminolevulinate dehydrase leads to accumulation of aminolevulinic acid, and decreased aminolevulinate dehydrase activity is a sensitive indicator of lead poisoning. Lead also inhibits ferrochelatase and leads to marked elevation of erythrocyte zinc protoporphyrin IX, making measurement of zinc protoporphyn IX levels a means of monitoring lead exposure.[5]

Depression Anemia

Johanna L. Watson • Gary P. Carlson

The most common form of anemia in domestic animals is associated with inadequate erythropoiesis or bone marrow depression. Depression anemia can be caused by (1) deficiencies of vitamins or minerals essential for erythrocyte production, (2) systemic disease processes that interfere with normal erythropoiesis, or (3) processes that damage or displace normal bone marrow elements. Common causes of depression anemia are listed in Box 37.2. Depression anemia is mild to moderate in severity and generally is slowly progressive. Depressed erythropoiesis is occasionally associated with processes that also result in blood loss and/or an increased rate of erythrocyte destruction. When this occurs, a profound rapidly progressive and potentially life-threatening anemia can develop. With the possible exception of chronic iron or copper deficiency, depression anemia tends to be normocytic and normochromic. Bone marrow evaluation is an extremely useful diagnostic tool in animals with nutritional deficiencies or when bone marrow damage or dyscrasia is suspected.

BOX 37.2

Causes of Depression Anemia

Nutritional Deficiency
- Iron deficiency
- Copper deficiency
- Cobalt deficiency
- Vitamin B_{12} deficiency
- Folic acid deficiency

Anemia of Inflammatory Disease
- Chronic infection
- Chronic inflammation
- Fractures and severe trauma
- Neoplasia

Anemia Secondary to Organ Dysfunction
- Chronic liver disease
- Chronic renal disease
- Chronic gastrointestinal disease
- Parasitism (trichostrongylosis)

Bone Marrow Damage/Dysplasia
- Myeloid and megakaryocytic bone marrow hypoplasia in Standardbred horses
- Bracken fern poisoning
- Congenital dyserythropoiesis and keratosis in polled Hereford calves
- Trichloroethylene-extracted soybean meal toxicity
- Myelophthisic disorders (myeloproliferative disease, lymphoma)
- Aplastic anemia

Iron Deficiency Anemia

Johanna L. Watson • Gary P. Carlson • Monica Aleman

Iron is present in most forages and grains. In neonates, the major source of iron is colostrum (≈0.79 mg/L in mare's milk).[1] Soil, dam's feces, and milk are other important sources of iron.[1] Iron deficiency is most commonly associated with chronic blood loss due to internal or external parasitism, bleeding GI lesions, or hemostatic defects. Dietary iron deficiency is seldom the sole cause of anemia, even in neonates on an all-milk diet, unless they are raised on cement or in barns or hutches with no access to the soil. A modest anemia is anticipated in veal calves. The anemia seen in some young calves during the first few days to weeks of life is apparently the result of congenital iron deficiency.[2] Altered immune function, high incidence of infection, and reduced growth performance are reported in veal calves on low-iron diets.[3] Alterations in GI pH may alter absorption of iron by the small intestine. States of inflammation and infection cause iron sequestration, not deficiency, by the reticuloendothelial system and lactoferrin. Iron deficiency has been well documented in calves and piglets housed exclusively indoors or in hatches with no access to soil.[4] Absolute iron deficiency anemia is not commonly reported in horses.[5-8]

Circulating erythrocytes account for about two-thirds of the total iron reserves found in the body. The remaining iron stores are distributed in the liver, spleen, and bone marrow. With chronic blood loss anemia, iron depletion is first indicated by decreased marrow iron, which can be appreciated with special staining of the bone marrow with Prussian blue stain for iron. As blood loss continues and iron deficiency progresses, serum iron is decreased, whereas iron-binding capacity may actually increase. Late in this process, iron-deficient erythropoiesis results in the typical microcytic, hypochromic erythrocytes generally thought to be characteristic of iron deficiency anemia (decreased PCV, hemoglobin concentration, mean corpuscular volume, and mean corpuscular hemoglobin concentration).

Other laboratory findings include echinocytosis, keratocytosis, schistocytosis, acanthocytosis, ovalocytosis, hypoferritinemia, and hypoferremia.[5-8] The observed RBC morphologic abnormalities are thought to be due to oxidative damage. Normal serum iron and iron-binding capacity for most domestic animals is 100 and 300 μg/dL, respectively.

Treatment

Treatment of iron deficiency anemia is contingent on evaluation of the cause and correction or resolution of the process responsible for chronic blood loss. Iron is usually supplied as an oral supplement or feed additive, and many commercial preparations are available. Injectable iron dextran intended for use in baby pigs should be avoided in horses and cattle, because it can induce anaphylaxis, especially if administered repeatedly.[9] An injectable iron preparation intended for use in horses was reported to result in acute iron overload, massive hepatic necrosis, and severe death losses in a group of young cattle.[10] Iron overload has resulted in acute death losses in neonatal foals fed an iron-containing microbial supplement and in hemochromatosis and extensive liver damage in adult horses.[11]

Copper Deficiency

Johanna L. Watson • Gary P. Carlson

Copper deficiency can occur as a primary problem in milk-fed animals or in pastured animals in copper-deficient areas. More commonly, copper deficiency occurs secondarily in association with other trace mineral imbalances such as dietary molybdenum excess and is influenced by the sulfur and zinc content of the diet. Copper is an essential cofactor for a wide variety of enzymatic reactions, and copper deficiency produces a constellation of clinical signs related to impairment of these reactions.[12] Clinical signs of copper deficiency are most prominent in young, growing animals and may include reduced growth rate, rough and depigmented hair, diarrhea, osteoporosis with spontaneous fractures, and anemia. In lambs, copper deficiency can produce a demyelinating syndrome known as *swayback* or *enzootic ataxia*. Copper deficiency has also been associated with hemolytic anemia in postparturient dairy cattle in New Zealand.[10] Copper plays an important role in iron transport from the gut to the marrow and in the incorporation of iron into the heme moiety. The anemia produced by copper deficiency is generally moderate and slowly progressive. It closely resembles iron deficiency in that it is usually a microcytic, hypochromic anemia. Bone marrow evaluation often reveals intracellular accumulations of iron known as *sideroblasts*. This finding indicates that the principal problem is a function of altered incorporation of iron into the erythrocyte hemoglobin rather than an actual deficiency of iron. Copper deficiency can be documented by measuring serum copper as ceruloplasmin, erythrocyte superoxide dismutase, or the copper content of hair, liver, or kidney. Serum iron tends to be low in animals with copper deficiency. Copper can be supplied as a dietary supplement or as an injectable copper glycinate preparation.

Vitamin B_{12} and Folic Acid Deficiency

Johanna L. Watson • Gary P. Carlson

Nearly all of the vitamins are necessary for normal erythropoiesis, but in ruminants and horses only deficiencies of vitamin B_{12} and folate have been associated with development of anemia. These two vitamins play essential roles in DNA synthesis. When deficiency of both vitamins occur, as has been experimentally produced in pigs, a marked macrocytic anemia with hypersegmented circulating neutrophils and giant metamyelocytes and neutrophils in the bone marrow may be found. In ruminants, vitamin B_{12} deficiency has been associated with grazing cobalt-deficient pastures. A macrocytic to normocytic anemia may be noted in these animals.

Anemia of Inflammatory Disease

Johanna L. Watson • Gary P. Carlson

A depression anemia associated with characteristic disturbances of iron metabolism is often found in animals with conditions that result in a chronic inflammatory response.[13,14] These conditions include chronic internal or cutaneous infections, infectious diseases, or immune-mediated processes that result in chronic inflammation, severe traumatic injury or fractures, and active malignant neoplasia. The anemia tends to be mild, slowly progressive, and of little clinical consequence. Clinical signs relate to the primary disease process, and hematologic features are those of a mild, unresponsive anemia, often with indications of a chronic inflammatory response. Serum iron and iron-binding capacity are decreased, but marrow iron reserves and serum ferritin are increased.[14] Anemia in these animals is partially due to a modest decrease in circulating red cell life span, but it is primarily caused by major alterations in iron metabolism and depressed bone marrow response to the anemia. These alterations represent part of the body's response to inflammation, which includes release of interleukins and other mediators and production and release of acute-phase proteins from the liver. The body sequesters iron from the circulation into storage forms, primarily in the liver and bone marrow, where it is retained and relatively unavailable for erythropoiesis. This general reaction may play a protective role by denying readily available iron to potential bacterial pathogens that require iron for growth. Iron supplementation is not indicated to treat the anemia of chronic inflammation; therapeutic effort should be directed at resolving the primary disease process.

Anemia Secondary to Organ Dysfunction

Johanna L. Watson • Gary P. Carlson

A mild to moderate unresponsive anemia can develop in patients with chronic endocrine, hepatic, renal, or GI diseases. These disorders can produce bone marrow depression by reducing absorption, processing, and distribution of elements essential for erythropoiesis; allowing elaboration or accumulation of toxic compounds; or interfering with the production or action of erythropoietin.[15,16] These effects can occur independently of the alterations in iron metabolism that characterize the anemia of inflammatory disease.[14] However, should inflammatory processes be responsible for the specific organ damage or dysfunction, the same pattern of anemia as described in the previous section would apply. Specific therapy for anemia in these patients is not indicated, and resolution of the anemia depends on successful management of the primary disease process.

Internal parasitism, particularly *Trichostrongylus* spp. in ruminants, can result in a marked anemia that is primarily the result of bone marrow depression in which failure to absorb iron, copper, and essential amino acids plays a major role.

VetBooks.ir

Myeloid and Megakaryocytic Bone Marrow Hypoplasia

Johanna L. Watson • Gary P. Carlson

Myeloid and megakaryocytic bone marrow hypoplasia has been reported in eight young Standardbred horses sired by the same stallion.[17] Clinical signs were variable and in some individual horses included nonhealing wounds, unresponsive fevers, pleuritis, pneumonia, ataxia, hemoperitoneum, and bleeding into the bowel. Seven of eight horses died or were euthanized. The principal laboratory findings were a variable red cell count from normal to modest to marked anemia, moderate to profound neutropenia, and intermittent thrombocytopenia in most of the horses. There appeared to be a cyclic variation in neutrophil and platelet counts. A familial basis for the disease is suspected.[17]

Aplastic Anemia

Johanna L. Watson • Debra Deem Morris

Aplastic anemia is a stem cell disorder characterized by reduced marrow production of all blood components in the absence of a primary disease process infiltrating the bone marrow or suppressing hematopoiesis.[18,19] Peripheral pancytopenia secondary to marrow aplasia is apparently uncommon in horses, although idiopathic hypoplastic anemia has been reported,[20-22] as well as rare cases associated with phenylbutazone use.[15-23] Hemorrhagic diathesis caused by thrombocytopenia is often the first indication of disease, manifested by epistaxis, mucosal petechiae, or prolonged hemorrhage after trauma or injections. Pallor may be present, with other signs of anemia (e.g., reduced exercise tolerance) depending on the severity and rapidity of aplasia progression. Neutropenia causes increased susceptibility to infections, which may result in intermittent fever or weight loss. Lymphocyte production is reportedly not impaired, but absolute lymphopenia is common in aplastic anemia. Circulating lymphocytes are often highly reactive, producing the suspicion of neoplasia or a preleukemic syndrome.[15]

The diagnosis of aplastic anemia is based on the combination of peripheral pancytopenia and bone marrow hypoplasia with fatty replacement. Because the normal erythrocyte life span in horses is roughly 140 days and in cattle exceeds 160 days,[24] neutropenia with no left shift and thrombocytopenia are earlier hematologic manifestations.

The major aims in treatment of aplastic anemia are to remove the animal from suspected causative agents and provide supportive care, in the hope spontaneous remission will occur. Broad-spectrum antimicrobials are necessary to control infections. Blood transfusions are rarely indicated, and platelet transfusion should be reserved for severe bleeding episodes, which rarely occur. Bone marrow transplantation is used with some success in humans, although graft-versus-host disease poses significant risk. The latter would presumably limit this therapy in horses; too few horses with aplastic anemia have been studied to give a clear indication of prognosis.

Bracken fern toxicosis in ruminants causes bone marrow depression and subsequent pancytopenia.[24] The toxic effects of the plant are cumulative, and clinical signs occur suddenly 2 to 8 weeks after cattle gain access to the plant. Clinical signs include fever, melena, epistaxis, hematuria, mucosal petechiae, hyphema, and bleeding from the eyes and vagina. Hematology reveals a platelet count less than 40,000/μL and profound leukopenia with essentially no neutrophils present. Death may follow in 1 to 3 days as a result of the combined effects of multiple internal hemorrhages and bacteremia. The major toxic factor in bracken fern is thought to be ptaquiloside.[24] Necropsy of cattle with bracken fern toxicosis reveals multiple hemorrhages throughout most tissues, necrotic GI tract ulcers, and pale bone marrow. Antibiotics and blood and platelet transfusions may be appropriate, but cattle with advanced bracken fern toxicosis (platelet count <50,000/μL, leukocyte count <2000/μL) usually die.

Paradoxical Erythroid Hypoplasia

Johanna L. Watson • Monica Aleman

Recombinant human erythropoietin (rhEPO) has been used in racehorses to enhance their athletic activity by stimulating erythrocyte production in the bone marrow. Mild to moderate anemia and paradoxical erythroid hypoplasia based on bone marrow cytology were reported in two Standardbred racehorses following rhEPO administration.[25] Serum from these horses inhibited the rhEPO-induced activity of mouse bone marrow in vitro. The degree of inhibition was inversely proportional to the amount of exogenous rhEPO added to the serum, suggesting the presence of anti-rhEPO antibodies. Anti-rhEPO antibodies to exogenous rhEPO likely cross-reacted with the horses' endogenous rhEPO. These horses were treated with corticosteroid and returned to athletic activity.

Erythrocytosis (Polycythemia)

Johanna L. Watson • Debra Deem Morris

Absolute erythrocytosis is caused by increased erythropoiesis that creates a circulating erythrocyte mass above normal for the species. Relative erythrocytosis caused by hemoconcentration, endotoxemia, and splenic contraction (horses) must be ruled out because these conditions are much more common in large animals than absolute erythrocytosis. Diagnosis of absolute erythrocytosis is based on persistently elevated PCV, hemoglobin, and erythrocyte count without clinical evidence of shock or dehydration and without response to IV fluid therapy. Primary erythrocytosis is associated with normal arterial oxygen tension and reduced plasma erythropoietin, whereas secondary erythrocytosis is due to increased production of erythropoietin.

All disorders characterized by an absolute erythrocytosis share clinical manifestations caused by expanded blood volume and increased blood viscosity. Generalized vascular expansion and venous engorgement cause the characteristic "muddy" hyperemia of mucous membranes. A marked decrease in cardiac output accompanies blood hyperviscosity and ultimately impairs tissue oxygenation, producing the vague signs of lethargy and weight loss. There may be an increase in thrombotic complications like laminitis and renal failure.

Congenital Erythrocytosis

Familial erythrocytosis, described in cattle[1] and humans,[2] is due to autonomous erythropoietin production without a demonstrable lesion. Congenital erythrocytosis is thus a form of inappropriate secondary erythrocytosis. Chronic hypoxia should be ruled out by measuring arterial oxygen concentration. The only way to definitively differentiate secondary erythrocytosis from primary erythrocytosis is by determination of serum erythropoietin.

Acquired Erythrocytosis

Primary Erythrocytosis

Polycythemia vera, an idiopathic myeloproliferative disorder characterized by excessive proliferation of erythroid, myeloid, and megakaryocytic elements, without an increase in the plasma erythropoietin, is rare in animals.

Secondary Erythrocytosis

PHYSIOLOGICALLY APPROPRIATE ERYTHROCYTOSIS. In domestic animals, absolute erythrocytosis is usually secondary to chronic diseases that produce tissue hypoxia. Chronic tissue hypoxia that attends residence at high altitude, congenital heart defects that produce right-to-left shunting, and some forms of chronic pulmonary disease induce a compensatory increase in plasma erythropoietin that results in absolute secondary erythrocytosis.[3]

The partial pressure of oxygen (P_{O_2}) in capillaries must be maintained close to 40 mm Hg to ensure adequate off-loading of oxygen to tissues. At elevated altitudes, diminished atmospheric oxygen tension produces a much smaller alveolar capillary P_{O_2} gradient and an inadequate driving force for tissue oxygenation. Erythropoietin production in response to hypoxia causes erythrocytosis to increase the oxygen-carrying capacity of circulating blood. Cattle are most susceptible to the effects of high altitude, and some develop polycythemia at 1800 m above sea level. Horses develop an increased erythrocyte mass above 2200 m, especially when in training. Sheep are similar to cattle, but goats are apparently least susceptible to elevation hypoxia.

Congenital cardiac disorders that produce right-to-left shunts are a common cause for absolute erythrocytosis in large animals. Tetralogy of Fallot is the most common defect to cause shunting of unoxygenated blood into the peripheral circulation, although a number of other defects (ventricular septal defect [VSD] being the most common) may eventually result in right-to-left shunting and secondary erythrocytosis.[4]

Chronic impairment of alveolar ventilation may eventually cause erythrocytosis, although most chronic pulmonic diseases in large animals are not associated with significant hypoxemia. Equine asthma (RAO, COPD) may produce enough ventilation/perfusion mismatching to reduce the pressure of arterial oxygen below normal, but the resultant hypoxemia is insufficient to induce erythrocytosis.

PHYSIOLOGICALLY INAPPROPRIATE ERYTHROCYTOSIS. Inappropriate elaboration of erythropoietin (i.e., normal P_{O_2} and secondary erythrocytosis) may rarely accompany renal, hepatic, or endocrine disorders, especially those caused by neoplasia. Secondary erythrocytosis may accompany nonmalignant renal disorders, in which local intrarenal ischemia is believed to mediate increased erythropoietin production. Paraneoplastic erythrocytosis with normal serum erythropoietin is due to tumor production of androgenic steroids or a protein with erythropoietin-like action.[5] Increased plasma erythropoietin and secondary erythrocytosis has been identified in horses with hepatocellular carcinoma.[3,6] Erythrocytosis was described in a horse with hepatoblastoma[7,8] and in another with lymphoma,[9] but serum erythropoietin levels as measured by a human assay were normal in both instances. In the horse with lymphoma, erythropoietin gene expression was identified in the lymphoma tissue. Typically, the diagnosis of inappropriate secondary erythrocytosis is based on elevated serum erythropoietin in the absence of hypoxemia. Elevated serum erythropoietin may not be demonstrated because of the nature of the assay or other compounds causing erythrocytosis.

Treatment of Erythrocytosis

When erythrocytosis is not in response to an appropriate physiologic stimulus (e.g., primary erythrocytosis and inappropriate secondary erythrocytosis), phlebotomy to keep PCV below 50% is the mainstay of treatment to control hypervolemia and blood hyperviscosity. Initially 2 to 4 L of blood may have to be removed every 2 to 3 days, but as iron deficiency supervenes, the frequency of phlebotomy may be reduced. The myelosuppressive drug hydroxyurea is used in humans and dogs with *polycythemia vera*.[2,10]

Appropriate management of secondary erythrocytosis is more complex because there is a need for increased oxygen-carrying capacity of the blood. The beneficial effect of expanded red cell mass is ultimately offset by the detrimental effect of increased blood viscosity on oxygen delivery. Oxygen delivery is impaired when PCV exceeds 60%, although continued erythropoietin output may result in overcompensation. Phlebotomy is indicated when PCV is over 60%, but the optimum PCV for patients residing at high altitudes or those with right-to-left cardiac shunts must be determined by trial and error.

The long-term prognosis for patients with erythrocytosis is determined by the severity and cause of the disorder. Congenital cardiac defects, neoplastic diseases, and chronic organ insufficiency carry a guarded to poor prognosis. Familial or primary erythrocytosis may be managed by phlebotomy, although there are no long-term follow-ups for large animals with these disorders.

Proliferative Disorders of Lymphoid and Myeloid Systems

The lymphoproliferative disorders reported in large animals are lymphoma, lymphocytic leukemia, and plasma cell myeloma. The myeloproliferative disorders are myeloid leukemias and malignant histiocytosis. The following sections will describe lymphoma, leukemia, and myeloma.

Bovine Lymphoma

John A. Angelos

Bovine lymphoma (lymphosarcoma) is characterized in terms of the frequency of occurrence (sporadic or endemic/enzootic), age at onset, organ involvement, and associated etiologic agent. Sporadic bovine lymphoma occurs as generalized lymphadenopathy in calves (calf or juvenile form), as thymic involvement in cattle between 6 months and 2 years of age (thymic or adolescent form), and as a cutaneous form in cattle between 1 and 3 years of age. Lymphoid tumors of cattle with sporadic bovine lymphoma are of the B- or T-cell lineage.[1] The most common form of lymphoma appears endemically in adult cattle more than 2 years of age and is associated with *bovine leukemia virus* (BLV) infection and typically involves multiple organ systems; BLV-associated lymphomas of adult cattle are of the B-cell lineage.[2] BLV is an oncogenic type C retrovirus classified in the genus *Deltaretrovirus*, subfamily *Orthoretrovirinae*, and family *Retroviridae*.

VetBooks.ir

Sporadic Lymphoma

Calf or Juvenile Form

The prevalence rate of juvenile lymphoma is unknown, but this form of lymphoma is rare. The cause of juvenile lymphoma is unknown and does not appear to be associated with BLV infection. The age at onset ranges from 3 to 6 months but can be seen in calves as young as 1 month or in cattle as old as 3 years. There have been reports of fetal involvement with the calf form.[3] Calves generally present with a history of slight to moderate depression, weight loss, weakness (mainly in older calves and despite good appetite), or lymphadenopathy (mainly in younger calves). The onset of signs can be sudden (within a week).

Physical examination may reveal generalized bilateral enlargement of lymph nodes (deep cervical, parotid, subiliac [prefemoral], and mandibular) and occasionally hemal nodes. Rarely, node enlargement is restricted to a regional anatomic site and not generalized. Enlarged nodes tend to be smooth and firm but are not hot or painful. In addition to enlarged lymph nodes, common presenting clinic signs include bloat and dyspnea. Mucous membranes are usually pale as a result of anemia. Tachycardia, tachypnea, hyperpnea, cough, and harsh respiratory sounds may be evident on auscultation. Less frequently reported signs include fever, ruminal tympany, an enlarged liver, ataxia, and diarrhea.

Hematologic features include a microcytic hypochromic anemia, a low hemoglobin (<7 g/100 mL), a low packed cell volume (typically mid-20s), and a leukocytosis primarily caused by a lymphocytosis. Bone marrow examinations may reveal an elevated myeloid/erythroid ratio with massive neoplastic infiltration. Affected calves also tend to have low serum globulin and elevated AST. Neoplastic involvement may affect a variety of organs, including the spleen, heart, kidney, liver, pancreas, uterus, and thymus. Less thymic involvement occurs versus the thymic form of lymphoma; neoplastic tissue is found only as small, microscopic nodules. Subperiosteal neoplastic infiltration may produce spinal cord compression and result in paresis. The disease is rapidly progressive and usually fatal within 2 to 8 weeks of onset.

Thymic or Adolescent Form

The thymic form of lymphoma is rare. The disease is usually seen in cattle 6 to 24 months of age but may occur in newborn calves and cattle up to 4 years of age. Clinical signs are produced by space-occupying lesions in the neck or thorax. Metastatic mammary lymphoma along with thymic lymphoma was reported in a 3-year-old beef heifer.[4] Cattle with thymic lymphoma typically present with brisket enlargement or firm swelling in the presternal area of the brisket, associated with pitting edema.[5] Loss in body condition, rumen tympany, and dysphagia are common. Bloat may occur as a result of inability to eructate rumenal gas as a result of a space-occupying lesion around the esophagus. Generalized lymphadenopathy is uncommon; rather, enlarged superficial cervical and prescapular nodes are usually observed. The jugular veins are distended and nonpulsating; there may be muffled heart sounds and diminished resonance on thoracic percussion. Tachycardia, dyspnea, coughing, or respiratory distress may be present. Fever is also a common clinical finding; however, the exact mechanism is poorly understood but could be due to tumor necrosis, inflammatory mediators, and/or secondary respiratory infections. Hematologic features are generally unremarkable. Anemia is not a consistent feature, and lymphocytosis is only seen occasionally. The course of the disease from the time of recognition is generally from 2 to 9 weeks. The disease is fatal, often as a consequence of bloat.

Although thymic lymphoma is not associated with BLV infection, there has been one report of a BLV-positive 18-month-old heifer with thymic lymphoma. In situ PCR was used to detect the presence of BLV proviral DNA in lymphocytes of the thymus and in liver and kidney epithelium.[6]

Atypical Forms

A 7-month-old Holstein heifer with diffuse swelling over the left thigh, difficulty ambulating, and peroneal and tibial nerve deficits had an infiltrative B-cell lymphoma involving the semitendinosus, semimembranosus, and gluteal muscles.[7] This heifer was serologically positive for BLV antibody, but the possibility of maternally derived antibody could not be ruled out. In another case report, an 18-month-old Friesian heifer with cutaneous lymphoid tumors also had extensive lymphoid nodules covering the external and luminal surfaces of the trachea.[8] An 8- to 9-year-old beef cow with weight loss was reported with pleural and pericardial invasion with a lymphoid tumor of T-cell lineage; the animal tested negative for BLV by PCR.[9] Four of 10 cattle 3 years of age or younger diagnosed with sporadic lymphoma had BLV provirus in tumor DNA as detected by PCR, and a possible role for BLV in some cases of sporadic lymphoma of cattle has been suggested.[10] A 13-month-old alpaca affected with mandibular masses and weight loss of 2 weeks duration was diagnosed with disseminated small cell lymphoma involving the pancreas, kidney, liver, omentum, and the caudal vena cava; BLV proviral DNA was identified in normal liver and mandibular mass tissue adjacent to neoplastic lymphoid tissue, but it was not found in pancreatic or renal tissue.[11]

Cutaneous Form

Cutaneous lymphoma is not as age specific as the other forms of sporadic lymphoma and may affect cattle between 1 and 3 years of age. The history may reveal an initial period of 1 to 3 months, during which cutaneous swellings are observed around the anus, vulva, escutcheon, shoulders, or flank. These signs may regress and subsequently recur. Lesions are generally raised, about 2 to 3 cm in diameter with necrotic centers, and can become ulcerated and painful. Other clinical signs depend on additional organ system involvement of the tumor and may include cardiac insufficiency, with brisket edema extending along the ventral abdomen and jugular pulsation. Pulse and respiration may be elevated as a result of anemia. Hematologic features include anemia and presence of atypical lymphocytes. The mandibular, prescapular, subiliac, and supramammary lymph nodes are usually enlarged.

At necropsy, a variety of organs may be involved, including heart, brain, skin, spinal cord, liver, lung, kidney, and abomasum. The massive lymphoid infiltration of the skin resembles the clinical manifestations of mycosis fungoides of humans. In a report of a 12-month-old red Holstein heifer with cutaneous T-cell lymphoma, serum activity of lactate dehydrogenase (LDH) was moderately increased despite normal to minimally increased activities of liver- and muscle-specific enzymes.[12]

Hemonode Enlargement (Hemal Lymph Node)

A lymphoproliferative condition associated with hemonode enlargement and some generalized lymphadenopathy has been described for cattle infected with a lentivirus[13] that is now called bovine immunodeficiency virus (BIV).[14] BIV belongs in the genus *Lentivirus*, subfamily *Orthoretrovirinae*, and family *Retroviridae*. BIV has molecular similarity to human immunodeficiency virus and is associated with persistent lymphocytosis, lymphadenopathy, central nervous system (CNS) lesions, progressive weakness, and emaciation. Infected calves may develop enlarged superficial nodes *(hemonodes)*, mainly in the cervical region anterior and dorsal to the prescapular lymph node, over the spine of the scapula, in the paralumbar fossa, and dorsal to the subiliac (prefemoral) lymph node. Lymphocytosis

is possibly related to an increase in B lymphocytes. In utero transmission of BIV has also been documented.[15]

Adult Lymphoma (Bovine Leukemia Virus)

The adult, or enzootic, form of lymphoma is the most common neoplastic disease of cattle and is most commonly caused by a BLV infection. Rates of lymphoma in cattle vary considerably, probably reflecting variation in BLV infection rates. A 2007 USDA National Animal Health Monitoring System study estimated that 84% of dairy herds in the United States are infected with BLV,[16] and a 2015 study concluded that 78% of Canadian dairies were infected.[17] Rates of BLV seroprevalence in beef and dairy cattle in Japan have risen 4- and 10-fold between 1980 and 2011.[18] Although less than 5% of BLV positive cattle are reported to develop lymphosarcoma,[19] the rate of cattle condemnations due to lymphoma appears to have increased over time.[20] Most BLV-infected cattle are asymptomatic, immune competent, and maintain adequate production.[21-23]

Epidemiology

Horizontal transmission of BLV has been demonstrated by the transfer of blood from infected cattle to susceptible cattle. Iatrogenic (reuse of common hypodermic needles between animals, reuse of syringes, dehorners, ear notchers or ear tattoo pliers, castration instruments, or even nose tongs) are considered to be risk factors in transmission; however, some studies were unable to demonstrate transmission after use of a common needle.[24-26] A role for Tabanids in BLV transmission has also been demonstrated.[27] A reduction in seroprevalence to BLV was documented following management changes that presumably reduced exposure to BLV-contaminated blood; these changes included switching from gouge to electrical burning dehorners, single use of needles and obstetrical sleeves, disinfection of tattoo equipment, replacement of whole milk feeding with high-quality milk replacer, and heat treatment of colostrum before feeding.[28,29] Infection after use of a Tb needle dipped in blood of a BLV-infected animal could be prevented by wiping the needle with cotton before injection,[30] and transmission is considered less likely if instruments are disinfected. Rectal palpation has been postulated as a means of transmitting BLV, and experimental studies found that under extreme conditions of blood contamination and mucosal irritation, BLV can be transmitted rectally.[31-35] Under conditions typical of routine palpation during pregnancy examination, however, BLV may not necessarily be transmitted to any measurable degree.[33,35,36] Risk of spread from respiratory secretions is generally considered low, yet transmission from inhalation of BLV shed in nasal secretions is considered possible.[37-40] Herd size might be positively correlated with a high rate of lymphoma, which may reflect higher rates of BLV infection in large herds or a preponderance of susceptible pedigrees in some of the herds studied.[41,42] Close contact and heavy stocking/comingling of infected and susceptible animals also increases the incidence of horizontal transmission.[43,44] The presence of persistent lymphocytosis (PL) cattle greatly increases the chances of horizontal transmission.[19] PL is defined as an absolute lymphocyte count at least three standard deviations above the normal mean count that persists for at least 3 consecutive months.

Vertical transmission from infected dams to their fetus across the placenta can occur; however, studies have shown this occurs in only up to about 10% of pregnancies.[15,45] While transmission in colostrum and milk has been shown,[15,46] colostral antibodies also impart a protective effect against BLV infection in calves from BLV-infected dams.[47] Colostrum replacers can contain BLV antibodies that temporarily impart BLV seropositivity to calves; presence of BLV proviral DNA has also been detected in colostrum replacers, but it is unlikely that infectious BLV could survive the manufacturing process.[48,49]

Susceptibility to BLV infection is associated with BoLA type,[50,51] which may explain why higher rates of lymphoma are found in certain families of cattle. The progression of disease to persistent lymphocytosis in some BLV-infected cows has been linked to a shift away from cell mediated immunity toward a humoral response.[52,53] Polymorphisms at the MHC class II BoLA-DRB3.2 gene have been associated with differing circulating proviral loads in blood of Argentinian Holstein cattle and can be used to define BLV-resistant versus susceptible genotypes in these cattle.[54]

Antigenic and molecular evidence for the presence of BLV in mammary glandular epithelium has been demonstrated.[55] The effect of BLV persistent mammary infection on the mammary gland is not completely understood. Although one study identified increased average milk production in BLV-infected versus uninfected cattle,[56] others report negative associations between milk production and BLV status.[23,57]

Diagnosis

Cattle presented with the adult or enzootic form of lymphoma usually are older than 4 years of age but may be as young as 2 years. Cattle are often presented with a history of loss in condition, an abrupt drop in milk production (over a period of a few days), enlarged peripheral nodes, exophthalmos, or partial to complete anorexia, particularly with regard to grain or concentrates. Subclinical lymphoma may be diagnosed in cows submitted for routine reproduction examinations; other signs may include diarrhea, ataxia, paresis, ketosis, and infertility.

Common sites of lymphoid tumor predilection in adult lymphoma include heart (usually right atrium), abomasum, uterus, kidney, and spinal cord (epidural space); other common sites include the retrobulbar space and rumen/reticulum.[58] Physical examination often reveals an organ system failure resulting from tumor involvement. Thoracic auscultation may reveal cardiac dysrhythmia, tachycardia, tachypnea, and hyperpnea. Epicardial lymphosarcoma has been described in 3 dairy cows 3 to 19 months following diagnosis and treatment for idiopathic hemorrhagic pericardial effusion; at the time of initial presentation with pericardial effusion, none of 3 affected cows had cytologic evidence of neoplasia in pericardial fluid.[59] Dependent, pitting edema is common when cervical or supramammary lymph nodes are involved. Involvement of the intestinal lymphatics is often associated with generalized dependent edema anterior to the udder. Peripheral lymph nodes typically found to be enlarged are the prescapular, subiliac, and supramammary nodes. Feces may be scant, pasty, or watery and probably reflect the presence of lesions within the GI tract. Melena may be present in animals with ulceration of the abomasum and lymphoid cell infiltration in the abomasal wall. The main ultrasound finding in a case of abomasal lymphosarcoma was enlargement of lymph nodes caudal to the reticulum, as well as severe enlargement of the abomasum with thickening of the abomasal wall.[60] Rectal palpation can be useful in cases lacking peripheral node enlargement or exophthalmos. Tumor masses palpated in the abdomen typically are multiple and range in size from only slightly enlarged lymph nodes to massive lesions half a meter in diameter. The internal iliac nodes are involved in most cattle with abdominal tumors. Tumors tend to be firm but not hard and may feel slightly lobulated. Differentiation by palpation of lymphoma tumors from other masses is highly subjective. Exploratory laparotomy may be indicated as an additional diagnostic tool in difficult cases, particularly in valuable cattle.

The hemogram of cattle with lymphoma often is generally unremarkable, except in the case of PL animals in which circulating lymphocytes remain elevated for a prolonged period. Approximately 30% of cattle with BLV infection develop persistent lifelong lymphocytosis, composed mostly of B cells.[61,62] Lymphocytotic cattle have higher BLV proviral loads in

VetBooks.ir

peripheral blood lymphocytes than nonlymphocytotic cattle, although some nonlymphocytotic cattle may have high BLV proviral loads and could represent obstacles to successful eradication efforts.[63] Because neutrophil concentrations can be similar between BLV-antibody positive versus BLV-antibody negative cattle while lymphocyte concentrations are increased in BLV-antibody positive cattle, recommendations have been made to avoid the use of calculated neutrophil-to-lymphocyte ratios in favor of direct comparison of patient absolute leukocyte concentrations to updated lymphocyte reference intervals from healthy BLV-negative cattle.[64] Anemia may be present in cattle with GI hemorrhage as a result of abomasal wall lymphoma and ulceration with bleeding; such cases would also be likely to exhibit melena. Fibrinogen levels have been inconsistent in lymphoma, and therefore its measurement may be helpful only in differentiating an abscess.

Although helpful in some cases, cytology of aspirates of tumors or tumorous nodes may not always be a reliable diagnostic tool. Discrimination cannot be made between a normal node responding to an infectious agent and a node involved with neoplastic lymphocytes; in both situations, cells resembling young, poorly differentiated lymphocytes may be present. Examination of nontumorous active lymph nodes may reveal an elevated proportion of large, young lymphocytes that could resemble those of lymphoma. In a retrospective study, the sensitivity of antemortem diagnostic testing found peripheral lymph node biopsy to be 100% sensitive while fine-needle aspirate was only 41% sensitive.[58] When compared with core-needle biopsy of peripheral lymph nodes, fine-needle aspiration was more specific and more predictive for a positive test.[65] Cytology and culture of aspirates can be helpful in differentiating a tumor from an abscess. Failed attempts at collection of cerebrospinal (lumbosacral) fluid in cattle with recumbency or rear limb weakness may be associated with the presence of lymphoid tumors in the vertebral canal; cytologic examination of cells from the collection needle in such cases may reveal abnormal lymphoid cells.

At necropsy lymphomas are found enclosed in a capsular-like tissue that, when sectioned with a knife, results in an eversion of tumor stroma. Cut tumor tissue is cream colored and friable, with little binding structure. Centers of tumors may appear necrotic and mushy, whereas peripheral regions are firmer and pink to white. Histopathology provides the only definitive diagnosis. Tissue should be biopsied by surgical removal of as much of the node (or mass) as possible.

Standard serologic tests to diagnose BLV infection include agar gel immunodiffusion (AGID) and enzyme-linked immunosorbent assay (ELISA). The ELISA is more sensitive than the AGID.[66] Serologic tests identify antibodies to a BLV 51-kilodalton (kD) envelope glycoprotein (gp51) or 24 kD core protein (p24). Low antibody response to p24 was observed in cattle with low BLV proviral loads.[63] ELISA test kits that detect antibodies in milk samples are available commercially. The use of a milk ELISA to measure anti-BLV antibodies has been used successfully to determine lactation-specific BLV prevalence in dairy herds.[67]

Diagnosis is also possible by use of PCR to detect BLV nucleic acid,[68-71] as well as by a combined PCR-ELISA that is more sensitive than staining of PCR amplicons with ethidium bromide.[72] In a majority of calves that were experimentally infected with BLV, calves became PCR positive sooner than they seroconverted (as determined by a commercial BLV antibody test).[73] However, the measurement of antibodies to p24 antigen and whole-BLV antibodies by ELISA has been suggested as a cost-effective tool in BLV control programs as compared with real-time PCR methods.[74] ELISA-positive cattle that were not detected by PCR testing have been reported; this is most likely related to a low number of infected circulating lymphocytes at the time of sample collection.[75] The PCR by itself is considered unreliable for routine detection of BLV in herds with a high prevalence of disease,[76] and the ability of PCR to detect a BLV-infected animal is improved by means of a nested PCR, which was reported to be effective in diagnosing infection when seroconversion had not yet occurred.[77] A loop-mediated isothermal amplification (LAMP) assay has also been developed to diagnose BLV infection in cattle; this test has sensitivity at least as good as the conventional single PCR and has the advantage of not requiring specialized thermal cycling equipment.[78] Novel quantitative real-time PCR methods that use Coordination of Common Motifs (CoCoMo) primers to measure proviral loads of known and novel BLV variants were found to be more sensitive than some of the more traditional real-time PCR methods and antibody-based methods to detect BLV.[79,80] A luminescence syncytium induction assay (LuSIA) has also been shown to accurately detect and quantitatively measuring bovine leukemia virus infection.[81]

The presence of antibodies to gp51 is generally considered to be a prerequisite to a diagnosis of lymphoma, except for cows during the periparturient period when circulating antibodies may fall below the level detectable by a serologic test.[82] The mere presence of BLV antibodies does not necessarily mean that an animal has lymphoma, which is found in only about 1.7% of BLV-infected cattle.[83] However, serology can be helpful in predicting the chance of lymphoma in cattle seropositive to the gp51 antigen. Sera from cattle with lymphoma generally have high titers to the gp51 antigen (a score of 3 or 4 on AGID), compared with those of infected cattle without lymphoma (score of 1 or 2 on AGID). In addition, cattle that do not have lymphoma tend not to have antibodies to the p24 antigen of BLV, as detected by AGID. The percentage of cattle with histologically confirmed lymphoma but in which lymphoma was not diagnosed by a gp51-positive and p24-negative test result (false-negative rate of the diagnostic test) has been found to be only 0.21%, using the AGID test.[42] Unfortunately, most diagnostic laboratories do not have the capability to perform the test using the p24 antigen.

Control

Although there are not curative treatments for lymphoma in cattle, supportive therapy may be indicated to reduce discomfort and prolong life long enough to remove valuable ova/embryos or calves or to harvest semen. Presently no vaccines offer effective protection from BLV infection and control. As such, eradication of BLV requires reduction of blood transmission through iatrogenic means and through physical contact among cattle.[84] Basic disinfecting practices of instruments and equipment used on cattle such as dehorners, ear notchers, tattoo pliers, nose tongs, and others should help reduce the transmission of BLV between animals. In one study, disinfection of instruments with chlorhexidine and sodium hypochlorite was implemented as part of a set of corrective actions that were successful at reducing new cases of BLV.[44] Avoiding the reuse of hypodermic needles and syringes between animals is also recommended to reduce transmission through blood contamination. Transmission between infected and susceptible cattle can also be reduced by segregating infected and noninfected cattle,[44,85,86] and segregation of infected animals reduces seroconversion of uninfected neighbor cattle.[87] Separation of cattle by 10 feet is preferred, but a single fence may reduce sufficiently the degree of contact necessary for transmission. If potential for rectal transmission is a concern, palpation sleeves may be rinsed or replaced between cows. Although insect transmission of BLV is theoretically possible[88] and has been demonstrated experimentally by interrupted feeding of tabanids from cattle with persistent lymphocytosis to uninfected cattle,[27] studies of natural infection did not link flies with new natural infections.[89,90] Vector control to curtail stable fly feeding was, however, reported to be effective at reducing BLV transmission.[91] Although data have not shown

the use of common needles to be an important means of BLV transmission, it would be prudent to use individual sterile needles for treatment, testing, or vaccination. As animals with PL are potential sources for increasing horizontal and vertical transmission of BLV, routine testing of the herd and culling of PI animals should reduce infection rates.

Reduction of vertical transmission via milk or colostrum should address testing and culling PL- and BLV-positive cows and reducing BLV exposure of calves via infected colostrum or milk. In a sheep model of BLV infection, freezing and thawing of leukocytes from colostrum of a BLV-infected dairy cow appeared to be effective at inactivating the infectivity of BLV-infected leukocytes.[92] As calves born to BLV-positive cows are exposed to BLV during parturition, and because antibodies to BLV in colostrum from BLV-positive cattle appear to be protective against BLV infection, neonatal BLV transmission may be reduced by feeding a calf born to a BLV-positive cow the colostrum from its dam.[47] In Japan, feeding colostrum from the dam was also found to be protective against within-farm BLV transmission.[93] Because BLV proviral loads in blood rise following birth of calves to dams with high proviral loads, early identification and culling of infected calves could help prevent virus transmission.[94] Heat treating colostrum (65° C for 30 minutes) appears to be an effective means of inactivating BLV and should be considered when developing a control program.[29,95] Colostrum replacers may contain antibodies to BLV that render calves receiving such replacers to be seropositive to BLV; in one study these antibodies waned by 4 months of age.[48]

Transmission of BLV has not been shown in cows inseminated artificially using commercially prepared frozen semen.[96-100] Although infection resulting from the use of an infected bull in natural breeding may be possible,[101,102] one study found that bulls that were BLV PCR positive in peripheral blood had no evidence of BLV in semen by PCR testing.[103] Embryo transfer recipients should be tested for BLV before transfer.[104] Embryo transfer using noninfected recipients offers a means of producing phenotypically preferred cattle from BLV-infected cows and controlling in utero infection.[89,96,105,106] It is possible to produce transferrable in vitro–fertilized embryos that are free of BLV provirus from oocytes that are exposed to BLV during maturation, fertilization, or after fertilization through a washing procedure.[107]

For most herds, control and eradication of the infection would require modification of facilities, alteration of management practices, and serologic surveillance at least annually. Planning a control program should include a cost/benefit analysis to evaluate potential return on the investment. Knowledge of costs incurred as a result of BLV including costs of lost milk production are important in decision making relative to implementation of BLV control programs.[108,109] When considering the potential for BLV infection to cause immune suppression,[110,111] the various ways that BLV infection could cause economic losses in cattle populations are especially diverse. Financial benefit of a BLV control program has been documented in herds in which the prevalence of BLV infection is 12.5% or higher.[112] The elective culling of BLV-infected cattle based on positive lymphocyte BLV antigen expression in vitro was reported to be effective in preventing transmission of BLV infection.[113]

Lymphoma in Horses

Krista E. Estell

Lymphoma is the most commonly occurring hematopoietic neoplasia in horses. Previously, the terms *lymphoma* and *lymphosarcoma* have been used interchangeably, with the suffix "-sarcoma" used to characterize all malignant mesenchymal neoplasias. However, in accordance with the World Health Organization classification system, the term *lymphoma* has been adopted as there is no type of lymphoid neoplasia that is not malignant.[1] In addition, lymphoma and leukemia are now considered together, as they may be manifestations of the same disease process. It is important to emphasize that benign lymphoid hyperplasia is not synonymous with lymphoma.

Lymphoma is one of the most common malignant neoplasms in the horse; in postmortem studies, its prevalence is estimated to be 2% to 5%.[2] The underlying etiology of lymphoma in horses is undetermined. In humans there is an association between lymphoma and infection with the γ-herpesvirus Epstein Barr.[3,4] There are two case reports of horses with concurrent equine herpesvirus–5 infection and lymphoma or leukemia, one of which entered clinical remission after treatment with antivirals.[5,6] Virus-like particles have been described in lymph nodes of neonatal foals with lymphoma, though a causal relationship has not been proven.[7,8]

Lymphoma can occur at any age, with reports in an aborted fetus to horses older than 30 years.[8,9] A large-scale retrospective study reports a median age of onset of all types of lymphoma to be 10 years; a previous study reviewing intestinal lymphoma reported a mean age of onset to be 17 years.[9,10] There is no apparent sex predilection, though certain breeds are more likely to develop particular subtypes of lymphoma.[10,11] Clinical signs vary depending on tumor location, but the most common include nonspecific lethargy, weight loss, pyrexia, and lymphadenopathy. When affected, lymph nodes tend to be firm, cool, and nonpainful. Specific clinical signs are dependent on the location of the tumor with diarrhea, colic, neurologic signs, lameness, osteolysis, and pathologic fractures described.[12,13] Paraneoplastic conditions including pruritus and alopecia, hypercalcemia, IMHA, and IMTP have also been reported.[14-16]

Although the hematologic features of lymphoma vary, anemia is a relatively common finding and is thought to be due to suppression of erythropoiesis, neoplastic bone marrow infiltration, blood loss, or IMHA. A modest neutrophilic leukocytosis with an elevated fibrinogen is often seen. Atypical lymphocytes with or without elevated lymphocyte counts may be noted in the blood smears of more than 30% of affected horses, especially late in the disease course.[17] When frank leukemia is present, neoplastic cells are often, but not always, found in the bone marrow.[18,19] Serum biochemistry profiles may provide an indication of internal organ involvement. Serum protein alterations are frequently observed and include hypoalbuminemia, hyperglobulinemia with polyclonal or monoclonal gammopathy, and decreased albumin/globulin ratio.[19] Additional immunologic derangements that have been reported in horses with lymphoma include hypogammaglobulinemia, neutropenia, and lymphopenia.[15,20,21]

Though several different classification schemes exist, the World Health Organization classification system has been adopted for the accurate description of equine lymphoma. Using this classification system, tumors are characterized on the basis of anatomic location and cell lineage. In a recent retrospective study classifying 203 cases of equine lymphoma, 14 subtypes of lymphoma were identified and 13 anatomic sites were used for characterization: multicentric (involving at least 2 organs excluding the regional lymph node), gastrointestinal, cutaneous, bone marrow, nodal, splenic, hepatic, mediastinal, heart, ocular/orbital, central nervous system, oral cavity, and nasal. Multicentric (83%), cutaneous (19%), and gastrointestinal (11%) lymphoma were the most common anatomic locations identified in this study.[22]

The diagnostic sample of choice is a biopsy of the affected lymph node or organ. Lymphoma is variably exfoliative, and even if there is a considerable amount of effusion, cytology may be inconclusive. Likewise, lymph node needle aspirates

VetBooks.ir

may be difficult to positively diagnose. Morphologically, lymphocytes are classified as small-cell type if their nuclear diameters are 1.5 times the diameter of erythrocytes or less; cells are classified as large if their nuclei average 2 times or more the diameter of erythrocytes.[23,24] Small-cell lymphoma consists of 60% or more small cells while large-cell lymphoma consists of 60% or more large cells. The grade of lymphoma may also be assessed by determining the amount of mitoses seen within a high-powered field.[9,24]

Immunohistochemical classification to determine the cell lineage is performed using monoclonal antibodies such as CD79a and CD20 for B-cell lymphomas and CD3 and CD8 for T-cell lymphomas. All three—B-, T-, and mixed B- and T-cell lymphomas—have been reported in the horse.[9,23,25] Several retrospective studies have identified a total of 14 subtypes of lymphoma in horses, with T-cell–rich B-cell lymphoma (TCRBCL) the most common subtype of lymphoma in the horse.[9,17,26] T-cell–rich, large B-cell lymphoma is a neoplastic proliferation of large B cells associated with a prominent component of nonneoplastic T cells and a dense fibrovascular network that prevents tissue fragmentation during sectioning.[1] The presence of large numbers of nonneoplastic T cells within a B-cell lymphoma could result in erroneous diagnosis of a T-cell tumor or a benign reactive lymph node, particularly if a small sample is submitted. Discriminating between neoplasia and chronic inflammation with reactive lymphocytes can be difficult in some cases; molecular clonality assays can be used to make this determination. Clonality assay results indicating a polyclonal population of lymphocytes support a diagnosis of inflammation, whereas results indicating a monoclonal population support a diagnosis of neoplasia. There are several reports of polyclonal lymphoma in horses, though this likely represents lack of appropriate molecular markers (P. Moore, Personal communication, 2016). In addition, as benign clonal expansion has been reported with various infectious and immunologic conditions, results should be interpreted carefully.

In addition to immunophenotyping and tumor cell morphologic description, establishing tumor location and presence of metastasis is necessary to determine disease severity and recommend a course of treatment. A thorough diagnostic work-up includes complete blood count with cytologic review by a hematopathologist, serum biochemical assay, thoracic radiographs, and abdominal ultrasound.[27] Though tumor biomarkers are used routinely in human medicine, there is limited research on their significance in horses. A recent paper describes significant elevations in serum thymidine kinase in horses with lymphoma when compared with horses with inflammatory conditions and nonhematopoietic neoplasia, indicating that this biomarker may be a useful ancillary diagnostic in horses with suspected lymphoma.[28] Accurate lymphoma characterization and staging in human medicine have been critical to establishing effective therapeutic management plans and accurate prognoses, and as more therapeutic options are explored in horses, it is likely that accurate diagnoses will have a similar impact.

Multicentric Lymphoma

The definition of multicentric lymphoma is lymphoma that involves two organ systems, excluding the regional lymph nodes, or involves multiple lymph nodes at distant anatomic locations. In previous literature, the term *generalized lymphoma* has been used to describe multicentric lymphoma, though this likely represents a more chronic or severe stage of disease. Multicentric lymphoma is the most commonly reported anatomic location of lymphoma; it is often difficult to determine the site of origin if the horse is presented late in disease.[9,17] Horses with multicentric lymphoma often present with lethargy, emaciation, anorexia, generalized lymphadenopathy, and edema due to impaired lymphatic drainage.[9,10] In addition to lymphoid tissue involvement, infiltration of neoplastic lymphocytes has been reported in the spleen, liver, bone marrow, intestine, bladder, kidney, lung, heart, nasopharynx, eye, ovary, uterus, brain, and spinal cord.[9,10,16,20]

Alimentary or Intestinal Lymphoma

Lymphoma is the most common neoplasia of the intestinal tract in horses, and though the entire intestinal tract may be affected by lymphoma, disease occurs most frequently in the small intestine.[10,29] Though a breed predilection has not been established for lymphoma generally, a study reviewing intestinal neoplasia showed that Arabian horses are at an increased risk of developing intestinal lymphoma as compared with other breeds.[10,30] Lymphoma arises from the lymphocytes of the lamina propria of the intestinal tract, resulting in diffuse or segmental thickening, focal masses, or scattered crater-like ulcers with raised margins on the intestinal wall.[31-33] Peripheral lymphadenopathy is generally not present, though metastases to the lungs, mesenteric lymph nodes, liver, kidney, and spleen have been reported.[10,30,31] Intestinal lymphoma is usually associated with hypoalbuminemia secondary to protein-losing enteropathy, weight loss, edema, abdominal effusion, mild recurrent colic, and diarrhea.[10,29] Affected horses frequently have abnormal glucose or xylose absorption tests, indicating small intestinal malabsorption.[32] Transabdominal ultrasound is the imaging diagnostic of choice and typically reveals thickened (>5 mm) small intestine, large colon, and/or cecum. In cases of small intestinal thickening, duodenal biopsy via a 3-m gastroscope may be diagnostic, though the small sample size limits diagnostic utility. In cases where diffuse large colon thickening is seen, rectal mucosal biopsy may yield a diagnosis of lymphoma. Abdominocentesis may be performed, with one study showing that cytologic analysis of abdominal fluid was diagnostic in 38% of intestinal neoplasia cases.[10] It is important to note that a normal mucosal biopsy and normal abdominal fluid cytology do not preclude a diagnosis of lymphoma. The most accurate means of diagnosis for intestinal lymphoma is exploratory laparotomy and biopsy. If the segment of intestine cannot be resected with clean margins, treatment with chemotherapeutics other than corticosteroids is generally not recommended, as the neoplastic tissue often ablates the normal intestinal architecture and treatment with chemotherapy may result in GI rupture. (A. Theon, Personal communication, 2015)

Thoracic Lymphoma: Mediastinal/Thymic

Lymphoma is the most common thoracic neoplasia in horses, and it may involve mediastinal lymph nodes, pericardium, thymus, or lungs.[33,34] The prevalence of mediastinal lymphoma varies from 4.5% to 29% of all forms of lymphoma.[9] Primary and secondary (metastatic) mediastinal lymphomas have been reported, with the mediastinum and thoracic cavity commonly affected in horses with multicentric lymphoma.[17,34] Primary mediastinal lymphoma is usually seen in adult horses; however, the disease has been reported in a 1-month-old foal with a 1-week history of respiratory distress.[35] In the early stages of the disease, minimal clinical signs may be observed. Once disease has progressed, common clinical signs include nasal discharge, adventitious lung sounds, pleural effusion, thoracic ventral and limb edema, and regional lymphadenopathy at the thoracic inlet.[31,32] Other signs may include congestive heart failure, cough, pyrexia, pleurodynia, and respiratory distress.[29] Dysphagia may be observed in cases with retropharyngeal lymphadenopathy. An elevated nucleated cell count of several thousand cells/μL, with a large percentage of abnormal lymphocytes, may be evident in pleural fluid cytologic analysis. However, collection of multiple pleural fluid samples may be necessary to establish a definitive diagnosis.[36] Cytologic abnormalities include the presence of prolymphocytes, lymphoblasts, and lymphocytes with evidence

of nuclear blebbing, indented and cleaved nuclei, amorphous nuclei, altered nuclei/cytoplasm ratio, or mitotic figures.[17,29] Thoracic lymphomas may be of B-, T-, or mixed-cell origin, but T-cell lymphomas are most common.[23,34]

Cutaneous Lymphoma

Cutaneous lymphoma originates in the skin-associated lymphoid tissue. Single or multiple subcutaneous firm, nonpainful nodules ranging from less than 1 cm to greater than 20 cm in diameter can develop rapidly or slowly, regionally or over most of the body surface.[11,37] The predominant subtype of cutaneous lymphoma is T-cell–rich, large B cell (TCRBCL). One retrospective study revealed a potential breed predilection for cutaneous lymphoma subtypes; Quarter Horses were diagnosed almost exclusively with TCRBCLs, while Thoroughbreds had an increased likelihood of cutaneous T-cell lymphoma (CTCL).[11] In general, TCRBCLs tended to present with multiple nodules in different anatomic areas, while CTCLs and diffuse large B-cell lymphomas tended to be single masses. In some cases, the nodules are reported to wax and wane spontaneously or in association with sex hormone levels and seasonality, which likely reflects the presence of progesterone or other hormone receptors present within the tumors.[38] There is one report of complete regression of cutaneous lymphoma following surgical removal of an ovarian tumor.[39] Depending on the anatomic location, cutaneous lymphomas may cause mechanical lameness and limb edema secondary to vascular and lymphatic obstruction. In most cases, there are no associated hematologic abnormalities and generalized lymphadenopathy and internal organ involvement are rare in the early stage of disease. If the disease is allowed to progress untreated, cutaneous lymphoma may metastasize to internal organs or result in paraneoplastic syndromes.[11,33] If only a single or few tumors are present, surgical removal with clean margins may be curative.[11] Likewise, local injection with cisplatin in sesame oil, as previously described, has also resulted in regression of the injected tumor.[40]

Angiotrophic Lymphoma

Angiotrophic lymphoma, also known as *endotheliotropic lymphoma or intravascular lymphoma*, is lymphoma of the small blood vessels that spares the surrounding tissues. It has been described in humans, dogs, and cats.[41-43] There is a single report of angiotrophic lymphoma in a 12-year-old pregnant Thoroughbred presenting with anorexia, tachycardia, and mild fever.[44] The significant laboratory abnormalities in this case were profound anemia (PCV 12%) with a negative Coomb's test, marked anisocytosis, mild lymphopenia, low IgM, and marked erythroid hyperplasia and erythrophagocytosis on bone marrow biopsy. Histologic examination revealed pulmonary and renal vessels crowded with neoplastic lymphoid cells with scattered mitoses. The neoplastic cells were determined to be of T-cell origin based on immunohistochemical staining. Angiotrophic lymphoma may represent an antemortem diagnostic challenge owing to the lack of circulating neoplastic lymphocytes and identifiable masses.

Treatment of Lymphoma

If possible, surgical removal of lymphoma is indicated before treatment with ancillary treatments including radiation and chemotherapy. Radiation therapy has been effective in the treatment of cutaneous and paranasal lymphoma, though access to equipment makes treatment logistically challenging.[45,46] There are limited retrospective studies and clinical trials describing chemotherapy in the horse. The largest clinical investigation is a pilot phase II study evaluating the efficacy of doxorubicin in horses. Tumor response rate for lymphoma was 100% in the study population.[47] Signs of toxicity including hyperthermia and colic were controlled by premedication with diphenhydramine and flunixin before doxorubicin administration and treatment, at the recommended dose of 70 mg/m^2.[48]

There are several case reports describing the use of single or multidrug protocols for the treatment of lymphoma. A recent case report describes surgical removal of a TCRBCL followed by treatment with lomustine (CCNU; 60 mg/m^{2}q 30d for 4 treatments), followed by prednisolone, resulting in clinical remission for 16 months at the time of publication.[49] Other published protocols include single or multidrug therapies including L-asparaginase (10,000 to 40,000 U/m^2, IM q14-21d), doxorubicin (50 mg/m^2 IV), vincristine (1.4 mg/m^2 IV), and rituximab (375 mg/m^2 IV). A horse with thoracic lymphoma was treated with cytarabine (170 mg/m^2 IM) 2 weeks apart, alternating with cyclophosphamide (142 mg/m^2 IV) 7 days after each dosage of cytarabine, in addition to prednisolone.[50]

Palliative therapy of lymphoma has also been achieved with corticosteroids including dexamethasone, prednisolone, and betamethasone. Ideally, pulse-dose therapy or treatment with a relatively high dose of corticosteroid for a short period of time should be implemented until tumor regression has occurred, and then the steroid should be quickly tapered. This strategy may prevent the neoplasia from becoming resistant to corticosteroid therapy. If clinical signs recur during steroid tapering, then the lowest dose of steroid that controls clinical signs should be administered.

Complications associated with chemotherapeutic agents in horses depend on the drug used and should be considered before the institution of therapy. Though no large retrospectives on treatment of lymphoma in horses exist, periods of remission following treatment of 8 months to 5 years have been reported.[33,49,50] The long-term prognosis for horses with lymphoma when treatment is not elected is poor.

Leukemia in the Horse

Johanna L. Watson • Monica Aleman

Leukemia is a rare neoplasia of the hematopoietic system that originates from the bone marrow (primary leukemia). A leukemic phase (secondary leukemia) has rarely been reported in horses.[1-3] Based on the cell of origin, the major forms of leukemia include myeloid and lymphoid leukemias, which can have an acute or chronic clinical course. According to the Leukemia and Lymphoma Society, *acute leukemias* are rapidly progressing disorders that affect mostly primitive or immature cells that lack normal function, whereas *chronic leukemias* progress slowly, allowing some growth and cell maturation that may preserve limited normal function. Reported leukemias in the horse include myelomonocytic, monocytic, granulocytic, eosinophilic, and lymphocytic forms.[1,2,4-19] Based on the presence and numbers of cells in blood, other terms used are *leukemic*, *subleukemic*, and *aleukemic leukemia*. Leukemic leukemia is characterized by an increase in cell numbers in peripheral blood; subleukemic leukemia is defined by an increase in abnormal blast cells in blood, with a total white cell count within the reference range or low; and aleukemic leukemia is characterized by the presence of abnormal cells in the bone marrow but not in peripheral blood.

There is no apparent breed or gender predisposition, based on the few reported cases.[1,2,5-19] The age at onset of clinical signs ranges from 2 to 25 years. The most common clinical signs are weight loss, lethargy, anorexia, pyrexia, and lymphadenopathy if associated with lymphoma. Other signs are weakness, ventral edema, exercise intolerance, colic, and recurrent or concurrent infections.

At the initial stages of disease, laboratory features may show mild hematologic abnormalities and include one or more of the following: anemia, neutropenia, lymphopenia,

VetBooks.ir

VetBooks.ir

thrombocytopenia, hyperproteinemia, and hyperfibrinogemia. As the disease progresses (days to months), marked leukocytosis (counts may be >200,000 WBC/μL) and hyperproteinemia will be observed in leukemic leukemias.[16] Thrombocytopenia is a common hematologic feature.[1,15,16,19] Pancytopenia and high blast cell counts (up to 1.6×10^9 cell/μL) were reported in a lactating mare with myeloblastic leukemia.[19] Pancytopenia due to severe infiltration of leukemic cells in the bone marrow, ineffective hematopoiesis, and myelofibrosis has been reported.[15] Horses with multicentric lymphoma, pancytopenia, severe leukocytosis (more than expected for severe inflammation), or presence of atypical or blast cells in peripheral blood should prompt the collection of a bone marrow aspirate or biopsy. Bone marrow aspirates may have normal to altered myeloid/erythroid ratio (reference range, 0.5 to 3.76) with a disproportion of atypical or poorly differentiated blast or mature cells of certain lineage. Decreased or absent megakaryocytes is a common observation.

Hyperproteinemia due to hyperglobulinemia is a consistent finding. Serum electrophoresis typically shows a polyclonal increase of β_2- and γ-globulin fractions and, in some cases, α-globulin fraction. Marked increases in serum IgG and IgA concentrations have been detected in horses with lymphocytic leukemias.[1] Deficiencies in IgA and IgM have been reported in a single horse with chronic lymphocytic leukemia.[12]

Necropsy findings may include mucosal ulceration, edema, thrombosis, and hemorrhages of various organs due to intravascular leukostasis (aggregates of leukemic cells in blood vessels), disseminated intravascular coagulopathy, and thrombocytopenia secondary to decreased production of megakaryocytes. Leukemic-induced cell lysis may occur as the result of mediators released by neoplastic cells. Peripheral and internal lymphadenopathy may also be observed.

The diagnosis is based on results of a complete blood cell count (CBC) and chemistry panel, with cytologic and histopathologic evaluation of bone marrow, immunocytochemical analysis, flow cytometry, and immunophenotyping. Previously, leukemic cells in peripheral blood and bone marrow were described on the basis of their morphology. However, this may result in leukemia misclassification, especially in acute leukemias where mononuclear blast cells comprise the leukemic clone, which may lack specific morphologic identifying features. Numerous cytologic and cytochemical stains (e.g., Wright, Giemsa, Sudan black B, peroxidase, periodic acid-Schiff, alkaline phosphatase, acid phosphatase, various esterases, and surface glycoproteins) have been used to determine leukemia type. Leukemic cells may lack specific cytochemical properties, however. Currently, the various types of leukemias are identified by specific cellular antigens, using a panel of monoclonal antibodies and flow cytometry to analyze peripheral blood and/or bone marrow. Examples are B-cell/IgM-positive, B-cell/IgM-negative, CD3/CD4/CD5-positive T-cell, CD3-negative/CD4-positive T-cell, and CD13-positive/myeloid leukemias.[1,12,16] The various monoclonal antibodies for specific equine leukocyte antigens are shown in Table 37.2.

The prognosis is grave, resulting in death within days to a few months after its diagnosis. Treatment of leukemia in horses has been attempted with cytosine arabinoside, cytarabine, and prednisolone, but without much success.[8,12,18]

TABLE 37.2

Monoclonal Antibodies for Specific Equine Leukocyte Antigens (ELAs)

ELA Marker	Specificity
EqCD2	T cells
EqCD3	T cells
EqCD4	Helper T cells (T_H cells)
EqCD5	T cells
EqCD8	Cytotoxic T cells (T_C cells)
EqCD11a/18	Panleukocyte
EqCD13	Myeloid cells
CD21	Most B cells
CD79a	B cells
EqWC1	Large T-cell and neutrophil subsets
EqWC2	T cells and neutrophils
EqWC4	Minor T-cell subset
MHCI	Nucleated cells
MHCII	B cells, macrophages, dendritic cells, and a large T-cell subset
IgM	B cells

CD, Cluster of differentiation; *Eq*, equine; *IgM*, immunoglobulin M; *MHC*, major histocompatibility complex; *WC*, white cell.

Myeloma in the Horse

Johanna L. Watson • Monica Aleman

Myeloma is a neoplastic proliferation of plasma cells that primarily originates in the bone marrow but may have an extramedullary source.[20] Both forms have been reported in the horse.[21-23] Accumulation of neoplastic plasma cells outside the marrow is called *extramedullary plasmacytoma*.[20] Plasmacytomas can form in several organs and tissues, including the skin. The most common extraosseous sites in horses are lymph nodes, kidneys, spleen, and liver.[21,23,24] Multiple myeloma involves bone marrow at multiple locations and other tissues, and it is the most common form of myeloma in humans.[25] In human medicine, causes of myeloma include chromosomal translocation, irradiation, and chronic antigenic stimulation.[20]

Myeloma is a rare neoplasia of the horse (only 16 cases reported in the literature), with a median age of 14 years and a range of 3 months to 25 years of age.[21-24,26-35] Almost half of the horses were Quarter Horses, but various breeds including draft horses and ponies were represented. There is no apparent gender predilection. Clinical signs vary with the degree of plasma cell infiltration, extent, and location. The most common clinical signs are weight loss, anorexia, fever, pale mucous membranes, lethargy, limb edema, and recurrent infections.[21-24,35,36] Bone pain due to osteolytic disease is the most common early sign of myeloma in humans.[25] Four horses from the literature were reported to have osteolysis. The clinical signs in these horses included paresis, cervical pain, and lameness.[24,27,29,32]

Laboratory features are anemia, hyperproteinemia due to hyperglobulinemia, hypoalbuminemia, and proteinuria. Anemia results from reduced erythropoiesis secondary to myelophthisis, blood loss, and as a result of the osmotic effect of paraproteins. Pancytopenia is observed if myelophthisis develops. Hypercalcemia has been reported in a few cases.[21,23,24] Significantly different features have been reported (hypoproteinemia, hypoglobulinemia, hypoalbuminemia, hypocalcemia) in a gelding with systemic amyloidosis and multiple myeloma, thought to be the result of severe protein-losing enteropathy.[36] Concurrent systemic amyloidosis and multiple myeloma are common in humans but extremely rare in domestic animals, with only one cat and one horse reported in the literature.[36,37] Serum parathyroid hormone–related protein concentration was mildly elevated in one horse with multiple myeloma.[24]

In secretory myelomas, neoplastic plasma cells are responsible for overproduction of a monoclonal Ig called *M protein* or *paraprotein*. M protein may be fragments (mainly light chains also called *Bence Jones protein*) or a complete Ig. Subclasses of IgG are the predominant paraprotein associated with myeloma in horses,[21,35] but there are three reported cases with IgA paraprotein.[23,24]

VetBooks.ir

Plasma cells are relatively sparse in normal bone marrow. Involvement of marrow is usually focal rather than diffuse, requiring multiple marrow aspirates in some cases to confirm plasmacytosis. The diagnosis of multiple myeloma in humans is based on the presence of at least 10% of plasma cells in the affected tissue, monoclonal protein in serum or urine, and evidence of end-organ damage (hypercalcemia, renal insufficiency, anemia, or bone lesions). Renal insufficiency has not been reported in horses with myeloma.[21,23] Bleeding and blood hyperviscosity syndrome are common complications of multiple myeloma in humans.[25] These complications have been reported in four horses.[21,30]

The median length of survival after diagnosis in humans is approximately 3 years.[25] Owing to poor prognosis or deterioration of condition, most reported horses were euthanized within a few days to months of diagnosis. However, two horses survived for 1 and 2 years, respectively.[31,34] One horse was euthanized 3.5 years after the diagnosis for deteriorating condition.[23]

Lymphangioma in the Horse

Johanna L. Watson • Monica Aleman

Lymphangioma is a rare tumor in horses that originates from lymphatic vessels. Morphologically, lymphangiomas are classified into three types: simplex or capillary, cavernous, and cystic.[38] This tumor may involve cutaneous tissues of the mammary gland, thigh and inguinal regions, pleural cavity, and intestines and has only been observed in young horses.[39-41] Clinical signs vary depending on tumor location. At diagnosis, these tumors were extensive; surgical removal was not attempted, and all horses were reportedly euthanized.

Other Diseases of the Hemolymphatic System

Anthrax

Kristin A. Clothier

Anthrax is a soil-borne bacterial disease primarily affecting herbivores and most often presenting as acute septicemia with high mortality. Other animal species, including humans, can be infected. Anthrax occurs worldwide and is noteworthy because of both its impact on agriculture and potential to cause zoonotic infections. *Bacillus anthracis*, the etiologic agent of anthrax, has been classified by the Centers for Disease Control and Prevention (CDC) and USDA as a Tier 1 Select Agent because of its potential to be used as a bioterrorism agent.[1] Dissemination of genetically modified *B. anthracis* spores through the U.S. Postal Service (USPS) in 2001 demonstrated its usefulness in this capacity.[2] Possession of this organism is under federal jurisdiction and is highly regulated.

Etiology

B. anthracis is a member of the *B. cereus* group of genetically related *Bacillus* sp.[2,3] In the vegetative form found predominantly in tissues of infected animals, *B. anthracis* is a large, rectangular-shaped, gram-positive rod. Under nutritionally limiting circumstances it produces spores, facilitating survival in harsh environmental conditions including heat, drying, and chemical treatments.[3,4] Sporulation is an oxygen-dependent process and does not occur under anaerobic conditions. Although *B. anthracis* was previously thought to be an obligate pathogen, recent research demonstrates that vegetative cells can survive and replicate in soil, plant rhizospheres, and amoeba in the environment, which may enhance transmission.[4,5] Genetic transfer between members of this group has been demonstrated by the recent identification of *B. cereus* biovar *anthracis*, which contains molecular features of *B. anthracis* and *B. cereus*.[6]

Pathogenesis

Entry into mammalian hosts can occur via inhalation, ingestion, or cutaneous routes, although ingestion is most common in animal species. Grazing herbivores are often exposed via contaminated pastures or forage grown on anthrax-positive fields. Although considered less susceptible, carnivores and omnivores can be infected by ingesting meat from infected animals or from processed food products.[4,7] Once spores are introduced, they may be phagocytosed by macrophages and trafficked to regional lymph nodes or enter the circulation. After conversion to the vegetative state, bacteria replicate rapidly, lyse host cells, and escape to the extracellular environment. Plasmid-encoded virulence factors, particularly a poly-D-glutamic acid capsule encoded on pXO1 and a three-component toxin encoded on pXO2, are keys to bacterial survival in the host.[2,8] Presence of the capsule enables the bacterium to resist phagocytosis and mask surface antigens, resulting in evasion of the host's immune system. Toxin production is enhanced by increases in CO_2 and HCO_3^- present when the bacteria moves from the environment into the host.[2,3] Lethal factor and edema factor are secreted proteins that, when bound to the common receptor binding component (protective antigen [PA]), form lethal toxin (LT) and edema toxin (ET.)[8] Upon binding to host cells, PA oligeromizes to induce endocytosis into the host cell. In the acidic endosome, PA creates a stable pore through which LF and EF enter the cytoplasm. Both toxins interfere with cell signal transduction pathways by different mechanisms: EF increases cyclic adenosine monophosphate (cAMP) production while LF cleaves and inactivates cellular proteins. In early stages of infection, enzymatic effects of EF and LF disrupt innate immune cell functions and block inflammatory cytokine responses, particularly in neutrophils, macrophages, and dendritic cells, resulting in proliferation and dissemination of *B. anthracis*.[2,3] As septicemia progresses, toxins affect endothelial cells resulting in edema, hemorrhagic shock with hypotension, and multiorgan failure.[7,8]

Epidemiology

Anthrax occurs worldwide. Frequency of outbreaks depends on geographic location with some regions of the world (Africa, Central Asia, the Middle East, South America) considered endemic for the disease. Animal outbreaks impact humans both by disrupting livelihoods and through exposure to *B. anthracis*–affected carcasses and products.[7,9] In the United States, anthrax occurs more frequently in established "zones" of certain states (Texas, Minnesota, Montana, North and South Dakota), although sporadic cases have been reported from other locations.[10] Some areas with greater incidence of disease follow

old cattle trails, which may have been the primary source for contaminating those environments.[11]

Environments favorable for maintaining anthrax spores include soils with elevated pH, high concentrations of selected cations (Ca++, Mn++), and rich in organic material.[5,8,11] Droughts followed by heavy rainfall or flooding often precede outbreaks, as do earth-disturbing activities like excavations. Topography that favors collection of runoff and establishment of temporary water storage areas (seasonal ponds) may promote the concentration of spores.[7,10] Outbreaks usually occur during warmer months of the year.

Transmission can occur by access to blood or tissues from infected animals. Bites from blood-sucking insects have been shown to contribute to anthrax spread during outbreaks.[7] Carcasses of affected wildlife are an additional source for contaminating environments because they are unlikely to be disposed of properly and scavenging animals feeding on carcasses can disseminate organisms more widely.[10,11]

Clinical Presentation

Susceptibility to infection depends on the individual animal species and the route of infection.[10] Ruminants (cattle, sheep, and goats) are most susceptible to peracute infections, and clinical signs before death may not be observed. If present, nonspecific clinical signs include fever, depression, respiratory distress, congestion of mucous membranes, and convulsions. In more protracted cases, bloody diarrhea, hematuria, and localized tissue swelling may be observed. Cutaneous infections in animals are uncommon.[7,10]

Horses may develop an acute intestinal form and present with colic, diarrhea, cyanosis, fever, and depression followed by a fatal septicemia. A more localized form, possibly initiated by insect transmission, typically involves massive edema in the neck region, which may progress to dependent edema involving the thorax, abdomen, prepuce, or mammary gland.[7]

Swine are less susceptible to infection. Oropharyngeal involvement with swelling of the head and neck is the most common presentation; edematous tissue may obstruct breathing and swallowing. Cervical lymph nodes are prominently involved.[12] An intestinal form may present as dysentery. Pregnant animals may abort.[7,10]

Pathology

Animals that die of anthrax sometimes produce bloody exudates from body orifices and show incomplete rigor mortis. Blood often will not clot. Carcasses undergo rapid decomposition. If a carcass is opened, the spleen is frequently enlarged and has a "blackberry jam" consistency. Lymph nodes and internal organs may be edematous and hemorrhagic. Localized exposure may result in ulceration, regional lymph node involvement, or peripheral tissue edema.[12] Histologically, large numbers of bacilli are observed in affected tissues. Spleen and lymph node architectures are obscured by massive hemorrhages. The presence of intravascular organisms is typical for septicemic anthrax.[12]

Diagnosis

Initially, anthrax may be confused with other conditions that cause acute death (clostridial infections, lightning strikes, toxic or plant poisoning) and may not be recognized. If anthrax is suspected, carcasses should not be opened to prevent sporulation and further contamination of the environment. Definitive diagnosis is based on microscopic examination of blood or tissue smears (preferably collected within 24 hours after death) and bacteriologic cultures performed in the laboratory, particularly for index cases.[10] Samples that minimize potential for environmental contamination and maximize diagnostic accuracy include unclotted blood collected from superficial veins or ocular fluid collected in a sterile syringe using a large-gauge needle. An intact eye can also be removed and submitted to the laboratory for diagnostic evaluation. In the more localized form of anthrax, samples from regional lymph nodes may be required. Tissue samples containing normal bacterial flora (e.g., ear, skin, intestinal content) are not recommended for testing because recovery of normal flora may obscure the presence of *B. anthracis* in culture. Anthrax carcasses undergo rapid putrefaction and vegetative *B. anthracis* cells are destroyed during decomposition, so the time between death and sample collection can substantially affect the recovery rate of *B. anthracis*.[10,12] To ensure use of specialized diagnostic and safety procedures, always notify laboratory personnel when a case of anthrax is suspected.[8]

Gram stains performed on direct smears demonstrate typical large, gram-positive, squared-ended rods found singly or in chains of two to four cells. A polychrome methylene blue (M'Faydean) stain confirms the presence of the *B. anthracis* capsule surrounding organisms.[8] Anthrax bacilli must be distinguished from postmortem-invading clostridial species, which have more rounded ends and are acapsular when examined with M'Faydean stain. *B. anthracis* also stains well with other common laboratory stains, including Wright and Giemsa.

Isolation of *B. anthracis* is readily made on standard sheep blood agar.[8,10] Many organisms grow on this media, so cultures of samples from sterile sites are more likely to identify *B. anthracis* if it is present. With a doubling time of 30 to 60 minutes, colonies are apparent after as little as 6 hours of incubation.[13] Typical *B. anthracis* colonies after 24 hours of incubation are large, gray-white in color, have a rough, dry texture, and are usually nonhemolytic.[8] Gram stains of young colonies show long chains (10 or more cells) of large, square-ended, gram-positive rods often described as having the appearance of a row of "railway boxcars."

Verification of isolates as *B. anthracis* is based on lack of motility, capsule production on specialized media, lysis by a specific bacteriophage (gammaphage), and confirmatory PCR for toxin and capsule genes.[8,14] Gram stains from cultures incubated for approximately 48 hours show bacteria with centrally located spores, which do not cause the cells to bulge. Cultures must be handled using at least biosafety level 2 conditions to protect laboratory personnel during confirmatory procedures.[8,14] Care should be taken to prevent exposure to air and inadvertent spore dissemination from culture plates. Other available molecular- and antigen-based rapid screening tests are primarily used by first responders in potential bioterrorist events and to discriminate between vaccine and wild-type strains. Definitive diagnosis of a *B. anthracis* isolate must be made at a CDC Laboratory Response Network (LRN) confirmatory laboratory. All positive samples must be destroyed within 7 days of diagnosis (LRN).[14]

Treatment, Control, and Prevention

Any suspected anthrax case should be reported to appropriate local or state veterinary regulatory officials as soon as possible. The peracute nature of many anthrax infections can make early intervention impossible and treatment unrewarding. Field isolates are generally susceptible to penicillin and tetracycline drugs.[10,15] If attempted, treatment should be continued for a minimum of 5 days. *B. anthracis* strains resistant to these antibiotics have been reported. Antibiotic treatment will also interfere with detection of *B. anthracis* in laboratory specimens.[13]

Carcass management is critical in controlling anthrax outbreaks. Carcasses should not be opened or moved from

the area where they are discovered and should be destroyed by either burning or deep burial. Burning carcasses is preferred to burial because it is more effective at destroying spores, but it may not be permitted in certain areas. Any contaminated bedding or soil should be handled similarly.[8,9]

In the face of an outbreak, regulatory officials will likely quarantine affected premises. All potentially exposed animals should be closely observed for signs of infection. Clinically normal animals should be vaccinated using a commercially available live acapsular vaccine (Sterne) strain (Anthrax Spore Vaccine [Colorado Serum Co., Denver, Colo.]).[8,9] Prophylactic antibiotic treatment of unaffected herdmates is sometimes practiced; however, therapy will interfere with the efficacy of attenuated vaccines and should be considered carefully in outbreak management. Vaccination should be delayed for at least 7 days after antimicrobial administration.[8,10] Treatment decisions should be undertaken only after consultation with local veterinary public health or regulatory officials. Vaccination of neighboring herds should be initiated to prevent new infections due to either exposure to similar predisposing environmental conditions or through spread from initial outbreak sources. Controlling insects and both avian and mammalian scavengers will aid in preventing dissemination to neighboring premises.[7,10]

Prophylactic vaccination of animals in endemic areas should be performed annually 4 weeks before turning animals onto pastures where outbreaks have occurred. A single dose of vaccine is given subcutaneously in the neck. In heavily contaminated areas, a second dose may be given 2 to 3 weeks later to enhance protection. Follow the vaccine manufacturer's recommendations or local regulatory officials' instructions regarding postvaccination market withholding time for meat and discard time for milk.[9] Localized swelling may occur at the site of vaccination, particularly in horses. Goats and llamas may exhibit serious adverse reactions to the vaccine.[10]

Ensuring that pastures are of good quality so that grazing close to the soil is avoided will minimize exposure to spores. Avoiding rough feed that might traumatize mucosal surfaces will also decrease incidence rates. Use of lime or other calcium-containing products that alkalinize the soil should not be recommended.[8] If possible, avoid grazing animals on contaminated pastures altogether and encourage alternate uses for the land.

Public Health

Naturally occurring anthrax cases in humans in the United States are rare, and when they occur, the cutaneous form is most common.[11,13] Veterinarians are included among at-risk individuals because of the potential for contact with organisms while handling infected carcasses. If anthrax is suspected, avoid activities that result in bacterial contact. Do not open carcasses for necropsy to prevent sporulation and bacterial exposure. Use proper personal protective equipment, including physical barriers (e.g., gloves) and respiratory protection, when collecting diagnostic samples and during carcass disposal. Naturally acquired inhalational anthrax in humans is rare because of the relatively high LD_{50} (8000 to 10,000 spores) required for infection. Spores greater than 5 mm in diameter will be cleared by the mucociliary escalator. The size restriction along with static charges on spores make aerosolization and inhalation to terminal airways less likely.[13] A case report from 2009 identified exposure drums made from goat hides as the likely route of human contact, indicating that animal products can be a source of infection.[16] Exposure to *B. anthracis* should always be taken seriously, and owners of affected animals should be advised to consult with their physician for advice on medical care.

Lyme Disease

Johanna L. Watson • Monica Aleman • John E. Madigan

Lyme disease, also known as *borreliosis*, is one of the most important arthropod-borne bacterial infections in the United States. It is caused by the spirochete *Borrelia burgdorferi* and affects humans, horses, dogs, and cats.[1-4] Because Lyme borreliosis was first identified as the causative agent of an epidemic of juvenile inflammatory arthritis in children and adults in Old Lyme, Lyme, and East Haddam, Connecticut,[5,6] medical references commonly cite "Lyme disease" when referring to *B. burgdorferi* infection.

Epizootiology

B. burgdorferi is widely distributed in the northern hemisphere. Evidence of infection or exposure in horses has been reported in the United States in the Northeast, Midwest, Texas, and California.[7] Lyme borreliosis has been extensively reported in England and other European countries, nations of the former Soviet Union, China, Japan, Southeast Asia, and South Africa.[8] *B. burgdorferi* is transmitted to humans and animals by ticks belonging to the *Ixodes ricinus* complex.[9] These ticks each feed three times during the larval, nymphal, and adult stages.[5] The larvae and nymphs feed on wild animals, and adults are found most commonly on deer.[9] On the East Coast, *Ixodes scapularis* ticks are the principle vector, whereas on the West Coast *Ixodes pacificus*, the western black-legged tick, is the main vector identified.[10] *I. scapularis* is seen from the Atlantic coast to Oklahoma and Texas.[11] A much higher percentage of *I. scapularis* ticks (12% to 99%) will carry the spirochete compared with *I. pacificus*, in which the maximum number of infected ticks is 4% to 5%.[10,11] *I. scapularis* larval ticks principally acquire the spirochete from *Peromycus leucopus*, the white-footed mouse, and the nymphal stages are the major transmitters of disease to animals and humans.[12] With *I. pacificus*, the California kangaroo rat, *Dipodomys californicus*, and the dusky-footed wood rat, *Neotoma fusicipes*, are the likely enzootic reservoirs of *B. burgdorferi*.[13]

Public Health Considerations

The CDC initiated surveillance for Lyme disease in 1982, and in January 1991 it became nationally reportable. Cases have been reported from 46 states, and the annual number of Lyme disease cases has increased 18-fold, from 497 to 8803. It is now the most common tick-transmitted disease in the United States.

B. burgdorferi organisms have been recovered from the urine of feral white-footed mice *(P. leucopus)*.[14] Contact transmission has been reported between white-footed mice,[14] further complicating the understanding of transmission. Lacking any proof to the contrary, it is generally believed that any potential increased risk to humans from infected animals is due to animals bringing ticks into areas of human habitation, rather than any animal transmission.[15]

Molecular Biology

Immunochemical analysis of North American strains of *B. burgdorferi* reveal two abundant surface proteins termed *outer surface protein A* (OspA, 30 to 32 kD) and *outer surface protein B* (OspB, 34 to 36 kD).[16] The 41-kD antigen is located on the flagellum and is similar to the flagellar antigens of other spirochetes.[17] All isolates to date have four to nine pieces of

VetBooks.ir

extrachromosomal plasmid DNA. Plasmid may code for proteins that are important in pathogenicity, because the loss of infectivity of isolates that have been heavily passaged in the laboratory correlates with the loss of particular plasmids in culture.[18] Recent work suggests that *B. burgdorferi*, like the relapsing fever–causing *Borrelia* (e.g., *Borrelia hermsii*), can vary its antigenicity, although by a different mechanism and using subtle alterations in the genome.[19]

Clinical Signs

Equids

Clinical signs are nonspecific but may include low-grade fever, stiffness, lameness in more than one limb, muscle tenderness, hyperesthesia, swollen joints, and behavioral changes.[20,21] The most common signs are lameness and hyperesthesia. These signs have been more commonly reported in performance horses. *Borrelia* may be found concurrently with *A. phagocytophilum* in *Ixodes* ticks, resulting in dual infection in the horse.[22]

Horses from endemic areas have serologic evidence of exposure.[23-26] Attempts have been made to correlate individual cases of arthritis, uveitis, or brain infection with this organism.[25,27,28] Experimental infection has produced seroconversion and shedding of the organism in the urine and seroconversion in contact controls.[29] In the United Kingdom, most seropositive horses do not show clinical signs of disease.[30]

Ruminants

Although there are some reports in the literature of seropositive animals with arthritis, the evaluation performed on these patients makes it difficult to determine whether *B. burgdorferi* was the cause of the signs.[31] It appears many ruminants are seropositive to *B. burgdorferi* but do not have clinical signs. Whether these tests lack specificity in the ruminant or represent a host-adapted strain of the *Borrelia* organism is unknown.[32] A recent report correlates exposure of *I. scapularis* ticks in dairy cattle with titers to *B. burgdorferi*.[33] An attempt to develop a more specific test in cattle using the 41-kD flagellin antigen has been reported.[34]

DIAGNOSIS. A number of diagnostic methods are available, including IFA, ELISA, indirect complement fixation, and Western blot.[29,32] Culture of the organism requires special media (BSK) and is difficult but may be possible from blood, urine, or cerebrospinal fluid. Diagnosis of recent or active *Borrelia* infection has been based on high ELISA titers, positive Western blot, or PCR.[35] In an experimental infection study, *I. scapularis* ticks infected with *B. burgdorferi* were placed on healthy ponies for 7 days. These ponies developed detectable antibody at 5 to 6 weeks.[35] ELISA titers were elevated at 3 to 4 months post exposure and remained elevated for several months until euthanasia. Western blot became positive at 10 to 12 weeks post exposure.[35] Throughout the duration of the study, the organism was isolated from the skin where infected ticks were attached. Histopathologic examination revealed lymphohistiocytic nodules in the dermis, lymph node enlargement, and perivascular and perineural lymphocytic infiltrates in the skin, fascia, and perisynovial membranes. PCR was useful for detecting organisms in the skin, lymph nodes, skeletal muscle, fascia, and synovial membranes. Less commonly, organisms were detected in the heart, pericardium, kidney, bladder, and meninges.[35] Detection of serum antibodies to *B. burgdorferi* in horses has improved (84% detection) by using an ELISA based on whole-cell and recombinant antigens.[36]

TREATMENT. Antibiotic susceptibility of *B. burgdorferi* has been reported but may lack appropriate standardization.[37] *B. burgdorferi* is sensitive to tetracycline and moderately sensitive to penicillin. Amoxicillin, ceftriaxone, and imipenem are highly active against *B. burgdorferi*. Aminoglycosides, ciprofloxacin, and rifampin lack activity.[38] Doxycycline twice daily in humans has been frequently used. Probenecid and ampicillin or amoxicillin also have been used.[38] When CNS involvement is present, ceftriaxone or IV penicillin G has been used. The appropriate duration of therapy is unknown but is related to the stage of infection.

Three different antimicrobials that included ceftiofur sodium (2.2 mg/kg/day IM), doxycycline (10 mg/kg/day PO), and tetracycline (5 mg/kg/day IV) were used for a 28-day period in experimentally infected ponies.[39] High titers and *B. burgdorferi* isolation from skin biopsies confirmed infection. Antimicrobial therapy was initiated 3 months post exposure. Tetracycline was the most effective antimicrobial; it decreased antibody titers during and months after treatment, and bacterial isolation became negative in tissues. However, tissues were still positive for the spirochete on PCR.[39] The efficacy on decreasing titers of tetracycline in the clinical setting has not been highly successful.[40] Proposed treatment for *Borrelia* infection includes tetracycline (6.6 mg/kg IV q12h), doxycycline (10 mg/kg PO q12h), or ceftiofur (2.2 mg/kg IM q12h) for 3 to 4 weeks.[35]

A recombinant outer surface protein A (rOspA) subunit vaccine was shown to be effective in preventing infection in challenged horses with infected ticks.[22,41] Specific recommendations for its use in the clinical setting are lacking.

Tularemia

Bradford P. Smith

Tularemia, an infectious disease of humans, wild animals, livestock, and pets throughout the northern hemisphere, is caused by *Francisella (Pasteurella) tularensis*. There are four major subspecies: *tularensis*, *holarctica*, *mediaasiatica*, and *novicida*, with *tularensis* being the most virulent.[1] The organism is a facultative, intracellular, non–spore-forming, gram-negative coccobacillus that survives frozen or in mud and water for a period longer than 1 year,[2] but it only survives for hours in carcasses. The natural hosts are rabbits and rodents, and transmission to livestock occurs chiefly through food, water,[3] ticks, fleas, deerflies, and other insects.[4] Sheep are the most frequently affected livestock species, along with dogs, cats, and humans. Massive epidemics with high mortality in range sheep have been reported.[4] One paper describes three late-term abortion outbreaks, with one also including sick/dead ewes, between 1997 and 2007 in Wyoming and South Dakota.[5]

Humans are stricken with a plague-like illness when bitten by infected ticks, fleas, or insects and from handling infected rabbits or hares or other infected animal carcasses.[6] The disease has also been called *rabbit fever*, *deer fly fever*, and *meat cutter's disease*.[7] Sheep shearers may become infected by bites of parasites from the sheep. Disease in horses has also been documented.[8] Oral infection from contaminated water occurs, so fresh water should be provided.[4]

The disease causes an acute septicemia, with localization and lymphadenopathy and granulomatous lesions in the organs (particularly the liver and spleen). Signs are nonspecific, as expected with bacteremia, and include fever, anorexia, lethargy, and in some cases cough, rapid respiration, or diarrhea. Stiffness and edema of the limbs may be seen. Exposure to eyes can result in oculoglandular disease.[3] The course of disease is usually 2 to 14 days.

Agglutination titers in recovered affected sheep range from 40 to 5000. Agglutination titers persist for short periods (21 days) in horses,[4] probably because they measure mainly IgM.

Diagnosis is based on culture of the organism from blood or organs. Samples must be specially handled and tests done in BSL-3 laboratories.[7] Diagnosis can also be made by IFA testing or PCR[9] or ELISA.[7]

Necropsy usually reveals ticks on the carcass. Often, reddened or necrotic areas appear in and under the skin at the site of infected bites. Regional lymph nodes may be swollen and congested. Congestion and edema of the lungs are common. Fetal lesions from abortions have multifocal pinpoint necrosis of the liver, spleen, and lung.[5] Differentials include other bacteremias such as *Mannheimia (Pasteurella) haemolytica* in sheep, *Histophilus somni* (formerly *Haemophilus somnus*) in cattle, *Mycoplasma mycoides* subsp. *mycoides* in goats, and anthrax in all livestock. Treatment early in the course of infection is effective. Aminoglycosides, tetracyclines, cephalosporins, chloramphenicol, or quinolones all are likely to be beneficial initially until results of antimicrobial susceptibility testing are available. Insecticide removal of ticks from affected animals and herdmates is important. No animal vaccine is currently available, so insect and tick control in endemic areas remains the major prevention. Because oral infection from contaminated water has also been documented, fresh water should be provided.

Corynebacterium pseudotuberculosis Infection

Sharon Jane Spier • Monica Aleman

Definition

Corynebacterium pseudotuberculosis infections occur worldwide and cause external and internal caseous lymphadenitis in sheep and goats; cutaneous excoriated granulomas and mastitic, visceral, or mixed infection in cattle; and ulcerative lymphangitis and external and internal abscesses in horses.[1-4] Subacute to chronic lymphadenitis and pneumonia have been reported in humans handling infected sheep.[5,6] Several zebras in the United States developed severe or multiple internal abscesses and died weeks after being exposed to horses in California.[7] There have been reports of the disease in camels, alpacas, and buffalo.[8,9]

Microbiology

C. pseudotuberculosis infection is caused by a 2-µm, gram-positive, intracellular, nonmotile, pleomorphic, rod-shaped facultative anaerobe.[10] *C. pseudotuberculosis* grows well at 37° C on blood agar in 24 to 48 hours, and it forms small, pinpoint in diameter, whitish, opaque colonies that are surrounded by a weak zone of hemolysis. Because of the high lipid content in the bacterial cell wall, particularly corynomycolic acid, the colonies spatter in a flame and hold their shape when pushed across the surface of an agar plate.[11] High lipid content may facilitate survival of the organism in macrophages.[12] Two species-specific biotypes of *C. pseudotuberculosis* have been identified on the basis of differences in nitrate reduction[5] and DNA fingerprinting techniques.[11,13,14] Strains isolated from small ruminants are nitrate negative, strains from horses are nitrate positive, and both strains have been isolated from cattle.[1,5,13,15] From the results of DNA studies, the terms *biovar equi* for nitrate-positive and *biovar ovis* for nitrate-negative strains were proposed.[11] Molecular studies revealed that there is considerable heterogeneity of the isolates of *C. pseudotuberculosis* from small ruminants and from horses[13,14,16] and concluded that nitrate reduction may not absolutely distinguish between the isolates, as does ribotyping.[13] On the basis of genome sequencing, sheep and goats have specific isolates throughout the world, and horses and cattle have distinct groups of isolates depending on geographic locations.[13] Natural cross-species transmission between small ruminants and horses has not been reported.

C. pseudotuberculosis produces various exotoxins: phospholipase D (PLD), sphingomyelinase, inhibitory factor of staphylococcal β-hemolysin, hemolysis factor, dermanecrotoxins, and mouse lethality toxins.[17] Phospholipase D and sphingomyelinase are important in the pathogenesis of the disease because they hydrolyze lysophosphatidylcholine and sphingomyelin, respectively, enabling degradation of the endothelial cell wall and increasing vascular permeability.[18] The synergistic activity of sphingomyelinase with the exotoxin of *Rhodococcus equi* in lysing red blood cells in agar forms the basis for the synergistic hemolysis inhibition (SHI) test. The SHI test measures IgG to PLD exotoxin.[19]

Molecular characterization of *C. pseudotuberculosis* isolates causing various clinical forms of disease, including genome sequencing, has been reported. At present, phenotypic and genotypic strain differences have not been linked to clinical disease presentation (internal or external abscesses), suggesting that other environmental or host factors determine the course of disease.[20,21]

Clinical Signs and Differential Diagnosis

Sheep and Goats
