C. pseudotuberculosis causes caseous lymphadenitis (CLA) in sheep and goats worldwide. Caseous lymphadenitis is a major cause of poor production, premature culling, and mortality. Two forms of CLA exist which manifest as external and internal abscesses.[22] The infection in small ruminants is primarily characterized by suppuration and necrosis of the large superficial lymph nodes. External abscesses are found more commonly involving the mandibular, parotid, prefemoral, or prescapular lymph nodes. The exudate present in those abscesses is thick or inspissated and may appear white in sheep and greenish in goats.[4] A breed association with the type of CLA cutaneous lesion was observed in an outbreak in a commercial ram stud in Scotland.[23] The disease is commonly known as "cheesy gland" in Australia. Differential diagnosis should include abscesses caused by other organisms, trauma, seroma, hematoma, foreign body, injection reaction, and, less commonly, tumors. *C. pseudotuberculosis* infection represents a major herd health problem, so abscess culture to determine the precise causative agent is important. Mastitis occasionally develops.[2]

Internal abscesses can be found in the lungs, kidneys, and mediastinal, bronchial, mesenteric, and lumbar lymph nodes.[22] Chronic weight loss is the most common presenting complaint. Other clinical signs are related to the organ or tissues affected. Other diagnostic procedures may be necessary for the differentiation of internal abscesses as the cause of weight loss. Signs of spinal cord compression by vertebral abscesses have been seen in lambs born in unsanitary conditions.[4] Knowledge of the local prevalence can aid diagnosis of the infection when uncommon anatomic locations are affected. The prevalence in large breeding operations in endemic areas is estimated to be between 5% and 10%.

Cattle

C. pseudotuberculosis infection in cattle occurs as a herd problem with sporadic incidence. The most common clinical form affecting cattle is cutaneous excoriated granulomas; other forms are mastitis, visceral, and mixed infections.[2] In the most common form, the lesions do not occur as abscesses but as ulcerative, exuding granulomatous lesions as large as 20 cm in diameter, with necrotic areas that are easily surgically removed, leaving granulation tissue underneath.[3,4] Lesions are usually located in the lateral exposed areas of the body: face, neck, thorax,

VetBooks.ir

and flanks. The exudate varies from bloody to thick greenish in color. Lesions heal spontaneously in 2 to 4 weeks and do not appear to cause significant illness or decrease milk production in cattle in California.[4] However, monthly milk production was decreased by 6% in Israeli cattle.[3] The prevalence of the infection has been reported to be up to 10% in California dairies.[4] Morbidity was reported to be up to 35% in Israeli herds.[3] Management problems like broken posts or exposed wires traumatize the skin of cattle, allowing penetration of the organism. Young cattle appeared to be less susceptible to the disease than older cattle in Israel.[3] Differential diagnoses include trauma, foreign body, and other masses like tumors. Cutaneous lesions and mastitis were seen in 6%, and cutaneous lesions with concurrent visceral involvement in 1.6% of the cases in Israel with the remainder of the cows (92%) exhibiting only the cutaneous form.[3] The most affected organ in the visceral form was the lung.[3] The infection has been reported in bison from Egypt, resulting in severe emaciation and edema in the ventral areas and flanks.[24]

Camels and Camelids

Caseous lymphadenitis has been reported in old and new world camelids worldwide.[25] One study documented five young alpacas (aged 22 days to 14 months old) in North America with caseous lymphadenitis or subcutaneous abscesses that developed during late summer and early fall.[9] The alpacas did not appear clinically ill but developed swellings that progressed to abscesses. The abscesses (1 to 3 per alpaca) were located in the submandibular and cervical areas and in one case adjacent to the eye. Abscess excision appeared to be the most effective treatment in those cases. Differential diagnoses include abscesses caused by *Streptococcus* spp., *Corynebacterium* spp., and *A. pyogenes*.[26] Severe lymphadenitis with internal and external abscesses was reported in camels in Asia and Jordan.[8] A study of experimental infection of adult alpacas resulted in abscesses at the inoculation site and renal lymph nodes.[27]

Horses

Three forms have been described in horses: ulcerative lymphangitis and external and internal abscesses (Figs. 37.1 and 37.2). In a previous study of *C. pseudotuberculosis* infection in horses from California, ulcerative lymphangitis was diagnosed in 1%, external abscesses in 91%, and internal abscesses in 8% of the cases.[28] There appears to be no breed or sex predilection for development of infection. Ulcerative lymphangitis appears as a severe cellulitis, where the lymphatics are affected in one or more limbs, with multiple draining ulcerative lesions. Horses often develop a non–weight-bearing lameness, fever, lethargy, and anorexia. This form of the disease occurs worldwide and often becomes chronic, resulting in limb edema, lameness, weakness, and weight loss.[4] The differential diagnosis should include blunt trauma, fracture, foreign body, puncture wounds, nonseptic cellulitis, staphylococcal cellulitis, and other septic cellulitis. Musculoskeletal infection can result in marked lameness (grades 4 to 5 out of 5) and most commonly involves the axillary and triceps areas, followed by the stifle area.[29] In addition to diffuse lymphangitis of the limbs, it can also cause osteomyelitis and septic arthritis.[28,29]

The median age for horses with external abscesses is 5 years (range, 3 months to 28 years).[28] Young horses appear to be predisposed to infection; 52% of the cases in a large retrospective study in California were 5 years old or younger.[28] Few cases involved foals younger than 6 months of age, suggesting that foals born to mares in endemic areas may be protected for several months by colostral antibodies.[28] External abscesses located primarily in the pectoral and ventral abdominal regions are most commonly diagnosed in areas of the western United States (Texas, Oklahoma, New Mexico, Colorado, Nevada, Utah, California, Wyoming, Arizona, Oregon, and Washington);

FIG. 37.1 Typical ripe pectoral external abscess in a horse, containing a large pocket of pus, caused by *C. pseudotuberculosis.*

FIG. 37.2 Severe ulcerative lymphangitis in a horse leg caused by *C. pseudotuberculosis*.

VetBooks.ir

however, disease incidence is increasing and spreading to all regions of the United States, including Hawaii, with reports in Mexico and Western Canada.[1,4,20,28,30,31] This clinical form of external infection is commonly known as "pigeon fever" because of the large size of pectoral abscesses, giving the appearance of a pigeon's breast. "Dryland distemper" is another name that reflects its geographical distribution in arid areas. Other common anatomic locations are the prepuce, mammary gland, axilla, inguinal region, limbs, and head.[28] Abscesses involving the head include the ears, eyelids, forehead, maxillary, and mandibular regions.[28] Severe facial suppurative cellulitis and panniculitis with skin sloughing have also been reported.[32] Other less common areas are the thorax, neck, parotid gland, guttural pouches, larynx, flanks, umbilicus, tail, and rectum.[28] Central nervous system infection has also been reported.[28,33] A large area of edema develops in the area of abscess formation. While the abscess matures, the area becomes hard and painful, and some get large, particularly in the pectoral area. These abscesses typically have a thick capsule measuring up to 10 cm, and can cause severe lameness if located in the axillary or inguinal region.[1,28] Maturation can be slow and drainage difficult to establish if the abscess lies deep to muscle. Once drainage is established by spontaneous rupture or lancing, the majority of cases resolve within 10 to 14 days, but many horses can experience a protracted course of disease lasting months with recurring abscesses. Generally, weight loss is not observed in absence of internal infection. Abscesses may contain from 5 to 400 mL of thick, tan, purulent exudate.[1] The majority of affected horses present with a single abscess rather than multiple abscesses.[28] Fever up to 40° C develops in about 25% of cases. Other signs are nonhealing wounds, lameness, ventral dermatitis, and (less commonly) depression, anorexia, mastitis, and other problems, depending on abscess location.[28] In the majority of horses (91.4%), complete recovery occurs with no recurrence of infection in subsequent years, implying a long-lasting immunity. However, 8.6% of equine infections may persist for longer than 1 year or recur as external or internal abscesses.[28] In sheep and goats, humoral and cellular immune responses develop following infection, and macrophages acquire the ability to kill the organism.[6] The case fatality for horses with external abscesses is low (0.8%).[28] The differential diagnosis for external abscess, particularly pectoral, should include trauma, seroma, hematoma, foreign body, or abscess due to a different organism.

In a large study of *C. pseudotuberculosis* infection in the horse, 8% of 538 horses developed internal abscesses.[28] In two different studies, up to 63% of horses with internal abscesses also had a history of, or concurrent, external abscesses.[28,34] In a study of 30 horses with internal abscesses, a sex predisposition (70% female) was apparent.[34] Mean age is 8 years, with a range of 10 months to 23 years.[28,34] The most common clinical signs are anorexia, lethargy, fever (up to 41.1° C), tachycardia, and modest weight loss. Other signs are colic, pale mucous membranes, ventral and/or limb edema, ventral dermatitis, ataxia, hematuria, nasal discharge, and abortion.[28] The most commonly affected anatomic location is the liver, followed by mesentery, mediastinum, lungs, kidneys, diaphragm, spleen, pericardium, blood, and uterus.[1,28,34] A postmortem examination was performed on an aborted fetus from a mare with pneumonia and revealed *C. pseudotuberculosis* abscesses in the liver, lungs, spleen, diaphragm, kidney, and bladder.[34] Both single and multiple organ involvement has been documented.[34] Bacteremia may also occur. The case fatality for horses with internal abscesses ranges from 30% to 40%.[28,34] The differential diagnosis should include other types of abscesses, such as *Streptococcus*, *Actinomyces*, *Staphylococcus*, *R. equi* in foals, *Coccidioides immitis*, anaerobes, neoplasia, and other causes of weight loss. The clinical signs and differential diagnosis will depend on the location of the abscess.

Humans

Human infection may result from consumption of unpasteurized infected milk or milk products, continued close contact with infected animals, handling contaminated equipment, and exposure to wounds with exudates.[6,35] Human infection has been reported from strains of small ruminants.[6] Transmission from horses to humans has not been reported, but precautions should be taken when handling infected horses. Infection in humans occurs as a subacute to chronic lymphadenitis and pneumonia.[6]

Clinical Pathology and Laboratory Diagnosis

Common findings include anemia of chronic disease and an inflammatory leukogram.[28,29,34] Leukocytosis with neutrophilia and increased fibrinogen and serum amyloid A (SAA) are common features of developing bacterial infections, particularly in the case of internal abscesses.[28,29,34] Leukocytosis with neutrophilia was seen in 36% and 76% of horses with external and internal abscesses, respectively.[28] Hyperproteinemia due to increased globulins was observed in 38% and 59% of horses with external and internal abscesses, respectively.[28] Similarly, infected cattle and small ruminants had increases in white blood cell counts.[2,3]

Peritoneal fluid from 93% of horses with abdominal abscesses was abnormal.[28] The remaining horses with abdominal abscesses and normal peritoneal fluid had abscesses located retroperitoneally involving the kidneys, without involvement of other abdominal structures. *C. pseudotuberculosis* was isolated by bacterial culture in 32% of the samples of peritoneal fluid in horses with internal abscesses,[28] and infection can also be detected by PCR. Failure to detect the organism from peritoneal fluid does not rule out the disease as infection could be in a retroperitoneal location, sequestered within a thick capsule, or suppressed by local factors or nucleated cells.[36]

The ELISA test for detection of cell wall antigens appears to have some utility for detection and control of infection in sheep.[37-40] The synergistic hemolysis inhibition (SHI) test measures IgG response to the PLD exotoxin in the patient's serum by detecting the highest dilution that will prevent hemolysis of *R. equi* exotoxin–sensitized bovine red cells when mixed with *C. pseudotuberculosis* exotoxin of a known concentration.[19,41] Increasing titers may be seen with exposure, or active external or internal infection and there exists considerable overlap in values among these groups of horses. In a case control study, SHI test results had greatest utility for determining internal *C. pseudotuberculosis* infection in horses when there was no evidence of external abscesses.[43] A high probability of internal infection with titers greater than or equal to 512 was previously reported, yet a recent case control study of 171 horses revealed higher titers were more indicative of active external or internal disease rather than internal disease specifically. The SHI test was unable to distinguish the occurrence of internal infection when external abscesses were present. Titers increase with chronicity of infection and bacterial culture is the preferred method of diagnosis for external infection. In horses *without external abscesses*, increased titers greater than 1280 are significantly associated with internal infection. Clinicians are advised against diagnosis of internal infection on the basis of SHI titer; rather, the test should be used in conjunction with other clinical and clinicopathologic evidence of inflammation.

The SHI test can be used in sheep and goats to monitor prevalence and exposure of incoming animals and to detect subclinical infections.[4,41] In horses, a low SHI titer does not rule out the disease as horses that are seronegative at the time an external abscess is drained seroconvert later. High SHI

VetBooks.ir

titers in horses with internal abscesses probably reflect the chronicity of the disease and the resulting prolonged immune stimulation. In summary, high titers can be seen with both internal and external abscesses and abdominal and thoracic ultrasonography is useful for confirmation of internal infection in suspect cases.[28,34,43] Exposed herd mates can also have SHI titers in the absence of clinical infection. Prolonged seropositivity has been observed in horses and goats.[28,41,44] Other serodiagnostic tests used in sheep and goats are tube agglutination, complement fixation, and gel immunodiffusion.[17,45]

A presumptive diagnosis can be made on the basis of history, local prevalence, time of year, clinical signs, and exudate characteristics.[4] For the diagnosis of internal abscesses, the previous features must be considered, as well as the presence of an inflammatory leukogram with elevated fibrinogen, serum chemistry abnormalities, abnormal peritoneal fluid or transtracheal wash, positive blood culture, SHI titer of 512 or higher, and ultrasonographic and/or radiographic evidence of masses.[28,34] A definitive diagnosis is established by isolating the organism from abscesses or draining wounds. The organism is readily isolated and grows well in blood agar in 24 to 48 hours, even when contaminant bacteria are present.[28]

Pathophysiology and Epidemiology

C. pseudotuberculosis is a soil-borne organism that survives for long periods of time, months to years, even in direct sunlight at environmental temperatures.[6,46,47] The incidence of infection in horses varies considerably from year to year. External and internal abscesses in horses can present at any time of the year but are more commonly observed during the fall and early winter months, with the highest incidence in September, October, and November.[28] However, internal infections are more frequently seen in November through January, 1 to 2 months following the peak number of cases with external abscesses.[34] The largest numbers of equine cases have been observed during the dry months of the year, following heavy rainfall, which may result in optimal breeding conditions for insects.[1,28,30] The seasonal incidence in horses has been associated with the presence of biting insects like *Haematobia irritans* (horn fly); this insect's feeding pattern causes ventral midline dermatitis. Insect vectors involved in transmission of disease in horses (e.g., *H. irritans*, *Stomoxys calcitrans*, *Musca domestica*) were identified by detecting the PLD exotoxin gene of *C. pseudotuberculosis* in an endemic area.[48] Disease transmission may occur by direct contact with exudates or contaminated soil or by vector-borne routes.[49] Temporal and spatial analysis indicated an incubation period of 3 to 4 weeks in horses.[50] There is no breed or sex predilection[28]; however, a retrospective study indicated a predilection for internal abscesses in females.[34] A case-control study in an endemic area revealed young adult horses (<5 years of age) had increased risk of infection.[49] Horses housed outside or with access to an outside paddock or in contact with other horses on pasture appeared to be at higher risk than stabled horses.[49]

The disease in cattle from Israel occurred during the spring and summer dry season (March to October) when the housefly population is high.[3] *C. pseudotuberculosis* was isolated from houseflies collected over an Israeli cow lesion.[51] The infection in cattle may spread by direct contact or indirectly by houseflies or fomites.[3] The disease in sheep and goats is not seasonal, and transmission is through contact of exudate from a draining abscess from animal to animal or via contaminated equipment.[1] Lambs born in contaminated surroundings can be infected through the umbilicus, mouth, or inhalation.[4] Sheep that acquire the organism orally or from shearing wounds tend to have parotid, submandibular, prefemoral, or thoracic abscesses.[4] Goats can be infected when wounds are exposed to contaminated milking equipment. The incubation period is long and variable. In experimental infections in small ruminants, the incubation period was from 2 weeks to several months.

The pathogenesis of the disease in horses is unclear, but it has been speculated that the organism enters the equine host through skin or mucous membrane abrasions or wounds, as has been confirmed in sheep.[52,53] Experimentally induced infections in small ruminants revealed that once *C. pseudotuberculosis* gains access via wounds or abrasions, the organisms spread to subcutaneous or submucosal lymphatics, where they are phagocytosed by macrophages that migrate to the invasion site to engulf them.[54] The organism survives intracellularly because of its high lipid content (corynomycolic acid), resisting the action of lysosomal enzymes.[10] *C. pseudotuberculosis* replicates in the phagolysosome; if large numbers of organisms are engulfed, phagocytic cells die. Experimental inoculation of the organism in sheep revealed a massive infiltration with polymorphonuclear leukocytes,[55] which are believed to carry the bacteria to regional lymph nodes.[4] A PLD toxin of approximately 31.5 kD, produced by all *C. pseudotuberculosis* isolates, increases vascular permeability, causing spread of the organism regionally and systemically.[6,42,56] Development of abscesses at secondary locations in horses can occur in up to 25% of cases.[28] PLD toxin can cause lymphatic necrosis and thrombosis and may enhance survival and multiplication of the organism via complement depletion and inhibitory effects on phagocytic cells.[6] Corynomycolic acid and PLD toxin contribute to inflammation, edema, and pain during abscess development.[57] The profound reaction of these compounds is probably responsible for the formation of a thick abscess capsule that develops as phagocytes accumulate in the abscess core. The abscess eventually matures and drains, but if removal of infected material is incomplete, recurrence may be expected, particularly in small ruminants.[4] The development of internal abscesses in horses is unclear but has been postulated to result from hematogenous or lymphatic spread of bacteria from more superficial sites.[4,28,34]

Treatment and Prognosis

Important features to consider when treating external abscesses are to (1) allow the abscess to mature, (2) establish drainage, (3) collect and properly dispose of the infective exudate, (4) lavage the wound with an antiseptic solution, and (5) apply insect repellant ointments and other measures of fly control. In a retrospective study in horses, the majority of external abscesses were incised to establish drainage, then some received antimicrobial therapy after drainage in an effort to decrease cellulitis.[28] Many horses received no treatment; abscesses broke and drained without clinical intervention.[28] Other horses were only treated with antimicrobials.[28] Outcomes were successful for 99% of horses with external abscesses.[28] Horses with abscesses in the axillary region or deep within muscles have considerable pain, necessitating incision and drainage. Ultrasound is useful for localization of deep abscesses.[34]

Antimicrobial therapy for uncomplicated external abscesses is often not indicated. Horses with external abscesses that have systemic illness, recurrent infections, or poor immunity and horses with internal infection or ulcerative lymphangitis require antimicrobials until infection has completely resolved. If antimicrobials are used, long-term (minimum 4 to 6 weeks) therapy is necessary for the treatment of internal abscesses and ulcerative lymphangitis. Median resolution time for horses with internal abscesses treated with antimicrobials was 36 to 42 days, with a maximum duration of 97 days.[28,34] The case fatality for horses with internal abscesses treated with antimicrobials was 30% to 40%, but 100% if not treated.[28,34] A study describing 35 horses with musculoskeletal infection reported surgical drainage in 60%, antiinflammatories in 97%, and antimicrobials in 86%.[29]

VetBooks.ir

In vitro, *C. pseudotuberculosis* is susceptible to nearly all commonly used antimicrobials, and resistance is uncommon.[54,58-60] Trimethoprim sulfamethoxazole (30 mg/kg PO q12h), trimethoprim sulfadiazine (24 mg/kg PO q12h), and procaine penicillin (22,000 IU/kg IM q12h) are often effective for external abscesses. Horses with internal abscesses respond well to minocycline (4 mg/kg PO q12h), doxycycline (10 mg/kg PO q12h), enrofloxacin (7.5 mg/kg PO q24h), trimethoprim sulfas (doses above), and potassium penicillin (20,000-40,000 IU/kg IV q4-6h). Rifampin (5 mg/kg PO q12h) is highly effective and is used in combination with another antimicrobial (e.g., trimethoprim sulfa or enrofloxacin) due to concerns for rapid emergence of microbial resistance when used as monotherapy. Ceftiofur is less effective due to high minimum inhibitory concentrations (MIC) and therefore not recommended. Ulcerative lymphangitis should be treated aggressively with long-term antimicrobials (3 to 4 weeks). In horses, colitis is a risk of antimicrobial use. In addition, enrofloxacin is contraindicated in growing horses due to risk of cartilage damage. Fortunately, a recent study of antimicrobial susceptibility patterns (MIC) in 207 equine isolates showed no differences in MIC over 16 years.[54]

Nonsteroidal antiinflammatories (NSAIDs) to control discomfort and inflammation are often used to control the pain and/or fever while waiting for external abscesses to mature.

The prognosis for external abscesses is good. Most resolve in 3 weeks from the day of drainage.[4] The prognosis for horses with internal abscesses and ulcerative lymphangitis is guarded but improves if infection is detected early and appropriate long-term therapy is administered. Horses with musculoskeletal infection tend to have a favorable prognosis, but osteomyelitis and septic arthritis can complicate recovery.[29]

In a study in cattle, skin lesions on individual cows healed (on average) in 23 days after local or parenteral treatment; 17% of severely affected cattle were culled.[3] Simple drainage in small ruminants does not usually result in resolution of the disease and can become a potential source of infection. Dilute betadine solutions can be used for abscess lavage. Complete excision of the abscess under general anesthesia may be necessary to keep the abscess from draining and prevent spread of the infection to other animals.[4] The treatment of choice in small ruminants is complete surgical removal of affected lymph nodes.

Prevention and Control

Even though *C. pseudotuberculosis* infection is one of the most commonly diagnosed infectious diseases in California, little is known about its prevention and control. General recommendations to prevent its spread are isolation of infected animals, fly control, good sanitation, careful shearing practices, disinfection of contaminated fomites, and careful disposal of bedding. On small-ruminant farms, morbidity can reach 100%, with depopulation being the most economic option. Because *C. pseudotuberculosis* can survive in soil and on fomites, the potential for environmental contamination is high.[46,49]

Immunization trials using whole cells, cell wall toxoids, and bacterin-toxoid combinations have been used to prevent CLA in small ruminants.[61-65] These vaccines have been shown to provide a high degree of protection, decreasing the number of infected sheep and number of abscesses per sheep.[61-65] *C. pseudotuberculosis* toxoids are commercially available for sheep and goats (e.g., Caseous D-T [Colorado Serum Co., Denver, Colo.], Glanvac [Rhodes, New South Wales, Australia]). In horses, autogenous bacterin-toxoids have been used for many years with anecdotal success.[66,67] A bacterin-toxoid vaccine with a conditional license (Boerhinger Ingelheim, Ingelheim am Rhein, Germany) is available for horses. Vaccinated animals demonstrate increased SHI titers following a 2-dose primary series; however, conferred protection remains to be established.

Physitis (Epiphysitis)

Berkley Chesen

Definition and Etiology *Physitis* is a term used to describe a developmental orthopedic condition in which there is a disturbance in endochondral ossification at the physis or growth plate. Of the developmental orthopedic diseases (osteochondrosis, physitis, subchondral bone cysts, flexural limb deformities, cuboidal bone malformation, acquired angular limb deformities, and juvenile arthritis), physitis is the most common.[1,2] In one study of 1711 Irish Thoroughbred foals, 67% had signs of developmental orthopedic disease.[2] The term *physitis* may better be defined as physeal dysplasia, since there is typically no evidence of an inflammatory process.[3] Physitis has been seen in growing cattle due to copper deficiency and interactions with molybdenum, zinc, and sulfates, as well as in calves raised on slatted floors.[4] Two common antagonists of copper are zinc, which when prevalent at high levels prevents absorption of copper by the body; and molybdenum, which is found in alfalfa.[5] Other animals in which physitis has been reported include show rams being heavily fed and sheep and goats due to pregnancy-associated ephiphysitis.[4] Physitis typically affects the given physis during its active growth phases. Many factors have been implicated as causes of physitis in horses, including[4]:

1. A genetic component for faster-growing horses and for specific conformation (such as an upright and pigeon-toed appearance)
2. Overweight foals
3. Growth spurts in foals
4. Intake of high levels of carbohydrates causing hormonal changes affecting the physis
5. Improper mineral balance (such as copper or zinc deficiencies)
6. Excessive or deficient calcium intake
7. Excessive exercise, especially on hard ground, causing strain on maturing cartilage

More recently, physitis has been implicated as a complication after treatment with a transphyseal screw for angular limb deformities in the distal radius. It was shown that a single transphyseal screw had a significantly higher complication rate of physitis when compared to the technique using screws and wires.[6]

Clinical Signs Physitis in horses is seen mainly in three specific locations at certain ages. Foals ranging in age from 3 to 6 months most commonly have signs of physitis at the distal metacarpal or metatarsal growth plate (with or without involvement of the proximal physis of the first phalanx).[7] Older foals (8 to 24 months) may have signs of physitis at the physis of the distal radius.[7] Less frequently, the distal physis of the tibia may be involved. Physitis is characterized by firm swellings, which may be warm and painful upon palpation. Typically the swellings are medial due to increased weight bearing on this portion of the limb.[7] Foals may or may not be lame. Changes radiographically include a sclerotic, roughened physis with an irregular metaphyseal shape.[2] If the physitis continues, the growth plate may close prematurely, leading to an irreversible angular limb deformity (usually a varus deformity due to the decreased growth on the medial physis).[7]

Diagnosis A diagnosis of physitis is usually made by appreciation of the clinical signs, including warm, sometimes painful, firm swellings in the above-mentioned locations. Physitis at the fetlock may appear to have an hourglass appearance if the proximal physis of the first phalanx is affected.[7] A convex appearance just proximal to the distal tibial and radial physis may be seen early in the disease process.[7] A quantitative method for detection of physitis was investigated in Thoroughbred foals.[2] This method was based on the observation that when the physis is enlarged, there is more concavity of both the metaphysis and the ephiphysis.[8] Results of this study show that epiphyseal concavity may indicate the degree of physeal swelling by using the maximum second derivative value of that contour.[2] Radiographically, physitis is characterized by a growth plate that is irregularly thickened with sclerotic adjacent bone.[2]

Treatment and Prognosis Treatment of physitis should begin with management changes. Special attention should be given to the nutrition of these foals and weanlings. Ensuring proper balance of minerals, especially calcium and phosphorus, and adequate amounts of trace minerals, such as copper and zinc, is necessary. Copper is required for successful crosslinking of collagen. When there is a copper deficiency, the cartilage matrix weakens and microfractures occur.[5] Because mare's milk is very low in copper, foals rely on hepatic stores gained during the last trimester of gestation.[5] One study showed that supplementation of mares with copper during gestation significantly reduced radiographic signs of physitis in their foals at 150 days of age.[9] Supplementation of foals did not affect the incidence of physitis in the same study. Due to the results of this study, supplementation of mares during the second half of gestation with copper on farms with a high incidence of physitis may be beneficial in preventing physitis in their foals.[9] A new

VetBooks.ir

supplement available to veterinarians, Leg Aide™, produced by Progressive Nutrition (Hopkins, Minn.), has anecdotally positive results for supplementing foals in rapid growth phases or with nutritional shortages.

A general reduction in energy is needed to slow growth rates and when necessary to decrease body weight. Total concentrate should be 0.5 to 0.75 kg/100 kg body weight for nursing foals, 1 to 1.5 kg/100 kg body weight for weanlings, and 0.5 to 1 kg/100 kg body weight for yearlings.[4] Varying degrees of discomfort are involved with physitis. For horses with very painful, warm physes, the judicious use of nonsteroidal antiinflammatory drugs (NSAIDs) is indicated. Exercise restriction, specifically stall rest, is indicated in affected horses. Without exercise restriction, these horses continue to load the physes, which may lead to permanent conformational changes, such as angular limb deformities. The prognosis for physitis is good for athleticism with early detection and treatment.

Osteochondrosis

Jarred Williams • Jason C. Mez

Definition and Etiology

Osteochondrosis is a developmental orthopedic disease characterized by failure of, or a defect in, endochondral ossification; it can lead to cartilage flaps, osteochondral fragments, or subchondral bone cysts. It is classified as a developmental orthopedic disease (DOD) along with physitis, angular limb deformities, subchondral bone cysts, flexural deformities, incomplete ossification of the cuboidal bones, and juvenile arthritis.[1] *Chondrodysplasia* and *dyschondroplasia* are more descriptive terms because they imply a primary defect in cartilage maturation, but their use is generally reserved for abnormalities of limb and vertebral development. The terms *osteochondrosis*, *osteochondritis*, and *osteochondritis dissecans* have all been used synonymously in discussing the condition. To maintain consistency and avoid confusion, the following designations are used in this discussion: *osteochondrosis* refers to the disease, *osteochondritis* refers to the synovial inflammatory response caused by the disease, and *osteochondritis dissecans* refers to the condition when a cartilaginous flap is identified.[2]

Osteochondrosis has been recognized in most domestic species, including horses, swine, and less often cattle, sheep, and goats. The focus has been osteochondrosis in horses, because of the economic impact and performance-limiting characteristics of the disease; and in swine, due to the effects on production traits[3] and development of comparative models for study of the disease.[4]

Clinical Signs and Differential Diagnosis

Osteochondrosis can present with a variety of clinical signs that are frequently recognized in juvenile animals. Effusion of the affected joint with or without accompanying lameness is common. The tarsocrural and femoropatellar joints are most often affected, but the condition can be seen in any joint. In young animals, physitis (i.e., inflammation at the physeal plate) can have a similar appearance, with generalized enlargements adjacent to synovial structures. Osteomyelitis can cause a periosteal reaction that, if located in the area of a joint, can have a similar appearance. Septic arthritis can closely mimic the signs of osteochondrosis, but the associated lameness is often much more severe. Physitis, osteomyelitis, synovitis, and septic arthritis should all be considered in the differential diagnosis of osteochondrosis in juvenile animals. In older animals the clinician should consider synovitis, osteoarthritis, and trauma in the differential diagnosis.

Osteochondrosis is generally diagnosed in horses when they begin training programs or athletic activity. They often present with a complaint of joint effusion that can be acute or insidious. Lameness, if any, is usually mild, except in cases with large osteochondral fragments or subchondral bone cysts. Severe cases seem to be more common in the stifle, and associated clinical signs may be present in foals as young as 6 months. Reports in cattle indicate that young, intact male, purebred animals are most often affected. The typical clinical signs are lameness with associated joint effusion. Osteochondrosis in swine has been associated with a syndrome known as "leg weakness." Affected animals can show a range of signs from mild lameness to difficulty rising and/or inability or refusal to mount.[5] Evaluation of performance data from swine herds can be a useful indicator of osteochondrosis because it has been shown to have a significant effect on production traits.[3,6] Production animals are often slaughtered prior to 2 years of age; thus recognizable clinical signs of the disease in cattle and swine may be apparent only in breeding animals.

Sites of Predilection

Osteochondrosis can be found in any diarthrodial joint, but sites of predilection exist in all species affected. In horses the stifle, tarsus, and fetlock are most frequently affected, and to a lesser degree the shoulder and vertebrae. In the stifle, in order of frequency, the lateral trochlear ridge of the femur, medial trochlear ridge of the femur, trochlear groove, and distal end of the patella are affected.[7] The medial femoral condyle is the site of predilection for subchondral cystic lesions. In the tarsus, the distal intermediate ridge of the tibia, lateral trochlear ridge of the talus, and medial malleolus are affected.[7] The most common manifestations in the fetlock joint are along the dorsal aspect of the sagittal ridge and the condyles of the metacarpus or metatarsus, and of the dorsal aspect of the proximal phalanx.[8] Predilection sites in cattle are similar to those in horses, with the hock and stifle most often affected and similar distribution in the joints.[9] Swine show a slightly different pattern, with the medial condyle of the humerus and femur most frequently affected.[6]

Diagnostic Tests

Animals presenting with signs of joint effusion and lameness should undergo a thorough physical examination. A compete blood cell count (CBC) indicating a septic process, along with radiography, helps differentiate osteomyelitis, septic physitis, and septic arthritis from osteochondrosis. Horses should be observed in motion and given flexion tests when possible. Regional and intraarticular anesthesia can be used to localize the site of lameness, though often the primary sign of osteochondrosis is swelling without lameness. Swine and cattle can be observed in their normal surroundings for signs of lameness. The joint in question should be radiographed, as should the corresponding joint on the contralateral limb in the tarsocrural and femoropatellar joints, because lesions are frequently bilateral. If lesions are detected in the metacarpophalangeal or metatarsophalangeal joint, the remaining three limbs should be evaluated. Joint effusion with or without lameness is more reliably seen in cases of osteochondritis dissecans (OCD) and subchondral bone cysts than in osteochondrosis.

Swine and cattle will often present with signs of lameness and mild joint effusion. Careful physical examination of the restrained animal should localize the lesion and guide appropriate radiography. As with equine patients, the lesions are commonly bilateral, and corresponding limbs should also be radiographed. Reviewing production records of finishing or breeding swine herds may be of diagnostic value, because osteochondrosis has been shown to cause significant reductions in performance and production traits.[3]

The manifestation of osteochondrosis may not be adequately represented by clinical signs and radiographs. Clinical signs of lameness and joint effusion have been shown to precede changes within the joint, and serial radiographs may be needed to diagnose the condition.[10] Radiographic abnormalities

VetBooks.ir

consistent with osteochondrosis of the distal intermediate ridge of the tibia and lateral trochlear ridge of the femur can return to a normal appearance by 5 and 8 months, respectively, in warmblood foals.[11] Radiographs often underrepresent the severity or size of the lesion seen at surgery. Evaluation of osteochondrosis along the lateral trochlear ridge of the femur indicated that ultrasonography provided a better overall subjective assessment of the lesion (length, depth, and width) compared with radiography.[12]

Pathophysiology Endochondral ossification is the process of bone formation in which cartilage scaffolds, arranged in zones, are gradually replaced by bone. It occurs at the articular/epiphyseal and metaphyseal growth plates and at secondary centers of ossification, such as the carpal and tarsal bones. Directly beneath the articular cartilage is a zone of resting chondrocytes that divide to form the next zone of proliferating chondrocytes. These proliferative cells divide rapidly, organizing into columns perpendicular to the long axis of growth. The cells swell in the hypertrophic zone, where the columns become more organized. The chondrocytes in this zone are surrounded by increasing amounts of extracellular matrix, which becomes mineralized in the zone of calcification. These columns of chondrocytes are vascularized by metaphyseal blood vessels supplying nutrients. It is on these calcified cartilage columns that bone forms, creating the primary spongiosa, which is subsequently remodeled into mature bone.

The exact pathogenesis of osteochondrosis is unclear. The traditional theory is that the process of endochondral ossification is disrupted, resulting in areas of thickened cartilage. The deeper layers of affected cartilage do not receive adequate nutrients, resulting in necrosis of the cells and failure of proper ossification. These retained cartilage "plugs" have less structural integrity than normal cartilage and are prone to damage. Specifically, shear forces acting on the abnormal cartilage can lead to fissure formation, which progress into fragments of cartilage and subchondral bone. When compressive forces predominate on an area of thickened cartilage, it is surmised that infolding of the cartilage plug occurs with normal endochondral ossification proceeding around it, possibly leading to the formation of a subchondral bone cyst.

The traditional theory of defective endochondral ossification may be a simplistic view of a more complex, multifactorial condition. Limited reparative responses of bone and cartilage make it difficult to determine whether the origin of a lesion is developmental or traumatic. One report failed to distinguish articular cartilage differences in naturally occurring osteochondrosis versus healing osteochondral fragments.[13]

Computed tomography and magnetic resonance performed on fetuses and foals demonstrated that there was greater cartilage thickness in areas of joints that commonly develop OCD. More specifically, at 8 to 9 months of gestation, the lateral trochlear ridge of the femur, medial malleolus of the tibia, and distal intermediate ridge of the tibia, all OCD-susceptible sites, had the greatest percentage of cartilage compared to unsusceptible sites. Postpartum, the percentage of cartilage in the medial malleolus and distal intermediate ridge of the tibia remained high. These findings suggest that greater cartilage thickness at specific joint sites could play a role in the development of OCD.[14]

Arthroscopic observations of normal-thickness cartilage defects and normal subchondral bone, as well as lesions occurring preferentially at single sites at the limits of articulation, suggest causative factors other than defective endochondral ossification.[15] The development and then spontaneous regression of osteochondrosis lesions in young animals suggest that the condition is a dynamic process that can be affected by numerous intrinsic and extrinsic factors, and a "window of susceptibility" may exist whereby lesions are constantly changing and result in the development of normal articular cartilage. Alternatively, these developmental lesions may not regress, leading to osteochondrosis.[16] It is currently impossible to predict how a lesion may behave while developing; thus treatment recommendations should be reserved until the lesion has been fully developed.

Etiology The etiology of osteochondrosis is unclear and commonly described as multifactorial. Such factors as nutrition, genetics, growth rate, failure of normal vascularization, altered or excessive biomechanical forces, and hormonal influence have been implicated.

The consistent distribution of lesions at specific anatomic sites within the joint suggests trauma or regional biomechanical forces as causative factors, particularly when the lesions are bilateral or quadrilateral. It has been established in pigs that microtrauma or disruption of the metaphyseal blood vessels supplying the developing cartilage canals causes ischemic necrosis, failure of mineralization, and a retained cartilage plug.[17] The same vascular pattern has been shown to be present in young foals, with the arterial supply crossing the ossification front from metaphyseal blood vessels to nourish the developing cartilage canals.[18-20] Therefore such failure of vascularization, resulting in ischemic necrosis of the cartilage canal and retention of a cartilage plug, appears to play a role in the development of osteochondrosis in swine and horses.[21]

Nutritional influences have been evaluated. Studies have focused on dietary energy levels and mineral composition (copper and zinc). The growth rate of the animal is directly affected by energy intake and use as well as its genetic predisposition. Animals fed high-energy diets resulting in accelerated growth rates have a much higher incidence of osteochondrosis.[4,22-23] More specifically, foals fed with concentrates had a higher probability of developing OCD lesions, whereas foals not receiving concentrates had a higher probability of healing from existing OCD lesions.[24] In pigs, it was shown that for every 100-g increase in average daily gain during the weaning and finishing period, a 20% increase in cartilage lesions or osteochondrosis in the humeral condyle occurred.[25] This is important when considering ration planning and growth rates of replacement animals, where longevity is a greater concern than in the production animal.

Low copper levels and increased zinc concentrations have both been implicated in the etiology of the disease. Low copper is thought to play a role through lysyl oxidase, a copper-dependent enzyme essential in the crosslinking of collagen molecules. Increased levels of zinc antagonize copper and could work indirectly through a similar mechanism. There is conflicting evidence on the causative nature of low copper levels, and lesions seen in copper-deficient animals do not always mimic those of naturally occurring osteochondrosis. In addition, evidence suggests that neonatal copper levels exert a positive effect on the resolution of osteochondrosis lesions but are not directly involved in the pathogenesis of the disease.[26]

Genetics have been implicated in the etiopathogenesis of osteochondrosis in different species. A recent review article summarized the advancements in quantitative and molecular genetics in refining estimation of genetic parameters and identifying predisposing genetic loci. Whole genome scans were performed in Thoroughbred, Standardbred, French and Norwegian trotter, Hanoverian, and Dutch warmblood populations. Heritabilities were highest for tarsal osteochondrosis in Hanoverian warmbloods and Norwegian trotters, whereas in Thoroughbreds a low genetic variation seemed to be present in similar lesions. Validation studies in Spanish Purebred and Hanoverian warmblood horses corroborated osteochondrosis risk loci on horse chromosomes (ECAs) 3, 14, 27, and 29. A strong association with tarsal OCD was found for a single nucleotide polymorphism on ECA 3.[27] In pigs, Landrace and Yorkshire breeds show a high frequency of osteochondrosis,

whereas domestic pigs crossed with wild hogs do not develop the disease.[4]

Numerous hormones (e.g., insulin, somatotropin, thyroxine) are involved in endochondral ossification, and alterations of these, or their derivatives, could theoretically lead to the development of osteochondrosis. The current focus of research has been on the molecular mechanisms involved in the development of the disease. The mechanisms of normal endochondral ossification are not fully developed, further complicating an understanding of the disease process.

Treatment and Prognosis Treatment of osteochondrosis should take several factors into account: clinical signs, lesion severity, species, age, intended use, relative value of the animal, and owner expectations. Treatment options include both nonsurgical and surgical management.

Nonsurgical management should consist of rest, controlled exercise, and dietary evaluation.[24] Dietary mineral and carbohydrate levels should be evaluated carefully, and any deficiency or excess should be corrected. Systemic NSAIDs and intraarticular medications like corticosteroids, hyaluronic acid, and polysulfated glycosaminoglycans (GAGs) can be administered, but minimal clinical evidence exists to support their use. In food-producing animals the clinician must take into consideration that these are not approved treatments and that withdrawal times may not be established.

Animals with OCD are frequently treated with arthroscopic surgery. Cases with no radiographic evidence of degenerative joint disease (DJD) before surgery and minimal articular damage at arthroscopy have a favorable prognosis. Animals that show radiographic evidence of DJD before surgery or considerable damage to the articular surfaces at arthroscopy have a less favorable prognosis. There is a site predilection for performance. Lesions in the stifle have a less favorable outcome for full athletic potential than do lesions within the tarsus. In addition, surgeon experience and age of the horse at the time of surgery also affects outcome; more experienced surgeons and older horses demonstrate improved outcomes.[28] Arthroscopic approaches to the joints of cattle have been described, but the procedure is more difficult than in the horse.[9] In selected cases, reattachment of large cartilage flaps with absorbable poly-*p*-dioxanone pins has been described.[29] Dietary evaluation of surgical patients should be included and appropriate adjustments made.

Treatment of subchondral cystic lesions vary. Nonsurgical management should consist of rest, controlled exercise, and intraarticular injection of corticosteroids with or without hyaluronic acid or polysulfated GAGs. The prognosis is variable, and alternate treatments should be considered in refractory cases; these treatments include intralesional deposition of corticosteroids, arthroscopic cystic débridement, and transcystic placement of a cortical bone screw.

Arthroscopic-guided injections into the fibrous lining of the cyst have a 67% success rate in horses without preexisting secondary radiographic changes.[30] Arthroscopic débridement and curettage of the cystic lesion have similar success rates, and horses younger than 3 years have a better prognosis. Packing the remaining defect with either a cancellous bone graft covered by a chondrocytic growth factor or various bone substitutes has shown promise, although it is more costly and technically challenging.[29,31] Transcystic screw fixation has shown greater than 80% success rate and gained more recent acceptance as a suitable second-line treatment should intralesional injection of steroid fail.[32] Treatment of osteochondrosis in food animals is generally limited by the economic value of the animal. Show animals or valuable breeding animals may be treated by any of the methods described, and the surgical options may offer a better prognosis than nonsurgical treatment. In production herds, ration evaluation and genetic predisposition may be the most important variables to address.

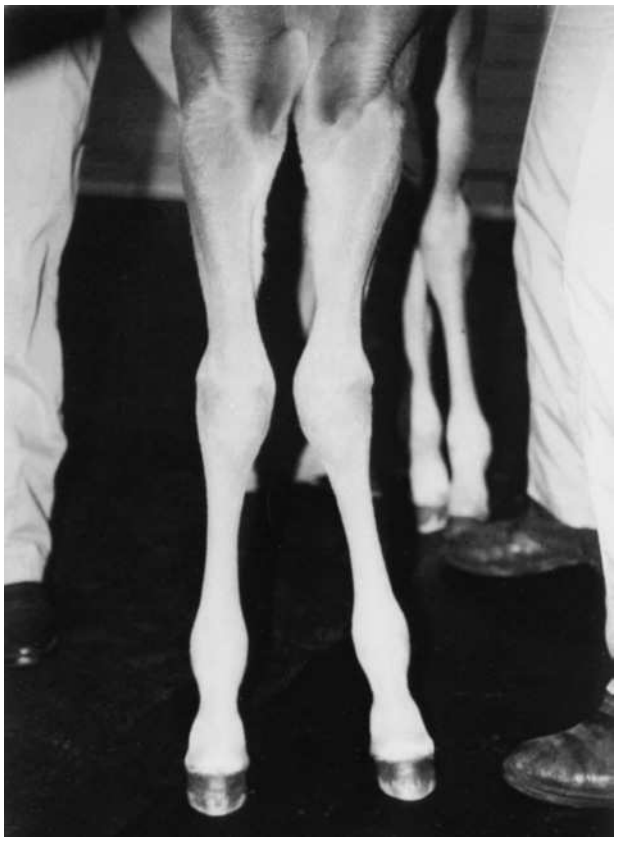

FIG. 38.1 Carpus valgus deviation.

Angular Limb Deformities

Jeffrey P. Watkins

Definition, Etiology, and Clinical Signs Angular limb deformities are deviations in the axis of the forelimbs or hindlimbs in the frontal plane. *Valgus deformity* denotes a lateral deviation of the limb distal to the origin of the deformity; *varus deformity* denotes a medial deviation. The deformity is further described by naming the joint adjacent to the origin of the deformity; for example, *carpus valgus* describes an angular deformity arising in the carpal region, with lateral deviation of the metacarpus (knock-kneed conformation; Fig. 38.1).

Angular limb deformities may be either congenital or acquired. In general, they are due to laxity of periarticular supporting structures, incomplete ossification, or asynchronous physeal growth. Potential causes include intrauterine malpositioning, relative immaturity, hereditary predisposition, rapid growth, dietary imbalances, osteochondrosis, and trauma.[1-3]

Congenital angular deformities are frequently attributed to intrauterine malpositioning and laxity of periarticular supporting structures. They typically originate in the region of the carpus and tarsus, resulting in bilateral valgus deformity. It is also common to identify a "windswept" foal with valgus deformity of one limb accompanied by varus deformity of the contralateral limb. Acquired angular deformities usually occur secondary to asynchronous growth. In addition, a foal born with incomplete ossification may acquire an angular deformity secondary to crushing of the cartilaginous precursors of the cuboidal bones. A hereditary angular limb deformity of Suffolk, Suffolk crossbred, and Hampshire sheep is known as *spider lamb syndrome* (see the Ovine Hereditary Chondrodysplasia [Spider Lamb Syndrome] section later).

VetBooks.ir

Pathophysiology Incomplete ossification is an important cause of angular deformities originating at the carpus and tarsus. The epiphyses and cuboidal bones of the carpus (ulnar, third, and fourth carpal bones) and tarsus (central and third tarsal bones) are primarily affected.[1] Most ossification of the cartilaginous precursors of these bones occurs in late gestation and is complete by the first month after birth. Prematurity or relative immaturity results in the birth of a foal before these precursors are completely ossified (Figs. 38.2 and 38.3). If laxity of the periarticular supporting structures accompanies incomplete ossification, the deformity is congenital and may worsen progressively with weight bearing as the cartilaginous cuboidal bone precursors become deformed. If laxity is not present, the foal may be born with straight legs and with unrestricted exercise acquire an angular deformity due to deformation of the precursors of the cuboidal bones during weight-bearing activity. Foals that acquire significant deformation of the developing cuboidal bones are likely to develop osteoarthritis early in life and have limited ability to perform athletically as adults.

Foals can acquire an angular limb deformity because of asynchronous growth at the metaphyseal and epiphyseal growth cartilages.[2,3] An important cause of asynchronous growth is trauma to a portion of the growth cartilage of the physis.[4] In many foals this trauma is in the form of nonphysiologic compression of the growth cartilage. Excessive exercise in foals with mild angulation and normal activity in foals with moderate to severe preexisting angular deformity may result in sufficient trauma to the growth cartilage to cause progressive deformity.

Asymmetric loading also occurs when severe lameness is present. With the change from a rectangular stance with four weight-bearing limbs to a triangular stance with three weight-bearing limbs, asymmetric, nonphysiologic loading of the contralateral support limb occurs, which predisposes it to developing an angular deformity. Chronic excessive loading stretches the periarticular ligamentous support on the lateral aspect of the limb. Combined with compressive forces that are concentrated along the medial aspect of the growth cartilages negatively affecting normal growth at the physis, a varus deformity often develops in the overloaded support limb.

Abnormalities of the growth cartilage that affect ossification (e.g., osteochondrosis) may also be responsible for angular deformities caused by asynchronous growth. Foals with a predisposition for rapid growth or those exposed to nutritional imbalances appear to be at greatest risk for developing the disease. Rapid growth may also result in a foal with a large body size disproportionate to its skeletal structures. This condition may cause increased compressive forces, nonphysiologic loading of the growth cartilages, and angular deformity.[4] Rarely, hypothyroidism in foals, either due to maternal influences related to excessive or inadequate dietary iodine or due to plant toxicity, has been related to delayed ossification of the cuboidal bones.[5] In addition, in the northwestern United States and adjacent area or Canada, hypothyroidism of undetermined cause in foals has been associated with skeletal abnormalities.[6]

Ruminants raised in confinement may experience endochondral dysplasia and angular limb deformities if dietary iron

FIG. 38.2 Premature foal with incomplete ossification of the cuboidal carpal bones, showing marked bilateral carpus valgus.

FIG. 38.3 Specimen from a foreleg of the premature foal in Fig. 38.2, cut in the frontal plane. Note the thick cartilage surrounding the centers of ossification of the cuboidal bones of the carpus.

is high or dietary vitamin D is low[7] (rickets). Elevated dietary iron results in elevations in serum phosphorus, which in turn may inhibit 1,25-dihydroxycholecalciferol synthesis by the kidney, resulting in rickets.[5] Pregnancy-associated epiphysitis in primiparous dairy goats[8] can also result in angular limb deformities.

Evaluation and Radiographic Findings When evaluating a foal with an angular deformity, important historical information includes gestational length, age of the foal, onset and progression of the deformity, and intended use of the foal. The foal should be observed carefully while standing and walking to characterize the degree of deformity and determine the presence of compensatory problems or lameness. Physical examination includes careful palpation of the affected limb and, in neonates, determination of whether the deformity can be corrected by manual manipulation of the limb and whether there is evidence of prematurity or dysmaturity. In neonates, deformities resulting from laxity of periarticular supporting structures and incomplete ossification can often be corrected manually. In older foals, if deformities secondary to incomplete ossification have been left untreated and the cuboidal bones are in a collapsed configuration, or if deformities are the result of asynchronous growth, the angulation in the limb cannot be corrected manually.

Visual assessment of the forelimbs and hindlimbs from all angles is necessary, making note of the relative angulation through each joint in the sagittal plane of the evaluated limb. It should be noted that the degree of external rotation of the limb being inspected determines the position where the examiner should make his or her evaluation. In most cases external rotation is present in the limb, which necessitates examining each limb independently from a position that is slightly oblique to the median axis of the body (cranial to caudal, lateral to medial). A normal foal should have alignment of the third metabone with the phalanges, and any deviation should be considered abnormal. There is normally a mild valgus deformity in foals through the carpus and tarsus, which at weaning is in the vicinity of 5 degrees, that usually resolves as they approach their yearling year. In addition to evaluating the angulation of the hindlimb in the sagittal plane, it is important to assess hock angulation in the frontal plane. Sickle-hock conformation can be the result of incomplete ossification with collapse of the central and/or third tarsal bones.

An arthropathy should be suspected if lameness is present. A reduced range of motion and pain on passive flexion of affected joints may also be present. Collapse of incompletely ossified cuboidal bones may cause deformation of articular surfaces resulting in DJD and be manifest by the above findings. When this occurs in the carpus, the prognosis for athletic performance is guarded to poor. If the cuboidal bones of the tarsus are affected, mild collapse may not adversely affect performance, but with significant collapse, degenerative change is likely. A less common cause of lameness in foals with angular limb deformity is osteochondrosis. The prognosis for athletic performance in foals with osteochondrosis-associated angular limb deformities depends on the severity of the osteochondral lesions.

Radiographic evaluation of foals with angular deformity is important. If a diagnosis of incomplete ossification is delayed, irreparable damage may occur. In fact, a strong argument can be made for radiographic evaluation of all foals shortly after birth before uncontrolled exercise is allowed. Radiographic evaluation is mandatory to determine the degree of ossification in premature foals, twins, foals that appear to be relatively immature at birth, and foals born with angular deformities.

In addition to assessing the maturity of the cuboidal bones, radiographic evaluation allows the examiner to identify the origin of the deformity and determine its severity. Dorsopalmar views for the carpus and fetlock and a lateromedial view of the tarsus are recommended. In the carpus and fetlock, the origin of the deformity may be subjectively determined by two geometric methods (Fig. 38.4). One method is to draw longitudinal lines bisecting the long bones above and below the joint. Where these lines intersect is the *pivot point*, which is considered the origin of the deformity; the angle of incidence of these lines is an estimation of the degree of deformity. Another method is to draw lines through the joints and adjacent physes. These lines should be parallel to each other and perpendicular to the long axis of the long bones proximal and distal to the affected joint. The origin and degree of deformity are estimated by determining where and by what degree these lines deviate from normal. Both asynchronous growth and incomplete ossification can occur concurrently, which is most easily determined with the latter method of geometric evaluation[1] (Fig. 38.5). Geometric examination to determine the degree of deformity in the tarsus is less reliable because the tibia and third metatarsus are not in the same frontal plane. The severity of the angular deformity in this location is best determined by a careful visual assessment.

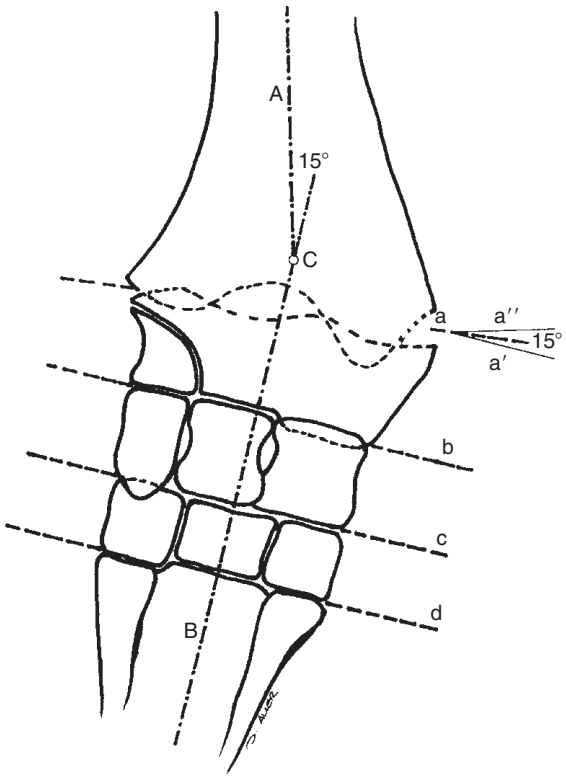

FIG. 38.4 Two methods for geometric evaluation of an angular deformity at the carpus. Lines A and B are drawn through the long axis of the radius and metacarpus, respectively. The angle of incidence is 15 degrees. Lines a, b, c, and d are drawn through the distal radius physis, antebrachiocarpal (radiocarpal), middle, and carpometacarpal joints, respectively. Line a′ is drawn parallel to line b, and line a″ is perpendicular to A. Their angle of incidence is 15 degrees. *(Reprinted with permission from* Compend Contin Educ Pract Vet *4:S330, 1982.)*

Radiographic findings in foals with incomplete ossification vary depending on the degree of mineralization of the precursor cuboid bones and amount of malformation that has occurred subsequent to birth. In severe cases, there may be only small, centrally located centers of ossification surrounded by radiolucent precursor cartilage (which will undergo endochondral ossification as maturity progresses). More commonly, affected cuboidal bones have a rounded contour instead of their normal angular appearance. The width of the radiolucent precursor cartilage is increased, appearing radiographically as an increase

VetBooks.ir

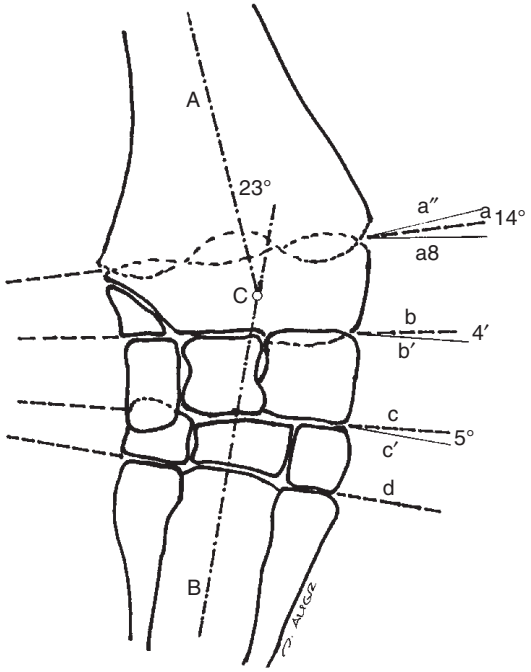

FIG. 38.5 Geometric evaluation of an angular deformity at the carpus caused by a combination of asynchronous growth and incomplete ossification. The pivot point, C, identified by lines A and B, indicates that the origin of the deformity is in the distal radial physis. However, lines a, b, c, and d are not parallel to each other, and lines a, b, and c are not perpendicular to the long axis of the metacarpus and radius. Their orientation indicates that the deformity is in the distal radial physis and the cuboidal bones as well. Note that the sum of angles a-a′, b-b′, and c-c′ equals the angle of incidence of lines A and B. *(Reprinted with permission from* Compend Contin Educ Pract Vet *4:S330, 1982.)*

FIG. 38.6 Dorsopalmar radiograph of a foal with mild incomplete ossification of the cuboidal carpal bones. Note the difference in width of the medial aspect *(a)* and the lateral aspect *(b)* of the third carpal bone. Normally, width *a* should be approximately three-fourths the width of *b*. Also note the appearance of an increase in the width of the joint space *(c)* as a result of incompletely ossified joint cartilage.

in the width of the joint space (Fig. 38.6). As ossification progresses, the bones may develop a normal anatomic shape or appear wedge shaped or crushed because of deformation of the cartilage secondary to weight bearing prior to ossifying. This phenomenon often is noted in the ulnar, fourth, and intermediate facet of the third carpal bones in the forelimb and the central and third tarsal bones in the hindlimb. In severe cases the affected bones may be grossly deformed and, particularly in the tarsus, appear to be partially extruded from the joint (Fig. 38.7). In the tarsus, lateromedial radiographs are used to determine whether ossification is complete and malformation is present (Fig. 38.8).

Radiographic evaluation of foals with angular deformity caused by asynchronous growth may show wedging of the epiphysis (Fig. 38.9), widening of the physis, and sclerosis adjacent to the physis. Geometric evaluation places the deviation in the metaphysis or the epiphysis of the long bone proximal to the affected joint. The joints are parallel to each other and perpendicular to the longitudinal axis of the adjacent long bones.

■ ***Treatment and Prognosis*** Neonatal foals with an angular deformity should be confined to a stall until clinical and radiographic examinations are completed. If the deformity is 10 degrees or less and radiographs reveal normal ossification, stall confinement with periods of controlled exercise is recommended. This regimen promotes continued development of the supporting structures while minimizing trauma to growth cartilages that could result if the foal were allowed uncontrolled exercise. Foals that have angular deformity severe enough to cause the hoof to break over the lateral (varus deformity) or medial (valgus deformity) wall will benefit from the application of a hoof plate. The hoof plate is intended to extend the solar surface of the hoof to counteract the forces resulting in the abnormal breakover.

Foals with a congenital angular deformity of more than 10 degrees that can be manually corrected should be considered candidates for external support, especially if incomplete ossification is present. Patients with incomplete ossification accompanied by angular deformity that is not supported in axial alignment will often deform the cartilaginous cuboidal bone precursors with continued weight bearing. Subsequent ossification results in permanent deformity of the affected bones (see Fig. 38.7) and is often associated with end-stage osteoarthritis.

Methods of externally supporting the carpus and tarsus vary from tube casts or rigid splints to custom-made orthotic devices. Tube casts have been recommended and used successfully,[1-3] and although they provide the rigid external support necessary to maintain axial alignment while ossification progresses, several potential complications are associated with their use. The most serious is the potential for coxofemoral luxation when tube casts are used on the hindlimbs. In addition, foal skin is easily

VetBooks.ir

FIG. 38.7 Dorsopalmar radiograph of a foal with incomplete ossification that was not externally supported. Severe deformation and collapse of the fourth and third carpal and proximal fourth metacarpal bones have occurred.

FIG. 38.8 Lateromedial radiograph of a tarsus from a foal with incomplete ossification. Note the lack of an angular appearance of the central tarsal bone and incomplete ossification of the third tarsal bone.

traumatized by a poorly fitting cast, and deep ulcerations may occur. Other considerations include the cost of materials and the need for constant monitoring to detect signs of a poorly fitting cast. Monitoring the status of a cast requires daily evaluation by a trained individual, and owners are seldom capable or willing to take on this responsibility; hospitalization is recommended. Rigid splints, usually fashioned from cut sections of polyvinyl chloride (PVC) pipe, are an alternative method of support. The leg is protected with a well-padded support bandage, and the splint is applied with nonelastic tape while the limb is held in alignment by an assistant. These splint bandages are changed frequently, as pressure sores beneath the splint bandage are a concern and are difficult to prevent. A splint for the tarsus may be fashioned from synthetic casting material molded lengthwise over the cranial aspect of a padded bandage centered at the joint. Once the material has dried, the splint is taped to the dorsal surface of the bandage. Alternatively, a PVC splint can be heated and bent to the desired angulation.

Regardless of the means of external support used for the carpus or tarsus, it should not extend beyond the distal metabone. Continued weight bearing by the suspensory apparatus of the fetlock helps prevent the development of fetlock hyperextension after removal of the external support. A degree of carpal hyperextension is usually present immediately after removal of external support from the forelimb, and exercise should be controlled until the tendons and periarticular supporting structures regain their normal tone.

Foals with an angular deformity resulting from asynchronous growth should have their exercise limited to minimize the magnitude of asymmetric loading at the growth cartilages and to encourage spontaneous correction. In these cases, reducing the magnitude of the forces acting asymmetrically at the growth cartilage should encourage compensatory growth to occur and correct the deformity. Additional therapy consists of corrective hoof trimming. Because foals with valgus deformity typically have a toe-out conformation, emphasis in the past has been to lower the lateral hoof wall of the affected limb. If this mode of therapy is vigorously pursued, compensatory varus deformity may develop in the fetlock region. This form of corrective trimming concentrates forces asymmetrically on the medial aspect of the distal metacarpal and proximal phalangeal growth cartilages. Currently, trimming the hoof level and squaring the toe to promote breakover at the toe are recommended.

Foals with angular limb deformities that fail to respond to conservative methods are candidates for surgical intervention. Animals with angular deformities arising distal to the physis were not considered candidates for surgical therapy in the past, but it has been shown that they can respond favorably to surgery.[9,10]

The decision for surgery should consider the area affected (fetlock, carpus, and/or tarsus) amount of correction required (degree of deformity), and age of the foal. In general, the more severe the deformity, the earlier the surgical intervention should be. Timing of surgery should consider the periods of rapid and predictable growth at the physis. The most rapid and

VetBooks.ir

FIG. 38.9 Dorsopalmar radiograph of a foal with angular deformity caused by wedging in the distal radial epiphysis, the result of asynchronous growth of the epiphysis growth cartilage.

predictable rate of growth occurs from birth to 10 weeks of age.[11] In the distal radius, continuous but declining growth occurs until 60 weeks of age. In the distal third metacarpal and metatarsal bones, growth rate slows dramatically by 10 weeks of age and is minimal thereafter. For these reasons, it is important to be more proactive and intervene at an early age when deformities are present in the fetlock region since there is limited time for conservative therapy to effect correction. However, there is more opportunity for correction to occur spontaneously in the carpal and tarsal region; therefore surgical intervention can be delayed in mild to moderate deformities.

Surgical manipulation of physeal growth is intended to asymmetrically alter the elongation occurring at the physis, thereby realigning the axis of the limb. Growth at the physis can be altered surgically in one of two ways: retardation or acceleration. Growth retardation is accomplished by bridging the physis with metallic implants. When applied to the convex side of the affected physis, growth is disallowed on the long side of the bone while continued growth on the opposite side of the bone brings the limb into alignment. As long as the implants are in place, the effect continues and is limited only by the amount of growth remaining at the physis. If the physis is still active once the limb is aligned, it is extremely important that the implants be removed, or overcorrection will occur. Techniques of transphyseal bridging include stapling, screw and wire implants, use of a small bone plate, and more recently a single transphyseal screw. Indications for transphyseal bridging include deformities that have a limited window of opportunity to correct (e.g., moderate to severe deformity in the fetlock region), those presenting after the period of rapid and reliable physeal growth, severe angulations, and based on the author's experience, deformities of the carpus and tarsus resulting from cuboidal bone malformations.

The second surgical approach to altering physeal growth, periosteal transection and elevation (stripping), is intended to accelerate growth on the concave side of the bone.[12] Reported advantages include rapid correction without the potential for overcorrection.[9,12] Because periosteal transection does not require implants, the likelihood of infection and excessive fibrosis is reduced. Implant failure is not a consideration, and a second surgery for implant removal is unnecessary. The procedure does not require specialized equipment and is technically easy to perform. In one series of foals, correction of the deformity occurred in 22 of 25 limbs treated with periosteal transection.[12] In a second series of 23 foals, 83% had straight limbs and were sound for their intended use at long-term follow-up.[9] The success rate was not affected by the origin of the deformity, degree of deviation, or presence of mild to moderate morphologic changes in the involved bones.[12] There are reports that question the efficacy of this procedure, particularly for treating carpus valgus deformities.[13,14]

Indications include mild to moderate deformities present during the rapid, reliable growth at the involved physis. Furthermore, it should be reserved for deformities in locations that will allow ample time for a second procedure to be performed if the initial treatment is not effective. The periosteum will reestablish itself, so the surgical effect is short-lived, and if correction is not adequate within 4 to 6 weeks, additional therapy is indicated.

Ovine Hereditary Chondrodysplasia (Spider Lamb Syndrome)

Juan E. Romano, Sr.

Ovine hereditary chondrodysplasia, also known as *spider lamb syndrome* (SLS), is an inherited, semilethal musculoskeletal disease primarily affecting lambs of Suffolk or Hampshire breeding. The clinical signs are characterized by deformities affecting the appendicular and axial bones, with elongated extremities, scoliosis, abnormal rib, and sternum concavities.[1] Other signs include extreme height, fineness of bones, Roman nose with facial deformities, lack of body fat, and scarcity of muscling. At present, it is the most common inheritable skeletal disorder in sheep.[2] Males and females are affected equally[3] and called *spider lambs*, *spiders*, *monkey lambs*, and *crooked-legged or corkscrew lambs*.[4] The disease was first described in 1980 in the United States in the Suffolk breed[5,6] and then in the Hampshire breed. The disorder was also reported in Shropshire, Texel, Southdown, Oxford,[7] and Kermanian breeds.[8] It has now been disseminated into several sheep breeds that used Suffolk for breeding purposes and has propagated worldwide in the United States and Canada,[7] Australia,[9] New Zealand,[10] Brazil,[11] Germany,[11] and Iran.[8] The frequency of this disorder was reported to be 4% in Germany by detecting the mutation using blood samples.[12]

Transmission Pedigree analyses and breeding studies have established that the gene responsible for this disease has a simple autosomal recessive mode of inheritance.[13-16] The breeding of carrier animals will produce 25% of offspring with the genetic disorder.[15,16] The breeding of a spider ram in a population of carrier females produces 50% of offspring with spider lamb syndrome.[6,14] The breeding of a carrier ram with his daughters also produced offspring with this disorder. The transfer of embryos produced between a spider ram and spider

FIG. 38.10 Twin Suffolk lambs (12 weeks old), with normal lamb (78 lb) at left and lamb with spider lamb syndrome (37 lb) at right. Note extreme height, narrow chest, scoliosis, kyphosis, and facial deformity of the affected lamb.

donor females to normal recipient ewes resulted in all offspring with spider syndrome.[17]

Etiology Genetic linkage between SLS and several microsatellite markers have been detected. Mapping the SLS locus was suggested to be the telomeric end of ovine chromosome 6.[7] The causative mutation was identified after positional cloning of the ovine fibroblast growth factor receptor 3 (FGFR3).[7,18] A transversion at nucleotide position 69 of ovine FGFR3 exon 17 causes a nonconservative amino substitution of nonpolar valine (V) to charge glutamate (E) at residue 700 in the second tyrosine kinase domain of the receptor. The mutation leads to loss of receptor function in homozygotes. FGFR3 acts as a negative bone growth regulator by restricting chondrocyte proliferation and endochondral bone elongation.[18,19] Heterozygous (Ss) animals are phenotypically indistinguishable from unaffected, normal (SS) animals. The genotypes of presumed heterozygous carriers of SLS are detectable only after test-mating of suspect animals to proven heterozygous carriers with subsequent evaluation of all resulting progeny or by using blood or hair follicles to detect the mutation in FGFR3.

Clinical Signs Clinical presentation of the syndrome is also highly variable, with some lambs severely affected at birth and others developing the condition in the first 6 weeks after lambing.[1] External symptoms characteristic of the disease include extreme height, fineness of bones, and lack of muscling and angular deformities of the limbs (Fig. 38.10) along with kyphoscoliosis. Affected lambs tend to be thin and arthritic, with poor muscling and insufficient weight gain. The affected individuals rarely survive and are an economic liability in market lamb production.

The abnormalities are most frequent in the forelimb (81% to 87%), hindlimb (63% to 69%), spine (52% to 62%), and skull (19% to 35%).[20] No differences between Suffolk and Hampshire lambs were detected in the type, extent, or incidence of lesions.[20] The forelimbs and hindlimbs were characterized by mild to severe carpus (Fig. 38.11) and tarsus valgus, respectively. The most common spine abnormality was kyphoscoliosis. SLS was observed in aborted fetuses, stillborns, viable neonates, and young lambs less than 6 weeks of age.[20]

Detection of this abnormality during pregnancy by either radiography or transabdominal ultrasonography even at the second or third tiers was not possible.[17] Diagnosis was possible only by direct examination of the fetus.[17]

FIG. 38.11 Rotation and deviation of front legs (carpus valgus) characteristic of spider lamb syndrome in a 16-week-old Suffolk lamb.

Laboratory Analyses No differences in hematologic and biochemical analyses between chondrodysplastic lambs and normal flockmates were detected. Serum levels of vitamins A and E and liver levels for selenium and vitamin E were within normal parameters.[4] Trace elements in serum for iron, magnesium, zinc, and copper were no different compared with normal lambs.[4] Serum alkaline phosphatase activity has been reported either high or low in affected lambs compared with healthy lambs.[1] The only difference was a trend in a high level of skeletal muscle enzymes in serum.[4]

Some data suggest that the regulation of insulin-like growth factor 1 (IGF-1) and IGF-binding proteins may be involved in this disorder. SLS lambs between 50 and 80 days of age showed a significant decrease in serum level of IGF-1 levels and an increase in IGF-binding proteins compared with a control group of lambs of the same age.[21]

No differences in the number of morphologic features of the chromosome were detected, and there was no evidence of deletions, duplications, translocations, or inversions when lymphocytes from clinically normal lambs and lambs affected with ovine hereditary chondrodysplasia were cultured, G-banded, and karyotyped.[22]

Necropsy The primary lesions affect the musculokeletal system. The gross lesions observed were similar to the changes noted radiographically. Lesions were observed in the skull, sternebrae, atlas, elbows, other vertebrae, and physes of the long bones, as well as other areas. The lesion noted in all locations was an excess of cartilage.[4] Marked muscle atrophy was also present. The principal lesions in bones are an increase in the width of the zone of proliferation and hypertrophy and an unevenness of the growth cartilage. A cartilage column

VetBooks.ir

FIG. 38.12 Lateral radiograph of the front leg of a lamb with spider lamb syndrome. Note thick growth plates and multiple ossification centers near the olecranon and distal humerus.

disorder, with failure to form or maintain orderly columns of chondrocytes, is characteristic.[1] The chondrocytes and cartilage matrix appear histochemically normal and have proper ultrastructure.[23]

Radiography Chondrodysplastic lambs have characteristic radiographic patterns in the elbow, sternum, shoulder, and spine, with multiple irregular islands of ossification.[1] Radiography may be the technique of choice for identifying affected lambs prior to detecting clinical signs or when in doubt.[24] A flexed lateral radiograph of the elbow of a suspect lamb appears to be diagnostically reliable when there is a suspicion of the syndrome (Fig. 38.12).[1]

Control The mode of inheritance for SLS is autosomal recessive, making the identification and culling of carrier (heterozygous) animals difficult due to their normal phenotype. Eliminating these heterozygous animals from affected sheep flock is possible by identifying individuals that are carriers of the mutation. This can be done by collecting peripheral blood or hair follicles and performing polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP) analysis. The best approach is to perform this test in males, but depending on the objectives of the program, the test also can be run in females. Genetic testing using blood and then PCR-RFLP permits a quick and accurate detection of heterozygotes. The presence of a lamb spider is an indication that both parents are heterozygous for the disorder, so no test is required. Since the introduction of this test in 2000, a significant reduction in the incidence of heterozygous animals in New Zealand and the United States has been reported.[25,26]

Another possibility is to run breeding tests, which is time consuming and costly and requires adequate numbers of breeding animals to be accurate. In addition, correct identification of the animals is paramount. A ram can be progeny tested by breeding females that produced spider lambs or his own daughters. The number required to be highly accurate is 16 normal offspring from mating with a known carrier's ewes or 32 normal lambs from breeding with his own daughters. However, with these numbers the probability that the ram is a carrier is 1% or less of the cases.[27]

Differential Diagnosis A complete clinical history and physical examination as well as radiologic and pathologic examinations are essential to the diagnosis of this disease. Some of the lesions seen in spider syndrome require differentiation from abnormalities produced by viruses, chemicals, toxic plants, and nutritional factors. Infection with bluetongue and Akabane virus may result in arthrogryposis and hydranencephaly. Border disease can cause abnormalities of the nervous system, skin, fleece, and skeleton. Cache Valley virus and bluetongue can also produce these kinds of anomalies.[28] Benzimidazoles, antiparasitic drugs, have been implicated as a cause of skeletal deformities when used in pregnant ewes during specific periods.[29] Toxic plants such as locoweeds are known to cause limb deformities in utero.[30] Deficiency of vitamin D or phosphorus can cause skeletal deformities or rickets.[31] Deficiency of either zinc or manganese during gestation could lead to chondrodysplasia.[32]

Septic (Infectious) Arthritis and Osteomyelitis

Joanne Hardy

Incidence and Risk Factors Septic arthritis can result from extension of a periarticular wound infection, traumatic inoculation, iatrogenic inoculation, or hematogenous inoculation. The hematogenous route is the most common avenue of inoculation of organisms in a joint in foals, and bacteremia and septicemia are the most important risk factors for septic arthritis in foals. In one study, septicemia was the most common cause of death (30%) in foals younger than 7 days of age; septic arthritis was identified as the cause of death in 12.5% of foals ages 8 to 31 days.[1] In adults, articular wounds are reported to be the most common cause of joint infection, followed closely by iatrogenic intraarticular injection; postsurgical infection and idiopathic (unidentified cause) infection are also reported in association with septic arthritis in adult horses.[2-4] Although uncommon, hematogenous spread from a distant focus is possible in adult horses.[5]

Establishment of infection depends on several factors, including size of inoculum, host defense, virulence of the organisms, and local joint factors. In foals, host defense is mainly associated with passively acquired immunity. Failure of transfer of passive immunity (FTPI) is the greatest risk factor for development of septicemia in foals.[6] The incidence of disease resulting from FTPI has been reported to be as high as 78%. Organism virulence is related to the ability to establish infection. Attachment factors, ability to resist phagocytosis, and resistance to cell killing all contribute to the establishment of infection. Local joint factors that may predispose to establishing or maintaining infection include low blood flow, particularly in end-capillary loops, and poor blood supply, more prominent in bone. In adults, certain intraarticular medications (e.g., corticosteroids, hyaluronate, polysulfated GAGs) have been associated with a higher risk for septic arthritis, potentially by decreasing articular defense.[7,8]

In calves, septic arthritis is associated with FTPI and septicemia and with feeding of mastitic milk *(Mycoplasma)*.[9,10] In older cattle, direct spread from a perisynovitis is the most common cause, and the distal interphalangeal joint (DIJ) is most often involved.

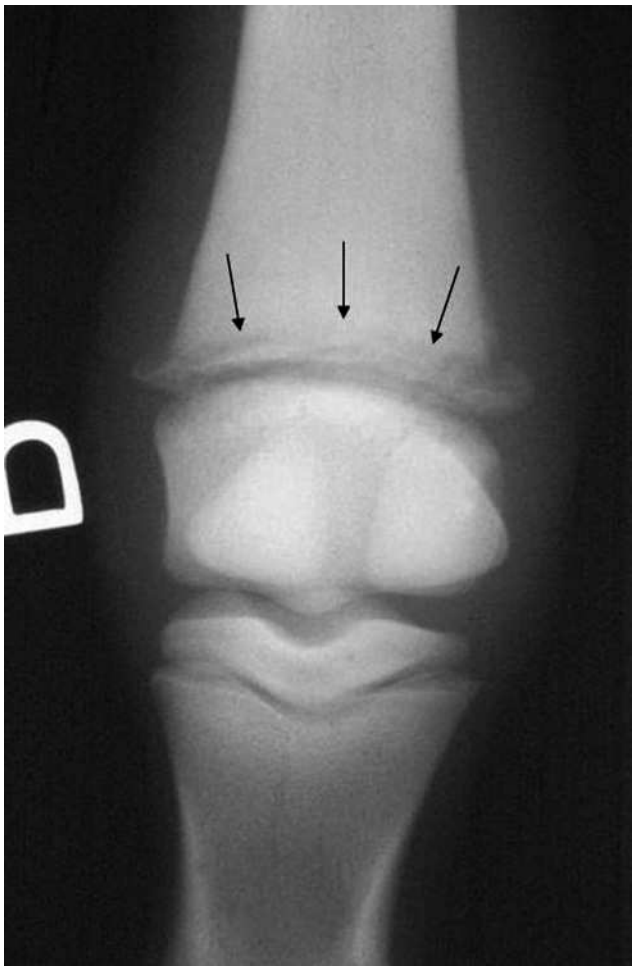

FIG. 38.14 Radiograph of a foal with type P septic arthritis, showing involvement of the distal metacarpal physis *(arrows)*.

Pathogenesis Articular blood supply is provided through a main arteriole that branches to the synovial membrane and epiphysis. Blood supply to the metaphysis is provided by the nutrient artery, but in young foals transphyseal vessels exist that connect the metaphyseal and epiphyseal blood supply.[11] Experimental intravenous (IV) injection of bacteria results in rapid inoculation of articular and periarticular capillaries. Five types of hematogenous articular infection have been described: *type S* (synovial), where a septic arthritis results from inoculation of the synovial membrane; *type E* (epiphysis), where subchondral bone infection is present (Fig. 38.13); *type P* (physis), where infection of the physis occurs on the metaphyseal side of the growth plate (Fig. 38.14); *type T*, observed in premature foals, with infection of the small tarsal or carpal bones (Fig. 38.15); and *type I*, where joint invasion occurs after a periarticular soft tissue abscess (Fig. 38.16).[12] In young foals, functional transphyseal vessels allow communication of the metaphysis and epiphysis, such that bacteria localize preferentially in the synovial membrane and subchondral bone. Thus young foals predominantly have infectious arthritis types S and E. Closure of transphyseal vessels occurs after about 7 to 10 days of age, such that localization of infection to the metaphyseal vessel loops occurs in older foals.[11] Although bone inoculation can occur simultaneously with synovial inoculation in young foals, determination of bone involvement can be delayed until radiographs identify the lesions. In foals the hock, carpus, and stifle are frequently involved in hematogenous joint infection, but it is important to remember that any joints, including those of the vertebral column, can be affected. In young foals, *Actinobacillus equuli*, *Salmonella* spp., *Escherichia coli*, and other Enterobacteriaceae are often involved; in older foals, *Streptococcus* spp. and *Rhodococcus equi* are common isolates. In foals with type P (physeal) involvement, *Salmonella* and *Rhodococcus* spp. are typically involved.

In adults, inoculation of the joint from an articular wound is the most common cause of joint sepsis. The establishment of infection will depend on size of the inoculum, pathogenicity of the bacteria, and duration before treatment. In one study, 53% of horses examined within 24 hours of an open joint wound developed septic arthritis, versus 92% of horses examined within 2 to 7 days of injury and 100% of horses examined after 7 days.[13] However, two studies failed to find a relationship between interval before admission and outcome.[14,15] This suggests that many other factors influence the prognosis following joint infection. Joints of the lower limb (fetlock, coffin joint) are often involved in open joint injuries because of the poor tissue coverage in those areas.[3,16] Organisms frequently encountered in open joint wounds include Enterobacteriaceae, streptococci, and staphylococci.[3,16] These injuries are also likely to have multiple bacterial infections. Wounds near the hoof are more likely to have anaerobic infection, and *Clostridium* is the most common isolate. Fungal organisms are a rare cause of septic arthritis in horses but should be considered if isolated in pure culture more than once.[5]

Iatrogenic joint injection is the second most common cause of septic arthritis in adults, followed by postoperative infection. The tarsus is the joint most often involved in septic arthritis after joint injection, whereas the carpus is the most common joint

VetBooks.ir

FIG. 38.15 Radiograph of the tarsus of a premature foal with type T septic arthritis, showing involvement of the distal tarsal bones *(arrows)*.

FIG. 38.16 Photograph of a foal with type I septic arthritis where a soft tissue abscess *(arrow)* dissected down into the coxofemoral joint.

involved after surgery.[2,3] Staphylococci, particularly *Staphylococcus aureus*, are the most common organism isolated after iatrogenic joint injections or surgery. When *S. aureus* is isolated from a joint infection, care should be taken to determine the possibility of methicillin resistance.[17,18] The risk of septic arthritis after arthroscopic surgery is low, seen in only 8 of 627 joints (1.3%) in one study.[19] Interestingly, in these horses clinical signs did not develop until several days after discharge.

In calves, the most common isolates are *Streptococcus* spp. and *Mycoplasma bovis*.[20] In adult cattle, common pathogens involved in septic arthritis include *Mycoplasma bovigenitalium*, *Mycoplasma mycoides*, *Brucella* spp., and *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), which is most often involved.[21] In sheep, goats, and calves, *Chlamydia psittaci* polyarthritis can occur as an endemic or epidemic disease and may be accompanied by keratoconjunctivitis.[22,23] In lambs, *Erysipelothrix rhusiopathiae* is also a cause of polyarthritis, gaining systemic entrance through the stump of docked tails or a castration site. Improving hygiene during these procedures helps prevent the disease.[22] In sheep and cattle, the obligate intracellular organism *Chlamydia pecorum* has received increased recognition.[24] Involvement of this organism is thought to be underrecognized because diagnosis is based on serology and histopathology, which are not necessarily diagnostic methods used in the early stages of the disease.

Diagnosis

Septic arthritis, osteomyelitis, or physitis should be ruled out in any lame foal. Foals with septicemia are at high risk of developing septic arthritis, which generally is noted clinically hours to days after the initial signs of septicemia. Although owners often complain of external trauma, septic arthritis is the most common cause of lameness in foals. In young foals with types S and E arthritis, inoculation of the synovial membrane is the first event, which the astute clinician can identify as periarticular edema. Joint effusion rapidly follows. Involvement of multiple joints is common, and identification of all affected joints is essential for successful management. Because effusion of the shoulder, elbow, or hip joints is more difficult to detect by palpation, arthrocentesis of these joints should be performed in foals with an unidentified lameness. In the stifle, femoropatellar joint involvement results in marked effusion, but femorotibial joint effusion is usually more difficult to discern. Because of the usual communication between the femoropatellar and the medial femorotibial joint, both are typically involved concurrently. Lateral femorotibial infection is more subtle and can occur separately. Distention of the long extensor pouch is often present in lateral femorotibial infection and suggests involvement of that joint. In foals older than 7 days, physeal infection may be observed. With physeal infection, presence of concurrent synovial effusion depends on the intraarticular or extraarticular localization of the growth plate. For example, distal metacarpal physeal infection results in periphyseal edema, initially without joint effusion. The infection can break through the skin rather than involve the joint. In foals with septic arthritis, the CBC is consistent with an inflammatory response and includes a neutrophilic leukocytosis and hyperfibrinogenemia. In one study in foals, a plasma fibrinogen concentration of 900 mg/dL or higher (as measured by the heat precipitation method) was useful as an indicator of physeal or epiphyseal osteomyelitis, with positive and negative predictive values of 84.2% and 98.2%, respectively.[25]

Adult horses usually show minimal changes on the CBC and little change in systemic signs, so development of or increasing lameness after a wound, joint injection, or surgery indicates the need for further examination. In one study, the mean and median times for readmission for septic arthritis after an elective arthroscopic procedure were 47 and 20 days, respectively.[19] In that study, the authors speculated that the delay in onset of septic arthritis following surgery was an indication that joint inoculation occurred in the postoperative period rather than intraoperatively, supporting careful joint closure and continued aseptic technique when changing bandages in these horses.[19] Because of their potent antiinflammatory properties, corticosteroids may delay the onset of clinical signs of septic

PMNs, Polymorphonuclear leukocyte neutrophils; *WBCs*, white blood cells.

arthritis after joint injection. In one study of experimentally induced septic arthritis, changes in synovial fluid were present before the onset of clinical signs, and clinical signs of lameness were delayed for 3 days in these horses.[26]

Arthrocentesis is the mainstay of diagnosis of septic arthritis.[26] Table 38.1 lists the characteristics of synovial fluid according to conditions in large animals. A high protein concentration (>2.5 g/dL) and high white blood cell (WBC [leukocyte]) count are observed. Classic counts diagnostic for septic arthritis in foals exceed 30,000 cells/μL, with more than 80% neutrophils; cell counts above 10,000/μL may indicate early infection. Neutrophils are not always degenerate. Gram stain is a useful diagnostic tool because it may identify the etiologic agent in up to 25% of cases in which culture results are negative.[27] In foals with a separate physeal infection where the physis is extraarticular, sympathetic joint inflammation and effusion can occur.[28] This manifests as a moderate increase in WBC count, with less than 90% neutrophils. The presence of such cytologic findings should alert the clinician and practitioner to the presence of physeal sepsis. Several studies have examined the usefulness of synovial fluid markers to predict joint sepsis. In one study, synovial fluid D-dimer concentration was markedly increased in septic joints, and this was not influenced by the presence of septicemia.[29] However, inclusion criteria for the study included the presence of a synovial fluid analysis consistent with sepsis, so it is not known whether D-dimer concentration would be a useful marker earlier in the disease process or when results of synovial fluid analysis are equivocal. In another study, synovial fluid equine myeloperoxidase (MPO) activity was compared in different forms of joint disease. In cases of septic arthritis, MPO activity in synovial fluid was significantly increased compared to control. Although the study concluded that synovial fluid MPO may be useful as a marker of septic arthritis in horses, further studies are needed because horses were included in the study when they already had synovial fluid analysis indicative of septic arthritis.[30] Serum amyloid A (SAA) is an acute-phase protein that is markedly increased (>1000 mg/dL) in horses with septic arthritis.[31] Interestingly, SAA concentration was not increased in synovial fluid collected after repeated intraarticular injections of amikacin in healthy horses.[32] Intraarticular injection of various substances such as antibiotics, saline, or therapeutic agents often cause a transient inflammatory reaction where total protein and nuclear cell counts are consistent with sepsis.[33] The use of SAA to differentiate inflammation from infection warrants further study. Increased lactate concentration has recently been measured and used as a rapid test for identification of septic arthritis, but the sensitivity and specificity of this measurement are currently unknown.

In adult horses with a wound localized near a synovial structure, it is crucial to identify as early as possible whether there is synovial involvement. The most convincing evidence is demonstration of synovial communication with a wound by injecting a sterile solution into the synovial structure and observing fluid exiting the wound. For this purpose, a site remote from the wound and covered with normal skin should be prepared aseptically, and depending on the structure involved, 20 to 200 mL of a sterile solution (e.g., saline, balanced electrolyte) is injected after collecting synovial fluid samples using aseptic technique.[34] If synovial involvement is detected, therapy is immediately instituted.

Radiographs of all affected joints are essential. The presence of osteomyelitis may affect prognosis and dictate prolonged antibiotic therapy. Radiographs should be repeated weekly until clinical signs resolve themselves or at any time there is deterioration in the clinical condition. Radiographs are also indicated whenever a change in therapy is planned (e.g., from IV to oral antibiotics).

Nuclear scintigraphy has been used to diagnose infectious foci in odd localizations in foals. For example, vertebral and atlantooccipital involvements have been diagnosed using this imaging modality. It must be remembered that local bone infarcts, which are often present in osteomyelitis, will result in areas of decreased rather than increased uptake. Scintigraphy using technetium-99m (^{99m}Tc)–labeled WBCs or ciprofloxacin labels has potential uses in foals with multiple-limb involvement and warrants further investigation as an imaging modality for septic arthritis.[35]

Computed tomography (CT) is a useful imaging modality to identify osteomyelitis (Fig. 38.17). It is particularly useful for imaging areas that are difficult to detail with radiography.[36] The main disadvantage is that it is currently limited by the size of the animal.

Magnetic resonance imaging (MRI) has been used in foals and adults with septic arthritis.[37,38] In a limited series comprising 6 foals with infectious arthritis, 4 of the 6 had infectious lesions on MRI indicative of osteomyelitis, and only 4 of 19 lesions were detected on digital radiographs. Osseous lesions in the T2-weighted, short tau inversion recovery (STIR), and proton density MRI sequences appeared as hyperintense foci.[38] In addition, joints with infectious arthritis had heterogeneous signals within the synovial fluid, whereas all nonseptic joints

FIG. 38.17 Computed tomography scan of a foal with septic arthritis of the left coxofemoral joint, showing osteomyelitis of the acetabulum *(arrows)* that was not radiographically evident.

had homogeneous fluid signals.[38] In adult horses with septic arthritis, MRI findings included diffuse hyperintensity within bone and extracapsular issue on fat-suppressed sequences (Fig. 38.18). The study concluded that MRI may allow earlier and more accurate diagnosis of septic arthritis in horses, particularly when the clinical diagnosis is challenging.[37]

Identification of the organism should be attempted in all cases of septic arthritis. Gram stains, culture of synovial fluid in blood culture bottles, and culture of synovial biopsies have been suggested to increase the likelihood of identifying the organism. In general, the positive culture rate from synovial fluid samples is approximately 50%, and synovial biopsy culture has a low yield to increase this figure.[39] Appropriate culture techniques should be used for organisms such as *Chlamydia* or *Mycoplasma* spp., and special stains may be required. Serology and histopathology are required for the diagnosis of *C. pecorum* in sheep and cattle.[24] In foals, because bacteremia or septicemia precedes the local signs, blood cultures should be obtained. In addition, any other local sites of infection should be cultured. In cases of septic physitis, needle aspiration of the affected site under radiographic or fluoroscopic guidance can be performed. In the future, other techniques for early identification of synovial sepsis may become available.[39]

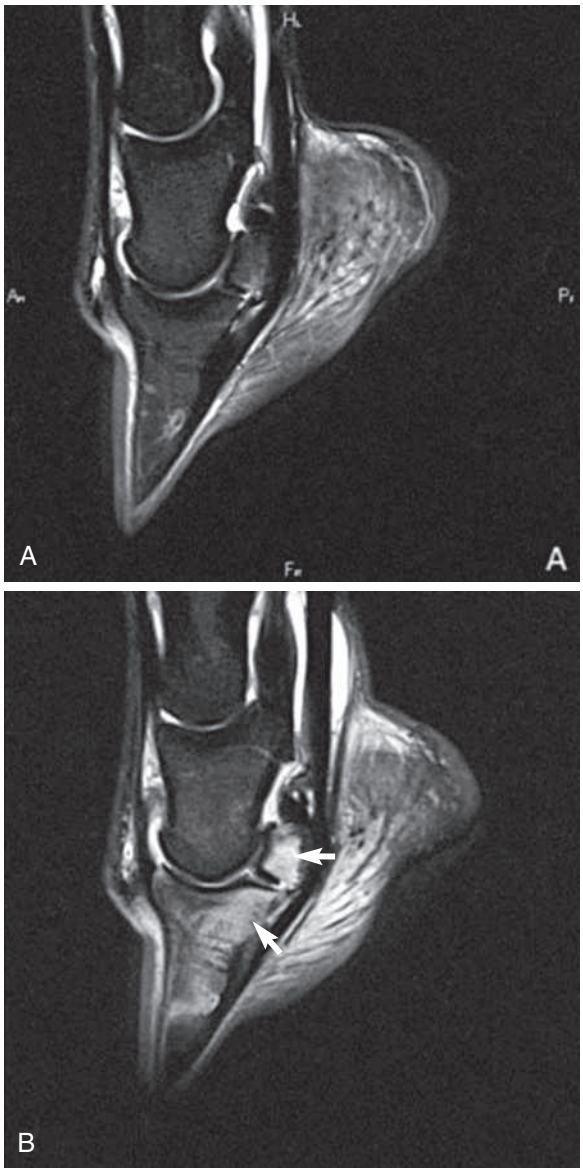

FIG. 38.18 Sagittal short tau inversion recovery weighted magnetic resonance imaging sequence of the left **(A)** and right **(B)** feet of a horse with septic navicular bursa and septic navicular bone, showing severe hyperintensity of the navicular bone and distal phalanx *(arrows)*.

Treatment Septic arthritis is an emergency. Assessment followed by institution of treatment should be done as soon as possible after problem identification. The principles of treatment of septic arthritis include systemic broad-spectrum antibiotics, local joint lavage and débridement, and local antibiotic delivery. Systemic antibiotics are best administered intravenously to ensure adequate tissue concentrations. Most often the combination of a β-lactam and an aminoglycoside or fluoroquinolone is used in adults; a β-lactam and aminoglycoside combination is most often used in foals, because fluoroquinolones may have detrimental effects on articular cartilage in young animals. In open joint injuries, particularly if an anaerobic organism is suspected, metronidazole may be added to the antibiotic regimen. Gram-positive organisms can be isolated from blood cultures in up to 33% of foals with sepsis, so gram-positive coverage is also important.[40,41] In foals with physeal involvement, Gram stain and culture of a physeal aspirate are helpful to identify the causative agent. The most common organisms isolated from septic physitis are *Salmonella* spp. and *R. equi*. If *R. equi* is identified, appropriate therapy with macrolides and rifampin should be instituted, keeping in mind that macrolide-resistant organisms have been reported; obtaining susceptibility patterns may be warranted.[42] Intestinal uptake of clarithromycin is significantly impaired when it is administered in combination with rifampin, so use of that combination should be questioned.[43] The presence of osteomyelitis warrants an antibiotic combination that reaches effective bone levels; rifampin with another antibiotic is often used. Rifampin should not be used as the sole antimicrobial because resistance is acquired rapidly with this antibiotic. Other antibiotics that reach effective bone concentrations include tetracyclines, chloramphenicol, fluoroquinolones, and cephalosporins. If cephalosporins are chosen, third-generation agents (e.g., ceftiofur, cefotaxime, ceftriaxone, ceftazidime) are preferred because they are more effective against gram-negative bacteria. In foals, fluoroquinolones should be reserved for organisms that are only susceptible to this class of drugs because evidence shows cartilage lesions developing in immature animals with their use.[44,45]

Local lavage of the joint or synovial structure is an important component of therapy; removal of debris, fibrin, and inflammatory mediators helps minimize damage and eliminate the

VetBooks.ir

organism. In foals, joint lavage can be performed under heavy sedation or short-term general anesthesia. In adults, sedation and a regional block or short-term general anesthesia can be used. Joint lavage can be performed using through-and-through needle technique; use of a pressure bag or a pump will facilitate efficient lavage of several liters of fluids through the joint. This technique may be sufficient in joints where the diagnosis was made early, where the infection is not severe, and in simple joints (fetlock, carpus). If there is poor response to treatment after one or two sequential joint lavages, arthrotomies should be performed without hesitation. Often fibrin accumulation in the affected joint precludes effective lavage and allows sequestration of bacteria. Once arthrotomies have been performed, the affected joint needs to be covered with a sterile bandage. During subsequent lavages, a teat cannula inserted in the arthrotomies may be used to lavage the joint. The arthrotomies are left to heal by second intention; the joint needs to remain bandaged until the arthrotomies are closed. Occasionally, delayed closure of the arthrotomies is necessary, particularly in arthrotomies localized over high-motion joints. In joints with multiple compartments (stifle, hock), in severe infection or osteomyelitis, in cases of longer duration, or in animals with poor response to joint lavage, arthroscopic débridement is indicated.[15] Arthroscopy has several advantages over simple needle lavage. It allows thorough débridement, removal of fibrin, and lavage of all compartments; evaluation and débridement of cartilage and underlying bone lesions; and in the case of wounds, identification and removal of foreign material. In one study, foreign material was identified on arthroscopy in 41 of 121 (43%) horses and 34% of joints with wounds involving synovial structures; these were predicted in only 15% of cases, suggesting that endoscopic evaluation is important diagnostically in wounds involving synovial structures.[15] In addition, arthroscopy may have prognostic value when radiographic lesions are equivocal. The arthroscopic portals can be left open for drainage and subsequent lavage but must be kept under a sterile bandage.

Local or regional delivery of antibiotics is advocated for the management of septic arthritis.[46] Delivery of local antibiotics to the affected joint can be achieved by intraarticular injection, isolated IV or intraosseous (IO) infusion, isolated retrograde venous injection, continuous antibiotic delivery, or implantation of antibiotic-impregnated biocompatible materials. Intraarticular injection is the simplest method but requires repeated injections. Aminoglycosides (gentamicin, amikacin) and ceftiofur have been shown to maintain levels above the minimum inhibitory concentration (MIC) for 24 hours after a single intraarticular injection.[47,48] Intrasynovial catheter placement and repeated antimicrobial injection was described successfully in one study where a modified over-the-wire catheter system was placed directly in the synovial structure and used for antibiotic injection and lavage of the synovial structure.[4] Continuous infusion of antibiotics can also be accomplished by placing a small catheter into the affected synovial structure and attaching it to an infusion system, providing constant rate infusion of the antibiotic.[49,50]

Isolated regional IV perfusion or IO perfusion techniques are also advocated for the treatment of septic arthritis.[51,52] Although the term *perfusion* is often used in the veterinary literature, the term *infusion* should probably be used, because in most studies a single injection of the antibiotic is made at the start of the treatment period, whereas perfusion techniques establish an extracorporeal bypass system for the extremity or organ under treatment.[53] Isolated limb infusion techniques are based on isolating the area of interest with a tourniquet, followed by a single IV or IO injection of the antimicrobial. These techniques rely on transient pressure and concentration gradients to distribute a drug to the tissues. The type of tourniquet used is important; escape into the systemic circulation must be avoided during the treatment period. Wide rubber or pneumatic tourniquets are recommended.[54] An Esmarch tourniquet has also been shown to be effective.[51,53] Tourniquets should be 20% wider than the diameter of the limb on which they are used.[54] After tourniquet placement, a regional vein is catheterized using a 23-gauge butterfly catheter for isolated limb infusion. Alternatively, a long-term indwelling catheter can be placed in the vein to facilitate treatment and avoid repeated injection and possible damage to the vein.[57,58] The antibiotic is diluted in a volume of sterile fluid (20 to 120 mL have been reported) and subsequently injected, and the tourniquet is left in place for 30 to 45 minutes. In theory, the increased volume serves to increase the vascular pressure and therefore antibiotic distribution, but it remains unknown whether distribution of the antibiotic is a result of a pressure gradient or a concentration gradient. The increased pressure generated after a single infusion of 60 mL returned to baseline after 10 minutes in one study.[53] For IO infusion, a tourniquet is placed in a similar manner, and an IO screw is placed in the medullary cavity and used to inject the antibiotic. Alternatively, a sterile infusion line can be placed in a hole drilled into the medullary cavity. In one study, the IV infusion method had fewer complications than the IO route.[59] Several drugs have been used for IV infusion, including aminoglycosides, cephalosporins, erythromycin, enrofloxacin, vancomycin, and amphotericin B.[51,60-64] The irritating property of drugs like enrofloxacin makes their repeated use undesirable unless no alternative is available.[65]

Isolated limb retrograde venous injection (ILRVI) was compared to isolated limb infusion (ILI).[53] The ILRVI technique was similar to that reported for regional limb perfusion in horses. The ILI technique consisted of catheterization of one digital artery and vein followed by application of a tourniquet. The antibiotic was then injected over 3 minutes, followed by circulation of infusate and blood from the venous to the arterial circulation in 5-minute aliquots for 25 minutes. In the ILI technique, high pressure within the venous system was sustained for the duration of treatment, compared to the ILRVI technique. There was no difference between the two techniques in the pharmacokinetics of synovial fluid amikacin in the metacarpophalangeal joint, but significantly higher amikacin concentration was measured in the DIJ.[53] The authors concluded that either ILRVI or ILI may be used for antibiotic delivery, but that the technically less demanding ILVRI technique may be more practical.[53] Recently, time to reach maximal concentration of amikacin in the DIJ after ILVRI was shown to be only 15 minutes,[66] suggesting that tourniquet application could be shortened to 15 minutes, compared to the traditional 30 minutes. This would be an advantage when the technique is used in standing horses, who often become uncomfortable after approximately 20 minutes of tourniquet application, resulting in motion and possibly systemic leakage of the antibiotic.

Antibiotic-impregnated polymethylmethacrylate (PMMA) beads can also be used, although direct implantation into a joint can result in cartilage damage.[67-69] PMMA implants are fabricated by mixing the desired antibiotic with the powder before adding the polymerizer. Antibiotics evaluated for inclusion in PMMA include gentamicin, metronidazole, vancomycin, ceftiofur, cefazolin, and amikacin.[70-77] Antibiotic combinations have also been used, but combining antibiotics can change their elution properties. For example, cefazolin or amikacin elute at concentrations greater than MIC for 30 days in vitro, but the combination elutes above MIC for only 6 days.[76,77] Antibiotic-impregnated biodegradable implants include synthetic and natural carriers. The advantage of these implants is that a separate procedure for their removal is unnecessary.[78-80] Synthetic carriers are degraded by hydrolysis, which may affect the antibiotic prior to its implantation.[46] Although synthetic biodegradable carriers have been evaluated in an experimental

VetBooks.ir

model of synovial membrane sepsis, they are not currently clinically available.[78] Gentamicin-impregnated collagen sponges consist of highly purified cattle collagen; the gentamicin molecules are embedded within the pores of the collagen. No stabilizing agents or foreign substances are added. Clinical use of successful treatment of septic arthritis in horses and cattle has been reported.[80-82] However, a recent study performed in healthy horses failed to detect sustained antibiotic release beyond that obtained with a single intraarticular injection.[83]

As high levels of antibiotics are reached within the targeted tissues with these techniques, it remains unknown whether systemic antibiotics are still required. In addition, the best dosing interval between treatments is unknown; for example, with concentration-dependent aminoglycosides, there is a transient reversible adaptive resistance for some bacteria to a second dose of aminoglycoside up to concentrations 128 times MIC. These same bacteria revert to original susceptibility when exposed to drug-free media.[53,84] Another unknown is the potential interaction of aminoglycosides and β-lactam combinations, which depending on the drug combination, can be synergistic or antagonistic. Although inactivation of certain β-lactam antibiotics by certain aminoglycosides in vitro has been documented, several studies document in vivo synergism.[85,86] Significant postantibiotic effects were detected with several antibiotic combinations.[87]

With extensive physeal lesions in foals, curettage, autologous bone grafting, and external coaptation may be required.[88,89] The addition of tricalcium phosphate granules or bioresorbable paste may be considered.[90] Angular limb deformities may result from growth disturbances or collapse of the physis on the affected side. In adults with septic arthritis and osteomyelitis, curettage of the bone lesion followed by bone grafting and external coaptation may also be indicated.[91] Adjunctive therapies that may help alleviate inflammation include sodium hyaluronate, polysulfated GAGs, and dimethyl sulfoxide (DMSO). Sodium hyaluronate and polysulfated GAGs can be used systemically or locally, but local use should be reserved for when infection is under control because these agents decrease joint defense mechanisms.[8,92] Although DMSO has significant anti-inflammatory properties in joints, it should be used with caution because of its negative effects on cartilage metabolism.[93]

In addition to specific therapies, management of pain, stress, and other metabolic disturbances are indicated. Pain can be managed by judicious use of NSAIDs, using the smallest dose that will keep the animal comfortable. If a foal continues to show severe pain despite appropriate treatment, it is important to ensure that other joints in the limb are not involved. Other pain management modalities (e.g., opiates, fentanyl patches, epidural analgesia) can be used. It is important to remember that in foals, continued pain in one limb may result in development of a varus deformity in the contralateral weight-bearing limb owing to the tripod stance these foals acquire to maintain the weight-bearing limb under the center of gravity. Application of a lateral extension to the contralateral foot may help increase the weight-bearing surface and prevent development of this complication. Continued pain is a negative prognostic indicator in the affected foal. In adults, continued pain in one limb may result in the development of contralateral limb laminitis.[94] When continued pain in the treated limb is a problem, preventive measures (e.g., hoof support, therapeutic shoeing) should be undertaken.

Gastroprotective agents are indicated in foals and adult horses that are in pain, stressed, and receiving high doses of NSAIDs. Omeprazole is currently the only medication that has been shown to significantly prevent formation of gastric ulcers and promote healing of existing ulcers in adult horses. Although evidence for its efficacy in preventing and treating NSAID-induced ulcers is lacking, omeprazole is still indicated when NSAIDs are used in stressed animals.

In cattle, facilitated ankylosis is a reasonable alternative when the disease is too advanced, and it is a particularly good option for involvement of the DIJ. Articulations of the distal limb in general are well suited to facilitated ankylosis. In brief, the involved joint is opened and débrided of all debris, all infected tissue is curetted and removed, and a cast is applied and maintained until ankylosis is achieved.[95] Alternatively, the digit may be amputated, although a reduced production life should be expected.[96]

Prognosis

In clinical studies, treatment is often limited by economic considerations, so the true long-term outcome of treatment is unknown. Outcome variables used in clinical studies range from discharge from the hospital to pasture soundness to racing potential. Owner expectations should be clear, keeping the animal's welfare in mind. The prognosis for septic arthritis should always be guarded, and owners should be informed of the high cost of treatment. In foals, factors that influence prognosis are systemic condition of the foal, number of joints involved, localization of joint involvement, severity of the infection, early versus delayed identification and institution of treatment, presence of osteomyelitis, and virulence of the organisms. In one study, 73 of 93 (78%) foals survived to discharge, but only a third reached racing performance.[97] Isolation of *Salmonella* spp. and presence of multisystem diseases were negatively associated with survival and ability to race.[97] A multidrug-resistant *Enterococcus* species was associated with unresponsive septic arthritis in three horses.[98] In another study, 58 of 69 (84%) foals survived to discharge, although signs were present for less than 24 hours in 74% of foals, only 5 foals had more than one joint involved, and only 1 foal had osteomyelitis.[99] This population of foals therefore appeared to be less severely affected. Of the affected foals, only 40.5% started in one race, and of the affected foals that were discharged, only 48.3% raced versus 66.2% in the control (sibling) group. This study concluded that even if foals are successfully discharged from the hospital, they are significantly less likely than their siblings to start in at least one race. Furthermore, these foals took significantly longer to appear on the track than their siblings. In another study of foals with osteomyelitis of hematogenous origin, 87 of 108 (80.6%) foals were discharged from the hospital, and 79 of 87 foals reached racing age.[100] Overall, 52 of 108 (48%) foals raced. Of the 21 nonsurvivors, only 1 died; the other 20 were euthanized, but none was euthanized for economic reasons. Factors associated with nonsurvival in that study included foals less than 30 days of age, critical illness, multisystem disease, multiple bone lesions, lesions of the proximal phalanx, concurrent septic arthritis, multiple septic joints, and involvement of the coxofemoral, stifle, hock, or navicular bursa. In that study, the bacterial isolate involved had no significant effect on short-term outcome.[100] In a study evaluating the factors associated with survival and racing performance in 423 neonatal Thoroughbred foals with bacteremia, the presence of septic arthritis increased the likelihood of nonsurvival by 4.54 times.[101]

In adults with open joint injuries, the prognosis can be favorable if the joint is contaminated but not yet infected and if aggressive treatment is started immediately. However, with established infection, the prognosis should always be guarded. In one study of horses with open joint injury, 53% of those examined within 24 hours developed septic arthritis, and overall survival was 65%. In horses presented within 2 to 7 days of injury, septic arthritis developed in 92%, and survival was 38.5%; in horses examined more than 7 days after injury, septic arthritis developed in all, and survival was 50%.[13] In one study of 101 horses with heel bulb lacerations, those with involvement of synovial structures had worse outcomes than those that did not; 5 of 17 horses with synovial involvement were euthanized.[16] Horses with contaminated or infected synovial structures treated

by arthroscopic débridement appeared to have a better long-term outcome, with 106 of 118 (90%) surviving and 96 (81%) returning to previous use.[16] In a study of horses with septic tenosynovitis, 40 of 51 (78%) horses were discharged, and 37 of 40 (73%) survived long term, with 21 (57%) returning to intended use.[102] Surgical technique did not influence outcome in this study. One study reported on the use of matrix metalloproteases 2 (prommp2) and 9 (prommp9) and WBC count to monitor treatment and predict outcome in horses with septic arthritis.[14] In that study, survivors had a significantly lower WBC count, prommp9, and ratio of prommp9/prommp2, with the latter being the best predictor for survival.

In cattle the prognosis for septic arthritis is generally better than in horses, probably because of the lack of expectation for athletic use. Prognosis depends on time of presentation, degree of bone involvement, and degree of extracapsular ankylosis. In two studies the success rate was reported as 72% and 85%; cattle with septic tarsi had a worse prognosis.[103,104] In another study, arthroscopic lavage and implantation of gentamicin-impregnated collagen sponges resulted in recovery in 12 of 14 cattle.[105] After arthrodesis of the DIJ, 85% success was reported.[96] For carpal arthrodesis, 87% success was reported if no carpal bone was removed, 72% success if one row of carpal bones was removed, and 35% success if both carpal rows were removed. Tarsal arthrodesis has a reported success rate of 87% in cattle.[96] A recent study indicated a positive outcome in 55% (35 of 62) of calves affected with septic arthritis.[20]

Mycoplasma Polyarthritis in Goats

Evelyn MacKay

Definition and Etiology *Mycoplasma* are small bacteria without a cell wall responsible for a multitude of diseases affecting domestic ruminant herds worldwide. Pathogenic species include *Mycoplasma capricolum* (subsp. *capricolum*, subsp. *capripneumoniae*), *Mycoplasma bovis*, *Mycoplasma mycoides* subsp. *capri*, *Mycoplasma putrefaciens*, *Mycoplasma conjunctivae*, *Mycoplasma ovipneumoniae*, and *Mycoplasma agalactiae*.[1] *M. mycoides* subsp. *mycoides* LC (large colony variant) has been reclassified as *M. mycoides* subsp. *capri* based on phylogenic data.[2] It is closely related to *M. mycoides* subsp. *mycoides* SC (small colony variant), the causative agent for contagious bovine pleuropneumonia. Contagious agalactia is the common name of the disease syndrome caused by *Mycoplasma* infection of kids and does. It classically presents as a triad of clinical signs: mastitis in lactating does and polyarthritis with keratoconjunctivitis in kids, though pneumonia is common as well. *M. mycoide*s subsp. *capri* is the most common etiology in the United States, though *M. agalactiae* is more prevalent in Mediterranean countries, where it is responsible for 90% of outbreaks.[3,4] Clinical signs, disease progression, and virulence vary with strain and host factors.

Clinical Signs and Differential Diagnoses Incubation period can range from a few days to weeks, depending on species, management practices, and environmental factors. Initial signs of infection in kids include fever, lethargy, anorexia, and weakness.[5] Polyarthritis, keratoconjunctivitis, and pneumonia develop following initial bacteremia.[6] Meningitis and sudden death have been reported in some outbreaks.[7] Polyarthritis most commonly occurs in the carpal and tarsal joints; multiple joints often become warm, swollen, and painful.[3,5] Differential diagnoses include environmental organisms colonizing the joints after bacteremia. Peracute, acute, and chronic disease syndromes may develop, and *Mycoplasma* often can be cultured from the ear of asymptomatic carrier animals.[2,8]

Clinical signs in does include alterations in the appearance of milk, agalactia or drop in milk production, supramammary lymphadenopathy, fibrosis of the mammary gland, fever, anorexia, and lethargy.[1] Agalactia and mastitis of does must be differentiated from other causative agents of mastitis, including environmental coliforms, *S. aureus*, fungal organisms, and caprine arthritis encephalitis virus. Adults may also develop polyarthritis, keratoconjunctivitis, and pneumonia, and infection is not limited to females. *Mycoplasma* can colonize the reproductive tract and has been isolated from abortions and semen.[3,9] Infected herds may have decreased reproductive performance.[2]

Clinical Pathology and Diagnosis Hematologic changes are variable and may depend on severity of disease and *Mycoplasma* species. Changes in experimentally infected kids included leukopenia, decreased erythrocyte count, thrombocytopenia, decreased clotting factors, and increased clotting times consistent with disseminated intravascular coagulation.[10] Total protein and albumin concentrations may be decreased in infected animals.[6] Arthrocentesis will reveal a fibrinosuppurative arthritis.[1] Culture can be obtained from synovial fluid or milk, which requires special medium and extended time intervals for growth. *M. agalactiae* colonies typically resemble a "fried egg" on agar.

In endemic areas, a presumptive diagnosis may be based on clinical signs. Antemortem diagnosis can be made with samples of milk, blood, urine, and auricular, nasal, and ocular secretions.[3] Species and subspecies differentiation can be challenging, and techniques used include serology and molecular diagnostics such as PCR and genome sequencing.[11] Biochemical tests are not useful due to extreme similarity between species. Combination of multiple diagnostic modalities may be required for accurate differentiation.

Pathophysiology and Epidemiology Infection of kids usually occurs through ingestion of infected milk and colostrum from the doe or supplemented bovine milk in the case of *M. bovis*.[1] Disease may also spread via oral and nasal secretions of infected animals or contaminated milking equipment.[3] Polyarthritis develops after systemic bacteremia. Strain virulence, immune and nutritional status of animals, and environmental factors all play a role in severity and spread of the disease. Morbidity is often high, but mortality varies greatly. An asymptomatic carrier introduced into the herd is often responsible for outbreaks. Disease occurs in wild ruminants, and they may represent a reservoir for transmission to domestic animals.[2]

Necropsy Findings Affected joints are swollen with decreased range of motion. Fibrin deposits and hemorrhage of the articular cartilages can be seen.[1] Microscopically, neutrophils and mononuclear cells infiltrate the synovium.[5] Gross pulmonary lesions may include diffuse interstitial pneumonia, bronchopneumonia, fibrinous pleuritis, or a combination of lesions.[5,12] Microthrombi may be present diffusely in vasculature, and microabscesses may be found in the spleen and kidney.[10]

Treatment and Prognosis Mortality and morbidity vary based on the isolate but can climb above 90% in kids. An outbreak in a dairy resulted in the euthanasia of 700 goats.[7] Treatment is often unrewarding, and resources may be best directed toward prevention and control of infection. As *Mycoplasma* lack a cell wall, treatment with antimicrobials that disrupt cell wall synesthesia are ineffective. Antimicrobials used include tetracyclines, macrolides, fluoroquinolones, and florfenicol. There is evidence of existing resistance to antimicrobials, and even susceptible isolates may not be eliminated with appropriate antimicrobial therapy.[2] Damage to joints may be permanent and crippling by the time antimicrobial therapy is initiated.

VetBooks.ir

Prevention and Control A closed herd with careful screening of new animals is the best method to prevent infection. Recommended screening strategies include PCR or culture of ear swabs; serology may be performed, but asymptomatic carriers are often negative.[2,9] Hygienic milking practices help reduce spread between does, and sanitization of supplies and housing is recommended. Feeding of colostrum and milk replacers reduce likelihood of transmission to kids, though pasteurization will reduce mycoplasma numbers.[2] Culling of affected animals or complete depopulation of herds has been used in control efforts.[7,11] Killed and attenuated live vaccines exist and have shown efficacy in reducing clinical signs and shedding, but these are not commercially available in the United States.[13]

Caprine Arthritis Encephalitis Virus

Kevin Washburn

Definition and Etiology Caprine arthritis encephalitis virus (CAEV) is an RNA-enveloped lentivirus from the Retroviridae family that infects cells of the monocyte-macrophage lineage, with clinical manifestations ranging from subclinical disease to severe encephalitis. Time from viral infection to clinical disease may vary from months to years, and because infection is lifelong, efforts to eradicate and control its prevalence and incidence are paramount to maintaining successful goat herds. Loss of productivity, death, and restrictions on the export of dairy goats are just some of the economic impacts of this disease on worldwide herds and the goat industry.

Clinical Signs and Differential Diagnoses Only about 20% of CAEV-infected goats display clinical signs of disease during their lifetime, but recognized forms of disease include a leukoencephalomyelitis, interstitial pneumonia, chronic mastitis, and debilitating polysynovitis-arthritis.[1] Leukoencephalomalacia is observed primarily in kids 2 to 6 months of age, but reports have been noted in adults.[1] This form is characterized by an ascending paresis leading to paralysis, beginning in the rear limbs and sometimes involving the forelimbs. These signs may or may not be accompanied by a mild interstitial pneumonia. Goat kids may continue to be bright, alert, and appetent. The most severe manifestation of this form of CAEV infection is progressive paresis to paralysis to urinary retention and bloating. Differentials for this form of CAEV include meningitis, meningeal worm, and trauma. Chronic interstitial pneumonia with progressive weight loss and dyspnea is another recognized form of CAEV infection. Primary ruleouts for this form include lung worms, internal caseous lymphadenitis, pulmonary abscessation, and chronic bronchopneumonia. The mammary gland is a target organ for the virus as well, resulting clinically in a firm udder with decreased milk production. Although quantity of milk is reduced, there are no apparent gross abnormalities; however, chronic bacterial mastitis should be a consideration during initial evaluation.

The most common form of CAEV infection is polysynovitis-arthritis, which is most frequently recognized in mature goats but has been reported in goats as young as 6 months of age. Lameness caused by this form is intermittent and insidious in onset, but eventually affected joints become painful and enlarged. Enlargement of the joints is most typically due to hyperplasia of the synovial tissues and their associated sheaths rather than increased volume of joint fluid. The carpus is most frequently involved, but the stifle, coxofemoral, atlantooccipital, and hock joints are also potential locations. Affected goats have a stiff, stilted gait and progress to walking on their carpus or recumbency. Range of motion is greatly affected, contributing to chronic soft tissue contracture. The polysynovitis-arthritis form can be accompanied by a chronic interstitial pneumonia and weight loss, as well as some degree of mammary involvement.[1] Ruleouts for this common form of CAEV include septic arthritis and chronic degenerative joint disease.

Clinical Pathology and Laboratory Diagnosis Arthrocentesis to confirm suspicion of the polysynovitis-arthritis form of CAEV infection usually yields a brown to red-tinged fluid with an increased cell count and protein. Joint fluid cell counts in affected joints are dominated by mononuclear cells, differing from bacterial synovitis, where cells consist predominantly of neutrophils. This predominance of mononuclear cells in CAEV infection is also seen in the cerebrospinal fluid (CSF) of goats affected with the leukoencephalomyelitis form. Radiographs may be a useful diagnostic tool for CAEV polysynovitis-arthritis; early cases display soft tissue swelling dorsal to the carpus. As the disease progresses, mineralization can be observed in the periarticular tissue, tendon sheaths, joint capsules, and ligaments. Roughened bone proximal and distal to the joint becomes apparent, as does periosteal reaction. A commercially available immunoenzymatic assay of antibody against surface glycoprotein was found to have a sensitivity and specificity of 86.9% and 84.4%, respectively, in its ability to discriminate between arthritic and asymptomatic goats.[2]

The U.S. Department of Agriculture (USDA) recognizes an agar gel immunodiffusion (AGID) test using ovine progressive pneumonia virus antigen as the official test for CAEV. However, an enzyme-linked immunosorbent assay (ELISA) has been developed for detection of whole virus, core, or envelope proteins. Both AGID and ELISA are considered reliable enough to be incorporated into prevention and control programs. The AGID test is reportedly more specific but less sensitive than the ELISA.[3] Polymerase chain reaction techniques have been developed for detection of antigen in milk, tissue, and blood. A study evaluating the performance of PCR and ELISA against viral culture for the detection of CAEV in goat kids found that PCR tended to have a lower sensitivity and higher specificity than ELISA, but combining these two tests in series or parallel may optimize the advantages and disadvantages of each technique, thereby maximizing detection.[4] Surveillance measures on goat dairies have included the use of ELISA tests on bulk milk samples that appear to be applicable for early detection of CAEV infection.[5]

A positive AGID test or ELISA in adults is synonymous with lifelong viral infection. Generally, time from infection to seroconversion ranges from 4 to 16 weeks, but some infected goats shed virus for long periods of time without seroconversion.[6] Goat kids may be transiently positive for the presence of antibodies during the first 8 to 16 weeks of life after consuming CAEV antibody–containing colostrum, but because of the nonprotective nature of maternal antibodies, such kids may seroconvert to true viral infection shed from the infected dam.

Pathophysiology The characteristic granulomatous inflammatory pathology produced in affected tissues is thought to be due to immune complexes generated by the interaction of nonneutralizing antibodies produced by lymphocytes and associated virus-infected macrophages. Localization of such inflammatory lesions occurs where tissue-associated macrophages are found. Tissues of importance for CAEV localization include the synovium, mammary gland, lung, and central nervous system (CNS), therefore the manner in which the disease manifests itself is to be expected.

Epidemiology Transmission involves the transfer of virus-laden cells from one animal to the next. Transfer of CAEV to neonates through colostrum and milk is a highly efficient natural mode of transmission.[7,8] Transmission has also been

VetBooks.ir

reported through direct contact, so herd owners who do not practice segregation of seropositive animals continually have difficulty controlling and eradicating the disease.[7-10] Complete separation of kids from dams immediately following parturition and during the periparturient period is necessary; evidence exists that even kids not allowed to nurse become infected. CAEV proviral DNA has been detected in the caprine genital tract,[11] and experimental infection of goat embryos with CAEV has been reported.[12] In addition, intramammary and in utero transmission have been described.[10,13] All of the described means of acquiring the virus are potential explanations for continued transmission in herds where segregation and sound colostrum and milk management are practiced.

Maedi-visna virus (MVV), also known as *ovine progressive pneumonia*, is another lentivirus that together with CAEV is commonly referred to as *small ruminant lentivirus* (SRLV). Although sheep are most likely to display clinical signs of MVV and goats signs of CAEV, studies have shown that these viruses can be transmitted from sheep to goats and vice versa.[14] Therefore eradication programs aimed at eliminating SRLV from herds and flocks should not allow contact between sheep and goats.

A study examining the prevalence of antibody to CAEV in the United States found that 31% of all goats tested were seropositive, and 73% of herds had at least one seropositive member. Serum samples in this study were obtained from 28 states. Prevalence was highest in the western Pacific and northern plains regions on family-owned farms and increased with age. Prevalence in this study was lowest in the Angora breed.[15]

Necropsy Findings

Grossly, goats affected with the polysynovitis-arthritis form of CAEV have thickened, sometimes folded synovium consistent with synovial hyperplasia due to chronic inflammation. Microscopically, synovial hyperplasia is characterized by mononuclear infiltration of lymphocytes, plasma cells, and macrophages. Synovial spaces contain fibrin, and synovial villi and collagen are necrotic.[1]

No gross lesions are apparent in the CNS of goats affected with the leukoencephalomyelitis form of CAEV, but microscopically, perivascular infiltration of lymphocytes, macrophages, and plasma cells is observed. Perivascular infiltration is often accompanied by malacia of the brain and spinal cord, in addition to loss of myelin. Occasionally, degenerative lesions are seen in the gray matter.[16]

Treatment and Prognosis

Prognosis for CAEV infection varies because most goats do not show clinical disease; once signs begin, however, rapid deterioration ensues. Arthritis and accompanying weight loss progress, and there is no treatment. Kids or mature goats affected with the leukoencephalomyelitis form do not survive and should be euthanized for humane reasons. Reportedly, a genetically determined predisposition for development of CAEV arthritis exists and can be identified with DNA fingerprinting.[17]

Prevention and Control

Prevention and control centers on colostrum and milk management, but kids should also be prevented from any contact with the dam following parturition. Heat treatment of colostrum by holding it at 45° C (113° F) for 1 hour effectively inactivates the virus.[10] Kids can then be fed pasteurized milk until weaning. Unpasteurized goats' milk from seronegative dams is a risky substitute for heat-treated milk because some seronegative goats shed virus for long periods before seroconversion occurs. Pooling of colostrum increases the prevalence of disease in goat dairies, so this practice should be restricted. Kids should be tested serologically at periodic intervals to detect and remove infected individuals. Seronegative goats should be isolated from seropositive ones by a minimum of 6 feet.[10] Sharing of feed and water troughs should not be allowed, nor should use of common needles during routine vaccination or administration of medication. During breeding, seronegative does should not be housed with seropositive bucks, but they can be hand mated and quickly re-isolated. New additions to the herd should be tested and isolated until seronegative status is confirmed prior to entry into the herd.

Despite diligent prevention and control programs based on elimination of colostrum and milk transmission, isolation of seronegative goats, and serologic monitoring, obstacles to a CAEV-free herd are often encountered. Detection of virus has been reported in properly treated colostrum.[7] Overheating colostrum denatures immunoglobulin, thereby preventing effective passive transfer of immunity, but not heating colostrum long enough or at high-enough temperatures fails to inactivate the virus. Feeding overheated colostrum may also cause diarrhea in kids.[18] Attention to time and temperature details during heat treatment of colostrum and pasteurization of milk are of the utmost importance for effective colostrum and milk management. Some farms routinely feed cow colostrum, but neonatal isoerythrolysis has been reported in kids consuming cows' milk, and the lack of goat-specific immunoglobulin transfer is less than ideal.[18] Serologic monitoring can be complicated by the fact that viral shedding precedes seroconversion, so all goats should be tested a minimum of twice yearly to ensure that any new cases are detected and managed accordingly. Unfortunately, no vaccine is currently available for CAEV.

Osteoarthritis

Canaan Whitfield-Cargile

Terminology

The term *osteoarthritis* (OA) is one of many terms used to describe a broad category of disease that ultimately results in bone *(osteo)* and joint *(arthron)* pathology. Other terms used to characterize this category of disease include degenerative joint disease (DJD), osteoarthrosis, osteoarthropathy, and simply arthritis. The suffix *-itis* refers to inflammation, but the role of inflammation in the etiopathogenesis of OA remains controversial in both people and animals.[1,2] While many of these terms are justified, for the purpose of clarity we will use the term OA, as it appears to be the most widely used term to describe this condition. OA is a progressive disease ultimately characterized by destruction of articular cartilage, changes in the subchondral bone, and alterations of periarticlar soft tissues including synovium, ligaments, and joint capsule, although not necessarily in that order.

Evidence exists to suggest that OA was present in the earliest examples of diarthrodial joints found in the fossil record.[3,4] Not surprisingly, OA is the most common joint disorder in people and is also highly prevalent in dogs.[5] In large animal species, OA is regularly diagnosed in horses, cattle, pigs, and small ruminants. Although there are specific causes of OA in some species (e.g., caprine arthritis encephalitis virus in goats), more often the etiology of the underlying causes remains unknown.[6] The obvious exception to this is cases of OA secondary to joint trauma, septic arthritis, or chronic increased weight bearing following injury or amputation of the contralateral limb.[7,8] Although the exact prevalence is unknown, OA is a common disease of horses often resulting in loss of use for high-end athletes and all too often progressing to debilitating pain and humane euthanasia. To highlight the prevalence of this condition in horses, one study examined the prevalence of OA in the metacarpophalangeal joint of racehorses, based on macroscopic and microscopic cartilage examination, and found that nearly one third of 2- to 3-year-olds in training had evidence of cartilage injury.[9] The cause of OA in this population of horses is unknown.

VetBooks.ir

Pathophysiology and Classification

Several theoretical explanations underlie the pathophysiology of OA. As stated above, occasionally there is a clear explanation of the development of OA (i.e., following joint trauma, infection, etc.), but in most cases the cause is not clear. At a basic level, two major factors are involved in the development of OA: mechanical load and tissue turnover or metabolism. In many cases of OA, it is likely that both of these factors play a role in the etiopathogenesis, and to consider them separately is likely an oversimplification. For example, a normal load placed on a joint that has increased catabolic processes will eventually lead to the development of OA as that "normal load" overwhelms the repair capacity of that specific joint. Conversely, an abnormal load placed on a normal joint (i.e., balanced catabolic and anabolic processes) will also eventually develop OA, in part due to eventual increased turnover of components of the joint resulting in an inability for that joint to repair itself. For the purposes of this chapter, however, these processes will be considered independently.

ABNORMAL BIOMECHANICAL LOAD. Examples of an abnormal mechanical load that overwhelms a joint's capacity for repair can be an obvious acute injury resulting in instability. Examples of these types of injuries include injury to collateral ligaments and other supporting structures of joints, fractures involving the articular surface, and injuries in the contralateral limb resulting in increased weight bearing.[10] Importantly, these examples represent a single traumatic event resulting in joint instability and eventual development of OA if not managed appropriately or, in some cases, even if managed appropriately. The other broad category of biomechanical load resulting in OA is repeated low-grade damage that occurs with routine use, resulting in repeated microdamage to the structure of a joint. At no one point are these low-grade injuries apparent, but over time this microdamage overwhelms a joint's capacity for repair and ultimately leads to development of OA. A primary example of this phenomenon is the changes that occur within the metacarpophalangeal joints of racehorses.[11] In this context, there is a wealth of evidence suggesting that stress placed on the distal end of the third metacarpal bone results in increased stiffness of the subchondral bone and eventual microcracks that may progress to condylar fractures.[12] Even if condylar fractures do not develop, the structural and molecular alterations induced by repetitive trauma lead to changes in the articular cartilage and predispose these horses to developing OA.[13] Similarly, abnormal biomechanical forces are placed on joints when there are anatomic abnormalities such as severe angular limb deformities and hip dysplasia in calves, among others. Although the underlying causes in these situations are obvious, this too represents a form of repetitive injury, albeit one more obvious than what occurs with the microdamage associated with performance or the forces placed on joints on a regular basis due to the shear size of many large animal species. Irrespective of the underlying biomechanical cause, the result is initiation of a series of complex biochemical and metabolic events that result in an imbalance of anabolic and catabolic processes in the joint, eventually overwhelming the repair processes. This culmination of events leads to fibrillated and ulcerated articular cartilage, eburnation and sclerosis of the subchondral bone, hyperplasia of the synovial membrane, and development of periarticular osteophytes and enthesophytes.

TISSUE METABOLISM. All tissues have capacity for turnover and repair, and the tissues in the joint are no exception. OA can be thought of as an imbalance between anabolic processes (repair) and catabolic processes (turnover).[14] As discussed, factors that can upset this balance include biomechanical factors (see above), other trauma, inflammation, and sepsis. Much of the discussion examining these factors focuses on the articular cartilage, but other tissues associated with joints are also important, including synovial membrane, ligaments, and subchondral bone. Recall that synovial fluid is an ultrafiltrate of plasma, thus the synovial membrane is the bidirectional interface between the joint and the remainder of the animal. Equine synoviocytes have recently been shown to be an important player in the development of OA in horses by regulating several pathways in cartilage associated with the progression of OA.[2,15] In addition, synoviocytes are responsible for the production of several elements of synovial fluid, the critical component that along with articular cartilage is responsible for maintaining frictionless motion in joints. Taken together, these findings suggest that synoviocytes play an important role in development of OA, although their exact role and the clinical implications of these findings remain unclear.

Loss of articular cartilage is a hallmark of OA, and therefore clearly the balance of anabolic and catabolic processes in this tissue is an important aspect of OA. Articular cartilage is composed of cells, primarily chondrocytes, and an extracellular matrix (ECM) produced by these chondrocytes. The ECM consists of water (>70%), collagen (>90% type II), proteoglycan (aggrecan and aggrecan aggregates linked to hyaluronan). Loss of any of these components is critical, as inherent repair capacity of large (>3 to 5 mm), full-thickness defects is minimal and restoration of the critically important hyaline cartilage is difficult. Loss of articular cartilage is due to either biomechanical disruption (see above) or proteolytic enzymes synthesized by chondrocytes, synoviocytes, or other cell types that have invaded the joint in response to injury (e.g., neutrophils following joint sepsis). A major class of proteolytic enzymes involved in cartilage destruction include the matrix metalloproteinases (MMP), which are a family of more than 25 different enzymes, each with some degree of specificity to a component of the ECM. For example, MMP-1 is also called collagenase 1 and is capable of cleaving type II collagen molecules. Similarly, a disintegrin and metalloproteinase (ADAM) class of enzymes, which are closely related to MMPs, is responsible for enzymatic destruction of aggrecan molecules. Although not always clear, these enzymes are produced by chondrocytes, synoviocytes, and other cells found in joints in response to various cytokines. The principal cytokines associated with stimulating production of these enzymes are the proinflammatory cytokines interleukin (IL)-1 and tumor necrosis factor (TNF)–α. These cytokines not only induce production of these enzymes but also encourage production of other mediators of joint destruction, including prostaglandin E2, oxygen free radicals, and nitric oxide. In a normal joint under normal condition, production of these catabolic compounds is countered by production of anabolic compounds that inhibit cartilage degradation. For example, tissue inhibitors of MMPs (TIMPs) are produced by several cell types within the joint, as is IL-1 receptor antagonist, which binds to IL-1 receptors thus preventing signal transduction. Delving into the host of mediators that regulate cartilage destruction is beyond the scope of this chapter; suffice it to say that the process is complex and involves the interaction of a wealth of mediators. Identification of these mediators of OA, along with their natural inhibitors, is important as this information offers a plethora of potential therapeutic targets to prevent progression of OA (see the Treatment section later). Ultimately, however, OA develops when catabolic mediators outpace anabolic mediators, resulting in loss of ECM components, loss of chondrocytes, and eventual cartilage fibrillation and exposure of subchondral bone. In most cases the exact cause of this imbalance is not clear and is likely multifactorial. Typically the rate of disease progression and severity of OA are related to the nature and severity of the primary insult, the animal's age, the joint location, and the animal's type and level of activity.

Clinical Signs

OA can affect any joint, and therefore the clinical signs will vary greatly depending on which joint

VetBooks.ir

is affected. We focus primarily on OA of the appendicular skeleton, but OA is common in the axial skeleton and any diarthrodial joint. Lameness in horses is a major problem that costs the horse industry hundreds of millions of dollars each year. Lameness is also highly prevalent in other large animal species, resulting in decreased production and welfare concerns.[16] Undoubtedly, much of the lameness in horses is due to OA, although the exact locations, severity, and clinical implications of OA in horses depends on the age, use, severity, and individual response to the pathology associated with OA.[17,18] In other large animal species, lameness is the primary clinical sign of OA, although the exact manifestation of the lameness will be related to species, animal size, and severity of disease. The pain, resulting in lameness, in OA comes from several sources. As stated, the primary area of pathology is the articular cartilage. Cartilage is devoid of innervation, so the pain arises from sensory nerves in periarticular structures, including synovium, joint capsule, subchondral bone, and surrounding ligaments. Either *mechanical stimuli* or *chemical mediators* of pain stimulate these sensory nerves. An example of a mechanical stimulus resulting in pain is increased synovial fluid stretching the joint capsule and synovium. It remains unclear in both animals and people if osteophytes or bone spurs result in pain or are merely a radiographic manifestation of joint disease. Theoretically, periarticular osteophytes could result in stretching of the richly innervated periosteum, causing pain, but in people this has not been conclusively demonstrated and in some cases has been refuted.[19] In addition to lameness, other clinical signs associated with OA include synovial effusion of the affected joint, decreased range of motion, and angular limb deformities with visually obvious periarticular new bone formation as the disease becomes more severe.

Diagnosis

Perineural anesthesia and intraarticular anesthesia can be useful for localizing the source of lameness and is a mainstay for the diagnosis of OA in large animals as, in most cases, physical examination alone is insufficient to confidently localize the source of pain resulting in lameness.[20] Determining the origin of lameness, however, does not confirm the cause of lameness. Diagnostic imaging demonstrating articular changes consistent with OA is the primary means of confirming a diagnosis of OA. Diagnostic tests that can accurately identify OA prior to the onset of irreparable articular changes have clear clinical benefit over diagnostic imaging after these changes have occurred.

NON-IMAGING-BASED DIAGNOSTICS. Routine synovial fluid analysis of affected joints can distinguish pain and lameness associated with septic arthritis from OA, but in cases of OA, routine synovial analysis reveals only nonspecific changes. Therefore there has been a great deal of effort to identify specific biomarkers of early OA. Sources of these biomarkers have included serum, synovial fluid, and urine.[21] The idea of serum biomarkers is attractive, as such samples are more easily collected than synovial fluid. Examples of biomarkers that have been examined include glycosaminoglycans (GAGs), collagen degradation markers and fragments of collagen, osteocalcin, C-terminal of bone type I collagen (CTX1), and cartilage oligomeric matrix protein (COMP).[22,23] Many of these markers have shown promise in both naturally occurring OA and in vivo models of OA, but none has yet demonstrated sufficient evidence or feasibility for routine clinical use.

IMAGING-BASED DIAGNOSTICS. After identification of an involved joint, many imaging strategies can be used to confirm the cause of pain, evaluate the extent of injury, and determine which treatment approaches may be warranted in light of the exact pathology found within that joint. Radiographic evaluation has been the mainstay of these approaches for decades. Radiographic changes associated with OA can include loss of joint space, subchondral bone sclerosis, subchondral cystic lesions, periarticular marginal osteophyte formation, periosteal new bone production at sites of joint capsules and ligamentous attachments (enthesophytes), and occasionally subchondral lysis. These findings can progress from no abnormalities early in the course of disease to complete fusion or ankylosis of the joint as the disease progresses. The association of radiographic findings with clinical signs is not always clear, with severe pain occasionally being associated with minimal radiographic changes and, conversely, severe radiographic changes being associated with minimal to no pain. A well-studied example of this is OA of the distal metatarsal (i.e., tarsometatarsal and distal intertarsal) joints of horses.[24] Thus more advanced imaging modalities, including cross-sectional imaging, have been attempted to more accurately assess these joints. High-field magnetic resonance imaging (MRI) is superior to low-field imaging for evaluating articular cartilage, although both approaches can provide useful information. MRI is superior to radiographs for detecting early changes associated with OA in both the cartilage and the periarticular structures, including subchondral bone.[25] Scintigraphy can be particularly valuable in early disease states when other diagnostic methods have not revealed bone or soft tissue changes; anatomic detail, however, will be lacking. Computed tomography is an excellent imaging modality to examine increased density of subchondral bone, a major component of the pathophysiology of OA, especially in the context of repetitive trauma.[26] The use of sonographic imaging to aid in the diagnosis of OA in horses is rapidly expanding due to the utility of this imaging technique and to the inability of perform cross-sectional imaging of many large animal species due to size. Ultrasonographic evidence of OA is limited to evaluation of the contours of the bone, as the sound beam cannot penetrate bone. Effusion, presence of osteophytes, periarticular soft tissue structures, and in some cases limited views of articular cartilage can be obtained.[27,28] Finally, surgical arthroscopic evaluation of the articular surface likely provides the best ability to evaluate the articular cartilage of joints where arthroscopic evaluation is possible. This technique provides the added therapeutic benefit of simultaneous joint lavage and is used for these purposes in all large animal species.[29,30]

Treatment

Because of the importance of lameness and OA in horses and other large animal species, there has been a great deal of research into developing effecting treatment approaches. As a result, there are many choices, with seemingly more each day. Clearly the choice will depend on the inciting cause of OA, stage of disease, joint involved, species involved, and use of that animal. In general, treatment of OA should be directed at eliminating any primary causes, halting disease progression, and encouraging repair and regeneration of damaged articular cartilage. An important point is to make the diagnosis early so that effective interventions can be implemented prior to the onset of irreparable joint damage. Examples of primary causes that should be addressed include recognition and surgical intervention of osteochondritis dissecans lesions, joint sepsis, and other underlying causes amenable to treatment. Specific treatments for OA are discussed in broad categories of treatment options, recognizing that there is a great deal of overlap among these options.

ANTIINFLAMMATORY AGENTS. NSAIDs are a mainstay of this class of drugs and are used ubiquitously in equine veterinary medicine in the management of OA. Prostaglandin E2 (PGE2) contributes to the pain, inflammation, and cartilage destruction that accompanies OA. Thus inhibition of the cyclooxygenase (COX) enzyme that is responsible for the breakdown of arachidonic acids into various prostaglandins is desirable from both a pain and a disease-modifying perspective. Because

VetBooks.ir

inhibition of COX-1, the constitutively expressed isoform of the COX enzyme, contributes to damage to the gastrointestinal (GI) tract by NSAIDs, great effort has been made to generate NSAIDs that selectively inhibit COX-2, the inducible isoform considered to cause inflammation.[31] The effectiveness of this approach remains unclear in terms of safety, but likely both classes induce the desired antiinflammatory effect in OA.

Intraarticular steroids are the most potent antiinflammatory agents available and widely used in the management of OA in horses and other large animal species.[32] These drugs are administered both systemically and intraarticularly for the management of OA, but they have been associated with progressive cartilage damage and chondrocyte cell death both in vivo and in vitro in multiple large animal species.[33] These effects seem to be somewhat steroid dependent, with some steroids (i.e., methylprednisolone acetate) being more severe than others (i.e., triamcinolone).[34] Moreover, the negative effects of steroids, especially triamcinolone, appear to be mitigated by combining these products with hyaluronan in some contexts. Thus current recommendations are for judicious use of steroids in joints, paying attention to steroid used, mobility of joint (i.e., high-motion versus low-motion), and frequency of injections to mitigate the negative effects of steroids on articular cartilage.

THERAPEUTICS BASED ON REPLACEMENT OF COMPONENTS OF NORMAL JOINTS. Numerous medications that consist of compounds found in joints have been specifically designed and marketed for treating OA in human and veterinary patients. Examples of these include polysulfated glycosaminoglycans (PSGAGs), hyaluronan, GAG peptide complexes, and chondroitin sulfate. These types of products are variably labeled for several routes of administration, including oral, intravenous, intramuscular, and intraarticular. Many of these products exert broad biological function from antiinflammatory properties to providing substrate to support the host repair process. Among these products, hyaluronan is the most widely studied. Most sources agree that larger molecular mass (i.e., >500 kDa) is important for any biological function to exist.[35] At masses greater than 500 kDa, hyaluronan is thought to improve the viscoelasticity of synovial fluid and exert antiinflammatory properties.[36] Much work remains to be done to clarify the effectiveness of hyaluronan, dose, ideal mass, and route of administration in regard to management of OA in large animals, although evidence exists that it is safe and appears to be beneficial in some contexts. Data on PSGAGS and similar products are equally equivocal regarding mechanisms, effectiveness, ideal product, and dosage. Despite these shortcomings, there are findings suggesting that this class of medications has benefit in the management of OA, primarily by exerting antiinflammatory properties and influencing proteoglycan degradation and production following administration. Importantly, intraarticular PSGAG administration has been shown to lower the number of bacteria required to cause synovial infection, and thus concurrent administration of intraarticular amikacin is recommended when administering PSGAGS in this manner.[37,38]

REGENERATIVE AND BIOLOGIC THERAPIES. Several regenerative and biologic therapies exist for management of OA, and this is especially true for equine OA. Examples of such therapies include autologous conditioned serum (ACS), also called IL-1 receptor antagonist protein or IRAP; platelet-rich plasma (PRP); and mesenchymal stem cell (MSC) therapy. ACS is thought to inhibit the effects of IL-1 and induce several additional antiinflammatory cytokines within the joint. ACS is widely used for early OA, with both anecdotal and scientific literature supporting its efficacy, although not universally.[39,40] PRP is thought to provide a host of growth factors found in platelets to induce a beneficial change in joints affected with OA. Although strong evidence supporting its use for OA is lacking, there are data suggesting beneficial effects either alone or when combined with MSC therapy.[41,42] The therapeutic potential of MSC therapy offers an attractive means of regulating inflammation and regeneration of critical tissues lost in OA. As with PRP, data exist suggesting that this approach may offer advantages in the treatment of OA, but much work remains regarding dose, source (i.e., allogenic or autologous), timing of administration, and safety.[43,44]

In summary, a wealth of treatment options are available for the management of OA in large animals. Unfortunately, many of these approaches are not well understood, and work remains to determine many aspects of the management of OA in large animals. Recognition of disease, treating the underlying cause as early as possible, and making management decisions based on case specifics are a mainstay of therapy to have the best possible outcome.

Prognosis Prognosis for large animals with OA depends on the initiating factors, duration and extent of joint destruction, joint affected, species of animals, and intended use of the animal. With early and aggressive treatment, many animals can return to soundness and athletic performance. In other cases, salvage in the form of surgical arthrodesis may provide the most favorable outcome.

Sprains, Subluxations, and Luxations

Will C. Jordan • Canaan Whitfield-Cargile

Definitions Sprains and luxations have been classified as type 2a traumatic arthritides.[1] These injuries have been categorized in three forms: mild, moderate, and severe. *Mild sprains* constitute injuries that involve the tearing or disruption of a minimal number of ligament fibers with no loss of integrity to the ligament. Hemorrhage and edema are typically present in the ligament. Injuries that involve a portion of the ligament, with loss of integrity, are considered *moderate sprains*. Laxity of the joint is often present with moderate injury, but complete separation of the ligament from the bone or complete separation of the body of the ligament is not seen. Significant hemorrhage and edema are present in the ligament. Injuries that involve tearing of the ligament, resulting in either complete separation from the bone or widening of the tendon fibers, are considered *severe sprains*. These injuries result in some form of joint instability, especially when the affected joint is manually stressed.

Luxations and subluxations are usually the result of severe sprains of periarticular or articular ligaments. *Luxations* represent the complete dislocation of the articular surfaces, whereas *subluxations* have only partial and incomplete disarticulation (Fig. 38.19).

Etiology and Pathophysiology Sprains can be associated with acute injuries in which the ligaments are suddenly overloaded, resulting in acute failure or secondary to repetitive strains of submaximal loads resulting in less obvious breakdown but ultimately ligamentous injury. The latter results when maximal or near-maximal loads are repeatedly applied to the ligaments and associated structures, causing a degenerative type of lesion. Age can also be a contributing factor in these degenerative changes. Muscle fatigue can contribute to the weakening of adjacent structures, increasing the stresses applied to the supporting ligaments. It is suspected that most sprains of ligaments are due to acute overload, whereas tendon injury most likely occurs as a result of repetitive low-grade trauma resulting in molecular degeneration.[2] Luxations and subluxations are usually of traumatic origin, such as stepping in a hole or

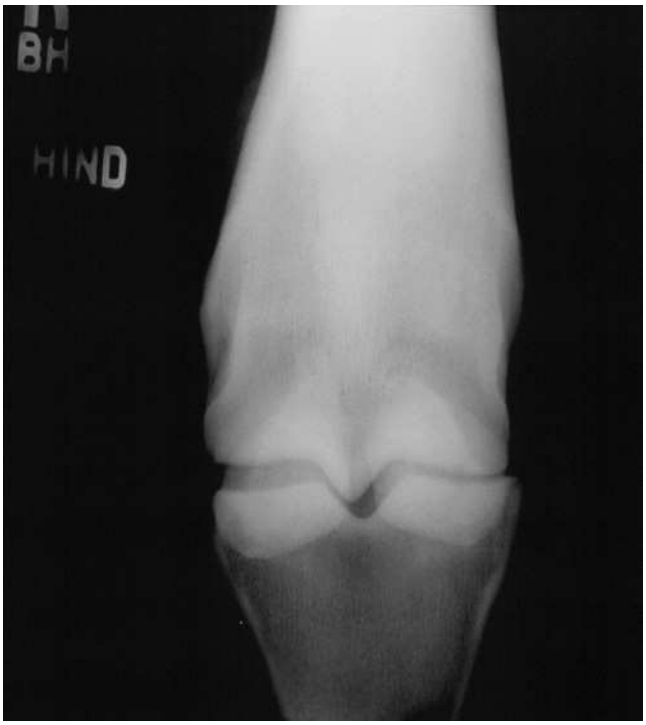

FIG. 38.19 Dorsopalmar radiograph of a subluxated metaphalangeal joint after the joint has been manually stressed.

entrapment of a limb in a gate or fence, or subsequent to traumatic complete ligamentous disruption.[1]

Typically, hemorrhage and edema form within the ligaments surrounding the joint capsule, or in severe lesions the hemorrhage can be periligamentous or intraarticular. Inflammation ensues, and the ligamentous or capsular lesion heals through fibrosis, forming a scar, with the predominant production of type III collagen. Type III collagen contains smaller-diameter fibrils and has fewer crosslinks than type I collagen, which is the predominant collagen type in normal tendons and ligaments. As the lesion matures, both fibril diameter and number of crosslinks increase, in addition to the proportion of type I collagen. This increases the strength of the injury, which can take weeks to months to heal but will ultimately be weaker than normal tissue.[3] Often the affected joint capsule and surrounding ligaments become fibrotic as healing occurs, resulting in decreased range of motion (ROM) in the affected joint. Secondary dystrophic mineralization of the affected soft tissue structures may occur and also adversely affect the joint's mobility.

Luxations of the coxofemoral joint in calves may be associated with calving injuries during dystocia or in cows being ridden while in estrus, or with a traumatic fall in the immediate postpartum period.[3] Shoulder joint luxations are usually the result of trauma.[4]

Clinical Signs and Differential Diagnosis

Clinical signs vary depending on the severity of the sprain, location of injury, and time since the initial injury. The animal may have a history of mild lameness or decreased performance, as well as a history of a positive response to NSAIDs or stall rest. Patients with moderate to severe sprains will typically have a more pronounced, acute lameness or may be non–weight bearing on the affected limb. There may also be localized swelling, heat, increased joint effusion, or pain elicited on palpation or manipulation of the affected joint. Other signs may include abnormal limb positioning, decreased ROM, crepitus, and joint laxity. Injuries may present after an acute or traumatic insult as chronic lameness, or a chronic mild injury can present acutely with severe lameness if the collateral ligament completely ruptures. Chronic injuries are characterized by joint capsule thickening or enthesophyte formation at the origin and insertion of the affected collateral ligament.

Subluxations and luxations result in loss of joint function, loss of structural integrity of the limb, and potentially an acute varus or valgus deformity. Complete luxations in the horse are most common in the pastern, fetlock, and hock joints.[5-8] Luxations can occur in the shoulder,[19] carpus, and coxofemoral joint, but these luxations are less common in horses.[9,10] Coxofemoral luxations are the second most common type of luxation in cattle.[3]

Differential diagnoses vary depending on the region affected and duration of injury but may include soft tissue contusion, synovitis and capsulitis, osteoarthritis, bursitis, musculotendinous injuries, fractures, physeal fractures, septic arthritis, tenosynovitis, and flexural or angular limb deformities.

Diagnostic Tests

A thorough history and physical examination should be performed at presentation. The examination should include assessment of pain, swelling, heat, joint effusion, and joint instability. Patients presenting with only mild lameness should have a thorough lameness examination. Caution should be exercised in regard to perineural anesthesia, especially if there is evidence of joint laxity or instability or severe lameness, as perineural anesthesia could exacerbate the extent of joint damage or result in complete luxation once the affected area is desensitized, resulting in increased weight bearing.

Confirmatory diagnostics include diagnostic imaging to confirm sprain, luxation, or subluxation. The imaging modality of choice will vary greatly depending on species affected, size of animal, location of injury, and physical exam findings. Radiographs should be obtained to assess the joint's bony structures because concurrent fractures are common, with traumatic insults resulting in luxation. Stress views can be performed to assess the level of joint instability (see Fig. 38.19). One study reported on 17 horses with luxation or subluxation of the metacarpophalangeal (MCP) or metatarsophalangeal (MTP) joints.[5] All had rupture of at least one collateral ligament (CL) of the joint. In those horses, radiographs showed that 8 of 17 horses sustained fractures, 6 of which were avulsion fractures located at the origin of the CL. Other types of fractures identified in that study were splint bone fractures and small articular chip fractures. Fractures of the proximal or middle pastern bones can cause luxation or subluxation of the proximal or distal interpastern joint. Nuclear scintigraphy can also be used to evaluate insertional desmopathies that may not be radiographically apparent.

Ultrasonography is very useful in localizing and depicting the severity of ligamentous lesions and for confirming the association of fracture fragments identified radiographically. In acute cases, ultrasound evaluation often shows hemorrhage within the joint capsule (Fig. 38.20). Ultrasonography is often a useful imaging modality to assess the integrity of joints that may not be amenable to radiographs such as the coxofemoral joint, where this modality can be an important component of the diagnosis.[11] Cross-sectional imaging including CT or MRI is useful in the diagnosis of joint integrity, and MRI is the gold standard for imaging and diagnosing ligamentous injuries in large animals.[12,13]

Treatment

Treatment varies widely based on the severity of the injury, location, and associated structures involved. Mild sprains can be treated conservatively with support bandages, NSAIDs, polysulfated GAGs, and rest for 3 to 4 weeks, followed by a controlled exercise program before returning to normal activity. Adjunctive physiotherapies such as hydrotherapy or shock wave treatment may also be considered. Moderate sprains involving significant ligament damage may necessitate use of a

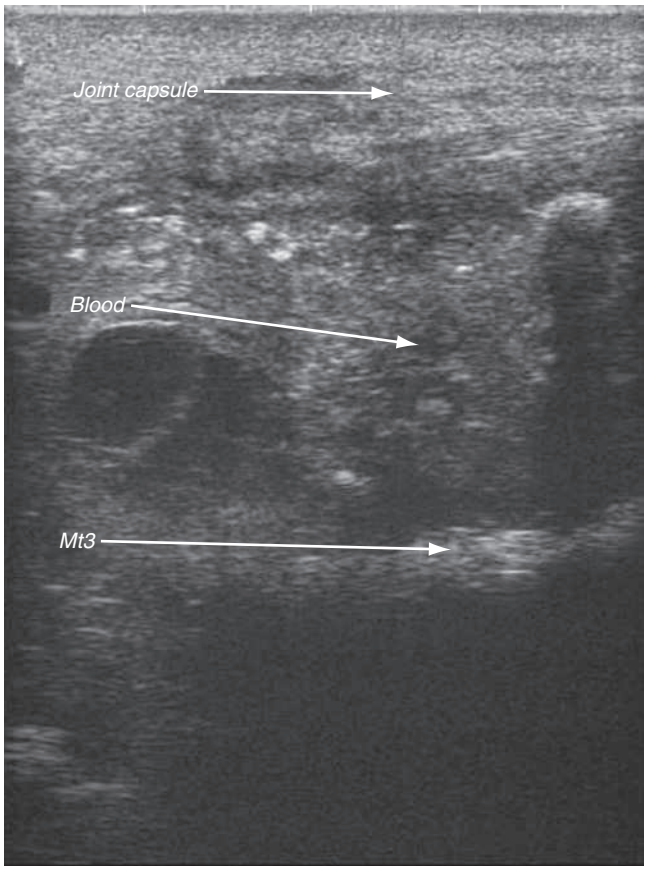

FIG. 38.20 Ultrasound image of a metacarpophalangeal joint from a horse with an acute sprain. Note the hemorrhage accumulation within the joint capsule. *Mt3*, Third metatarsal bone of fetlock joint.

cast or splint to provide joint stability during the initial healing process. Distal limb immobilization with a fiberglass cast and stall confinement was the initial treatment for 10 of 17 horses with MCP or MTP luxation and CL rupture. Duration of cast immobilization ranged from 14 to 132 days (mean = 71 days).[5]

In acute cases, hemorrhage is often present within the affected joint. This hemorrhage usually resolves after 7 to 10 days, but it can also subsequently form a fibrinous clot within the joint capsule, resulting in a chronic, mild synovitis that may necessitate treatment with intraarticular antiinflammatory agents, including sodium hyaluronic acid and triamcinolone.[14,15] Diagnostic arthroscopic surgery should be considered to evaluate articular cartilage integrity and remove persistent fibrin accumulation. If arthroscopic surgery is performed, a cast or splint should be applied to the affected limb during recovery from anesthesia to prevent luxation of the affected joint and further injury. Severe sprains may require some form of internal coaptation (surgical implants) or arthrodesis of the joint, depending on the degree of joint instability. Support of the contralateral limb should be considered for non–weight-bearing injuries.

Luxations of the coxofemoral joint in cattle can be repaired by open or closed techniques, and success depends on duration of the luxation, concurrent fractures or soft tissue injury, and age. Open reduction was reported as being more successful than closed reduction, although closed reduction should be attempted immediately after the injury if possible.[3] In select cases, femoral head otectomy can also be considered.[9,16] Shoulder joint luxations can also be reduced by closed and open techniques, with degree of injury, clinician preference, success of closed approach, and damage to other structures dictating which approach is chosen.[17,18]

Prognosis Prognosis depends on the severity of damage to the intraarticular cartilage and surrounding soft tissue structures. Horses that sustain mild joint or ligamentous strains have a good prognosis for returning to previous athletic use. Horses that sustain moderate or severe sprains or joint luxations usually develop secondary DJD in the affected joint, which may require intraarticular medications and NSAIDs or, in some cases, surgical arthrodesis of the affected joint. The prognosis for survival and returning to athleticism varies widely based on many of these factors. The long-term prognosis for returning to athletic performance may be poor. Eight of 17 horses with MCP or MTP joint trauma resulting in joint instability and rupture of the CL returned to riding, and one returned to jumping activity after limb immobilization and stall confinement.[5]

Arthrogryposis

Philippa Gibbons

Definition Arthrogryposis or multiple congenital contracture can be defined as a syndrome of persistent contracture present at birth.[1] In arthrogryposis, the limb cannot be straightened manually and there is improper articular alignment or rotational deformity.[2] Arthrogryposis is one of the most common congenital defects of cattle and is found more commonly affecting the forelimbs. Arthrogryposis should be differentiated from contractures as a result of congenital tendon contracture or contracture secondary to articular fracture, ankylosis, septic arthritis, agenesis, or dysgenesis of joints.[2]

Etiology There are several etiologies for arthrogryposis, including genetic, infectious, and toxic. A congenital syndrome comprising forelimb arthrogryposis, spinal dysraphism, and cleft palate has been documented in calves of primarily Charolais origin.[3] Arthrogryposis was documented as part of the clinical findings in Holstein calves with the inherited complex vertebral malformation syndrome.[4] Various other congenital syndromes have been reported in cattle, including vertebral agenesis and arthrogryposis of the pelvic limbs in a Holstein heifer calf[5] and arthrogryposis in Herefords.[1] Arthrogryposis multiplex, or "curly calf syndrome," is an autosomal recessive defect in Angus cattle where kyphoscoliosis and decreased muscling are also observed.[6] While not as common as in ruminants, arthrogryposis has been reported in equines, including Norwegian Fjords[7] and a Thoroughbred foal.[8] Arthrogryposis has been documented as an autosomal recessive condition in Suffolk[9] and Corriedale sheep.[10] There are no documented case reports of arthrogryposis in camelids.

Viruses of the family *Bunyaviridae* have a common tropism for fetal tissues and result in abortion, stillbirths, and arthrogryposis.[11] The viruses include Akabane virus, primarily found in Australia, Asia, and the Middle East,[11] and the Cache Valley virus in the United States.[12] Both wild and domesticated ruminants and horses are susceptible to the Akabane and Aino viruses.[11] Concurrent defects include hydranencephaly or microcephaly, cerebellar hypoplasia, and irregular neuromuscular development.[11,13,14] More severe defects are found with infection earlier in gestation.[11,14] In 2011, a syndrome comprising fever, decreased milk yield, diarrhea, and abortion or stillbirth was reported in adult dairy cattle in Northwestern Europe.[15] Abortions, stillbirths, and live births with congenital malformations were reported in calves, lambs, and kids.[16] Congenital defects included arthrogryposis, brachygnathia inferior, spinal curvature, hydrocephalus, hydraencephalus, porencephaly, and cerebellar hypoplasia. The syndrome was found to be caused

by a novel virus of the Simbu serogroup of the genus *Orthobunyavirus* and was named Schmallenberg after the town in Germany where it was first detected.[15] The virus is currently diagnosed by reverse transcription polymerase chain reaction (RT-PCR).[15,17] No vaccine is currently available. In utero infection with bluetongue virus in cattle and sheep primarily presents with hydranencephaly, although arthrogryposis, prognathia, brachygnathia, and excessive gingival tissue has been reported.[18] The pestivirus causing border disease in lambs was shown to result in several congenital abnormalities when experimentally inoculated into pregnant ewes, including arthrogryposis, tremors, brachygnathism, prognathism, and lateral deviation of joints.[19]

Arthrogryposis has been associated with the ingestion of toxic alkaloids during pregnancy, including those of the plant species *Conium*, *Lupinus*, and *Nicotiana*.[20] All three have been shown to also result in cleft palate deformities when fed to goats during days 30 to 60 of gestation.[20] Arthrogryposis as a result of lupine toxicity has been termed "crooked calf disease." Congential contractures have also been reported with the grazing of sorghum pastures by sheep[21] and feeding *Veratrum californicum* at day 29 of gestation in sheep.[22]

Pathogenesis The pathogenesis of arthrogryposis is thought to be a result of denervation resulting in muscle atrophy, with the functional opposing muscles resulting in contracture.[23] Reduced numbers of ventral horn cells have been reported in cases of multiple congenital contracture.[24] Restriction of fetal movement in utero has also been proposed.[24]

Treatment and Prognosis Animals with arthrogryposis may be aborted, stillborn, or born alive. The prognosis for survival, however, is poor. Treatment has been attempted by tenotomy of the ulnaris lateralis and flexor carpi ulnaris followed by stall confinement and bandaging.[25] In that study, a straight palmar carpal angle was achieved at the 8-month follow-up in 70% of the limbs. Outcome was improved in the less severely affected limbs.[25] Arthrogryposis in aborted or near-term fetuses commonly results in dystocia, leading to the need for manual removal of the fetus by fetotomy or cesarian section,[2,14] or in the death of the dam.[11] Severely affected animals commonly have secondary problems, including sepsis and metacarpophalangeal deformities.[25] Surviving animals should not be retained in the herd as breeding animals.

Ankylosis

Ricardo Loinaz

Definition and Etiology Ankylosis refers to the abnormal fusion of bones in a joint, which can occur naturally or as a desired result of treatment. *Facilitated ankylosis* refers to a medical fusion and thus is different from *arthrodesis*, or surgical fusion, of two or more bones into a single structure.[1] Naturally occurring ankylosis is often the result of disease or trauma to the joint and bones involved. Septic arthritis with subsequent DJD and associated prolonged therapy, including joint immobilization, are often the inciting factors for ankylosis. *Congenital ankylosis* is the absence of an articulation, and it is a rare condition in horses and cattle, often associated with other congenital abnormalities.[2] Congenital ankylosis of the DIJ in both hindlimbs, with concurrent dysplasia of the distal sesamoid bone in all four limbs, has been reported in a 2-year-old Arabian horse.[3] In calves and foals, congenital ankylosis may occur between vertebrae or in multiple joints of the limbs, resulting in dystocia related to musculoskeletal inflexibility.[2]

Joint fusion is initiated by biomechanical and biochemical factors, leading to instability and degeneration of cartilage and chondrocytes.[2] Periarticular contracture, joint capsule fibrosis, and chronic muscle spasm all contribute to joint immobility, which leads to synovitis and cartilage destruction. Ossification of periarticular soft tissues develops, resulting in partial bone bridging across the joint. The final stage of ankylosis is complete bone bridging with trabecular bone and joint obliteration.

Common sites of ankylosis in horses include the distal hock joints (distal intertarsal [DIT] and tarsometatarsal [TMT]), the thoracolumbar intervertebral articulations, and the proximal interphalangeal (PIP) joint. These low-motion joints are more likely to achieve complete bone bridging without surgical intervention. In high-motion joints (antebrachiocarpal, midcarpal, metacarpophalangeal, scapulohumeral, and distal interphalangeal), naturally occurring complete bone bridging is rare, and the resulting cartilage degeneration leads to severe lameness. In these cases, surgical fusion or arthrodesis using internal fixation techniques is required if treatment is to be attempted.[4] Large animals with vertebral ankylosis may show neurologic deficits caused by bony impingement on the spinal cord or by dynamic compression leading to abnormal motion or spinal ligament hypertrophy.[2]

Clinical Signs and Differential Diagnosis Indications for ankylosis include stiffness of a joint and associated immobility, degenerative joint changes, decreased range of joint motion, and varying degrees of lameness. Decreased ROM is most obvious if high-motion or multiple joints are involved. Degree of lameness can range from mild to severe, particularly in the acute phase when local inflammation contributes to the degree of lameness. Enlarged and thickened periarticular structures, conformational abnormalities, disuse atrophy of muscles or disuse osteopenia of bones, and gait stiffness may also be identified. Once bone bridging is complete and no articular cartilage remains, the condition is no longer painful, and the articulation is immobile.

Differential diagnoses include soft tissue injuries or contracture, intraarticular or periarticular adhesions, joint luxation, neoplasia, arthrodesis, spondylosis, an intraarticular mass, osteomyelitis, and fracture. Diagnosis of ankylosis should be based on a complete physical and musculoskeletal examination, lameness evaluation, and radiography. Multiple radiographic views should be available for definitive diagnosis, but additional imaging techniques such as ultrasonographic evaluation of relevant soft tissues and joint spaces, CT, and MRI may be useful and provide more detailed information that may influence the treatment option chosen.

Treatment and Prognosis Treatment in the acute phase focuses on providing comfort to the animal, because ankylosis is a chronic and progressive disease process. A complete treatment plan should be tailored to the specific case and is often determined by the presence or absence of infection or severe joint instability. Antiinflammatory medications (phenylbutazone, firocoxib, flunixin meglumine, intraarticular corticosteroids) are necessary in most cases. Additional oral joint supplements, hyaluronic acid, or polysulfated polysaccharides may also be beneficial as chondroprotectants. Although joint immobilization and a decrease in exercise are often necessary, low-level exercise appears to be beneficial in some cases because it helps increase and stimulate development of new bone formation, promoting faster and more complete ankylosis.[2] Unstable joints or actively septic joints, however, require immobilization with splints or casts to allow the fusion to progress and improve the animal's comfort level. Animals that remain lame, have end-stage joint disease, or are not completing ankylosis naturally require surgical or chemical arthrodesis to improve the comfort level and chances of returning to performance activity.

Different methods of facilitated ankylosis can be used to promote joint fusion. The speed at which complete bone

VetBooks.ir

bridging occurs may be enhanced through chemical chondrocyte destruction or surgical obliteration of the articular cartilage. Chemical methods of ankylosis include the use of sodium monoiodoacetate (MIA) and ethyl alcohol, but MIA has been associated with considerable morbidity and signs of severe pain.[1] In addition, postinjection soft tissue swelling, progression of osteoarthritis to adjacent unaffected joints, severe soft tissue necrosis, variable length of convalescence, and inconsistent outcomes are why MIA-mediated ankylosis can no longer be recommended.[5] Ethyl alcohol ankylosis works via nonselective protein denaturation and cell protoplasm precipitation and dehydration. One of the first controlled studies investigating the use of ethyl alcohol in horses found that 70% ethyl alcohol injected in the TMT joint of healthy horses with no radiographic evidence of joint disease resulted in a pain-free fusion by 4 months in 8 of 16 horses and complete fusion by 12 months post injection in 15 of 16 horses.[6] A recent study evaluated the safety and efficacy of ethyl alcohol–mediated ankylosis of the DIT and TMT joints in horses with lameness localized to those joints and found a significant reduction in posttreatment lameness in all treated horses but evidence of joint collapse and progressing ankylosis by 3 months post injection.[1] Another study looked at 24 horses that received ethyl alcohol injections in the distal hock joints; 52% had improved lameness scores at 6- and 9-month follow-up, whereas 19% had deteriorated.[7] A recent study looked at 70% ethyl alcohol injection alone or in combination with lag screw placement for PIP fusion, and in both instances alcohol treatment failed to produce reliable fusion of PIP joints.[8] Another recent study looked at facilitated ankylosis of PIP joints using ethyl alcohol and reported that 50% of horses were sound and 34% were improved but not sound at time of follow-up.[9] The median time for horses to become sound enough to return to work in this study was 8 months, suggesting that ethyl alcohol–facilitated ankylosis may be more effective and work faster in DIT and TMT joints than in PIP joints.

Facilitated ankylosis via surgical débridement of articular cartilage and use of casts or transfixation casts is recommended in the initial treatment of septic PIP joints instead of surgical arthrodesis in the acute phase.[5] Laser-facilitated ankylosis using a neodymium-doped yttrium aluminum garnet (Nd:YAG) or a diode laser to destroy articular cartilage by superheating and vaporizing synovial fluid, resulting in chondrocyte death, can also be used for facilitated ankylosis. Experimental studies using laser-facilitated ankylosis in DIT joints found that partial ankylosis was achieved in 5 to 12 months.[5] Transarticular drilling has been used as a method for ankylosis of the DIT and TMT joints, alone or in combination with laser application, and estimates of outcomes suggest that this technique is 47% to 85% successful.[5]

Ankylosis may require 6 to 12 months for complete bone bridging after surgical or chemical treatment methods. This process can take several years if left to natural ankylosis. Prognosis depends on which joint is involved and the expectations for use of the animal. Low-motion joints have a good prognosis for returning the horse to soundness and athletic performance once the fusion process is completed. High-motion joints have a poor prognosis for return to use in horses.

Osteomyelitis

Canaan Whitfield-Cargile

Definition and Etiology

Osteomyelitis is an inflammatory disease of bone and its marrow cavity characterized by bone destruction and caused by infection.[1] The location of infection along a bone can vary and will depend on the cause of infection. Possible locations of infection include a local infection of a single region of bone such as the physis or a focal infection along the diaphysis or a more generalized infection involving several structures, including marrow, cortex, periosteum, and surrounding soft tissue.[2] If only cortical bone is affected, it is classified as osteitis. Most osteomyelitis cases in large animals are bacterial in origin, although mycotic infections have been reported.[3,4] The origin of infection can be hematogenous spread following bacteremia, especially in neonates, or extension of infection from adjacent soft tissue infection or by direct inoculation often associated with a traumatic event.

Clinical Signs

Clinical signs will depend on location of infection, severity of infection, and in some cases the organism involved. Diagnosis is based on clinical findings and ultimately confirmed with diagnostic imaging with culture and histopathologic evaluation of samples from the affected bone. As stated above, there are some differences in osteomyelitis between neonates and adults. In neonates, osteomyelitis is frequently caused by hematogenous spread due to translocation of bacteria from the umbilicus or other sites of infection (e.g., respiratory, gastrointestinal). In the foal, common anatomic locations of established infections have been described and characterized by a classification system.[5] The classification system is based on anatomic location of the infection; *S-type infections* involve only the synovial membrane, *E-type infections* involve the articular epiphyseal complex, and *P-type infections* are infections of the long bone physis. Clinical signs vary based on location of infection, but typically S-type and E-type infections are associated with lameness and synovial effusion. P-type infections also appear lame, although potentially seem less severe that S-type and E-type infections, and instead of synovial effusion have soft tissue swelling in the area of the affected metaphysis. Irrespective of location of infection, pyrexia often accompanies osseous infection of neonates. Although any structure can be involved, the high-motion joints (i.e., femoropatellar, tarsocrural, carpal, and metacarpophalngeal) are most commonly affected.

Osteomyelitis in adults is usually associated with trauma resulting in direct inoculation of deeper tissues ultimately leading to bone infection.[6] Hematogenous spread, however, does occur, and this is especially true for cases of osteomyelitis involving the axial skeleton.[7] Clearly, clinical signs will depend on site of infection. When limbs are affected, the most common clinical sign is lameness, and the degree of lameness will vary depending on location and severity of infection but is frequently mild initially and then progresses to non–weight-bearing lameness. Other clinical signs of osteomyelitis of adults include regional soft tissue swelling, pain on digital palpation, fever, and draining tracts in the case of traumatic osteomyelitis where the wound has failed to heal.[2] Time of onset of clinical signs from injury (including postoperative surgical site infection) is highly variable and may be present as early as a few days or be delayed up to 3 to 4 weeks.[8] Chronic osteomyelitis becomes more localized as the disease progresses and often results in a firm swelling over the affected area. Persistent drainage from an incision or area of granulation tissue, mild to severe lameness, or a nonhealing wound are also often seen with disease progression in chronic cases. Drainage may be persistent or intermittent and is generally characterized as purulent. Osteomyelitis, in conjunction with septic arthritis or tenosynovitis, may result in only mild lameness if the wound is open and able to decompress but will result in non–weight-bearing lameness if the wound seals due to accumulation of exudate and/or synovial fluid resulting in stretching of the joint capsule and other structures.

Diagnosis

Prognosis rapidly decreases with duration of unmanaged synovial and osseous infections in all animals but especially in neonates, so prompt diagnosis is critical. In neonates, persistent lameness that is unresponsive to antiinflammatory

VetBooks.ir

treatment often precedes diagnosis, but lameness can be subtle during the early stages of osteomyelitis and easily mistaken for traumatic musculoskeletal injury rather than an infectious process. It is recommended that any lameness in a neonate be thoroughly evaluated for evidence of infection, including a complete physical examination, serial radiographic evaluation of any abnormal findings, and potentially more advanced imaging when in doubt. Additional diagnostics, especially in the case of subtle disease, include CBC, fibrinogen, and potentially other acute-phase proteins, although all of these have not been studied extensively in the context of osteomyelitis of neonates.[9] Fibrinogen greater than 900 mg/dL has been shown to be associated with septic physitis and/or osteomyelitis in foals and could help justify more advanced imaging in cases where the diagnosis is difficult. Advanced imaging, including CT and MRI, is increasingly used to diagnose or more accurately characterize the location and severity of osteomyelitis, especially in neonates, as their size greatly enhances the capability of these approaches and the complex nature of osteomyelitis in neonates frequently indicates a more advanced approach.[10,11]

In adults, osteomyelitis is difficult to diagnose with radiography in the acute stages, as radiographically apparent osseous changes will take time to develop. In fact, osteolysis does not appear on radiographs until 30% to 50% of bone mineral is lost, which may take up to 10 to 14 days after infection is established.[12] In early stages of disease, soft tissue swelling with or without gas opacities adjacent to the area of infection may be the only abnormalities noted.[13] In both adults and neonates, ultrasonography can aid in early diagnosis of osteomyelitis by detecting purulent fluid in soft tissues and periosteal involvement and can provide guidance for other confirmatory diagnostic tests, including aspiration of suspect areas for cytology and culture.[14] Radiographic signs of chronic osteomyelitis include soft tissue swelling with bone destruction and new bone formation. Infection of bone may result in the formation of an *osseous sequestrum*, an isolated portion of radiodense cortical bone that has lost local vascular supply (Fig. 38.21). The sequestrum is well defined by an outline of radiopaque productive new bone formation called an *involucrum*, which forms as a result of attempts to wall off infection.[2] An opening to the sequestrum, the *cloaca*, is usually present and allows drainage of purulent exudate to the skin surface. Sequestra are prevalent following trauma to horses, with more than 30% of wounds to the limbs resulting in sequestra formation.[15] The diagnosis of sequestra is usually made radiographically 3 weeks after initial injury and, occasionally, contrast fistulography can be useful in determining the extent of draining tract communication with bone or joints. Advanced imaging modalities provide greater diagnostic capabilities than radiography and may help in the early detection of osteomyelitis.[14] CT gives superior imaging of bone, can be reconstructed in three dimensions, and provides excellent information about the cortical bone and medullary involvement.[1] CT is also indispensable for evaluating anatomic locations where interpretation of other imaging modalities is complicated by superimposition of complex anatomy (Fig. 38.22).

Microbial culture and sensitivity testing should be performed to confirm a diagnosis of osteomyelitis and to guide selection of antimicrobial drugs for treatment. Samples should be collected aseptically and inoculated directly into culture media to improve the chances of obtaining bacterial growth. Swabs taken from an open draining sinus tract may include commensal bacteria that are not responsible for osseous infection. Both aerobic and anaerobic culture testing should be performed on samples when osteomyelitis is suspected. Blood culture may be useful in isolating the infectious organism in the neonate. If there is any suspicion that the osseus infection has spread to synovial structures, appropriate synovial fluid should be collected aseptically and submitted for cytology and culture

FIG. 38.21 Osseous sequestra formation on the dorsolateral aspect of the third metatarsal bone following a laceration to the level of the periosteum 2 weeks previously. Note the new bone formation (involucrum), the isolated portion of cortical bone (sequestrum), and the radiolucent area surrounding the sequestrum (cloaca).

VetBooks.ir

and sensitivity to confirm involvement. The most commonly isolated gram-negative bacteria from foals include *E. coli*, *Actinobacillus* spp., and *Salmonella* spp. Gram-positive isolates include *Streptococcus* spp., *Staphylococcus* spp., and *R. equi*.[16,17] In the adult horse, members of the Enterobacteriaceae family, *Streptococcus* spp., and *S. aureus* are the most commonly isolated microorganisms in cases of osteomyelitis, septic arthritis, and tenosynovitis.[8,18]

Pathophysiology

Development of osteomyelitis is related to host factors (i.e., trauma, immune response, etc.) and microbial factors (i.e., virulence, ability to form biofilm, etc.). In the case of sequestra formation, cortical bone becomes exposed, resulting in desiccation of the periosteum, and this may result in a devitalized portion of cortical bone that, if contaminated, can become infected.[19] The host response to these bacteria involves invasion of inflammatory cells, including neutrophils that release proteolytic enzymes in an attempt to clear the invading pathogen. These enzymes are nonspecific, and thus a portion of the surrounding tissue becomes collateral damage (i.e., the cloaca). If the host is unable to eliminate the infection in a timely manner, the exudate accumulates and bacteria colonize adjacent periosteal, cortical, and medullary regions of bone and form a biofilm. A recent study demonstrated that the majority of equine wounds have evidence of biofilm formation, so this should be considered when electing treatment approaches.[20,21] Within this biofilm, bacterial microcolonies develop and bacteria become quiescent and are able to evade host immune response and medical therapies while continuing to produce matrix material.[22] These defense mechanisms are the principal reason that osteomyelitis persists without aggressive therapy.[23] These issues are compounded when foreign material (i.e., metallic implant) or necrotic tissue (i.e., sequestered bone) exists.

Treatment

Early diagnosis and aggressive therapy are critical in preserving normal function to the limb in neonates affected by osteomyelitis and preventing extension of infection in all animals.[2] Left untreated, irreversible damage to the growth plate or articular cartilage may cause lifelong debilitating lameness in the affected limb in neonates. As noted above, because bacteria can evade host immune response and medical therapies by residing on necrotic tissue or, more commonly, in a biofilm, medical treatment is often unsuccessful once osteomyelitis is established, and surgical intervention is required. The goals of treatment are to physically remove bacteria, inflammatory debris, and devitalized tissue and to prevent recurrence, as physical removal of all bacteria is rarely possible and therefore recolonization occurs quickly without appropriate continued therapy.[24] Long-term medical therapy typically consisting of antibiotics is directed at preventing recurrence, although the length of time to continue and the effectiveness of long-term antibiotics remain questionable in both human and veterinary medicine.[25]

MEDICAL MANAGEMENT. Medical management, including parenteral antimicrobials and topical wound dressings, may reduce drainage and contain infection to a single area but is rarely successful as a single treatment of osseous sequestra or osteomyelitis. Medical therapy primarily consists of antibiotics, and the selection of antibiotics should ideally be based on culture and sensitivity results. If this information is not available, empirical selection of broad-spectrum antibiotics that will have good delivery to the site of infection is indicated although less than ideal.[26] In the neonate, another facet to consider is that osteomyelitis often occurs due to other disease processes, including failure of passive transfer, pneumonia, septicemia, gastroenteritis, colitis, and omphalophlebitis, and thus appropriate diagnosis and management of these comorbidities is a critical component of managing the entire animal when treating osteomyelitis in neonates.

SURGICAL MANAGEMENT. The goal of surgical treatment is to increase efficacy of antimicrobial treatment and host defenses by breaking down the biofilm matrix, removing necrotic debris with infected tissue, promoting vascularization of compromised tissues, and in most cases establishing drainage. For example, in cases of osseous sequestra, sequestrectomy with effective débridement can resolve infection rapidly and decrease the duration of antimicrobial therapy.[19] Successful treatment depends on removing necrotic tissue lining the draining tract, opening the cloaca to access and remove the sequestered piece of bone, and aggressive débridement of all infected bone and exudate. Cancellous bone graft or antibiotic-impregnated beads can be used to fill in large defects following sequestrum removal. For other cases of osteomyelitis, the surgical principles are the same and include the goals of débridement of all infection and necrotic tissues, removal of biofilm, and usually establishment of drainage. The surgical technique for accomplishing these goals will vary depending on the details of each case.

LOCAL DELIVERY OF HIGH CONCENTRATIONS OF ANTIMICROBIALS. When possible, local antibiotic delivery is preferred over systemic therapy, as local delivery techniques allow for much higher concentration of antibiotics at the site of infection while avoiding systemic toxicity. Several local delivery techniques are available, including antibiotic-impregnated beads, regional limb perfusion (RLP) techniques, and constant rate infusion systems for synovial structures, to name a few.

ANTIBIOTIC-IMPREGNATED BEADS. Antibiotic-impregnated beads have been used extensively to treat osteomyelitis in horses and other large animal species.[27-30] This technique has been shown to be beneficial to the treatment of orthopedic infection in both human and veterinary medicine.[31,32] Beads are most commonly made from polymethyl methacrylate (PMMA), which is not biodegradable, or plaster of Paris (POP), which is biodegradable. Although elution characteristics vary based on antibiotic, bead size, bead porosity, and nature of the site of implantation (i.e., highly exudative versus minimal exudate), PMMA elution characteristics are typically described as bimodal with a rapid release in the first 24 hours followed by low-grade, long-term release over weeks to months.[33] POP beads, by contrast, typically have rapid high concentration elution characteristics, and POP inherently possesses osteoconductive properties, making it an attractive choice for osteomyelitis, especially in situations where new beads can be easily added (i.e., open wound).[34] Antibiotic-impregnated beads can be commercially purchased or easily made. Other antibiotic-impreganated substances (i.e., collagen) exist for treating infections, and these have been occasionally used in large animals although not extensively studied.

REGIONAL LIMB PERFUSION. Regional limb perfusion of antimicrobials is an effective way to deliver a high dose of antimicrobials to an isolated area. For RLP to be effective, it is critical to have adequate venous access, appropriate tourniquet application, and adequate patient restraint. The technique involves a tourniquet placed proximal and distal (or proximal only in cases of distal limb infections) to the site of infection in order to isolate the venous system in the region of the infection from systemic circulation. The tourniquet's tightness typically occludes the venous system but only partially occludes the arterial system, resulting in a pressurized venous system that allows for antibiotics injected into this system to diffuse into the surrounding tissues and, in some cases, even poorly perfused tissues.[26] Vascular access can be obtained by placing a needle or catheter into an accessible vein located between the

VetBooks.ir

tourniquets. Alternatively, intraosseous access can be obtained with a cannulated screw or similar device and effective delivery of antibiotic can be obtained with either approach, although there appear to be differences in concentrations achieved when comparing vascular RLP with intraosseous RLP.[35,36] The exact volume of perfusate, type of tourniquet, and duration of tourniquet application is still debated.[37-42] Although many of these details still need to be optimized, a few points have become more clear: (1) volume of perfusate—it seems clear that higher volumes (60 to 100 mL) result in greater diffusion of antibiotics to the tissues, (2) antibiotic choice—although much work remains here, aminoglycosides are well studied and readily available, and their concentration-dependent action makes this class an excellent choice for RLP, (3) exangunation seems unnecessary, (4) timing of tourniquet application—greater than 20 to 30 minutes is difficult to achieve due to patient factors, and it seems there is minimal difference after 15 minutes, and (5) many other details are debatable and require more work to identify the correct decision.[39,43,44] In summary, RLP is an excellent choice for local delivery of antibiotics and should be considered when treating osteomyelitis in large animals.

Prognosis The prognosis of osteomyelitis in large animals depends on location of infection, severity of infection, synovial involvement, presence of orthopedic implant, and presence of other comorbidities, especially in neonates. Reports describing survival of adult horses with osteomyelitis vary from 10% to 100% based on many of these factors.[6,45] Similarly, reports describing survival and return to function of neonates with osteomyelitis also vary widely.[16,46] It is clear that with a prompt diagnosis, consideration of comorbidities, evaluation and management of synovial structures, initiation of appropriate therapy including removal of necrotic and infected tissue, biofilm removal and management, and appropriate use of antimicrobials with an emphasis placed on local delivery techniques, success can be achieved in many cases.

Heel and Foot Pain

Sarah N. Sampson

Introduction Lameness associated with the foot is the most common cause of lameness in any type of horse. Predominantly this is lameness affecting the front feet, but there are also a number of horses with hind foot lameness that blocks to the heel and foot. In this section, heel and foot pain is used due to our inability to specifically localize foot pain to the navicular region with any diagnostic block other than a navicular bursa (NBSA) block. Historically, lameness that blocks to a palmar or plantar digital nerve (PDN) block (aka "heel block") was called navicular disease. However, this term was changed to navicular syndrome once it was realized that the navicular bone is only one of many structures affected in horses that blocked to a PDN block. These navicular syndrome horses are now referred to as "heel pain" or "foot pain" horses, because we realize that a PDN block is not just blocking the navicular region. In 1996, when we started evaluating the feet of live horses with MRI, it became evident that the PDN block was actually resulting in anesthesia of many structures in the foot other than those in the navicular region. It is important to realize that in this section on heel and foot pain, all of the structures listed below can be anesthetized with a PDN block due to proximal diffusion of the block and the variable range of anesthesia achieved with this block. Depending on diffusion, it is also possible in some instances to block structures in the fetlock region.

1. Distal aspect of first phalanx
2. Middle phalanx
3. Distal phalanx
4. Collateral cartilages
5. Navicular bone (distal sesamoid bone)
6. Oblique and straight distal sesamoidean ligaments
7. Proximal and distal digital annular ligaments
8. Deep digital flexor tendon
9. Superficial digital flexor tendon branches
10. Collateral sesamoidean ligament (aka navicular suspensory ligament)
11. Distal sesamoidean impar ligament
12. Collateral ligaments (proximal and distal interphalangeal joints)
13. Proximal interphalangeal joint
14. Distal interphalangeal joint
15. Navicular bursa
16. Digital flexor tendon sheath
17. Laminar tissue

Pathophysiology The ability to use MRI on live horses has enabled us to obtain a definitive diagnosis in horses with heel and foot pain. Due to the number of different clinical presentations as well as the number of structures that may or may not be affected, the etiology of pathologic change in the heel and foot can vary widely. For example, if a horse has unilateral deep digital flexor tendon (DDFT) pathology in the heel and no other structures are affected, this is likely a traumatic injury. Conversely, if a horse has bilateral DDFT pathology with concurrent navicular bone (NB) pathology and distal sesamoidean impar ligament (DSIL) and collateral sesamoidean ligament (CSL) desmopathy, this is more likely to be a degenerative process with a possible genetic predisposition (Quarter Horses, warmbloods, and Thoroughbreds are overrepresented and Arabians are underrepresented in horses presenting with heel and foot pain).

The exact etiology of NB pathology remains unclear, but a biomechanical theory has the most experimental support at this time and suggests that the degenerative changes in the NB result from abnormal forces exerted on the bone and its supporting ligaments (the DSIL and CSL). The podotrochlear apparatus (NB, CSL, DSIL, NBSA) and the DDFT and distal digital annular ligament (DDAL) are intimately related in the heel region from a biomechanical perspective, and these structures are often affected concurrently. Compression of the distal half of the NB by the DDFT is an important aspect of this theory. The greatest forces to the NB are applied during the propulsion phase of the stride, during extension of the distal interphalangeal joint (DIJ) just prior to toe off. The DDFT, CSL, and DSIL act to stabilize the DIJ as they are put under tension during the propulsion phase. The biomechanical force applied to the NB depends on hoof conformation and is increased in horses with low heels and decreased in horses with more substantial heels. There are also cases in which unilateral NB pathology can be due to a traumatic event, although this is much less common. There are also a number of very young Quarter Horses (<5 years) that have been diagnosed with severe bilateral navicular region pathology, often including NB flexor cortical erosions. These horses have often not been in any significant work, and the severity of disease cannot be explained easily using the biomechanical theory. These horses may have an even higher genetic predisposition than the Quarter Horses that develop navicular region pathology in the 10- to 12-year-old range when they have been in high-level performance for many years.

History Quarter Horses, warmbloods, and Thoroughbreds are the most common breeds affected with lameness localized to the foot with a PDN block, so signalment in regards to breed can be an important finding.[1] Most commonly, horses present with heel and foot pain between 8 and 12 years of

VetBooks.ir

age,[1] but they can present at any age after 2 years. Heel and foot pain can present as an insidious onset of unilateral or bilateral lameness or as an acute unilateral lameness.

Horses with an insidious onset of lameness present with poor performance complaints and/or complaints of intermittent forelimb lameness. Often these horses will have had one or more episodes of acute, obvious lameness that then improves quickly, and they are able to continue in performance for a limited period. Sometimes these horses are thought to have a foot abscess, but no drainage is seen and the horse improves temporarily. Horses with heel and foot pain may become more lame toward the end of the trimming and shoeing cycle and/or may be "tenderfooted" right after trimming and shoeing. Owners may also complain of stumbling, stiffness in the front end, pointing one front foot, and/or a shortened, choppy stride. A common history is that the horse was out of work and confined to a stall for some other reason and then was observed to be lame on one or both forelimbs on resumption of work.

Acute injuries in the heel and foot can present with a history of acute lameness during an event or when brought out of the stall or pasture. They may have improved partially with rest or not improved at all. However, with any riding or exercise, the lameness typically worsens again. As noted previously, owners may think the horse has a foot abscess and manage it accordingly until it becomes evident that the horse is not improving or the lameness continues to recur. With bilaterally lame horses, owners often think shoulder lameness exists because the horses move very stiffly. Also, horses with severe pathology can present similarly to a laminitic horse with slightly elevated pulses and a "walking on eggshells" look. It is important to perform a complete radiographic evaluation that includes a navicular skyline view, particularly if the horses are not sensitive over the toe to hoof testers.

Diagnosis

CLINICAL EVALUATION. Clinical evaluation of any horse presenting for lameness begins with a thorough physical examination. The physical exam will often be normal in these horses, but some horses may have slightly increased digital pulses on the affected limbs and some horses may have palpable DIJ effusion on the affected limbs. Horses with DDFT and/or DDAL pathology in the pastern region may have thickening palpable in the palmar or plantar pastern. Abnormalities in hoof conformation are noted in many horses, but there is no correlation between the types of pathology seen within the foot and types of hoof abnormalities involving the internal structures of the foot. Horses with perfect feet can have the same pathology as horses with poorly conformed feet.

Hoof tester evaluation can be done either before or after the motion exam. Heel and foot pain horses may be negative to hoof testers, or they may have sensitivity in any area of the foot, although most commonly over the mid-frog region and heels. Hoof tester evaluation is a standard part of the lameness exam, but it does not correlate well with the type of pathology present in the foot and it is very important to remember that a negative hoof tester exam does not rule out foot pain. The hardness of the hooves, the thickness of the sole, and whether the horse is stoic can all influence whether the horse will respond to hoof tester pressure applied to the foot. Based on a group of bilateral forelimb lame horses that blocked to a PDN block, no correlation between hoof tester evaluation and MRI findings in the foot was found.[1]

LAMENESS EVALUATION. The lameness evaluation should be performed on smooth, hard ground. More severely affected horses can be lame at a walk (mildly lame to severely lame, depending on the pathology present). However, most horses with heel and foot pain will be sound at a walk and have mild to moderate lameness at a trot in a straight line. Horses that have a very symmetric, bilateral lameness may not look lame at a trot in a straight line but will be "choppy" or short strided.

Circling these horses with the lame limb on the inside of the circle will commonly exacerbate the lameness when compared to movement in a straight line. Circling these horses with the lame limb on the outside of the circle may reveal lameness in the limb that is now on the inside of the circle. For example, a horse that is right front lame in a straight line may have an exacerbated right front lameness when circling to the right but then show a left front lameness when circling to the left. If a horse is unilaterally lame, it may show the same unilateral lameness in all directions.

Flexion tests performed on horses with heel and foot pain will often be positive to lower limb flexion. Occasionally the limb contralateral to the one being flexed will show increased lameness after flexion.

DIAGNOSTIC ANESTHESIA. Localizing pain to the heel, foot, or pastern is commonly done with a palmar digital nerve block (1.5 to 2.0 mL/nerve). However, determining which structures are the source of pain can be challenging. It seems that the more we learn about diagnostic anesthesia, the more clouded the picture becomes. We used to believe that a PDN block localized the lameness to the heel or sole region, but this is not the case. Structures associated with the coffin joint, hoof wall, and pastern can also be desensitized with this block, depending on the amount of anesthetic diffusion that occurs.

The location of the lameness in the foot or pastern can be further defined using a DIJ (coffin joint) block, NBSA block, and/or digital flexor tendon sheath (DFTS) block in the lameness workup. When using these blocks, it is important to realize that a DIJ block can anesthetize the navicular region and a DFTS block can anesthetize some DDFT lesions within the proximal aspect of the foot. The NBSA block is the most specific block for navicular area pain, but it is also the most time consuming, so it is often not performed in a typical lameness evaluation. A positive response to NBSA block most likely reflects pathology in the navicular bursa, navicular bone, or supporting ligamentous or tendinous structures. Once the lameness has been localized to the pastern or foot region, diagnostic imaging is performed to attempt to identify the definitive cause of lameness.

Diagnostic Imaging

RADIOGRAPHY. A minimum of three high-detail radiographic views should be used to evaluate the foot (lateromedial, 60-degree dorsoproximal-palmaro/plantarodistal oblique, and palmaro/plantaroproximal-palmaro/plantarodistal oblique [navicular skyline]), with additional views including a horizontal dorsopalmar view and a dorsomedial and dorsolateral 45-degree oblique view of the navicular bone and distal phalanx palmar processes. Examples of abnormal radiographic changes in the navicular bone include variation in size and shape of the synovial invaginations, cystic changes within the medullary cavity, enthesophyte formation at the wings, flexor cortical erosion, loss of corticomedullary distinction, sagittal fracture, distal border remodeling, and proximal and distal border fragments. Horses that block to a PDN block may have pathology in other bones in the pastern or foot. Examples of pathology seen in the distal phalanx include fracture, pressure necrosis from a keratoma, osteolysis, bone cyst, osteochondral fragment, and osteoarthritis associated with the DIJ. Pathologic changes can also be seen in the proximal and middle phalanges that can potentially block to a PDN block and can include bone cyst, osteoarthritis of the proximal interphalangeal (PIP) joint, and osteochondral fragments. Ossification of the collateral cartilages of the distal phalanx is common and can be associated with lameness, particularly if there is a fracture at the base of

the ossified collateral cartilage. Mineralization of the soft tissue structures within the foot or pastern may also be identified and is most commonly seen associated with the DDFT just proximal to the navicular bone.

Previous studies have shown that variations in synovial invagination size and shape correlate poorly with lameness, rarely progress over time, and are inconclusive for the diagnosis of navicular bone degeneration. Radiographic abnormalities more strongly associated with lameness and relevant navicular bone degeneration include flexor cortical erosion (Fig. 38.23) and loss of the corticomedullary junction (e.g., medullary sclerosis) (Fig. 38.24). Navicular bone distal border fragments are more common, and the flexor cortex is thicker in horses with navicular pathology.[2] Although radiographic evaluation

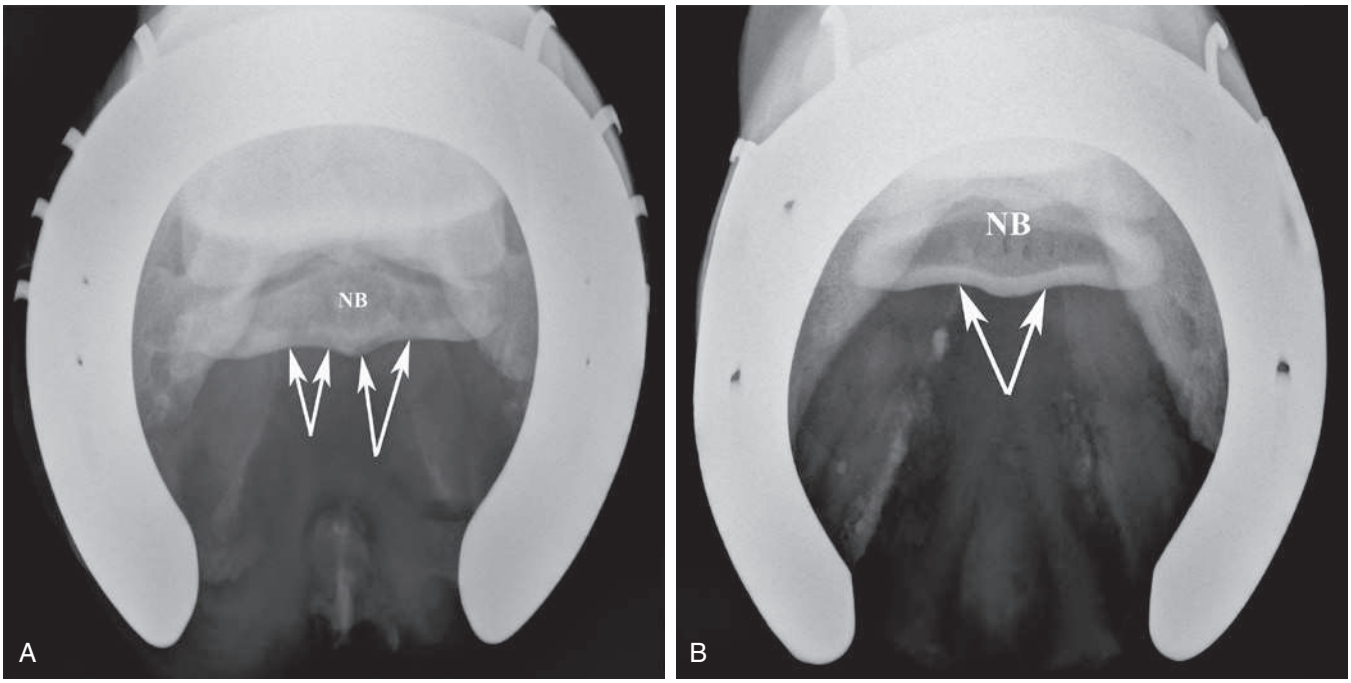

FIG. 38.23 Navicular skyline radiographic projections highlighting the flexor cortex and medullary cavity of the navicular bone *(NB)*. **A,** Arrows point to two flexor cortical erosions on the flexor cortex of the NB, which is indicative of severe NB degeneration. **B,** Arrows point to a normal flexor cortex of the NB.

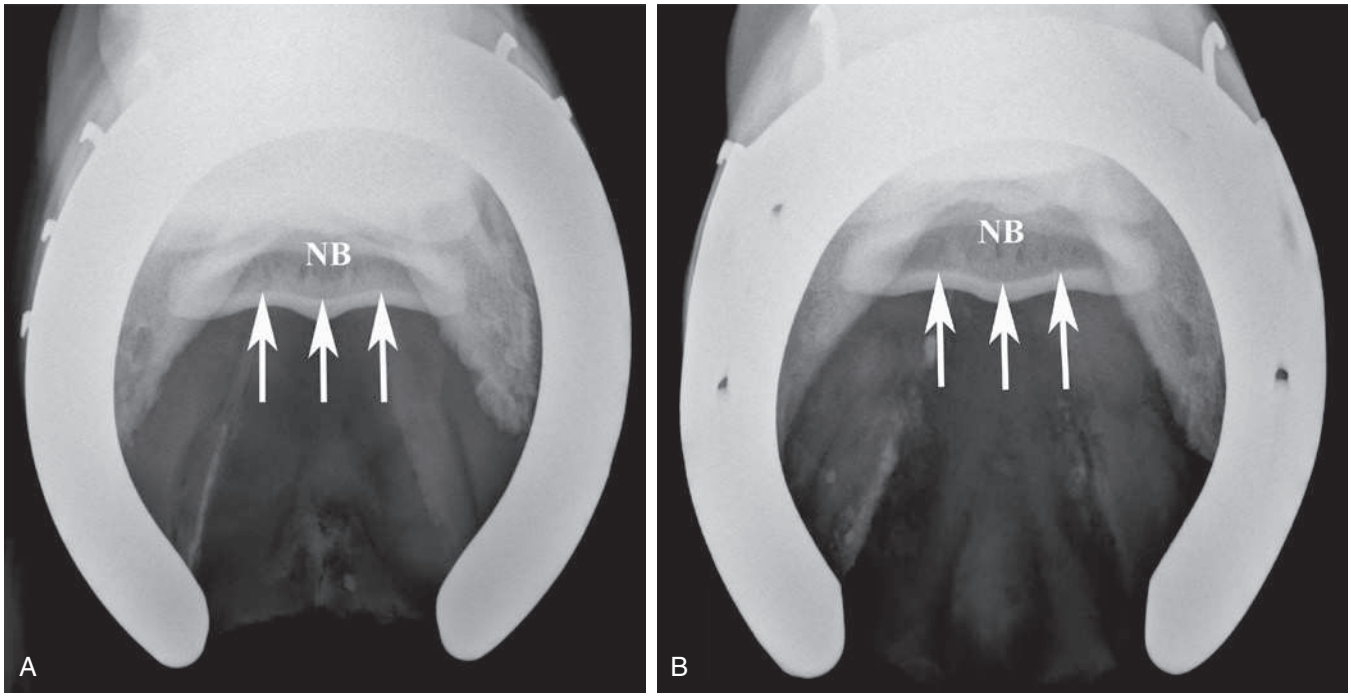

FIG. 38.24 Navicular skyline radiographic projections highlighting the flexor cortex and medullary cavity of the navicular bone *(NB)*. **A,** Arrows point to the corticomedullary junction where there is loss of distinction between the flexor cortex and the medullary cavity. This is indicative of NB degeneration. **B,** Arrows point to a very distinct corticomedullary junction in a normal horse.

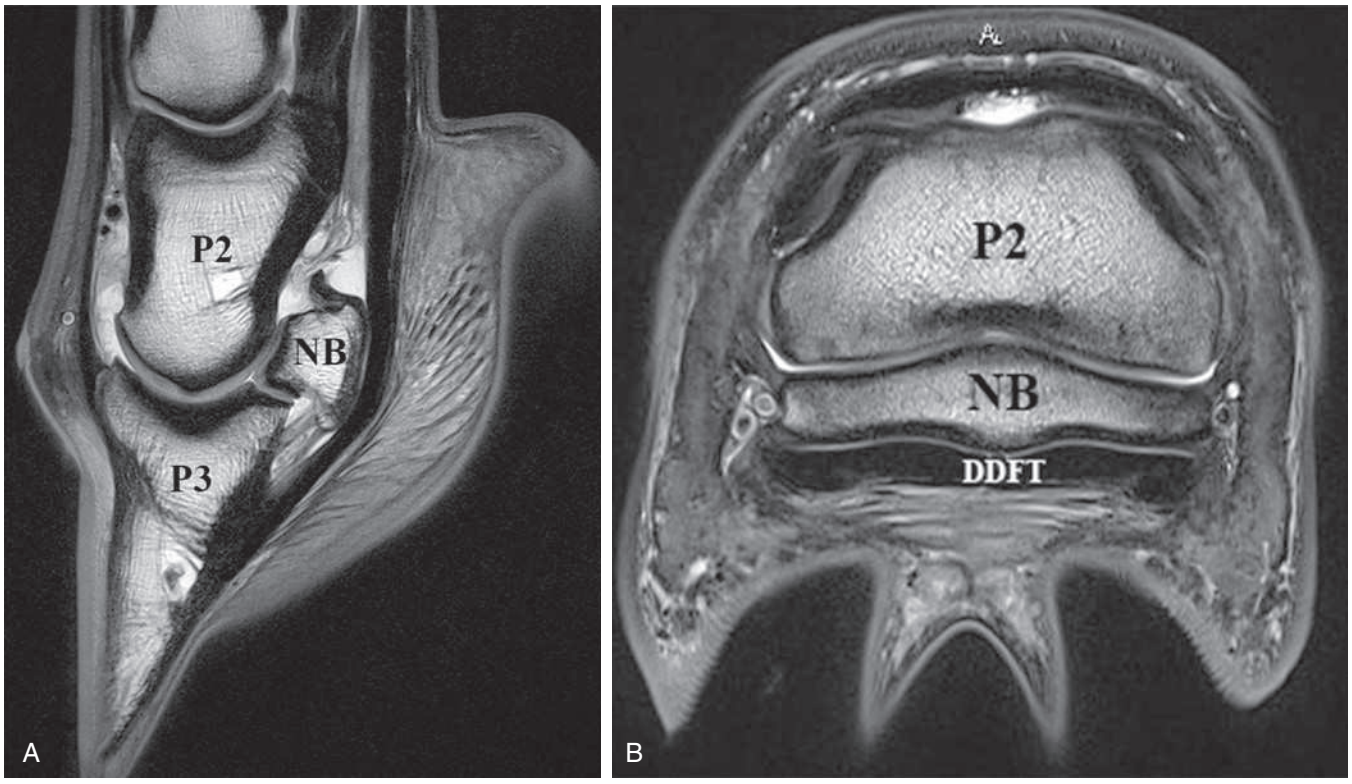

FIG. 38.25 Magnetic resonance images of the foot of a horse. **A,** Sagittal midline image of the foot. **B,** Transverse image of the foot at the level of the navicular bone *(NB)*. *DDFT*, Deep digital flexor tendon; *P2*, middle phalanx; *P3*, distal phalanx.

is important in the diagnostic workup of a horse showing heel and foot pain, it is not always very sensitive in defining the actual pathologic condition of the NB. Radiographs often underestimate the extent of pathology seen on necropsy in horses with navicular lesions, and many horses with lameness localized to the foot have normal radiographs even though they have multiple bone and soft tissue lesions on MRI.[1]

ULTRASONOGRAPHY. Ultrasonography can be used to assess the structures of the pastern circumferentially, which includes the DDFT, superficial digital flexor tendon (SDFT), distal sesamoidean ligaments, proximal digital annular ligament, proximal aspect of the DDAL, proximal aspect of the DIJ collateral ligaments, collateral ligaments of the PIP joint, and periphery of the first and second phalanges.

Within the foot, ultrasonography can variably identify effusion of the NBSA, the CSL, and the proximal margin of the NB when imaged through the heel bulbs. This is very dependent on the heel conformation of the horse and access to a microconvex probe that can fit in between the heel bulbs of the horse. If the frog is pared down and the foot is soaked in water for 24 hours, a thin window on midline that is imaged through the frog can be assessed using ultrasound. If the frog is excessively hard or has a deep sulcus, poor contact between the frog and transducer may prevent propagation of the ultrasound beam.[3] Unfortunately, the images obtained through the frog are difficult to interpret, and ultrasonographic findings do not correlate well with pathologic findings on MRI. The structures partially visible in this transcuneal ultrasound window include the axial aspect of the navicular bone flexor surface, distal portion of DDFT, DSIL, and palmar aspect of the distal phalanx.[3]

MAGNETIC RESONANCE IMAGING. Magnetic resonance imaging is the gold standard in orthopedic imaging evaluation. This modality can assess both the bone and soft tissue structures of the distal limb (Fig. 38.25). It uses hydrogen protons in the body that align with the external magnetic field to assess tissue at a molecular level. Perturbation of the hydrogen atoms within the body using a radiofrequency pulse results in a grayscale image of the anatomic area imaged. Pathologic change that is not visible with ultrasonography or radiography can be identified with MRI. In regard to the foot of the horse, MRI provides a look at the internal structures of the foot that is not possible with other imaging modalities. It is used for horses with heel and foot pain when a diagnosis cannot be made with radiographs or ultrasound or when nuclear scintigraphy localizes pathology to the foot. However, many owners also request MRI in order to more fully evaluate the foot or pastern (1) to determine if there are more than one issues, (2) to further define the severity of a previously diagnosed lesion, or (3) as a component of a prepurchase evaluation. For a definitive diagnosis in a horse with heel and foot pain that has an unremarkable radiograph and ultrasound evaluation, an MRI is the next diagnostic step.

Horses can be imaged in either high- or low-field-strength magnets. The higher the field strength (T; Tesla), the better the image resolution and the faster the image acquisition. All high-field magnets (≥1 T) require general anesthesia so that the horse's limbs can be placed in the bore of the magnet. Low-field magnets (≤0.3 T) can be either "standing" magnets, where the horse is sedated but standing during imaging, or magnets that require the horse to be anesthetized for the images to be acquired. The low-field, standing magnets produce the lowest-quality and lowest-resolution images due to the inherent movement of a standing horse. Motion correction software is used to decrease the image degradation, but it is not enough to make the image as clear as those obtained from a horse that is anesthetized for image acquisition. High-field-strength magnets have better-quality and better-resolution images, which is directly related to the field strength of the machine. High-field magnets are also much more costly to purchase, but the

cost to the client to image a horse is often similar between high- and low-field magnets.

NUCLEAR SCINTIGRAPHY. Nuclear scintigraphy in the horse involves intravenous injection with a radiopharmaceutical that is labelled to phosphorous and concentrates in areas of high bone turnover. This radiopharmaceutical emits gamma rays that are captured by a gamma camera during the procedure. In regard to the foot, if the navicular bone is undergoing active bone remodeling, the radiopharmaceutical will be concentrated in the navicular bone, and this will be evident on the images obtained. Increased radiopharmaceutical uptake in the foot is a good predictor of pathology, but a negative scintigraphic result does not exclude the presence of significant pathology.[4,5] Nuclear scintigraphy has been shown to have a high specificity but low sensitivity for detection of lesions of the NB, DDFT, and collateral ligaments of the DIJ when compared to MRI.[4,5] Nuclear scintigraphy can help determine the significance of pathology found with MRI, particularly if more than one structure is affected and the clinical relevance of a specific lesion is questioned.

COMPUTED TOMOGRAPHY. Computed tomography units used for horses typically involve general anesthesia, but a small number of units that can image the standing horse are being used now.

CT is used much less commonly than MRI for evaluation of the foot of the horse. It is excellent for detecting and evaluating bone pathology in the cortex or trabecula (fractures, sclerosis, peripheral remodeling), but it provides inadequate soft tissue detail when compared to MRI. It is based on density of tissue, similar to radiographs, and can show excellent peripheral bone detail, particularly for bone fragmentation, that is better than MRI, but MRI shows better internal detail of bone overall. Although less expensive than MRI, CT is less versatile and is most commonly used to assess fracture configuration or peripheral lesions of bone. CT is also used to guide some orthopedic injections and some complicated surgical procedures.

Treatment

There are numerous treatment options for horses with heel and foot pain. However, unfortunately many treatment options are only palliative, not curative. Horses with pain localized to the foot but without a definitive diagnosis will be treated based on the veterinarian's clinical evaluation and best guess as to the cause of the lameness. This decision will also take into consideration the use of the horse, the financial constraints of the owner, and any other concerns or constraints based on the individual horse-owner pair. When a definitive diagnosis is available, treatment is tailored to the structures affected, with the hope that by treating the specific cause of lameness, the prognosis for return to performance will be increased.

Medical Management

REST AND REHABILITATION. Injuries to the pastern or foot region that will most likely involve a rest and rehabilitation program include, but are not limited to, fracture, acute tendon injury, acute ligament injury, bone bruise ("edema"), and acute laminar inflammation. Depending on the structure affected and the severity of the lesion, the rest period could last from 3 to 12 months, and this is why a specific diagnosis is so important. Typically these types of lesions do not resolve with "pasture" rest, and stall or small paddock confinement is needed at the beginning of the rest and rehabilitation program. Conversely, standing a horse in a stall for 6 months is also not a reasonable rehabilitation program. When horses are rehabilitated after an injury, they should be in a controlled environment that limits their free exercise (typically a stall initially, then a small paddock, and then a larger paddock). During this confinement, it is important that the force the horses put on their limbs slowly increases in a controlled manner. A gradual increase in workload is done using hand walking, jogging in hand, and in some horses, using specific types of rehabilitation equipment based on the particular injury.

A recent study looking at 118 cases of primary DDFT injury in the pastern or foot region found that prognosis for return to use depended on injury severity, presence of concurrent injury to other structures in the foot, type of activity, and owner compliance with specific treatment recommendations.[6] Specifically, horses treated with intrasynovial corticosteroid injections and 6 months of rest and rehabilitation returned to use for a significantly longer duration than did horses treated without a rest period.[6] Also, Western performance horses returned to use for a significantly longer duration than English performance horses.[6]

FARRIERY. Therapeutic trimming and shoeing to reduce biomechanical forces on the heel region is a very important part of treatment for horses with foot and heel pain. Most often, horses will improve somewhat after corrective shoeing if they are not already shod appropriately, but they still require additional treatment to get them back in performance. The goals are to (1) restore hoof balance, (2) improve existing problems such as underrun heels, (3) reduce biomechanical forces on the heel region, and (4) protect injured areas of the foot. Although there is no standard shoeing technique for horses with heel pain, observing abnormalities in the hoof and lower limb and following basic principles can often accomplish these four goals. Proper trimming alone may restore correct hoof balance such that special shoes or pads are unnecessary. Even with proper trimming, however, many horses still require special shoes or pads to achieve the desired breakover and heel support, as well as offer protection to the bottom of the foot. The veterinarian, farrier, and owner must work together and consider the horse's hoof shape and hoof wall quality, environment, conformation, use, and severity of disease.

The configuration of the hoof capsule reflects the stresses applied to the foot during the previous year. *Hoof balance* refers to both mediolateral and dorsopalmar balance. *Dorsopalmar balance* refers to proper hoof-pastern alignment. Ideally, when viewed from the side, a line drawn through the central aspect of the first phalanx should bisect the hoof capsule, and the toe angle and heel angle should be parallel to this line. A broken back hoof-pastern axis is common in horses with long toe–low heel conformation and results in increased stress on the phalangeal joint capsules, navicular suspensory apparatus, and distal DDFT and increased pressure between the NB and DDFT.

Breakover (breakover point) of the foot is the terminal part of locomotion when the heel loses contact with the ground surface, followed by the toe. Breakover point on the bottom of the foot can be determined by finding the last point of contact of the foot or shoe with the ground near the front of the foot. A low heel angle and/or a long toe is associated with prolongation of breakover time. A high heel angle reduces breakover, causing a reduction in the forces exerted on the palmar and plantar structures of the foot and limb (e.g., navicular suspensory apparatus, DDFT).

Corrective trimming is often more important but can be more difficult than corrective shoeing. The toe is shortened as much as possible, and the heels are trimmed back to the widest aspect of the frog. Proper heel trimming (back to the widest aspect of the frog) increases the functional weight-bearing surface of the foot. The ground surface of the properly trimmed foot has a more rounded appearance. Palmar and plantar hoof support is essential for horses with heel pain. Full-fitting shoes provide more support by increasing the weight-bearing surface. Using a wedged shoe or pad to elevate the heels by 2 to 3 degrees after the foot is properly trimmed has been shown to

VetBooks.ir

VetBooks.ir

decrease tension in the DDFT, reducing pressure applied to the heel region. However, each horse is an individual, and the shoeing should be tailored to each horse and adjusted, if needed, at each shoeing cycle.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS (NSAIDS). Phenylbutazone is the most common NSAID used to decrease the pain associated with lameness in the foot region. It reduces pain by inhibiting the enzyme cyclooxygenase and the subsequent cascade of prostaglandins. The recommended dosage depends on individual horse needs and severity of disease. An initial dosage of 4.4 mg/kg daily as needed for lameness can be used. Often this is used in the first 1 to 2 weeks following joint injections or shoeing changes. Many horses will require additional treatment during competition if medication rules allow and the lameness is not fully resolved with other medical treatments. Horses that are retired due to lameness that is performance limiting can be treated with low to moderate dose (2.2 to 4.4 mg/kg) phenylbutazone as needed to help with chronic pain.

ISOXSUPRINE HYDROCHLORIDE. Isoxsuprine hydrochloride is a drug that causes vascular smooth muscle relaxation and may increase blood flow to the foot. Its absorption after oral (PO) administration in the horse is erratic, and its usefulness is questioned. The recommended dose of isoxsuprine is 0.6 mg/kg PO twice daily for 3 weeks; if no response is seen, the dose is increased to 1.2 mg/kg PO twice daily for 3 weeks, then once daily for 3 weeks, then every other day for an additional 3 weeks. No adverse drug reactions have been reported. At this time, isoxsuprine is not commonly used in the treatment of heel and foot pain due to the lack of evidence of efficacy.

INTRAARTICULAR MEDICATIONS. There are three synovial structures associated with the foot that can be accessed and used as a route for intraarticular medication: distal interphalangeal joint, navicular busa, and digital flexor tendon sheath (Fig. 38.26).

The *distal interphalangeal joint* can be medicated when there is pathology associated with the joint itself or its associated collateral ligaments. However, the DIJ also covers the dorsal surface of the CSL and DSIL, as well as the proximal, dorsal, and distal aspects of the NB where the synovial invaginations of the NB are actually contiguous with the DIJ.[7] Furthermore, triamcinolone acetonide that is injected into the DIJ in normal horses has been shown to diffuse into the NBSA in all instances.[8] Due to the broad coverage by the DIJ, this is often the first synovial structure medicated in horses when they are diagnosed with foot pain but do not have a definitive diagnosis. Since the DIJ is a high-motion joint, most veterinarians are injecting triamcinolone acetonide and hyaluronic acid into this synovial structure when treating horses with heel and foot pain.

The *navicular bursa* is medicated when (1) DIJ injections fail to improve the horse for a reasonable period of time, (2) there is pathology associated with the flexor cortex of the NB, (3) there is navicular bursitis, or (4) dorsal DDFT pathology is known or suspected. Navicular bursa injection should be done with radiographic guidance, and therefore this is a slightly more involved procedure than DIJ injection, it takes longer to perform, and it is typically more expensive. The navicular bursa contains fibrocartilage on the back of the NB, but no hyaline cartilage is present, thus practitioners will use either triamcinolone acetonide or methylprednisolone acetate in combination with hyaluronic acid when injecting the navicular bursa.

The *digital flexor tendon sheath* is medicated when pathology within it or in association with the sheath is known or suspected. Examples of pathology within the pastern or foot that may respond to DFTS injection include DDFT pathology within the sheath, SDFT branch tendinopathy, DDAL desmopathy,[9] and oblique and straight distal sesamoidean desmopathy.[10] Practitioners will most commonly use either triamcinolone acetonide or methylprednisolone acetate in combination with hyaluronic acid when injecting the DFTS.

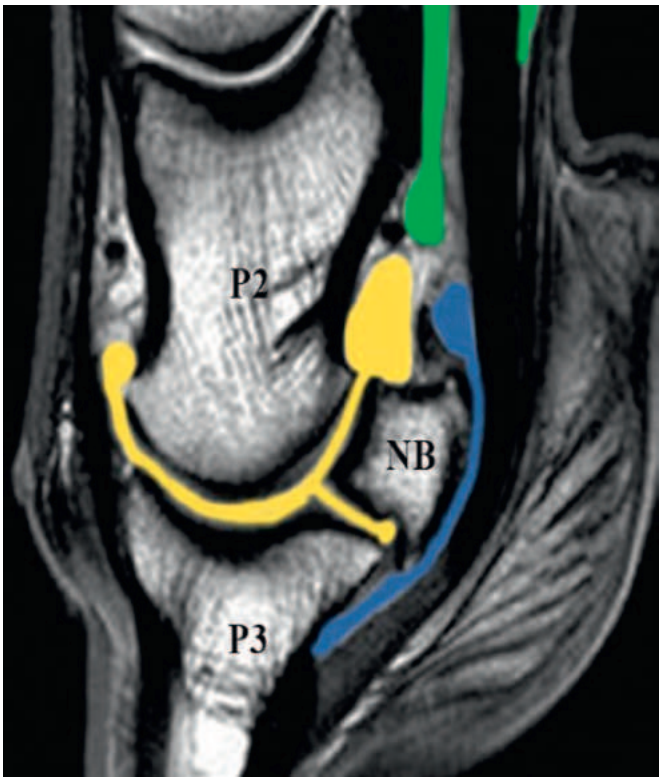

FIG. 38.26 Sagittal midline magnetic resonance image highlighting the boundaries of the distal interphalangeal joint *(yellow)*, navicular bursa *(blue)*, and digital flexor tendon sheath *(green)*. Dorsal is to the left. *NB*, Navicular bone; *P2*, middle phalanx; *P3*, distal phalanx.

A recent study evaluated 101 horses with clinical signs of heel pain that underwent MRI evaluation and had the NBSA medicated based on MRI findings associated with that region.[11] Seventy-six of 101 (75%) horses returned to their intended use for a mean of 9.6 months. Horses that had been lame for less than 6 months had a significantly better chance of returning to intended use than horses that had been lame more than 6 months.[11] Horses with primary DDFT pathology that had NBSA injections and were put through a 6-month rest and rehabilitation program responded for the longest period. If the DDFT pathology extended into the area of the DFTS, this synovial structure was also medicated. Horses with scar tissue and adhesions between the DDFT and CSL or horses with adhesions between the NB and DDFT were treated with pressurization of the NBSA with 30 to 50 mg of hyaluronic acid in an attempt to break down adhesions, but these horses were less likely to have a positive response to therapy.[11] Horses with multiple structures affected in the heel region were also less likely to respond well to treatment.[11]

HYALURONAN. Hyaluronan (HA) is a normal component of synovial fluid and functions as a boundary lubricant within the joint. It also appears to have some antiinflammatory properties, but the exact mechanism is unknown. Exogenous HA inhibits chemotaxis and phagocytosis of granulocytes, reduces the stimulation of lymphocytes, and has been shown to decrease prostaglandin E2 synthesis by cultured equine synoviocytes if given intraarticularly but not systemically.[12] The antiinflammatory properties of HA appear to be dose

VetBooks.ir

dependent, and HA with a molecular weight greater than 500,000 Daltons may be more effective. The effect of systemic HA on pathology within the pastern or foot region is unknown. The recommended dose is 40 mg intravenously once weekly for 3 weeks, then once monthly for maintenance, but there is not substantial research in the literature at this time regarding HA administration systemically.

POLYSULFATED GLYCOSAMINOGLYCANS. Polysulfated glycosaminoglycans (PSGAGs) are referred to as *chondroprotective agents* and have antiinflammatory properties. They decrease IL-1 and prostaglandin E2 and directly inhibit MMPs, proteinases, lysosomal enzymes, collagenase, and stromelysins. If given intraarticularly, they potentiate infection; therefore they must be given with an intraarticular antibiotic. PSGAGs given as 500 mg intramuscularly every 4 days for 7 treatments have been shown to provide positive effects (decreased joint circumference, greater carpal flexion) in a controlled study of equine carpitis.[13]

BISPHOSPHONATES. Biphosphonates are a class of drug that inhibits osteoclasts and are used in human medicine to treat osteoporosis. Bisphosphonates have not yet been shown to have the same inhibitory effects on osteoclasts at the doses used in horses.[14] The two bisphosphonate medications used commonly in horses are tiludronate (intravenous) and clodronate (intramuscular). One study has shown improvement in lameness using a 1 mg/kg dose of tiludronate when assessing horses with lameness that blocked to a PDN block and in which the horses had radiographic evidence of navicular bone degeneration.[15] At this time, the improvement in lameness seen with bisphosphonates is thought to be due to an antiinflammatory effect and not a bone remodeling effect.

EXTRACORPOREAL SHOCKWAVE TREATMENT. Investigated as a treatment for navicular bone degeneration in horses, extracorporeal shock wave treatment (ESWT) directs a pressure wave to a specific area of the body to increase osteogenic activity in bones and induce neovascularization. A single ESWT applied to the frog and heel bulb region does not influence lameness in horses with navicular bone disease.[16] ESWT over three treatments had no effect on pre- and postscintigraphic or radiographic images of the heel region.[17] In a study looking at collateral desmopathy of the DIJ, there was no effect of ESWT on outcome.[18] At this time, the benefit of EWST on pathology in the foot needs further investigation.

Surgical Treatment

PALMAR/PLANTAR DIGITAL NEURECTOMY. Palmar/plantar digital (PD) neurectomy is a surgical procedure that removes a section of the medial and lateral PDN between the fetlock and heel bulbs. This typically abolishes sensation in the heel and sole region of the foot. This procedure is an option for horses that block to a PDN block and are nonresponsive to medical management, with no other viable treatment options available. In a recent report in which MRI was used to guide treatment, 92% of horses responded favorably to PD neurectomy, with 80% able to return to their previous level of work for a median time of 20 months (range: 12 to 72 months).[19] Postoperative complications, including residual lameness, painful neuromas, or early recurrence of lameness, occurred in 36% of these horses.[19] Horses with DDFT pathology within the foot or pastern region are not good candidates for this procedure because they experience residual lameness or early recurrence of lameness after PD neurectomy.[19] Horses with other foot lesions or only dorsal border lesions of the DDFT had a better response to surgery.[19] In another study, 88% of horses were sound for at least 1 year after PD neurectomy.[20] Magnetic resonance imaging is used frequently to determine if DDFT pathology is present, and if so, these horses are not considered good candidates for a PD neurectomy.

FIG. 38.27 Transverse magnetic resonance image of a horse with a portion of the deep digital flexor tendon torn and protruding *(arrow)* into the navicular bursa. Dorsal is to the top.

NAVICULAR BURSOSCOPY. Navicular bursoscopy is being used more often as a treatment option now that we are able to use MRI on horses and determine optimal candidates for this procedure. Optimal candidates include horses that have a primary navicular bursitis with a mild to moderate amount of fibrinous or fibrous tissue within the proximal NBSA, as well as horses that have lesions located along the dorsal border of the DDFT at the level of the proximal NBSA (Fig. 38.27). This surgical procedure allows direct visualization of pathology within the proximal NBSA, along the dorsal border of the DDFT, and along the NB flexor cortex. This procedure also enables removal of scar tissue from within the NBSA and débridement of DDFT fibrils extruding from the dorsal border due to a tendon tear. In a recent study of 92 horses undergoing navicular bursoscopy, 61% returned to work and were sound, and 42% returned to their previous level of performance.[21] Horses in this study that had extensive tearing and combination injuries of the DDFT and navicular bone identified with MRI had poor outcomes.[21]

COLLATERAL SESAMOIDEAN DESMOTOMY. This procedure involves transection of the branches of the CSL, which is the ligament that suspends the NB from the middle phalanx. When this procedure was first developed, these branches were transected at the lateral aspect of the middle phalanx through skin incisions.[22-24] In the first study, 13 of 16 (81%) horses were able to work without lameness after the procedure.[22] In the second study, 76% of horses were sound at 6 months, and 42% of horses were sound at 36 months.[23] In the third study, 12 of 17 (70%) horses were sound at 6 months following surgery.[24]

More recently, a procedure was developed to transect the CSL branches from within the palmar pouch of the DIJ using arthroscopic guidance.[25] This technique provides the ability to verify full transection of the ligament by visualization of

transection and increased movement of the NB away from the middle phalanx.[25] Collateral sesamoidean desmotomy is performed when pathology associated with the suspensory apparatus (DSIL, NB, CSL) of the foot has been diagnosed but no flexor cortical erosion is present. In addition, other causes of lameness that would preclude the horse from responding positively to CSL desmotomy (e.g., DDFT pathology, navicular bursitis) need to be ruled out. Due to the specific diagnosis needed, MRI is highly recommended to determine whether this procedure would be a viable treatment option. Unfortunately, at this time there are no published reports of response to treatment using MRI as a screening tool. The hope is that by using MRI to define optimal candidates for this treatment, the prognosis for return to performance may be improved.

Summary No single treatment option is suitable for all horses with heel and foot pain. Each horse must be evaluated individually so that the structures affected, severity of disease or injury, use of horse, level of performance, and financial constraints are determined and used to guide treatment. Many treatment options are available to help these horses return to performance, but treatment can be much more successful in horses in which a definitive diagnosis has been obtained so that treatment is tailored to the individual horse. Magnetic resonance imaging is the best diagnostic tool we have to identify pathology within the foot of horse, and it should be used if at all possible to determine the cause of the lameness.

Spondylitis and Diskospondylitis

Sarah M. Reuss

Definition Spondylitis is inflammation of the vertebral body, whereas diskospondylitis is an inflammatory lesion that includes the intervertebral disc and its adjacent vertebrae. Although the etiologic agent may be difficult to isolate, infection is the most likely cause. Thus *vertebral osteomyelitis* and *spondylitis* are often interchangeable terms, and if the disc is involved, then *diskospondylitis* is the most appropriate term. Both spondylitis and diskospondylitis are rare in large animals but potentially career- and life-threatening when they occur. Diskospondylitis is described in swine,[1] horses, cattle,[2] goats,[3] and sheep. Neonates of all species are especially at risk for spondylitis. Diskospondylitis in large animals is most commonly reported in adult horses and cows in the cervical vertebrae.[4-6] Lesions have been less commonly identified in the thoracic,[7,8] lumbar,[9] and sacral[10] regions.

Clinical Signs and Differential Diagnoses The earliest signs of spondylitis may include fever, lethargy, stiffness, and localized spinal pain. Soft tissue swelling may be evident with paravertebral abscessation.[11] Muscle atrophy has also been reported.[8] Because diskospondylitis most commonly affects the cervical and thoracic vertebrae, neck pain and reluctance to lower the head to graze are common signs. Animals may develop an abnormal stance, with one forelimb forward and the other back, in order to graze.[7] Vertebral osteomyelitis may progress to spinal cord compression with variable degrees of ataxia, paresis, sensory and proprioceptive deficits, and recumbency. Neurologic signs are dependent on the vertebral section affected and the amount of spinal cord compression. Once present, clinical signs are usually progressive.

Clinical signs in ruminants are similar. Early signs include abnormal behavior, decreased appetite, and weight loss. Difficulty in extending the head and neck ventrally is often the reason for presentation to a veterinarian.[2] Varying degrees of neurologic deficits are reported, from occasional stumbling[2] to tetraparesis[12] and paraplegia.[3]

Differential diagnoses for spinal pain include spondylosis, vertebral fracture, muscle strain, dorsal spinous process impingement, vertebral subluxation, vertebral infarcts, and aberrant parasite migration.[13] Additional differentials for spinal cord ataxia in horses include cervical vertebral stenotic myelopathy, equine protozoal myeloencephalopathy, herpes myeloencephalopathy, and neoplasia.

Etiology and Pathogenesis Both spondylitis and diskospondylitis are thought to be septic conditions, although etiologic isolation is not often successful. Even in cases where bacteria are not isolated, response to antimicrobials may indicate a bacterial pathogenesis.[7] Bacterial infection is more common than fungal infection, and the hematogenous route of infection is the most common. Spondylitis occurs most frequently in neonates, which may be due in part to failure of passive transfer leading to sepsis.[1] In general, spondylitis is often secondary to a preexisting focus of infection elsewhere in the body.[1] Tail docking wounds,[14] umbilical infections,[1,12] pneumonia,[10] and lung abscesses[1] are possible sources of infection. Septic thrombi embolize into the metaphyseal arteries of the vertebrae, where flow is sluggish and bacteria can colonize.[14] In adults, direct injury to the intervertebral disc and/or the vertebral end plate may contribute to the formation of diskospondylitis. The injury disrupts the vasculature, increasing susceptibility to infection. Diskospondylitis is also reported to occur secondary to spread of local infection[5] and traumatic injury.[4] Infection results in destruction and remodeling of affected bone. Inflammation of the disc and vertebrae leads to spinal cord compression and the associated neurologic dysfunction. The intervertebral disc actually may prolapse into the spinal canal.[5] Lesions are usually confined to one intervertebral space. The neurologic signs may also be secondary to the infection eroding into the meninges and causing a suppurative meningitis.

Pathogens that have been cultured from adult horses with vertebral osteomyelitis include *Brucella abortus*,[15] *Aspergillus* spp., *Streptococcus zooepidemicus*,[1] *Staphylococcus* spp.,[6,9] and *Mycobacterium bovis*.[16] Vertebral osteomyelitis isolates in foals include *R. equi*,[10,11,17] *Streptococcus* spp., *Actinobacillus* spp., *Eikenella corrodens*,[18] *E. coli*, *Salmonella typhimurium*, *Staphylococcus* spp., and *Corynebacterium pseudotuberculosis*.[13] Isolates from cattle with vertebral osteomyelitis include *Aspergillus fumigatus*, *Bacteroides nodosus*, *Clostridium perfringens*, *Streptococcus* spp., *Staphylococcus* spp.,[2] *E. coli*,[14] *Actinomyces pyogenes*, *Fusobacterium necrophorum*, and *Pseudomonas* spp.[19] *Staphylococcus* spp. and *Arcanobacterium pyogenes* were cultured from the intervertebral disc of a goat.[3]

Diagnosis Diagnosis is based on clinical signs and imaging modalities. Clinicopathologic findings may include anemia, leukocytosis, neutrophilia, and hyperfibrinogenemia.[1] One retrospective study, however, found that 80% of affected horses had a normal white blood cell count.[20] Hyperproteinemia due to hyperglobulinemia may also be seen.[7] Cerebrospinal fluid is usually normal unless the osteomyelitis has progressed to meningitis. Blood and urine cultures should be obtained but are often not diagnostic.

Radiography is often the basis of diagnosis. Radiographic signs of spondylitis include bony proliferation, lysis, sclerosis, and localized soft tissue swelling.[1] Radiographic abnormalities in diskospondylitis include osteolysis of adjacent end plates with surrounding sclerosis and collapsed intervertebral disc space[9] (Fig. 38.28). Contrast radiography may be used to delineate spinal cord compression.[9] Radiographic changes may lag at least 2 to 8 weeks behind clinical signs, however, hampering the ability to make an early diagnosis.[1] With vague clinical signs, the neuroanatomic location within the vertebral column may be difficult to identify, making targeted radiographs impossible. Nuclear scintigraphy may help localize the lesion to a specific vertebral section that can then be radiographed.[1]

VetBooks.ir

FIG. 38.28 An 11-year-old Arabian cross gelding with fever and neck pain. The cortical margins of the caudal end plate of C5 and the cranial vertebral body of C6 are markedly thin and ill-defined. In addition, there is osteolysis and sclerosis associated with the cranial vertebral body of C5. The C5-C6 intervertebral disc space is narrow.

Scintigraphy may also allow earlier detection due to the lag time in radiographic changes. Ciprofloxacin and labeled white blood cell scintigraphy may also prove useful in the diagnosis of vertebral osteomyelitis. Ultrasonography is becoming increasingly used as a diagnostic imaging modality. Abnormalities include irregular end plates or bone surfaces, wide or narrow disc spaces, vertebral step formation, and associated abscessation or muscle involvement.[9] Transrectal ultrasonography of the lumbar vertebrae may be performed, while transcutaneous studies can image the rest of the vertebral column. Advantages to ultrasound are that it can be done in the field, it can be used for needle-guided aspirates of potentially infectious lesions, and it can be used as a screening tool to localize lesions.[9] Depending on the size of the animal and the availability of equipment, MRI and CT may also be considered, as these modalities can be used to assess the vertebral end plates, the disc, and the spinal cord.[3] CT has been used in a goat to diagnosis diskospondylitis. Bone lysis, bone proliferation, mineral opacity within the intervertebral disc, and spinal cord displacement were seen.[3]

Treatment Long-term antimicrobial therapy is indicated for cases of vertebral osteomyelitis. Blood, urine, or tissue cultures and sensitivities may be used to guide antimicrobial choices. When that is not possible, broad-spectrum, bactericidal antimicrobials should be used. Long-term treatment is necessary and may last for 3 to 6 months.[10] NSAIDs can also be used for pain control. In nonresponsive cases, curettage of infected bone may be necessary.[6,10] This also provides an opportunity to collect material for bacterial culture.[10] In horses with instability and spinal cord compression, surgical decompression and stabilization may be indicated.

Prognosis The prognosis for horses with diskospondylitis is guarded. If there are no neurologic deficits, and thus presumably no spinal cord compression, the prognosis is more favorable. Early diagnosis and long-term treatment is essential. In one retrospective, 13 of 19 adult horses survived to discharge, with 7 returning to their previous level of performance.[20] Foals may have a worse prognosis, with only 7 of 15 surviving to discharge.[21]

Spondylosis

Sarah M. Reuss

Definition Spondylosis is an ankylosing or degenerative condition of the intervertebral joints. Partial bridging occurs when osteophytes extend across the intervertebral space toward osteophytes on the adjacent vertebrae but a lucent line persists between the two. Complete bridging, or ankylosis, can occur without significant loss of intervertebral disc width. A variety of terms are used in veterinary medicine to describe vertebral enthesophyte formation: spondylosis deformans, vertebral osteophytosis, and ankylosing spondylosis.

Etiology and Pathogenesis In middle-aged and older animals, the thoracic and lumbar vertebrae are susceptible to chronic, progressive development of enthesophytes at the ventrolateral vertebral body margins. The exact cause is unknown but is apparently related to altered biomechanics and inflammatory mediators. One hypothesis is that spondylosis is a result of excessive dorsiflexion when the back muscles fatigue, as might be seen with exercise or breeding. There is then abnormal joint loading, mechanical stress, and degeneration of the annulus fibrosis and periarticular tissues.[1] Chemical mediators act on the periarticular ligaments and joint capsule, leading to metaplastic change, and ossification occurs within the anulus fibrosis and ventral longitudinal ligament, leading to partial bridging. Nerve roots may be compressed as they exit the intervertebral foramen, and spinal cord compression may occur if the bony proliferation extends dorsally into the vertebral canal. The cycle may continue until complete ankylosis and a continuous medullary cavity exist.[2] Partial or complete ankylosis at one site puts more stress on adjacent segments, so there is more active bone remodeling elsewhere in the vertebral column.[3] Sixty percent (14 of 23) of horses with radiographic evidence of spondylosis had more than one site involved.[4] The enthesophytes and then the ankylosed vertebral bodies are both at higher risk for fracture due to their inability to absorb normal forces. In a 22-year period in California, 38 Quarter Horse and 29 Thoroughbred racehorses that died on racetracks were diagnosed with a lumbar fracture. Closer postmortem analysis of a subset of these catastrophic caudal lumbar vertebral fractures all had evidence of preexisting abnormalities on the ventral aspect of the vertebral bodies consistent with spondylosis.[5]

A syndrome of posterior spinal paresis has been recognized in the bull artificial insemination industry, with calcification of the thoracolumbar vertebrae and ligaments. Over time there is fusion of the lumbar vertebrae with bilateral rear limb lameness and paresis. Spondylosis in bulls is not related to force of ejaculatory thrust at service, frequency of semen collection, or high-calcium diets.[6] Despite previous thought, limited dietary calcium does not reduce the prevalence of spondylosis in bulls.[7] In one study, a highly significant serologic association was found between posterior spinal paresis and the bovine major histocompatibility complex class I antigen BoLA-A8 ($P = 0.0015$).[8]

Clinical Signs and Differential Diagnoses Spondylosis can be an incidental finding in animals with no history or clinical signs of back pain. Spondylosis can, however, account for acute, recurrent, and chronic back pain in some animals. Pain is due to inflammation, impingement, and fracture. Palpation of the spine may be resented. Horses may guard their vertebral column by using muscle contraction to not allow ventroflexion. Resentment of girthing and mounting may be noticed. Riders may report poor performance, vague lameness, or altered gait.[1] Spondylosis is rarely the cause of back pain,

VetBooks.ir

however, as only 3.4% (23 of 670)[4] and 2.7% (8 of 443)[9] of horses presenting for back pain were found to have spondylosis in two separate studies.

Bulls with spondylosis will have a good appetite and be afebrile, but they may have difficulty rising, be reluctant to move, and have difficulty mounting or ejaculating.[2] In both horses and cattle, once clinical signs are present, they are slowly progressive. Lameness becomes more severe, and neurologic deficits may develop with nerve root impingement or spinal cord compression. Abnormalities then include bilateral proprioceptive deficits of the hindlimbs with hoof dragging, excessive hindlimb flexion, and incoordination. Hindlimb ataxia can progress to paralysis in some animals, especially older dairy bulls.[10]

Differential diagnoses for spinal pain include muscle strain, vertebral fracture, diskospondylitis, dorsal spinous process impingement, vertebral infarct, and aberrant parasite migration. Additional differentials for cattle with hindlimb neurologic deficits include lymphosarcoma, encephalopathy, progressive degenerative myeloencephalopathy, and downer cow syndrome.[2]

Epidemiology Spondylosis in horses is most common in mature animals and reportedly occurs in a higher proportion of mares.[9] The most common location in horses is from the tenth to the fourteenth thoracic vertebrae, and most horses with spondylosis have lesions at more than one intervertebral space. The osteophytes are usually ventrolateral when found in the thoracic region, whereas they are more lateral when found in the lumbar region.[3] Transrectal lumbosacral ultrasonography has detected ankyloses of the caudal lumbar vertebrae in 10% to 20% of horses.[11]

Bulls have a higher prevalence of vertebral enthesophytes than other cattle. Middle-aged bulls can have significant pathology, with 21 of 21 dairy bulls ages 65 to 90 months having some degree of lumbar vertebral osteophytes. Thirteen of those 21 bulls had complete ankylosis of at least one intervertebral space.[10] Bulls used for artificial insemination are especially at risk, with more than 49% of those 8 years and older having spondylosis.[12]

Diagnosis Diagnosis is suggested by clinical signs. Palpation of the dorsum may elicit signs of pain. Rectal palpation may reveal ventral osteophytes if they are located on the caudal lumbar vertebrae. A thorough neurologic examination is indicated if there are hindlimb deficits. Cerebrospinal fluid is usually normal.

Standing lateral radiographs are the mainstay of diagnosis. However, diagnostic radiographs can be difficult to obtain given the depth of the vertebrae in the thoracolumbar region. If one suspects spondylosis, targeting radiographs to areas of predilection is helpful. Spondylosis in horses is typically in the midcaudal thoracic vertebrae, commonly T10 to T14, but may also affect the lumbar vertebrae.[9] In bulls, the most common locations are C3 to C5, T2 to T6, and T11 to L5. The largest osteophytes occur in older bulls at the thoracolumbar junction.[6,12] Radiographic changes include smooth bone that blends with the vertebral body and bridges apparently normal intervertebral discs. A grading system has been developed, with grade 0 being normal, grade 1 having an osteophyte from one vertebral body, and up to grade 5 having complete bridging of the intervertebral space.[4] The clinical significance of radiographic change must also be determined based on history and clinical signs, as spondylosis can be an incidental finding. Nuclear scintigraphy can be useful for determining the activity and potential clinical significance of a lesion based on the radiopharmaceutical uptake. Scintigraphy may also be helpful in localizing the lesion for targeted radiography. Subjective assessment of scintigraphic images had a 21.7% sensitivity but a 95.0% specificity in a recent study using radiographic change as the standard.[4] Infrared thermographic imaging was used in one bucking bull to show surface hypothermia, thus confirming spinal nerve root irritation from spondylosis seen radiographically between L2-L3 and L3-L4.[13]

Treatment and Prognosis Treatment for clinical spondylosis consists of palliative care. Systemic antiinflammatories, cryotherapy, and stall rest are recommended during the acute phase. Extended turnout is then advocated in hopes of forming an osseous union because once complete fusion occurs, clinical signs should improve. Administration of local analgesics and corticosteroid drugs may provide relief and control of localized inflammation. Epidural administration of corticosteroids with concurrent administration of systemic polysulfated glycosaminoglycans has been reported in a bucking bull, allowing clinical signs to improve enough to permit breeding.[13] However, if vertebral fractures or neurologic deficits are present, the prognosis is poor.

Laminitis

Michelle C. Coleman

Definition Laminitis, defined as inflammation of the laminae of the hoof wall, results in degeneration, necrosis, and inflammation of the dermal and epidermal laminae in the hoof wall of equids and ruminants. The economic and welfare impacts of laminitis are high because of the associated poor prognosis, severe pain, and frequency of recurrence. Recognizing the impact of laminitis on horses and horse owners, veterinarians desire an improved understanding of laminitis, as evidenced by a 2009 survey (personal communication, Keith Kleine, AAEP Foundation) by the American Association of Equine Practitioners in which members identified laminitis as the highest priority for research funding and investigation.

Etiology and Pathogenesis Laminitis has a complex and multifactorial etiology, ultimately resulting in lamellar degradation of the suspensory apparatus of the distal phalanx.

Disease states thought to be associated with laminitis include sepsis and systemic inflammation, equine metabolic syndrome (EMS), pituitary pars intermedia dysfunction (PPID), and mechanical or traumatic overload. Septic processes including endotoxemia, gastrointestinal disease, pneumonia, and septic metritis are frequently associated with the development of laminitis. Laminitis has also been noted secondary to systemic inflammation resulting from an overload of carbohydrates, such as from overgrazing lush pastures or unrestricted access to concentrates. Excess weight bearing as a result of a contralateral limb lameness and trauma to the distal phalanx following exercise on hard ground can also result in laminitis. Exposure to a water-soluble toxin in black walnut shavings[1] and administration of corticosteroids have also been associated with the development of laminitis.[2]

In cattle, overweight heifers fed excess concentrates and housed on concrete surfaces appear to be at increased risk.

Pathophysiology The pathophysiology of laminitis has not been fully elucidated; however, it appears to involve a combination of events that lead to lamellar degeneration, impaired biomechanical function, and debilitating pain. Several experimental models for induction of laminitis have been developed, including carbohydrate overload,[3] fructan overload,[4] black walnut extract administration,[1,5] and hyperinsulinemic models.[6,7] Distinct pathophysiologic differences between these models exist, emphasizing the complexity of the pathophysiology of disease. Together, these models support several similar and interconnected theories on the pathophysiology of laminitis,

VetBooks.ir

including digital hemodynamic, enzymatic, inflammatory, endocrinopathic, and mechanical or traumatic events.

The bounding digital pulses and increased hoof wall temperature in acute laminitis gave rise to one of the earliest mechanisms to receive research support, which suggests a vascular component of the disease. Early research evaluated the role of hypertension[8] and the angiographic appearance of the laminitic equine digit,[9] with the thought that increased capillary pressures secondary to venoconstriction of the digital microvasculature resulted in laminar edema, increased arteriovenous shunting, and capillary collapse.[10] Further research has implicated the role of thrombosis,[11] vascular supply,[12-15] and insulin[16] on vascular dysfunction and lamellar ischemia, with increasing interest in endothelial dysfunction.[17]

Alteration of enzymatic activity within the lamella has been proposed as another potential mechanism of laminitis. Matrix metalloproteinase enzymes (MMP-2 and MMP-9) have been isolated in increased quantities from lamellar tissue affected by laminitis,[18] affected lamellar tissue has been shown to increase transcription of MMP,[19] and MMPs have been associated with neutrophil migration into the lamellae.[20] The activation of MMPs is thought to result in separation of lamellar cells from their basement membranes; however, the mechanism by which activation occurs has yet to be elucidated. Importantly, differences in MMP activity in the various models of laminitis have been noted.[21,22]

Experimental models of equine laminitis have displayed a number of inflammatory events. The presence of endothelial activation, leukocyte infiltration, proinflammatory cytokines, leukocyte activation and chemotaxis, and activation of degradative enzymes such as MMPs have been reported in the digital lamellae in different models of laminitis. Increased expression of inducible cyclooxygenase, COX-2, suggest that prostaglandins may play a role in laminar dysfunction.[23-25]

The role of endotoxemia in the development of laminitis remains unclear. Although systemic inflammation is a risk factor for development of laminitis, experimental endotoxin administration fails to induce the disease.[26] This could be explained by the fact that endotoxin does not act alone but rather in combination with several factors, including bacterial toxins, necrotic cell products, and proinflammatory cytokines. Endotoxin has been detected in the blood of horses following experimental carbohydrate overload[27] and is known to affect digital vascular function and platelet activation. Recent studies have hypothesized that the proinflammatory state of carbohydrate overload models is driven by an immune response to the rapid overgrowth of gram-positive and gram-negative cecal bacteria.[28]

Experimental models resulting in hyperinsulinemia reliably induce laminitis in ponies and horses.[6,7] Many theories on the pathogenesis of hyperinsulinemic laminitis exist, and it is probable that these theories are interconnected. Plasma or serum insulin concentrations can be used as predicitive[29] and prognostic[30] indicators for ponies at risk of developing laminitis. The role of insulin in glucose deprivation,[31,32] glucose excess,[33] upregulation of MMPs,[21] vascular effects,[34] and proinflammatory effects has been considered.

Laminitis has long been associated with mechanical overload on the distal phalanx, such as excessive concussion (road founder) and supporting limb laminitis. The mechanism of insult to the laminae is unknown, and currently models for studying this form of laminitis are poorly developed.

These theories of the pathogenesis of laminitis are complex and likely interconnected. The development of experimental models has accelerated our knowledge and understanding of the complex pathophysiology; however, the relationship of these models to the naturally occurring condition is unknown.

Clinical Signs Laminitis can affect a single foot or all four feet but is most commonly noted in the front feet of horses (likely due to an increased load on the forelimbs) and the hind feet of ruminants. Supporting limb laminitis occurs on the supporting forelimb or hindlimb opposite the non–weight-bearing limb. The lameness may vary in severity from subtle to prolonged recumbency due to digital pain. Because of this variability, the Obel grading system was developed to better describe severity.[35,36] Grade 1, the least severe classification, is characterized by shifting weight with no apparent lameness at the walk but a short-stilted trot. Horses with grade 2 lameness are willing to walk but have a stilted gait and are willing to lift a foot off the ground. Grade 3 is characterized by reluctance to ambulate and resistance to having a foot lifted off the ground. The most severe classification is grade 4, in which the horse refuses to move.[35] Shifting of weight to the hindlimbs if laminitis affects the forelimbs results in a characteristic "saw horse" stance and may be accompanied by anxiety, muscle fasiculations, anorexia, or reluctance to move in severe cases. Other clinical signs consistent with laminitis include bounding digital pulses, sensitivity to hoof testers over the sole at the toe, sensitivity to tapping of the hoof wall at the toe, heat over the dorsal surface of the hoof wall, and swelling of the coronary band. Rotation or distal displacement of the third phalanx within the hoof capsule may occur. With displacement, significant lameness often persists. A dropped sole or depression over the coronary band suggests that displacement has occurred.

Chronic laminitis results in lameness and deformation of the hoof capsule, which vary with duration of disease and type of displacement. In these cases, the sole is flat or dropped, the white line is widened, and the hoof wall shows signs of uneven growth. Irregular rings of growth may be noted around the hoof wall, more widely spaced at the heels. The abaxial white line develops apparent hemorrhages, and fissures of the hoof wall may be noted parallel to the coronary band. In ruminants, the sole softens and assumes a light-yellow discoloration.

Clinical Pathology and Radiology There are no clinicopathologic findings specific to acute or chronic laminitis, but changes may reflect an underlying disease process such as endotoxemia, enteritis, colitis, pleuropneumonia, or metritis. Changes may also be seen as a result of glucocorticoid and catecholamine release in response to pain and stress. One study showed that horses euthanized for chronic laminitis had higher white blood cell counts when compared to control horses and horses with less severe disease.[37] Baseline values for creatinine and total protein should be obtained, as these are important parameters to monitor for NSAID enteropathy.

Radiographic examination is an essential component in evaluating horses with suspected laminitis, for monitoring progress, and for providing therapeutic recommendations and prognostic information. Standard radiographic views, including lateromedial and 65-degree dorsoproximal-palmarodistal views, should be taken of all suspected digits in acute disease to serve as a baseline for subsequent radiographic studies and to determine if prior radiographic changes are present. Using a consistent technique is important to achieve a true lateral image and to allow accurate evaluation of radiographic parameters for comparison of serial studies. For both views, the foot should be thoroughly cleaned and placed on a wooden block such that the x-ray beam can be centered on the solar margin of the distal phalanx. A radiopaque marker placed on the middorsal hoof wall starting at the coronary band and extending distally can be useful in determining the position of the distal phalanx in relation to the surface marker.

Primary radiographic changes in acute laminitis include thickening of the dorsal hoof wall as a result of inflammation, separation of the laminae, and separation of the distal phalanx from the hoof wall. When the suspensory apparatus of the distal phalanx fails, the distal phalanx rotates away from the hoof wall or displaces distally, increasing the distance between structures. This distance can be measured as a line vertical to

VetBooks.ir

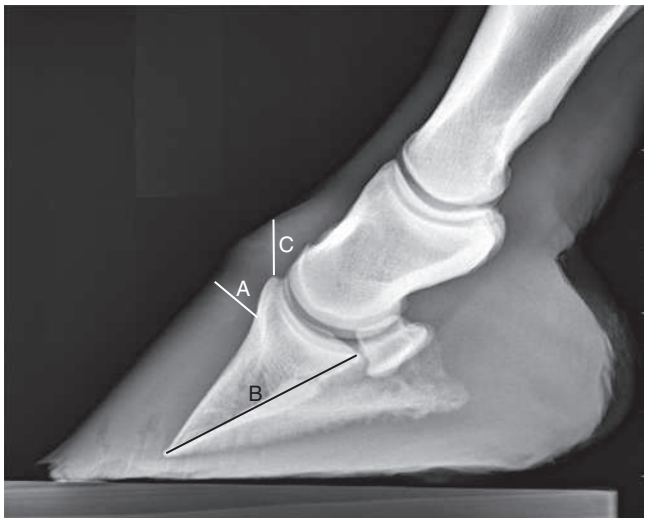

FIG. 38.29 Lateromedial radiograph of a horse with acute laminitis. **A,** Distance from the dorsoparietal surface of the distal phalanx to the dorsal surface of the hoof capsule. **B,** Length of the palmar cortex of the distal phalanx. **C,** Distance from the extensor process to the proximal aspect of the hoof wall distal to the coronary band.

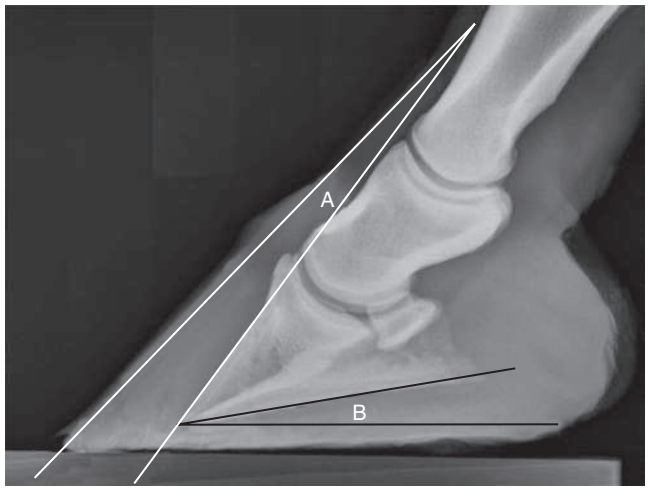

FIG. 38.30 Lateromedial radiograph of a horse with acute laminitis. **A,** Measurement of the degree of capsular rotation. **B,** Measurement of the angle of the solar margin of the distal phalanx to the ground surface of the foot.

the parietal surface of the distal phalanx and distal to the extensor process. In normal horses, this distance should be less than 18 to 20 mm (Fig. 38.29, *A*). A ratio between this dorsal measurement and the palmar cortical length of the distal phalanx measured from the dorsodistal tip of the bone to its articulation with the navicular bone (Fig. 38.29, *B*) can be used to account for changes in magnification and size of the foot. This ratio should be less than 28% in normal horses and more than 32% in horses with displacement of the distal phalanx. Sinking of the entire distal phalanx within the horny capsule can be assessed by measuring the vertical distance between the coronary band and the extensor process of the distal phalanx (Fig. 38.29, *C*). Soft tissue swelling of the coronary band may be apparent. Palmar or plantar rotation of the distal phalanx away from the hoof wall greater than 5 degrees is indicative of capsular rotation (Fig. 38.30, *A*).

In chronic cases, a radiolucent line may appear between the distal phalanx and the sole or hoof wall due to accumulation of serum between the dermal and epidermal laminae. The angle of the solar margin of the distal phalanx to the ground surface may be a more accurate assessment of rotation in chronic cases (Fig. 38.30, *B*). Radiographic evidence of a previous episode of laminitis may be evident in clinically normal horses. Changes may include increased thickness of the dorsal hoof wall, a radiolucent line in the dorsal hoof wall, modeling of the toe of the distal phalanx, and/or uncorrected rotation of the distal phalanx.

Positive contrast venography is useful in identifying filling defects in the digital vasculature, including the lamellar vessels, the circumflex area, and the terminal arch. Venographic studies are most valuable in early disease and may reveal damage in the hoof before radiographic changes are evident.[38]

The availability of MRI in equine medicine is increasing. High-field-strength MRI can provide detailed visualization of the laminae in the equine digit. Studies comparing digital radiography and MRI of horses with initial active laminitis suggest that measurements obtained with MRI were more sensitive and specific predictors of laminitis.[39]

Epidemiology

The estimated incidence of laminitis ranges from 1.5% to 34%,[40] with an estimated lifetime risk of 15%.[41] The term *endocrinopathic laminitis* has been used to describe laminitis in horses with hyperinsulinemia, PPID, or obesity or that have been administered glucocorticoids[42] and has been recognized as the most common cause of laminitis in private equine practice.[43,44] Further, in the National Animal Health Monitoring System equine study[45] performed in 2000, horse owners in the United States reported that pasture-associated laminitis and laminitis of unknown etiology were the most common forms of laminitis.

Epidemiologic studies on the risk factors for naturally occurring laminitis in horses are limited, with inconsistent results. A recent systematic review of publications assessing the risk factors for naturally occurring laminitis revealed only an association between chronic laminitis and increasing age. Results for other horse-level factors, including gender, breed, and body weight, were inconsistent. No consistent associations have been identified with other factors, including exercise and seasonality.[46] Associations between health conditions and laminitis in hospitalized horses has been investigated, with endotoxemia the only variable for which an association was noted.[47] Several cohort studies[48,49] have identified risk factors (e.g., hyperinsulinemia) for endocrinopathic laminitis in ponies, and a recent case control study in North America identified that generalized and/or regional adiposity, corticosteroid administration, and endocrinopathic disease were risk factors for development of pasture and endocrinopathic laminitis.[50] Duration of lameness was a risk factor for development of laminitis in the contralateral limb of horses with unilateral laminitis, and horses that developed this complication were more likely to be euthanized than horses that did not develop laminitis.[51] It is apparent that inconsistent and conflicting results regarding horses' risks of developing laminitis exist, supporting the need for well-designed observational studies to improve the strength of evidence.

Necropsy

Necropsy findings depend on the duration and severity of the disease. Separation of the primary epidermal laminae of the hoof wall and the collagen fibers of the corium occurs as a result of complete degeneration of the secondary epidermal laminae. The distal phalanx may sink, rotate ventrally, or penetrate the sole. Necrotic laminae are prone to abscessation. Severe changes include fractures of the solar margin, osteomyelitis, or resorption of the distal phalanx.

Treatment

An incomplete understanding of the pathophysiology and progression of laminitis limits our ability to prevent and treat the disease successfully and results in

VetBooks.ir

considerable controversy regarding appropriate treatment regimens. Therapy is often empiric and based on the experience of the clinician. Advancement in our knowledge of the complex pathophysiology of laminitis may result in more effective preventative and therapeutic approaches. Acute laminitis should be considered an emergency, and therapy should be initiated before or immediately following the onset of clinical signs. General principles of therapy include minimizing or eliminating predisposing factors, decreasing pain and inflammation, promoting digital circulation, reducing tension on the laminae, and reducing platelet activation and coagulation.

ELIMINATING CAUSES. Predisposing factors to the development of laminitis should be minimized or eliminated. Following ingestion of large amounts of grain, laxatives or purgatives including mineral oil or activated charcoal may be administered via nasogastric tube. Exhaustion, dehydration, and hypovolemia may be treated with appropriate intravenous fluid therapy. Appropriate therapy for combating the effects of endotoxemia and septic processes, including colitis, enteritis, pleuropneumonia, metritis, and retained placenta, should be initiated and may include intravenous fluids, parental antibiotics, NSAID therapy, polymyxin B, and hyperimmune serum or plasma. Treatment and management of other conditions associated with laminitis such as PPID and EMS are discussed elsewhere in this text.

Preventative measures in suspect cases include placing the horse in a deeply bedded stall, frog support, and corrective shoeing or trimming.

DECREASING PAIN AND INFLAMMATION. Antiinflammatory therapy is recommended to decrease lamellar inflammation, edema, and pain associated with laminitis. The most common NSAID used in horses is phenylbutazone at a dose of 2.2 to 4.4 mg/kg intravenously or orally every 12 hours. Flunixin meglumine can be administered at a dose of 0.5 to 1.1 mg/kg orally or intravenously every 8 to 12 hours for its antiinflammatory effects, or at a dose of 0.25 mg/kg intravenously every 8 hours to interrupt eicosanoid production associated with endotoxemia. Ketoprofen and firocoxib are also labeled for use in horses. Dimethyl sulfoxide (DMSO) is a free radical scavenger that aids in reduction of edema and may reduce ischemia-reperfusion injury. DMSO is typically administered at 0.1 to 1.0 g/kg intravenously diluted in a polyionic fluid to a concentration of 10% to avoid hemolysis. Pentoxifylline is a phosphodiesterase inhibitor with antiinflammatory and immune regulatory properties. It has been shown to have antiinflammatory effects[52] both in vivo and in vitro in horses and has recently been shown to effectively inhibit MMP in horses.[53] Further, evidence suggests that pentoxifylline reduces inflammation and blood glucose concentration after diabetes induction in rats by improving insulin sensitivity, making it a potential therapy for laminitis associated with metabolic disease.[54,55] In a recent study, the analgesic effects of tramadol hydrochloride administered in combination with ketamine hydrochloride were evaluated in horses with naturally occurring chronic laminitis. Tramadol provided little analgesic effect, but analgesia was enhanced by administration of subanesthetic doses of ketamine.[56]

PROMOTING DIGITAL BLOOD FLOW. Venous vasoconstriction may be involved in the pathogenesis of laminitis, but several therapeutic agents that have been suggested for increasing blood flow to the digit, including isoxsuprine and nitroglycerine paste, have not proven effective. Acepromazine, a phenothiazine tranquilizer, has been shown to increase digital blood flow in clinically normal horses with a short duration of efficacy of about 30 minutes.[57] Acepromazine has been recommended at a dose of 0.03 to 0.06 mg/kg intramuscularly or intravenously every 6 to 8 hours; however, at this dosage interval, the patient should be monitored for hypotension. If this complication is documented or suspected, the dosage interval should be extended or therapy with acepromazine should be discontinued. Caution should be taken in stallions due to the risk of paraphimosis.[57]

Continuous application of cryotherapy of the distal limb, in which hoof wall surface temperatures are maintained at 5° to 10° C for 48 to 72 hours, has been shown to limit the clinical, histologic, and biochemical abnormalities associated with experimentally induced acute laminitis in the oligofructose model.[58-62] The mechanistic effect is unclear, but involvement of the inflammatory[61,63] and vascular[64] pathways is suspected. Several methods of cooling the digit have been used, including ice water immersion bath, wader boots, ice packs, and 5-L fluid bags, with variation in the hoof wall surface temperature between methods.[65]

REDUCING TENSION ON THE LAMINAE. Because laminar deformity is likely due to tension placed on the suspensory apparatus of the distal phalanx, reduction of mechanical force and stabilization of the distal phalanx are essential in the treatment of acute laminitis. Horses should be confined to strict stall rest and not be exercised in the acute stages of the disease. The horse should be encouraged to lie down, and bedding in the stall, ideally sand, should be deep. Redistributing weight from the hoof wall to the bars, sole, and frog may decrease laminar tension. Various methods have been suggested, including silicone impression material (EquiFlex-Pak [Sound Horse Technologies, Unionville, Pa.]), styrofoam insulation board, Lily Pads (Nanric Inc., Lawrenceburg, Ky.), the Steward Clog (Equine Digit Support System Inc., Penrose, Colo.), and Soft-Ride boots (Soft-Ride Inc., Vermillion, Ohio). Regardless of the method of weight redistribution, it is important to remember that once the distal phalanx displaces, increased pressure over the sole where the distal phalanx displaces may cause severely increased discomfort. Various methods of distal limb casts have also been used to improve stability to the distal phalanx.

Decreasing tension on the deep digital flexor tendon will also help decrease tension on the laminae. This can be accomplished by elevating the heels with a wedge (i.e., the Redden Modified Ultimate Wedge [Nanric Inc., Lawrenceburg, Ky.]) or transecting the deep digital flexor tendon to reduce caudal pull on the coffin bone.

Depending on the degree of rotation and/or distal displacement in chronic laminitis, various methods of hoof care and shoeing have been used. More radical approaches, including hoof wall resection and coronary band grooving, have been historically used with varying efficacy.

ANTICOAGULANT THERAPY. Heparin has been recommended in the treatment of laminitis to reduce microthrombi and platelet-platelet or platelet-neutrophil aggregates that are thought to form during laminitis. Heparin was recently reported to have potential antiinflammatory effects on equine endothelium exposed to neutrophil-derived myeloperoxidase.[66] Unfractionated heparin was shown to reduce the proportion of horses with proximal enteritis that develop laminitis when administered prophylactically,[67] and low-molecular-weight heparin reportedly reduced the incidence and severity of laminitis in postoperative colics.[68]

Prognosis

There is little evidence-based research on prognosticating laminitic horses; however, it is likely that the prognosis of laminitis depends largely on the severity of the pathology, type of displacement, clinical signs, and underlying diseases or conditions. Prognosis may also be influenced by financial constraints, owner expectations, and owner compliance. In general, rotation is considered to have a more favorable prognosis than distal displacement, which is considered to have a more favorable prognosis than unilateral displacement. The degree of rotation and distance from the proximal margin of the extensor process of the distal phalanx to the proximal

VetBooks.ir

margin of the hoof were reported to be important factors in return to soundness and prognosis for survival.[69] General guidelines based on degree of lameness and rotation and progression of clinical findings proposed by Redden in 1988 can be found in the previous edition of this text. In one study, 75% of horses referred to a university veterinary hospital with acute laminitis did not return to athletic function, and a majority were euthanized within 1 year due to poor response to therapy or development of complications.[70]

Prevention and Control Preventative measures are aimed at decreasing risk factors for development of the disease, but our poor understanding of the etiology and pathophysiology of the disease make prevention challenging. In general, suspected risk factors such as uncontrolled grazing on lush pastures, unrestricted access to grain or concentrates, factors contributing to gastrointestinal upset including rapid changes in diet, and retained placenta should be avoided when possible.

Despite continued limitations in our understanding of laminitis, it is likely that developments in biomedical research, industrial pressures, and extensive research collaboration will continue to advance our knowledge and understanding of the pathophysiology of laminitis and improve our ability to prevent, manage, and treat the condition.

Fluorosis

John Maas

Definition and Etiology Ingestion of excessive fluoride by cattle, sheep, and horses can result in toxicosis. Acute fluoride toxicosis is relatively rare and is the result of accidental massive ingestion of fluoride compounds such as sodium fluoride or sodium fluorosilicate. Signs of acute fluoride toxicosis include restlessness, stiffness, anorexia, agalactia, salivation, vomiting or regurgitation, urinary incontinence, diarrhea, clonic convulsions, hyperemia, weakness, severe depression, and cardiac failure. Necrosis of the gastrointestinal mucosa and high concentrations of fluoride in plasma and urine are present in acute fluoride toxicities. Chronic fluoride toxicosis is most often referred to as *fluorosis*, a general term that includes osteofluorosis and dental fluorosis. Common sources of excess fluorides in the diet are (1) water with a naturally high fluoride content, (2) forages contaminated with fluorides from nearby (upwind) industrial plants (e.g., phosphate processing plants, aluminum plants, aluminum smelters), (3) mineral sources (nondefluorinated rock phosphorus) and feed supplements with excessive fluoride content, (4) forages contaminated by soil or water (particularly sprinkler irrigation water) with a high fluoride content, and (5) volcanic activity, which can deposit fluoride-containing ash on soil or plants or in water used for agriculture.

Recent outbreaks of fluorosis have been attributed to environmental fluoride contamination by superphosphate fertilizer plants,[1] ingestion of a commercial mineral supplement containing a contaminated phosphorus source,[2] fertilizer-grade phosphorus supplements (containing large amounts of fluoride) fed to cattle for lameness attributed to a phosphorus deficiency,[3] and fluorosis in sheep and cattle attributed to water with excess fluoride used for irrigation and drinking water.[4]

Clinical Signs, Differential Diagnosis, and Pathophysiology Clinical signs of fluorosis are usually first recognized as either dental fluorosis or osteofluorosis. Developing teeth are very sensitive to the ingestion of excess fluorides. The deciduous teeth rarely show signs of dental fluorosis, because a partial placental barrier to the accumulation of fluorides appears to be present in the fetus. During tooth development, excess fluorides cause ameloblasts to reduce in size prematurely and the enamel epithelium to form an irregular matrix. This matrix does not calcify normally, producing defects in the mature teeth. Cattle are susceptible to dental fluorosis during enamel matrix formation, from approximately 6 months to 3 years of age. Excess fluoride intake after 3 years of age does not result in the typical fluoride-induced dental lesions. Changes in incisor teeth are observed most frequently and include chalkiness, mottling (striations or patches in enamel), hypoplasia (defective enamel), and hypocalcification. Clinical lesions can be graded from normal to excessive.[5] Factors that influence dental fluorosis include the amount of fluoride ingested, the animal's age, the duration and consistency (intermittent versus continuous) of exposure to fluoride, and the source and chemical form of fluoride ingested. Although clinically important, dental lesions should not be used as the sole criterion to determine the degree of fluorosis.

Fluoride accumulation in bone occurs over a prolonged time; osteofluorosis can eventually develop if excessive fluoride is ingested. In cattle the first palpable lesions occur on the medial surface of the proximal third of the metatarsal bones. Later, lesions can be palpated on the mandible, metacarpal bones, and ribs. Radiographically, osteofluorotic bones are thickened with a chalky, roughened, and irregular periosteal surface.

The presence of osteoporosis, osteosclerosis, hyperostosis, osteophytosis, or osteomalacia depends on the amount of fluoride ingested and the duration of exposure to fluorides. The articular surfaces are not involved in osteofluorosis and can be used to differentiate osteofluorosis from osteomyelitis, osteoarthritis, and septic arthritis. The osseous lesions eventually cause intermittent lameness and stiffness, which may affect feed intake, body condition, milk production, and reproduction. Severe dental fluorosis causes reduced feed intake and efficiency, and affected animals are sometimes reluctant to drink cold water.

Clinical Pathology and Diagnosis Diagnosis of fluorosis is difficult and complicated by many factors that affect fluoride intake and deposition. Fluorosis may be suspected by history, clinical signs, and physical examination. Radiographic findings of bone disease without evidence of joint involvement are highly suggestive of fluorosis in the live animal. The fluoride concentration in the urine of cattle may help approximate recent fluoride exposure. The diagnostic value of urine fluoride analysis increases as the duration of excess fluoride ingestion increases. Normal cattle have a urine fluoride concentration of about 2 to 6 mg/L (2 to 6 parts per million [ppm]) or less than 10 mg/L (ppm).[6] Cattle exhibiting moderate fluorosis have a urine fluoride concentration of about 15 to 20 mg/L (ppm). Cattle with urine fluoride concentrations of 40 mg/L (ppm) or greater or a urinary fluoride/creatinine ratio of 0.025 : 1 or greater could be suspected of ingesting a diet with a fluoride concentration of 60 ppm or greater.[5,7] The concentration of fluoride in bone is also quite helpful in the diagnosis of fluorosis (Table 38.2). Fluoride content in cancellous bone (e.g., rib, pelvis) is greater than in cortical bone. In addition, fluoride concentrations may vary in different areas of the same bone.

Fluoride concentration of bone is usually expressed as mg/kg (ppm) of dry, fat-free bone. However, some bone samples are ashed before fluoride determination, so it is critical to note precisely which bone was sampled, how it was prepared, and what part of the bone was analyzed. The metatarsus and metacarpus are typically analyzed for fluoride content. For all practical purposes, fluoride concentration is equal in either of these bones from the same patient.[8] Using sawdust from a longitudinal section of bovine metatarsus (dividing the bone into lateral and medial halves or dorsal and palmar halves) yields virtually the same fluoride concentration as the whole bone.[8] The fluoride concentration of the fourteenth coccygeal vertebrae (ash basis) is approximately twice that of the metacarpus (dry, fat-free weight basis).[9] This can be a practical tool for clinical diagnosis in the live animal.

TABLE 38.2

Fluoride Concentration in Bones of Dairy Cattle Fed Various Levels of Sodium Fluoride[8,9]

Fluoride in Feed (ppm, Dry Matter Basis)	Fluoride in Bone (ppm; Dry, Fat-Free Basis)		
	2 years	4 years	6 years
0-15 (Normal conditions)	401-714	706-1138	653-1221
15-30 (No adverse effects)	714-1605	1138-2379	1221-2794
30-40 (Borderline fluorosis)	1605-2130	2379-3138	2794-3788
40-60 (Moderate fluorosis)	2130-3027	3138-4504	3788-5622
60-109 (Severe fluorosis)	3027-4206	4504-6620	5622-8676

ppm, mg/kg.

TABLE 38.3

Long-Term Tolerance of Dietary Fluoride for Cattle[11]

Animal	Dietary Fluoride (ppm, Dry Matter Basis)
Dairy or beef heifers	30-40
Mature dairy cows	40
Mature beef cattle	40-50
Feedlot cattle	100

ppm, mg/kg.

Analysis of dietary fluoride is a valuable adjunct to the diagnosis of fluorosis. The upper safe limit of fluoride in water for livestock is 2 mg/L (ppm).[10,11] This safe limit may not protect against fluorosis in all field situations because of the large number of variables involved in the pathogenesis of fluorosis. Table 38.3 lists the long-term dietary tolerances for cattle. Under field conditions, the clinician must consider all possible sources of fluoride ingestion in evaluating total intake. Because fluoride intake may be intermittent, a low dietary intake at one time may not necessarily eliminate a diagnosis of fluorosis.

Treatment and Prognosis No specific treatment is known for ruminants with severe fluorosis, and the prognosis is poor for cattle lame from extensive bony lesions. Animals removed from the offending diet or water may lose 50% of the fluoride from bone within 2 to 5 years,[12] but severe dental damage is irreversible.

Prevention and Control Prevention involves avoiding feeds, water, and supplements with excessive fluoride concentrations. Feeding aluminum sulfate at 0.5% of the total diet reduces bone fluoride storage by 30% to 40%. However, additional phosphorus must be supplied in the diet, or osteoporosis and possibly spontaneous fractures may occur. Aluminum chloride or calcium aluminate also can be fed to cattle to reduce fluoride absorption. Calcium carbonate added to soils high in fluorides aids in reducing fluoride in forages. Cereal grains do not accumulate fluorides and thus can be helpful in reducing overall fluoride consumption. In circumstances of high fluoride concentrations in water, use of flood irrigation rather than sprinkler irrigation decreases the fluoride content of crops such as alfalfa hay.

The effects of varying levels of dietary protein on long-term fluoride exposure have been examined. In this study the feeding of low-protein diets (75% of recommended amounts) increased the bioavailability of fluoride, but there was no significant influence on the susceptibility to fluorosis by varying the dietary protein concentration from low (75%) to normal (100%) to high (125%).

Hypertrophic Osteopathy

M. Keith Chaffin

Definition and Etiology Hypertrophic osteopathy (HO), also known as *Marie's disease*, is an uncommon condition in horses and is characterized by symmetric proliferation of connective tissue and subperiosteal bone along the diaphyses and metaphyses of the bones of the distal extremities.[1-7] The skeletal manifestations of HO are usually secondary to a primary underlying disorder elsewhere in the horse's body, often involving a space-occupying mass.[1-3,5-7] Most often intrathoracic disorders are the primary cause[1,2,6,7]; intraabdominal and intracranial lesions have been less frequently associated with HO.[6,8,9] In addition to horses, HO has also been described in humans, dogs, cats, cattle, sheep, deer, and fowl. In humans the term *hypertrophic osteoarthropathy* is used because the articular surfaces are usually affected; in animals, however, HO does not appear to frequently affect the articular surfaces.[1,6,7]

In the horse, HO has been associated with a number of primary intrathoracic disorders, including mycobacterial pneumonia,[2,6,10] lung abscess,[1,6] suppurative pneumonia,[1,6,11] granulomatous pneumonia,[2,3] systemic granulomatous disease,[6,7] fibrosing pneumonia,[12] primary and metastatic lung neoplasia,[11,13-16] pleuritis,[2] pulmonary infarction,[17] rib fracture,[18] pleural adhesion,[2,6] pericarditis,[2,4] mediastinal lymphadenitis,[6] and equine multinodular pulmonary fibrosis.[19] Reported primary extrathoracic disorders associated with HO include ovarian neoplasia,[5,20-22] abdominal tuberculosis,[2] peritonitis,[2] pituitary adenoma,[9] pyogranulomatous dermatitis,[3] and gastric squamous cell carcinoma.[8] There is one report of HO in a mare that was thought to be associated with pregnancy; signs of HO developed during three different pregnancies and regressed each time after parturition.[11] In some cases, an underlying disorder is never identified.[2,6]

Pathophysiology The pathophysiology of HO is not completely understood.[1,6-7] Initially, blood flow to the distal limbs is increased, followed by fluid retention and proliferation of connective tissue. Later there is bony proliferation along the inner aspect of the periosteum.[1,6,7] The periosteal proliferation results in the bony enlargements seen clinically. The link between the primary lesion and the skeletal abnormalities is poorly understood. Proposed explanations include hormonal abnormalities, hypoxia, arteriovenous shunting, and neurologic mechanisms.[1,6,7] The neurologic theory is based on increased vagal stimulation, and the endocrine mechanism involves a variety of local and systemic hormones increasing the production of vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF), causing release of megakaryocytes from the pulmonary circulation, resulting in platelet clumping in the periosteal capillaries.[7,19] No single theory offers a completely satisfactory explanation.

VetBooks.ir

Clinical Signs Horses of any age or breed and either gender can be affected with HO. Some evidence suggests that HO may be more common in male horses and large-breed horses.[6] Ponies and donkeys can also be affected.[11,14]

Common clinical signs of HO include lameness, stiff gait, and reluctance to move or trot.[1,6,7] Firm bony enlargements are present on the distal extremities. In some cases, there may be soft tissue swelling or edema adjacent to the bony enlargements. In some horses the limb swelling is warm and painful to palpation, whereas in others the swelling is cold and painless.[6] Pain can frequently be elicited by forced flexion of the major joints. Bony enlargements are usually bilateral and symmetric and often affect the cranial, lateral, and medial aspects of the affected bones.[1,6,7] All four limbs are often affected, although the forelimbs are sometimes more severely affected.[6] The metacarpal and metatarsal bones are most often affected; other sites that can be affected include the phalanges, carpus, tarsus, radius, and tibia, as well as the maxilla, facial crest mandible, and nasal bones.[2,6]

Affected horses may or may not show signs related to the primary underlying disorder, such as cough, fever, weight loss, ventral edema, tachypnea, or colic.[6] Clinicopathologic features are highly variable and depend on the underlying primary disease process. Generally, there is increased serum activity of alkaline phosphatase, associated with increased osteoblastic activity at the sites of periosteal proliferation.[6]

Radiographically, the bony enlargements are characterized by periosteal proliferative new bone formation of the diaphysis and metaphysis of affected bones.[1-3,6,7] The periosteal reaction often exhibits an irregular palisade pattern of osteophyte formation.[1,6,7] The bony reaction may extend to the chondrosynovial junctions; the articular surfaces are usually not affected.[7] Nuclear scintigraphy may reveal focal areas of intense uptake of radiopharmaceuticals at the sites of bony enlargement.[1,4]

Treatment and Prognosis The prognosis for horses with HO is guarded and depends on the underlying disorder. In one study, 71% of horses with HO were euthanized.[6] Gradually progressive limb swelling and pain are the typical clinical course in most affected horses for which an underlying cause is either not identified or effectively managed.[7] Thus management of HO should be directed at identification and treatment of the underlying primary disorder if possible. Common methods to help identify the underlying disease include hematologic studies, serum chemistries, fibrinogen, thoracic radiography, thoracic and abdominal ultrasonography, abdominocentesis, thoracocentesis, gastroscopy, rectal examination, laparoscopy, and in some cases computed tomography.[2,6,7] Successful management of the primary underlying disorder has resulted in partial or complete regression of the skeletal disease in a limited number of equine cases.[1,3-6,19] Regression of HO is characterized by a decrease in limb swelling and lameness, and a return to athletic performance is possible if bony lesions are not advanced.[1,6] In a few idiopathic cases in which an underlying disorder was not identified, lameness and bony reactions decreased with rest, phenylbutazone, or corticosteroid therapy.[2,6]

Fescue Foot

Meredyth L. Jones

Definition and Etiology Tall fescue *(Festuca arundinacea)* is a cool-season grass native to Western Europe and introduced into the United States perhaps as a contaminant of other seeds in the late 1800s. It is well adapted to the transitional areas between the northern and southeastern regions of the United States but can be found in areas across the country. Fescue is associated with several toxic syndromes in livestock when infected by endophyte *Neotyphodium (Acremonium) coenophialum*, a Clavicipitaceae fungus. Ergot alkaloids, most importantly ergovaline, are produced by the fungus and have vasoconstrictive effects on the feet and other extremities, leading to tissue slough. Fescue foot is considered a disease of cattle, but sheep may also be affected.[1]

Clinical Signs, Diagnosis, and Differential Diagnoses Clinical symptoms of fescue foot occur within 42 days of exposure to endophyte-infected fescue.[1] Affected cattle may arch their back and have a rough hair coat in addition to limb signs. Limb lesions occur most often in the hindlimbs, starting as a red line at the coronary band with edema,[2] and the hair is easily epilated. A gangrenous process leads to purple-black discoloration and eventual sloughing of the skin. The tips of the ears and tail may be similarly affected. Lameness becomes severe as lesions progress, and animals may knuckle and prefer not to stand. There appears to be individual variation in susceptibility to fescue toxicity and severity of lesions.

Diagnosis is based on characteristic clinical signs and documentation of high endophyte infection of fescue to which animals were exposed. A sharp line of demarcation will be present between perfused and nonperfused tissues. Histopathology reveals vascular thrombosis and necrosis of compromised tissues.

Fields can be screened for percent infection by endophytes by submitting tillers (grass shafts at ground level), seed stems, and seeds. The target laboratory for this analysis should be contacted regarding the best sample for current growth phase of the plant and sample handling instructions. Ergovaline testing via high-performance liquid chromatography (HPLC) is available through some reference laboratories, and samples should be shipped on ice or kept frozen until shipment.[3]

Differential diagnoses for the lesions of fescue foot include ergotism of *Claviceps purpurea*, selenium toxicity, salmonellosis, and frostbite. Sarcocystosis in cattle has been associated with hair loss at the tip of the tail.[4] In the very early phases of the disease when only redness and edema are present, traumatic injury, laminitis, and foot rot may be suspected.

Pathophysiology The toxicity of fescue is likely multifactorial and may include compounds produced by the grass itself (loline, pergoline, others); however, fungal endophytes are widely accepted as the primary mechanisms of toxicity.[5-10] *N. coenophialum* production of ergovaline, ergonine, ergosine, and lysergamide results in vasoconstriction and is noted to be the primary etiologic agent[5,6,10]; however, several other fungal types from infected fescue have produced dermal edema and necrosis when experimentally evaluated in rabbits.[11] Threshold dietary levels of ergovaline of 400 to 750 ppb in cattle and 500 to 500 ppb in sheep have been established for the production of fescue foot lesions.[1]

Studies of blood flow in sheep and cattle fed highly endophyte-infected fescue indicated that blood flow was reduced in the adrenal glands and limb skin of sheep and in the truncal skin, cerebellum, duodenum, and colon of steers.[12] Although the visible clinical lesions indicate peripheral vasoconstriction, core visceral vasoconstriction clearly occurs as well. Lesions occur most often in cooler weather,[1] which is the season favored by the grass, especially when there is snow and ice, which likely worsen vasoconstriction.

Treatment and Prognosis As soon as the disease is suspected, all animals should be removed from the pasture if possible. Once necrosis is occurring, treatment is unrewarding and euthanasia is recommended for animals whose pain cannot be controlled. Early cases may respond to supportive therapy on soft ground and local or systemic antimicrobial therapy for protection of deep digital tissues from bacterial invasion through compromised skin. The use of NSAIDs should be considered

carefully. Inhibition of the COX-2 pathway may result in vasoconstriction and platelet aggregation, making a theoretical case for avoiding NSAIDs in cases of fescue foot.

Control and Prevention In a USDA study of fescue pastures, 61.6% were infected with endophyte nationwide, with more than 75% of pastures in the Southern United States infected.[13] In such conditions, providing legume supplementation or overseeding with clover or lespedeza, along with sufficient protein and adequate trace minerals, has shown the most consistent benefit in reducing the impact of the toxin. Feeding fescue as hay before the seed heads are out may reduce the impact, but toxic pasture grass will remain toxic even as hay. However, one study in Missouri indicated that, with stockpiling and storage of hay, endophyte levels in infected fescue were reduced, while nutritive value was retained.[14]

When starting fescue, certain strains, such as Ky-31, should be avoided for livestock, as they have high toxic potential.[15] High soil nitrogen exacerbates toxicity, and fertilization of infected cultivars should be limited. Endophyte-free cultivars of fescue do exist, and some states require the packaging of fescue seed to declare the level of endophyte infection, with target levels of 0% to 5%. Unfortunately, endophyte-free fescues are less hardy and easily overtaken by infected fescue contaminating the pasture.

Interdigital Necrobacillosis (Foot Rot) in Cattle

Meredyth L. Jones

Definition and Etiology Interdigital necrobacillosis, also called foot rot, foul-in-the-foot, and interdigital phlegmon, is a bacterial infection of the interdigital tissues, leading to moderate to severe lameness in one or more feet of cattle. Animals at high risk include those housed in moist, muddy lots; pastures with standing water; or areas where sharp gravel, concrete, or stubble exists.[1] *F. necrophorum*, a gram-negative anaerobe, is most often associated with this syndrome. Other bacteria, including *Prevotella melaninogenica*, *Porphyromonas levii*, and *Dichelobacter nodosus*, may induce similar lesions alone or in concert with *F. necrophorum*.[2-4]

Clinical Signs and Differential Diagnoses Early cases of foot rot show mild to moderate lameness in one or more feet, most commonly the hindlimbs. On examination of the foot, there is symmetric swelling of the coronary band region that may progress upward to the level of the fetlock. The interdigital space will also be swollen, spreading the toes. One or more fissures will form in the interdigital space (Fig. 38.31), where tissue necrosis is apparent. The characteristic odor of anaerobic infection with necrosis is apparent. Exudate is present, and there may be pseudomembrane formation.

Severity of lameness may progress such that animals may refuse to bear weight on an affected limb. Young calves may hold up a limb and shake it or, when multiple limbs are affected, may walk in such a way as to appear ataxic from neurologic disease. Invasion of the tendons and synovial structures may occur if the disease is not treated appropriately early, worsening the lameness and the prognosis for recovery. Mild fever may occur, and affected cattle will increase laying time, which leads to reduction in feed intake. Animal performance is diminished, with reductions in weight gain or milk production.

Differential diagnoses include septic arthritis, sole abscess, tenosynovitis, pedal osteitis, interdigital fibroma, laminitis, and trauma.

FIG. 38.31 Interdigital fissure formation and necrosis are the hallmark of interdigital necrobacillosis. The lesion will also have a foul odor and variable amounts of swelling of the interdigital space and coronary band region.

Pathophysiology The bacteria implicated in foot rot are normal inhabitants of the ruminant gastrointestinal tract and are therefore ubiquitous in the environment in which ruminants live. The syndrome occurs when there is a breach in the skin of the foot, usually through maceration from prolonged exposure to moisture or trauma. Oxygen tension is reduced by early microbial invaders, creating an ideal environment for the anaerobic pathogens of foot rot.[5,6] From there, several mechanisms contribute to virulence and evasion of the immune response. The two subspecies of *F. necrophorum* currently recognized are biotypes A and B. Biotype A appears to be more virulent and is more frequently isolated.[7,8] Major virulence factors associated with this organism are a high-molecular-weight leukotoxin and lipopolysaccharide (LPS).[9,10] The leukotoxin is cytotoxic to ruminant neutrophils and, when combined with LPS, protects the organism from phagocytosis.[7] *P. levii* does not stimulate a significant chemotactic response in bovine macrophages in vitro, and suppression of phagocytosis occurs even when the organism is present in low numbers.[3] These properties of *P. levii* may facilitate a local tissue environment that allows other anaerobic organisms, including *F. necrophorum*, to colonize and evade host defense mechanisms.

Bacterial production of proteases and the products of white blood cell action and destruction further destroy local tissues, allowing for deeper invasion and necrosis. Swelling and pain result from tissue necrosis. Tenosynovitis, septic synovitis, and septic arthritis may all occur as the infection advances.

Systemic inflammatory responses do occur, and serum haptoglobin levels are increased in cattle infected with foot rot.[11] Other work has shown more extensive changes to plasma protein profiles, including those involved in pathways of inflammation, complement, and coagulation.[12]

Diagnosis The diagnosis of interdigital necrobacillosis is usually clinical, based on typical swelling pattern, interdigital fissures, and odor. Lesion culture may be performed but is limited in utility due to mixed populations of environmental and fecal contaminants. Histopathology may reveal intralesional spirochetes, but this is not consistent. Serodiagnosis has been reported with indirect ELISA for the detection of leukotoxin A antibodies using the recombinant protein PL2, yielding relatively high sensitivity and specificity.[13] Lack of expected response to parenteral therapy should result in reevaluation of the diagnosis and more extensive evaluation of the foot.

VetBooks.ir

Treatment and Prognosis Most uncomplicated cases of foot rot will respond to parenteral antimicrobial therapy within a few days, with return to full soundness. Antimicrobial selection should be based on animal type, withdrawal time, and dosing logistics. In the United States, commercially available preparations of oxytetracycline, florfenicol, ceftiofur, tylosin, sulfadimethoxine, and tulathromycin carry label indications for foot rot. A comparison of ceftiofur crystalline free acid (6.6 mg/kg subcutaneously [SC] in the base of the ear once) and ceftiofur sodium daily for 3 consecutive days revealed no statistical difference in recovery rates; however, the ceftiofur sodium resulted in more labor and time required for multiple administrations.[14] Another study comparing ceftiofur and oxytetracycline found no difference in the recovery rate between the two antimicrobials, concluding that the difference in withdrawal time should be considered in the treatment choice.[15]

Local treatment is generally unnecessary in most cases, and the use of bandages should be considered in light of the environment to which the animal is returning. A wet bandage can only worsen the situation. Some cases may benefit from wound cleaning and débridement of necrotic tissue.

Antiinflammatory and analgesic therapy may result in improved appetite and ambulation, improving welfare and lessening production losses. A transdermal preparation of flunixin is approved in the United States for pain control due to foot rot.

Regardless of the medical treatments used, animals should be returned to a clean, dry environment for recovery. They should be closely monitored for return to soundness and reduction in swelling. In cases treated early, improvement is expected in 2 to 4 days after parenteral antimicrobial treatment.[16] Animals that do not respond as expected should have their diagnosis reevaluated by thorough examination of the foot to determine if another lesion is present or if the infection has extended to deeper tissues.

Control and Prevention The bacterial agents of foot rot are residents of the alimentary tract and the environment of the ruminant. Their ability to cause pathology requires damage to the skin barrier in the form of moisture leading to softening and maceration of the skin or abrasions from rocks, concrete, or stemmy or frozen forage.

General principles for control involve evaluation of the environment for potential risk factors, including low-lying areas with standing water and congregation points that collect urine and manure. Hygiene should be improved wherever possible through the use of drainage systems, manure removal, and regrading areas or by avoiding certain pastures during wet times of year.

Some owners and veterinarians may be motivated to control foot rot using in-feed antimicrobials or other additives touted to improve control. No feed additives are approved in the United States for treatment, control, or prevention of foot rot, and extralabel use of feed additives is prohibited by the Animal Medicinal Drug Use Clarification Act.

The utility of footbaths is limited by the availability of efficacious compounds, environmental and occupational safety, contact time, and the ability to maintain the hygiene of the footbath. It can be difficult to get cattle to stand in the footbath long enough to achieve adequate bacterial killing, whereas standing too long results in contamination with fecal material, eventually leading to inactivation.[7] Antibacterial agents and astringents, including 3% formalin, 2% copper sulfate, oxytetracycline, and lincomycin-spectinomycin formulations, traditionally have been used. Dry footbaths have also been reported and include 10% copper sulfate and slaked lime.[6] Practitioners must check state and local laws regarding the use of these substances that can cause environmental contamination and occupational health hazards.

Commercially available vaccines against *F. necrophorum* exist for use in cattle. Independent studies regarding the efficacy of these vaccines are limited. One study evaluating the incidence of liver abscess and foot rot in vaccinated versus nonvaccinated feedlot cattle showed reduced incidence of both syndromes with vaccination, but that difference was confounded by diet, with improvement only occurring in cattle fed free-choice forage.[17] The role of this dietary influence on foot rot is unknown.

Trace mineral nutrition is an important consideration when evaluating foot health on any operation. Iodine, copper, selenium, zinc, and biotin support overall foot and hoof health. Variable results have been achieved in controlling foot rot using supplementation of trace minerals and biotin.[18,19]

Infectious Foot Rot in Small Ruminants

Philippa Gibbons

Epidemiology Lameness is a significant issue in small ruminant welfare and production. In the UK, lameness prevalence was estimated at 10.4%[1] in 2004, with 80% of lameness caused by foot rot.[2] In 2013 prevalence had decreased to 5.4%.[3] In the United States, 20.4% of sheep producers reported lameness as an important issue, and 24% of producers treated ewes for lameness.[4]

Pathophysiology Two organisms are involved in ovine foot rot: anaerobic gram-negative bacteria *Fusobacterium necrophorum*, found in the environment and feces, and *Dichelobacter nodosus*, an obligate parasite of the foot. It has been generally accepted that *D. nodosus* can survive in the environment (in feces, soil, or pasture) for only 10 to 14 days, which has influenced eradication protocols. However, survival up to 30 days has been reported,[5,6] with prolonged survival in clay soils.[5] Transmission occurs when mean daily temperatures exceed 10° C (50° F) and rainfall is greater than 50 mm per month.[7] However, in the UK foot rot has been reported year round when environmental temperatures are outside these parameters.[8] Transmission can also occur during periods of housing in warm, wet bedding.[7] Transmission of foot rot from ewes to lambs has been shown to be primarily through *D. nodosus* in the environment rather than direct transmission.[9]

Historically, *F. necrophorum* was thought to be the causative agent of interdigital dermatitis (or scald), with secondary infection with *D. nodosus* causing the sloughing of the hoof wall seen in foot rot cases.[7] Pasture conditions resulting in excoriation of the interdigital skin and maceration due to wet conditions predispose animals to developing interdigital dermatitis.[7] In recent studies, *D. nodosus* has been shown to have a primary role, with *F. necrophorum* secondary.[10,11] Current literature suggests that interdigital dermatitis and foot rot should be treated as one disease. Ten serogroups of *D. nodosus* have been identified, some of which are virulent strains. Virulence factors of *D. nodosus* have been identified as type IV fimbriae and AprV2 proteases.[12]

Foot rot caused by *F. necrophorum* and *D. nodosus* has also been reported in cattle, horses, pigs, deer, and mouflon.[13] There is little published information about the disease in goats,[14] but foot rot is a reported cause of lameness in goats.[15] Overgrown hoof wall is more common in goats than sheep.[15] Treatment with oxytetracycline is reportedly effective in goats.[16]

Clinical Signs and Differential Diagnoses Diagnosis of foot rot is by examination of the feet. This is commonly performed by producers. Studies investigating interobserver agreement for lameness diagnosis in sheep achieved good levels

VetBooks.ir

of reliability when both experienced and inexperienced observers were assessed.[17] Ovine foot rot infection is characterized by lameness, foul-smelling interdigital dermatitis, and sloughing of the hoof wall as a result of separation of the hoof horn from sensitive laminae.[11] Disease can be characterized as benign, intermediate, or virulent.[7] Australian studies typically define foot rot as benign or virulent, according to determination of the virulence factors of *D. nodosus*. British studies typically characterize the disease according to clinical signs and lameness severity. Virulent *D. nodosus* has been detected in the feet of nonlame sheep, however.[1] Interdigital dermatitis (scald) is a milder form of disease primarily limited to the interdigital skin and without a foul odor.[7] Foot rot should be distinguished from contagious ovine digital dermatitis (CODD), which has low reported prevalence in the United States and results in severe lameness and underrunning of the hoof wall at the coronary band, ultimately resulting in avulsion of the hoof capsule. Treponeme bacteria are the presumed causative agent for CODD. Due to treatment differences for the two conditions, identification of the cause of lameness is important.[18] Confirmation of foot rot is achieved by laboratory testing; however, culture of *D. nodosus* can be challenging due to the fastidious nature of the bacteria. Gelatin gel, elastase, and intA PCR were used in one study,[19] but agreement between the three tests was low. Real-time PCR has also been used in individual[20] and pooled samples.[21] Quantitative PCR showed poor diagnostic specificity compared to the elastase test for one study.[22]

Treatment and Prognosis Historically, foot trimming and topical administration of antibiotics formed the major treatment and control measures for foot rot; however, foot trimming is no longer recommended as a treatment for foot rot due to prolonged recovery in trimmed sheep.[23,24] The number of ewes bleeding post foot trimming has been associated with higher prevalence of lameness.[3] Oxytetracycline administered parenterally is the most commonly reported antimicrobial treatment.[7,23-25] Oxytetracycline is not labeled for treatment of foot rot in sheep in the United States; therefore regulations for the extralabel use of antimicrobials and withdrawal times should be followed. Sheep treated with gamithromycin showed a significant reduction in foot rot–affected feet and severity of lesions compared to those treated with oxytetracycline in a nonblinded study in Germany.[25] Whole flock treatment with Micotil (tilmicosin) was investigated in the UK. Treatment reduced but did not eliminate disease from farms. The authors did not recommend whole flock treatment with Micotil due to the failure to eliminate disease, along with concerns about use of a critically important antimicrobial.[26] Gamithromycin used on a whole flock level was successful but cannot be recommended for the same reasons.[27] Florfenicol was used on a single flock of ewes in Germany in a targeted, selective fashion, and resolution of lesions was achieved in 96% of animals.[28] Penicillin and dihydrostreptomycin combination has also been used in countries where it is available.[23]

Topical antibiotics (oxytetracycline) have been used to treat interdigital dermatitis successfully if dry conditions are maintained after treatment.[23] In a single flock study in the UK, prompt administration of parenteral oxytetracycline and topical tetracycline reduced lameness scores and improved production. Ewes had higher body condition scores and raised more lambs compared to those treated with trimming and topical antimicrobials.[29]

Prevention and Control Elimination of foot rot has been successfully achieved in Australia,[30] Norway,[31] and Switzerland.[32] The Australian eradication protocol used a combination of total destocking, inspection and culling of clinically infected animals, treatment with antibiotics, and culling and foot bathing.[30] Foot bathing took the longest time to achieve elimination and was the most labor intensive approach.[30] The Swiss eradication model involved careful claw trimming, weekly foot bathing in 10% zinc sulfate, and isolation or culling of nonresponders.[32] No antimicrobials were used. A similar protocol was used in Norway.[31] In the UK, a six-step method has been promoted; it involves treating sheep within 3 days of becoming lame; foot inspection without foot trimming; correct diagnosis; treatment of affected sheep with parenteral and topical antibiotics, not trimming; identification of treated sheep; and culling of chronic cases.[33] Eradication of the disease has been more easily achieved where there are periods of nontransmission (dry, hot weather); therefore eradication in wet, temperate climates is challenging.[23]

Foot bathing has been used for both treatment and control. Formalin at 2% to 3%, copper sulfate at 5%, antimicrobials, and zinc sulfate at 10% have been used.[23] To be effective, foot baths should be cleaned regularly and sheep should stand on a hard surface following bathing. Concerns about foot bathing include the use of formalin in meat-producing animals, the sensitivity of sheep to copper,[34] and the use of antimicrobials in an extralabel fashion.[23] Higher concentrations of formalin can cause cracking of the hoof wall due to overhardening.[23] Due to these concerns, zinc sulfate has been the most widely promoted. Foot bathing, however, is time consuming (2 to 20 minutes of contact time for zinc sulfate, depending on concentration) and should be repeated at least once a week for 3 weeks to be effective. Foot bathing has been shown to be economically feasible if minimized to treatment and prevention of interdigital dermatitis rather than treatment of foot rot.[35]

Vaccination has been used in both treatment and control of ovine foot rot. Commercially prepared vaccinations are not available in the United States. Vaccines available in other countries include recombinant fimbrial vaccine to 10 strains of *D. nodosus*. Monovalent and bivalent fimbrial vaccines are also available. Vaccination programs are most effective when used during a period of high-risk transmission.[23] Commercially available vaccines have been shown to protect for only 10 weeks, whereas monovalent and bivalent vaccines have been shown to be protective for longer periods. This effect is presumed to be due to antigenic competition.[36] Where multiple serogroups are present in a flock, antigenic competition can be overcome by sequentially targeting the serogroups with different bivalent vaccines every 3 months.[36] A contraindication of vaccination and simultaneous treatment with the anthelmintic moxidectin has been reported.[37]

Studies have shown that susceptibility to foot rot has some heritability[38,39]; however, there is also evidence to suggest that the infection rate and environment (bacteria die more rapidly in hot, dry conditions) are more significant than heritability in control of the disease.[40]

Selenium supplementation has been suggested to increase speed of resolution of foot rot lesions, although in a preventative model this finding was not replicated when selenium was fed at supranutritional levels.[41,42]

Other Infectious Conditions of the Foot

Canaan Whitfield-Cargile

Infections involving the feet of horses, cattle, and other large animal species are common and almost always caused by contamination from the environment gaining access to the soft tissue or bony structures of the foot within the hoof capsule. Typically the animal has an acute, progressive lameness such that it is almost non–weight bearing on the affected limb or will bear weight on the toe region of the foot but resist putting

VetBooks.ir

the heel on the ground. Other clinical signs include increased digital pulse pressure, heat, and sensitivity to hoof tester pressure over the affected area. Regional nerve blocks can be used to localize the lameness to the foot when doubt exists based on physical examination findings. Because the foot is encased in a shell of horny tissue, exudate from an infectious process often accumulates between the soft tissue and the horn. The exudate then spreads or dissects along that plane in the path of least resistance until an outlet is encountered, frequently near the coronary band and bulbs of the heels, where rupture and drainage can occur.

Problems Associated With Horseshoe Nails ("Nail Prick")

History and Clinical Signs *Nail prick* ("quicking") refers to penetration of the sensitive hoof structures, usually the sensitive laminae, by a driven horseshoe nail. Similarly, the term *hot nail* refers to a nail that does not necessarily penetrate the sensitive laminae but may put pressure on those tissues due to inappropriate proximity. The horse will usually react as the farrier drives or clinches the nail by jerking the foot from the farrier. In some cases, blood may appear on the nail or leak from the nail hole. It is important to realize that nail pricks occur for many reasons and are not always caused by a misdirected nail. Poorly made shoes, nails that are too large, poorly placed nail holes, and faulty nails can also result in a nail prick. Horses with poor hoof quality, thin hoof walls, or flaring hoof walls can be difficult to nail and thus are at greatest risk for nail prick. Fractious horses and young horses not previously shod may lean on the farrier or repeatedly pull the foot from the farrier, making nail driving difficult. Damage from an improperly driven nail can vary from minimal to serious infection, thus clinical signs also vary. Clinical signs include lameness, sensitivity to hoof testers, and increased digital pulses. Some horses will repeatedly stomp the affected foot or paw the ground immediately after shoeing. Others may point the affected limb after shoeing. Lameness may not be apparent immediately after shoeing and may occur days later when the nail hole becomes infected and the trapped pus begins to exert pressure. This delayed onset is especially common when the nail is too close to sensitive laminae but has not penetrated. The horse usually becomes acutely lame and worsens over time unless treated. Some infected nail holes will travel up the lamellae (white line) and create an abscess or soft spot at the hairline of the coronary band. The abscess will be directly aligned with the hoof wall tubules, leading to the infected nail hole, which is an important diagnostic aid.

Diagnosis Diagnosis of a misdirected nail warrants great diplomacy from the veterinarian, because many owners become unjustifiably upset with the farrier. Hoof tester examination, paying particular attention to pressure over the driven nails, is an essential diagnostic tool to locate the offending nail. Using a hammer to strike the outside hoof wall may also elicit a painful response over the nail, further increasing suspicion of that specific nail. When an abscess occurs days later, it can be very difficult to be certain that the cause of the abscess was a nail prick versus many other reasons. Unless there is irrefutable evidence of the cause of lameness and abscessation being a nail prick, it is advisable to not suggest that as a cause to avoid undue blame being placed on the farrier.

Treatment Pricks from nails can be potentially serious and require immediate treatment. If the nail prick is discovered by the farrier at the time of shoeing, the nail is removed. The nail should be examined for moisture or blood. The nail hole can be irrigated with antiseptics (i.e., povidone-iodine [Betadine] solution or hydrogen peroxide). The nail hole is then packed with iodine-soaked cotton and left open. Often the nail is redirected, and no further treatment is needed. If the horse's immunization status is not current, a tetanus vaccine should be given.

If the offending nail cannot be localized or the nail hole is infected, the shoe is removed. Hoof testers are then used to localize the painful nail hole. Frequently the pressure from the hoof testers will cause black, malodorous liquid pus to exit from the hole. The basis of treatment is to establish drainage. The infected nail hole often requires enlargement with a loop hoof knife or curette. Ideally, a cone-shaped hole is made, with the larger opening at the bottom of the hoof to facilitate drainage. The hole is irrigated and/or the entire foot is soaked in an effort to draw out any remaining infection. An important component of treatment is to protect the foot and nail hole from the environment (e.g., mud, dirt) by keeping the foot bandaged between treatment applications. Additional medications are usually unnecessary unless involvement is extensive. Antiinflammatory medications may be beneficial to decrease pain. Once the infection has cleared, the shoe is replaced and the horse can return to previous level of activity.

Prognosis Prognosis is usually good provided that minimal damage occurs to vital structures of the foot. Establishing drainage for sepsis is important to avoid potential complications, such as third phalanx osteomyelitis or coffin joint sepsis.

Subsolar Abscess

Subsolar abscess is one of the most common causes of lameness in the horse and cow, but it is relatively rare in sheep and goats. The vast majority of lameness in cattle is attributed to hoof problems including infection.[1,2] Most often, lameness is caused by a hole or crack in the horny sole, which then becomes packed with dirt, and eventually contamination extends to and is trapped within the sensitive soft tissue beneath the sole. Animals that are housed in exceptionally moist or filthy conditions and have inadequate hoof care or overgrown feet or have underlying pathology in either the hoof or systemic conditions are more prone to this problem. For example, a common presenting complaint of horses with keratomas is repetitive subsolar abscessation, and horses with pituitary pars intermedia dysfunction (PPID) often have recurring subsolar abscesses.[3,4] Horses taken from a very dry to a very wet environment, and vice versa, also tend to have a higher incidence of sole abscesses, apparently because of the sudden change in the moisture content of the hoof and the resultant cracking of the sole. Cattle with "corkscrew claw" (a hereditary condition) or other growth deformity in the claw are more prone to sole abscess. Puncture wounds or any form of trauma that introduces contamination to the soft tissue of the sole also may result in abscessation.

History and Clinical Signs Subsolar abscess is a common cause of acute lameness seen in all horses. There is no signalment or breed disposition. *Gravel* is a lay term describing the assumed etiology in which a piece of gravel migrates proximally from the white line to the coronary band, leaving an infected tract. Subsolar abscesses may originate from a penetrating wound in the white line, a nail hole, or a deep subsolar bruise. Lameness is usually acute and severe (grade 3 to 4 of 5) and may worsen over time until drainage is established. The horse will often point and may not bear full weight on the affected limb. Distal limb swelling often accompanies a subsolar abscess that has not had drainage established. Systemic signs of infection (fever, lethargy) usually are not associated with subsolar abscesses unless deeper structures are involved.

Diagnosis Digital pulses are usually increased, and the hoof capsule may radiate heat. A focal painful area can usually

VetBooks.ir

FIG. 38.32 Opened subsolar abscess draining gray and black purulent material.

(but not always) be located with careful hoof tester examination. Careful paring of the sole and frog may be helpful in locating the abscess, but the clinician must be careful not to damage good, healthy tissue while looking for the infection site. Foot poultices and hot-water foot baths will eventually help localize the affected area by softening the horny hoof tissue. Gray or black purulent material will leak from the infected tract (Fig. 38.32). Radiographs are useful to rule out other causes, such as third phalanx and navicular bone fracture. In some cases a gas or fluid pocket can be identified on radiographs.

Treatment Treatment is aimed at establishing adequate drainage. If an opening in the tract is present at the solar surface, it should be enlarged just enough for good irrigation and drainage. This may or may not require sedation or peripheral anesthesia of the foot. If pink tissue or blood is encountered, débridement is discontinued. Large holes should be avoided to prevent solar corium protrusion, which can be a painful sequela to overzealous hoof paring. If drainage occurs at the level of the coronary band and solar surface, through-and-through lavage is beneficial. Débridement at the coronary band level should be minimal to prevent iatrogenic coffin joint contamination. Once drainage is established, protecting the opened sole from the environment is recommended and can be accomplished with a foot bandage. Daily lavage and/or foot soaks in warm water with antiseptics and/or salt should be continued until sepsis and inflammation are eliminated. The shoe is replaced when the affected area is dry and cornified. Large areas may require a plastic pad under the shoe for solar protection. Antibiotics and NSAIDs are rarely needed except in severe cases or if penetration of deeper structures has occurred. The patient's tetanus immunization should be considered and a toxoid administered if needed, as foot abscesses are among the most common causes of tetanus in horses.[5] Principles of treating foot abscesses are the same for all large animal species.

Prognosis Prognosis for simple subsolar abscess is excellent but worsens if complications develop in which deeper structures of the foot become involved.

Deep Penetrating Injuries to the Sole

History and Clinical Signs Most animals' environments are filled with sharp objects that can penetrate the sole, causing severe damage to structures deep within the hoof capsule. All puncture wounds should be considered potentially serious, but those involving the solar white line or caudal frog area require special attention because of potential navicular bursa, digital tendon sheath, DDFT, or distal phalanx involvement.

The clinical signs of a penetrating wound to the sole vary with the anatomic structure involved and chronicity of the injury. The animal may show minimal lameness initially at the time of injury but severe lameness once sepsis is established days later.

Diagnosis If owners find a foreign body in the bottom of the animal's foot, they should be instructed to leave the object in the foot unless there is danger of further penetration. This facilitates the ability to determine the track of the offending object, as it can be very difficult even to find the puncture wound in some cases following removal of small, sharp objects due to the elastic nature of the hoof structures and collapsing of the penetration site. Once medical attention is sought, if the object is still present then radiographs are used to determine depth of penetration and location of penetration. If the object has been removed, a close examination of the solar surface of the hoof should commence. Systemic sedation and peripheral anesthesia using an abaxial sesamoid nerve block may be needed to thoroughly examine the penetrated equine foot. Regional IV anesthesia (Bier block) using a tourniquet is the method of choice for producing local anesthesia in cattle. A light paring of the sole and frog areas with a hoof knife may reveal a black spot indicating the penetration site. Paring should be performed carefully so that the solar corium is not injured with the hoof knife. If an entry wound is discovered, the foot is scrubbed and prepared for further diagnostic testing. A sterile flexible probe can be gently inserted into the hole and a radiograph taken to determine its depth and direction. The clinician must take care that inadvertent force or horse movement does not cause the probe to penetrate previously unaffected structures. Alternately, a less invasive and preferred method is to catheterize or place a sterile teat cannula into the hole and inject sterile radiopaque material to determine which structures are involved. Recently, advanced imaging modalities, including MRI, have been used to more accurately define the track of penetrating solar injuries.[6]

If sepsis of the podotrochlear bursa, DIJ, or digital tendon sheath is suspected or cannot be ruled out, synoviocentesis allowing for instillation of sterile saline to assess communication with the wounds and synovial fluid cytologic analysis and culture should be performed. If distal limb swelling is present, arthrocentesis should be delayed until the cellulitis subsides.

Treatment Broad-spectrum systemic antibiotics, anti-inflammatory medications, and tetanus prophylaxis are administered if penetration of deep hoof structures is suspected. If deemed necessary, antibiotics are initiated, ideally after synovial fluid has been obtained for bacterial culture. Establishment of drainage, copious lavage with sterile ionic fluid, and débridement of all necrotic tissue are indicated. Involvement of the podotrochlear bursa warrants use of navicular bursoscopy and

VetBooks.ir

aggressive medical therapy consisting of daily lavage of the bursa under general anesthesia and local treatment using antibiotics instilled within the bursa and regional limb perfusion. Surgical treatment such as the "street nail" procedure, which opens a window through the central frog and DDFT in the bottom of the foot to reach the navicular bursa, is a drastic and aggressive method of therapy not commonly used in favor of a less-invasive bursoscopy approach.

If the DDFT is involved (septic tendinitis), débridement and removal of frayed and infected tendon fibers may be performed on the standing, sedated horse using a tourniquet and peripheral anesthesia or under general anesthesia, depending on horse temperament and owner financial constraints. After débridement, heel elevation with a 4- to 8-degree wedge shoe decreases weight-bearing forces on the DDFT and provides some pain relief.[7]

Deep penetrating wounds to the sole, especially the solar–white line junction, can result in infectious osteitis of the distal phalanx. The horse usually presents with a chronic, recurrent draining tract at the coronary band or solar surface and varying degrees of lameness. Infection of the distal phalanx often results from undetected soft tissue infection or dissecting subsolar abscesses. As the bone infection progresses, blood supply to the area is compromised, and the area of avascular bone separates from the parent bone, forming a sequestrum or lytic area that is apparent radiographically (Fig. 38.33). Localized third phalanx septic osteitis and sequestrum formation may not become radiographically evident for weeks after the initial penetration injury.

Débridement and curettage of all soft and necrotic bone can usually be performed in the standing, sedated animal if its temperament permits. The infected bone is usually discolored and soft and should be curetted to healthy bone margins (see Fig. 38.33). Systemic antibiotics may be indicated in some cases, but in most cases postoperative antibiotics can be most easily administered locally via antibiotic-impregnated beads (polymethyl methacrylate or plaster of Paris) for continued antibiotic release at the infected site. Regional limb perfusion with antibiotics is also beneficial in some cases to treat infection locally and prevent extension to surrounding structures. A foot bandage is placed and changed every 1 or 2 days for the initial few weeks. Application of a bar shoe and hospital plate provides solar protection and decreases the labor and cost of daily bandage changes. The remaining care is as described for subsolar abscesses.

In cattle, simple sole abscesses following penetrating injury may heal quite satisfactorily without bandaging. Penetration of bone or synovial structures is managed as described above, although claw amputation is a treatment option in cattle that is not available to horses.[8] In cattle, a wooden block on the unaffected claw of the affected foot elevates the affected claw to a non–weight-bearing level and greatly reduces lameness. The block is attached with an epoxy adhesive and allowed to wear off over a period of weeks.

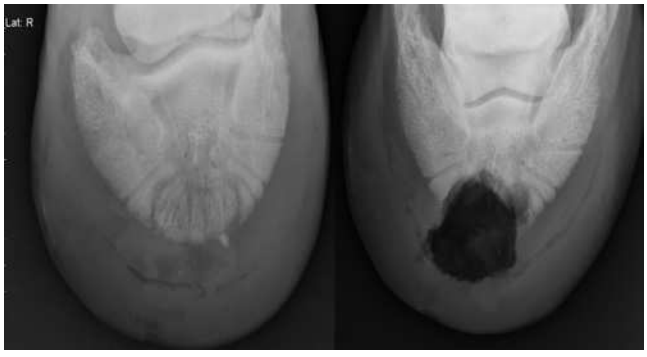

FIG. 38.33 Septic osteitis of the third phalanx before *(left image)* and after *(right image)* curettage of the infected region via a solar approach in the standing, sedated horse.

Prognosis Prognosis depends on severity of injury, structures involved, and chronicity of the problem before initiating treatment. Overall return to soundness has been reported to range between 36% and 60%, but horses with acute penetrating wounds that receive immediate and aggressive treatment have an excellent prognosis.[9,10] Factors that contribute to a poorer prognosis include involvement of a synovial structure, the distal phalanx, and time to presentation to the hospital. Established infection involving the podotrochlear bursa, digital tendon sheath, or distal interphalangeal joint has a poor prognosis.

Prognosis for infectious osteitis of the distal phalanx is good if sepsis is not caused by laminitis.[11] In one study, up to 24% of the distal phalanx was removed, and the horse returned to athletic soundness.[12]

Thrush

Definition and Etiology Thrush is a bacterial infection characterized by an accumulation of black, malodorous, necrotic material usually originating within the central or collateral sulci of the frog of the hoof. This degenerative condition may spread to involve deeper structures of the foot, such as the digital cushion, hoof wall, and heel bulb region, causing inflammation and breakdown of these structures.[13] This disease in horses is often considered similar to hoof rot in other large animal species.[14] Animals standing in soiled stalls, deep mud, swampy land, or wet pastures are at risk for developing thrush. Another predisposing factor is poor hoof conformation. Saddlebreds, Tennessee Walkers, and other gaited horses have long feet with naturally deep frog sulci and are at risk of thrush. Horses shod with full pads may develop thrush secondary to moisture and dirt collection under the pad. Other well-kept, clean horses can develop thrush for no apparent reason. Thrush is caused by a bacterial infection that appears to be most commonly associated with *Fusobacterium necrophorum;* in contrast, foot rot is associated with both *F. necrophorum* and *Dichelobacter nodosus*.[15]

Clinical Signs and Diagnosis Lameness may or may not be present, and severity can vary. Diagnosis is based on the presence of black, malodorous discharge, most often within the frog sulci. The central frog sulcus is often malformed and very deep. A painful response may occur when the affected sulci are cleaned because the degenerative process may extend to sensitive structures of the foot. If structural damage has occurred, the heels may move independently of each other, causing pain on manipulation. Horses with mechanical instability of the heels may show caudal heel pain.

Treatment The basis for treatment is removing the predisposing cause of the thrush. The horse should be moved to a clean, dry environment and have the feet cleaned daily, and if needed, proper farrier management should be pursued to correct existing problems. Any necrotic debris and undermined tissue are carefully débrided and cleaned using a hoof knife. Foot bandages may be necessary if the débridement is extensive. Infection is usually managed by topical medication. Several caustic materials have been recommended, including a combination of phenol, tincture of iodine and 10% formalin, Kopertox solution, dilute bleach, or methylene blue. Others have recommended soaking the foot in chlorine bleach (1 oz bleach per gallon water). Exercise is important to strengthen the caudal aspect of the foot and will naturally clean the feet. The best prevention for thrush involves educating the client on proper hoof hygiene.

VetBooks.ir

Prognosis Prognosis is favorable if the cause of thrush can be identified and eliminated and if the condition is treated before extensive hoof damage has occurred.

White Line Disease ("Seedy Toe")

History and Clinical Signs The white line, visible at the sole, is created by the junction of the insensitive laminae of the hoof wall and the horn of the sole. White line disease has historically described the separation of the hoof wall from its laminar attachments. A crack or opening occurs within the white line, allowing a bacterial or fungal infection to invade the stratum medium close to the laminae, causing cavities to develop between the laminae and the outer hoof wall. Several fungal organisms have been associated with white line disease in horses.[16] In environmental conditions with too much moisture (continuous wet pastures) or in drought conditions that produce excessively dry feet, animals are at risk of developing a crack or opening in the white line. Horses with poor-quality hoof walls that split or crack may develop white line disease. In addition, horses with chronic laminitis having a thickened or stretched white line in the toe region ("seedy toe") are predisposed to this disease.[17]

The hoof wall separation is usually a chronic condition beginning weeks or months before presentation. Horses with white line disease often show little or no lameness, and therefore the disease is not perceived as an immediate concern by many owners.

Diagnosis Visual examination of the white line, assisted by a probing instrument, will reveal a cavity with separation of the outer hoof wall from the laminae. Radiographic evaluation can determine the full extent of hoof wall separation. Often the cavity is either dry or filled with necrotic debris, which may involve a bacterial or fungal infection. The cavity is usually not painful to probing.

Treatment Treatment begins with removal of the separated outer hoof wall. After thorough débridement, large defects usually exist in the hoof wall and require protection. A heart-bar shoe redistributes weight-bearing forces to the frog and caudal region of the foot and away from damaged and weakened areas. The hoof wall defects prevent normal nailing procedures, and shoe clips can help secure the shoe to the hoof. After hoof wall removal, the exposed laminae may still have an active infectious component, requiring continued topical application of antiseptics. Once the exposed laminae are dry and inactive, the horse may be a candidate for prosthetic hoof wall repair using an acrylic polymer.

Prognosis Prognosis depends on response to treatment and the cause of the original white line problem. Horses with poor hoof quality or seedy toe will often have disease recurrence. If the horse responds to original treatment and if environmental conditions improve, prognosis is good.

Quittor

History and Clinical Signs *Quittor* is a term used to describe chronic infection of the medial or lateral collateral cartilage of the distal phalanx in the horse. This condition is characterized by local inflammation and necrosis of the affected cartilage, with subsequent formation of draining tracts proximal to the coronary band. The infection is usually caused by a wound, and the horse often presents with moderate to severe lameness and a history of chronic or recurrent drainage.

Diagnosis The diagnosis is based on clinical signs and radiographic findings. Specifically, obtaining a dorsopalmar radiographic view after injecting contrast dye into the draining tract helps demonstrate the infected collateral cartilage.

Treatment Although this condition occasionally responds to medical therapy, the treatment of choice is surgical débridement with the horse under general anesthesia, the foot in full extension, and a tourniquet around the pastern. An elliptical section that includes the draining tract should be incised above the coronary band and discarded. All underlying infected soft tissue and necrotic cartilage should be excised. The incision can be closed, partially closed, or left open to allow for continued débridement if necessary, based on severity of infection and the surgeon's confidence in complete resection of affected tissues. If the condition is chronic with extensive cartilage necrosis or multiple draining tracts, the infectious process usually extends below the level of the coronary band. In these cases it is best to trephine a hole in the hoof wall at the lowest point of the infection. This procedure provides better drainage, facilitates débridement of the necrotic cartilage, and allows for complete closure of the surgical incision above the coronary band. The wound should be packed through the trephine hole and treated as an open wound until it heals. In cases with extensive cartilage necrosis, care should be taken to avoid accidental opening of the coffin joint. If débridement is complete and the distal interphalangeal joint has not been entered during surgery, the prognosis for the return to soundness is fair to good.[18]

Fistulous Withers

Sarah M. Reuss

Definition Fistulous withers is a chronic inflammatory condition of the supraspinous bursa and associated tissues in horses, mules, and donkeys. The supraspinous bursa is located dorsal to the dorsal spinous processes of the second through fifth thoracic vertebrae. The normal bursa may extend laterally to the scapular cartilage, and it may be asymmetric. Normal bursal volumes range from 30 to 90 mL.[1]

Clinical Signs Affected horses may show nonspecific signs including lethargy, fever, and generalized muscle stiffness. These may progress to more specific signs of pain, heat, and swelling of the withers and cervical area. Over days to weeks, these swellings mature and rupture at one or more locations, releasing serous or mucopurulent drainage. The classically described discharge is yellowish-brown with white, yellow, or red flakes ("rice bodies").[2] Fistulous tracts may extend to the dorsal spinous processed of the vertebrae, as well as to the scapula, ribs, and occasionally the thoracic cavity. Lesions and drainage may wax and wane.

Etiology and Pathophysiology There are two forms of fistulous withers: idiopathic (or typical) and traumatic (or atypical). The more common idiopathic form results from the spread of inflammation and infection of the supraspinous bursa to surrounding structures, including the nuchal ligament and/or dorsal spinous processes. Organisms reported to be the primary cause of fistulous withers include *Brucella abortus*, *Actinomyces bovis*, and *Onchocerca cervicalis*. *B. abortus* has a predilection for synovial structures and is often associated with septic supraspinous bursitis in addition to septic atlantal bursitis ("poll evil"). In 1937, *B. abortus* was isolated from 80% of fistulous withers cases; 92% of those horses had contact with cattle, and 65% of affected horses were from farms with *Brucella*-positive cattle.[2] Currently there is some geographic variability. In New York, where the prevalence of *B. abortus* infection in cattle is low, *B. abortus* is rarely isolated from equine cases of fistulous withers. In 1988, the prevalence of *B.*

VetBooks.ir

abortus in horses presented to the New York State College of Veterinary Medicine had apparently decreased, with only 2 of 14 (14%) horses having positive titers.[3] However, in Texas, where seropositive cattle are still prevalent, 9 of 28 (37.5%) horses with fistulous withers were seropositive for *B. abortus*, and these horses were more likely to be pastured with seropositive cattle.[4] Researchers have also produced fistulous withers experimentally via injection of *B. abortus* and *A. bovis* into the supraspinous bursa.[5] *O. cervicalis* has also been proposed as an etiology for fistulous withers, especially in Australia. This parasite migrates through the nuchal ligament, causing inflammation that may extend to the supraspinous bursa. Fibrous and calcified tracts develop around dead and viable parasites, causing necrosis and degeneration of the nuchal ligament.[6] *Streptomyces* spp. have also been incriminated as the cause of fistulous withers in donkeys in Sudan.[7]

The traumatic form of fistulous withers is preceded by an open wound or blunt trauma to the withers and then secondary infection. Infection may result from external contamination or from hematogenous spread to devitalized tissue. Secondary contamination of open wounds with *Streptococcus equi* subsp. *zooepidemicus*[3] or environmental microorganisms is reported.

Diagnosis A careful history must be obtained, including duration and severity of clinical signs and response to previous treatment. Physical examination with careful palpation over the withers may reveal pain, swelling, or draining tracts. CBC may show leukocytosis due to neutrophilia as well as hyperfibrinogenemia indicating chronic inflammation.

If the swelling is encapsulated and not draining, needle aspiration should be performed to obtain a sample for culture and sensitivity. Once tracts are open and draining, culture is of questionable validity due to secondary bacterial contamination. Negative cultures can also be misleading, as *B. abortus* is difficult to grow in culture and may be overgrown by other bacteria. Biopsy of inflamed tissue may also be obtained for culture and histology. Blood cultures may also be diagnostic in febrile animals.

Serologic testing for antibodies against *B. abortus* should be performed in all animals with fistulous withers due to the public health implications. The plate agglutination test is more sensitive and specific than the card test. *Brucella* titers are considered to be negative when they are less than 1:50. Ideally, paired titers should be performed, with any rise in titers performed 2 weeks apart being indicative of current infection.[8] Chronic infections may not show an increase, however, so a single high titer with compatible clinical signs should be considered diagnostic. Animals should be isolated while awaiting test results, and public health officials should be contacted if *Brucella* is suspected.

Radiographs should be obtained to determine the extent of the lesions, the presence of osteomyelitis of the dorsal spinous processes, and/or the presence of a foreign body. There may also be swelling or granular opacity of the soft tissue in the withers region.[3] Horses with positive *B. abortus* titers are more likely than seronegative horses to have radiographic evidence of osteomyelitis of the dorsal spinous processes.[4] A positive contrast fistulogram may help determine the extent of any draining tracts. Ultrasonography may also help delineate draining tracts or foreign bodies.

Treatment Medical treatment may be attempted but is often unsuccessful alone. Antimicrobial selection should be guided by culture and sensitivity results. In the absence of a culture, systemic broad-spectrum antimicrobials may be used. This should be combined with lavage of the draining tracts. Systemic antiinflammatories are also indicated to control pain.

Brucella vaccination with the S19 strain has been reported in *Brucella*-confirmed cases as an effective extralabel treatment in horses. The vaccination regimens described vary from single-dose subcutaneous injection to a series of three subcutaneous injections 10 days apart. Success rates of 70% have been reported in horses treated with S19 vaccine.[2] However, subcutaneous injection reportedly causes severe local and systemic reaction, including fever, depression, and local abscessation.[8] Intravenous administration of S19 vaccine has also been reported, but it resulted in death in 3 of 4 horses.[4] At this time, there are no approved vaccinations for use in horses, and the RB51 vaccine has not been used in equids. Also, the apparent decline in frequency of *Brucella* in fistulous withers makes vaccination of questionable value.

Medical management alone is rarely effective and usually needs to be combined with aggressive surgical débridement. Reportedly 80% of traumatic fistulous withers treated conservatively will have recurrent lesions.[9] Standing drainage and débridement has been performed, but general anesthesia and aggressive débridement is the preferred treatment.[3] Ostectomy and curettage of the dorsal spinous processes may be necessary. Primary closure is difficult to achieve but will provide a more cosmetic result and quicker healing time. Wounds left open to heal by second intention may take months to heal.[3] Application of maggots (freshly emerged, germ-free larvae) in combination with light surgical débridement has been reported in five cases. Four of those resolved successfully, with the remaining case being lost to tetanus before complete healing was achieved.[10]

Prevention and Control *B. abortus* infection, if present, carries great public health implications. Horse owners and veterinary staff must be notified of the possible exposure and take appropriate precautions. Brucellosis in humans may cause acute fever with pneumonia, spondylitis, orchitis, or pyelonephritis. Chronic brucellosis causes a transient fever in humans.[1]

Parasite control is an important aspect of prevention of fistulous withers. Horses should also be kept separate from *Brucella*-positive cattle. Proper saddle and harness fit also decreases the incidence of traumatic fistulous withers.

Flexural Limb Deformities

Berkley Chesen

Definition Flexural limb deformities (FLDs) are defined as hyperflexion or hyperextension of a limb. Flexural deformities are described by the joint involved and occur in the sagittal plane, typically the distal interphalangeal joint, metacarpophalangeal/metatarsophalangeal joint, carpus, and rarely the tarsus. Although commonly referred to as "contracted tendons," the tendons themselves are not truly contracted but rather functionally short relative to the adjacent bone, as only the muscular component can truly contract. Flexural limb deformities can be classified as either congenital or acquired. Flexural deformities are very common in horses and cattle. Small ruminants and camelids are much less commonly affected.

Pathogenesis Congenital flexural deformities (present at birth) are likely caused by a multitude of factors. Although intrauterine positioning has been suggested, it is likely only one cause of FLDs. Exposure of the mare during pregnancy to diseases and teratogenic agents is a possible cause of congenital FLDs. Evidence behind an absolute inciting cause is lacking, but the following have been implicated in contributing to FLds: deficiency in glycogen branching enzyme in Quarter Horse foals that is transient, ingestion of locoweed and hybrid Sudan grass, equine goiter, defective crosslinking of collagen and elastin formation from lathyrism, neuromuscular disorders, and viruses.[1-5] It is common for foals with congenital flexural deformities to have other anatomic abnormalities, such as spinal

VetBooks.ir

FIG. 38.34 Flexural deformity of the distal interphalangeal joint.

FIG. 38.35 Flexural deformity of the metatarsophalangeal joint.

deformities that may result in dystocia. In a recent study of Thoroughbred foals in New Zealand, it was found that of 203 foals, 67% had at least one FLD (58% laxity, 38% contracted). At follow-up, 93% had improved with conservative management. Male foals were more likely than female foals to have FLDs, and gestation length was 347 ± 9 days for all foals. Age of the mare was found to be a significant factor (62% of mares younger than 12 years had foals with FLDs versus 79% of mares 12 years and older).[6]

Acquired flexural deformities typically are seen from 4 weeks to 4 months of age, as well as in yearlings up to 2 years old. These deformities have been implicated as part of the developmental orthopedic disease complex. There are two general theories to explain how acquired flexural deformities occur. The first theory is that the tendon unit is unable to passively elongate relative to the bone.[7] In the case of the distal interphalangeal joint, the rigid deep digital flexor tendon and its accessory ligament cause a palmar rotation of the foot (club-footed) (Fig. 38.34). Flexural deformities in the metacarpophalangeal joint often occur during rapid growth in the distal radius, leading to a functional shortening superficial digital flexor muscle-tendon unit. The second theory is that longitudinal bone growth cannot create a functional shortening of tendons and that increased tension within the tendon induces pain leading to the deformity.[8] Acquired deformities are often noticed with a very acute onset (24 hours), which may add validity to the latter theory. Pain may initiate the deformity, but this can become a permanent condition if not addressed promptly, causing contracture to occur. Contracture results from fibrodesis of the joint capsule and periarticular structures.[7]

Diagnosis

CONGENITAL DEFORMITIES. Digital hyperextension deformities occur in neonates due to lack of tension in the flexor muscles. Typically these deformities correct without intervention within a few weeks. In severe cases, the palmar or plantar surfaces of the foal's pastern and fetlock area may become ulcerated due to contact with the ground if not protected.

Contractural deformities may involve one or a combination of the superficial digital flexor tendon, deep digital flexor tendon, or suspensory ligament. Congenital flexural deformities most commonly affect the carpus and metacarpophalangeal/metatarsophalangeal joint (Fig. 38.35).[9] Flexural deformities of the distal interphalangeal joint and the tarsus occur less frequently. In some pony breeds and miniature horses, lateral luxation of the patella results in the stifle showing a flexural deformity. This is usually due to a hypoplastic trochlear groove. Depending on the severity of the deformity, if the metacarpophalangeal joint is affected, the foal may or may not be able to stand.[7] Although not truly a flexural deformity, rupture of the common digital extensor tendon results in a similar appearance. This can result secondary to flexural deformities. These foals have a characteristic swelling on the dorsolateral aspect of the carpus. Often these foals bow at the carpus due to the lack of support over the lateral aspect of the carpus.[2,10] More importantly, foals with ruptured common digital extensor tendons should be checked for incomplete ossification of cuboidal bones, as these conditions often occur together.[7]

ACQUIRED DEFORMITIES. The most common acquired flexural deformity involves the distal interphalangeal joint and typically occurs within the first 4 months of life. The affected limb will have a more vertical hoof wall angle with a shorter toe than the unaffected limb; however, the condition is often bilateral. The heel will get longer on the affected limb, the metacarpophalangeal joint will concurrently begin to hyperextend, and the toe will undergo more wear, potentially causing issues with the white line. Two stages have been used to describe flexural deformities of the distal interphalangeal joint: stage I is defined as an angle of less than 90 degrees between the dorsal hoof wall and the sole; stage II is defined as a dorsal hoof wall that exceeds vertical.[11]

Early detection of flexural deformity of the metacarpophalangeal joint is characterized by a straight fetlock angle, or upright conformation. More severe deformity of this joint is evident by buckling at the fetlock. By placing pressure in a dorsal-palmar direction on the fetlock, the flexor tendons are stretched, allowing the practitioner to determine which structure is tightest, which is important for selecting an appropriate treatment.[7] It is also important to palpate the limb while not bearing weight to determine whether adhesions are present.

Carpal flexural deformities tend to occur within the first 6 months of life. These foals tend to be fast-growing, heavier foals (Fig. 38.36). Although not as common, flexural deformities of the proximal interphalangeal joint occur and are usually bilateral, affecting the hind limbs.[7] The exact mechanism is unknown, but it is thought that as the musculotendinous unit of the deep digital flexor complex shortens, the superficial digital flexor tendon becomes more lax.[12] This can lead to a dorsal subluxation of the joint. Often a clicking sound is appreciated when the foal walks. This condition is most often seen in weanlings with a high growth rate.[7]

Flexural deformities also occur after foals or horses are non–weight-bearing for a period of time. These deformities

VetBooks.ir

FIG. 38.36 Bilateral, mild carpal flexural deformity.

can be permanent if the joint undergoes "contracture" or fibrodesis (fixed without osseous ankylosis).[7]

Treatment

CONGENITAL DEFORMITIES. Hyperextension deformities require exercise to hasten recovery. Excessive exercise is contraindicated, as this leads to fatigue and possible injury. Treatments include swimming, corrective shoeing, and light bandaging when indicated. Swimming allows muscle tone to increase without bearing weight on the limbs. If the foal's toe lifts off the ground when weight bearing, glue-on shoes with a heel extension may be indicated. It is important not to leave glue-on shoes on a growing foal for an extended period since they may prevent the foot from expanding normally; changing them every 10 days is indicated. Bandaging is necessary only in cases where the palmar or plantar surface of the pastern or fetlock is in contact with the ground to prevent ulcerations of the skin and should not be supportive of the structures. Excessive bandaging and support will only cause more laxity and should be avoided.

Treatment for congenital flexural deformities should include pain management by judicious use of NSAIDs such as phenylbutazone at 1.1 mg/kg IV or PO daily or flunixin meglumine at 1.1 mg/kg IV or PO daily. The use of gastroprotectants such as omeprazole (4 mg/kg orally daily) is strongly suggested to help avoid the ulcerogenic effects of NSAIDs.

Oxytetracycline at a dose of 44 mg/kg diluted in physiologic saline given slowly intravenously has been used for many years in foals with flexural deformities.[13] Renal function of the foal should be taken into consideration prior to administration of oxytetracycline. There are many proposed mechanisms for how oxytetracycline works to achieve a decrease in the angle of the metacarpophalangeal joint. One mechanism proposes the chelation of calcium resulting in muscle contraction.[13] Oxytetracycline has been shown to be a neuromuscular blocking agent; however, this mechanism does not explain why other muscle groups are unaffected.[13] An in vitro study showed that oxytetracycline also works through matrix metalloproteinase 1 mRNA expression to inhibit tractional organization of collagen fibrils by myofibroblasts (the primary cell type in the DDFT and accessory ligament of the DDFT); this interaction may cause relaxation of the musculotendinous unit.[14] Regardless of the mechanism of action, foals treated with oxytetracycline should also undergo forced exercise to make the improvement permanent. Without exercise, the angle of the metacarpophalangeal joint tends to return to its previous value within 96 hours.[15]

A fairly new product on the market available to veterinarians is Leg Aide (Progressive Nutrition, Hopkins, Minn.), which has anecdotally positive results when used in conjunction with other therapies.

Toe extensions benefit the foal in two ways. First, they help protect the toe from being overworn; second, they lengthen the breakover of the foot, adding strain to the flexor tendons, potentially helping stretch them. Toe extensions may be made using acrylic hoof products or glue-on shoes with built-in extensions. In severe cases, the dorsal hoof wall should be incorporated into the shoe to prevent excessive strain at the toe and separation of the white line. Shoes and extensions should be removed within 2 weeks, as they can prevent the hoof from growing and expanding naturally in a young foal. Typically, 2 weeks is plenty of time to achieve correction. For foals with deformity of the distal interphalangeal joint, frequent rasping of the heels will help stretch the deep digital flexor tendon.

Splints and casts have been used to treat flexural deformities by giving support to the limb, thereby allowing the muscle-tendon unit to relax. When using splints, it is vital to use plenty of padding on the limb and to change the padding every time the splint is changed to ensure that pressure sores are not developing. Pressure sores can be very serious and even life threatening. Splints are made from a variety of materials but most commonly from polyvinyl chloride pipe that has been cut in an appropriate length and width; commercially made splints are also available. Splints are applied by placing the splint over the padding on the palmar or plantar surface of the limb. If the flexural deformity involves the distal interphalangeal joint, the splint should touch the ground. If the deformity is in the carpal region, the splint should end at the fetlock. Splints should be left in place for a period deemed adequate for the individual patient, ranging from several hours to 2 to 3 days.[7,9] One major advantage of splints over casts is that they may be removed every few hours if desired. Casts used for the lower limb are typically half-limb casts, incorporating the foot. The exception to this is for the carpal region, where a tube cast is more appropriate, ending at the fetlock. Casts should never be left in place for longer than 2 weeks at a time due to the rapid growth rate of foals. Cast sores are a very serious complication and a legitimate disadvantage to using them.

A combination of conservative treatments should be considered when treating foals with flexural deformities. If nonsurgical management does not correct the problem, surgical intervention may be necessary; however, foals with severe congenital contractural deformities have a poor prognosis. Surgery is more often attempted for foals with carpal contracture. Other congenital contractural deformities usually respond to nonsurgical treatments. Surgical correction for contractural deformities in the carpal region involves transection of the tendons of the flexor carpi ulnaris and ulnaris lateralis as well as transection of the palmar carpal fascia.[7,9] The prognosis for mild to moderate congenital flexural deformities is good for an athletic future if the foal improves over the first 2 weeks and is able to stand and nurse.[9] Flexural deformities that can be straightened manually have a better prognosis than those that cannot be straightened.

Foals with ruptured common digital extensor tendons are best treated nonsurgically. Affected foals should be confined to stall rest with the application of a splint.[10] As with any splint, it should be well padded to protect the limb. The splint will provide support to the limb and help protect immature cuboidal bones, which often accompany this condition.[7]

ACQUIRED DEFORMITIES. Conservative management for acquired flexural deformities is very similar to that for congenital flexural deformities. Other conservative therapies include dietary restrictions, including early weaning. Surgical management is selected for those cases that are unresponsive to nonsurgical treatments.

VetBooks.ir

For flexural deformities of the distal interphalangeal joint, desmotomy of the accessory ligament of the deep digital flexor tendon (ALDDFT) is indicated. This surgery has an excellent prognosis for full athletic potential for stage I horses. For more severe flexural deformities of this joint (stage II), a tenotomy of the DDFT may be necessary.[16] This procedure is not performed to promote an athletic career. It is acceptable for pasture soundness, breeding animals, and some light riding. Gradual rasping of the heels should be combined with any treatment for flexural deformities of the distal interphalangeal joint. Integrative therapy such as acupuncture may be considered to help achieve analgesia, muscle relaxation, and a level of sedation to help achieve physical therapy.[17] A recent study evaluated desmotomy of the ALDDFT in 13 mature horses (2 years or older) suffering from lameness isolated to the foot with FLDs of the distal interphalangeal joint.[18] Lameness was decreased in 9 of 13, with 10 of 13 performing at their level of intended use, indicating that this procedure should be considered in older horses.[18]

Acquired flexural deformities of the metacarpophalangeal joint are treated nonsurgically with a combination of NSAIDs, corrective shoeing (raising the heel with or without a vertical bar shoe with rubber dorsal tubing), and splints. Physical therapy has been used to help stretch the tendons by having the horse hop on one leg by holding the other up in a flexed position moving in a lateral direction toward the down limb.[7] If surgical correction is needed, it is important to first determine which structure is creating the tension. Most commonly the superficial digital flexor tendon is involved; however, the deep digital flexor tendon and even the suspensory ligament may be involved. For treatment of contracture of the superficial digital flexor tendon, desmotomy of the accessory ligament of the superficial digital flexor tendon is performed. If the deep digital flexor tendon is the most taught, desmotomy of the accessory ligament of the deep digital flexor tendon is completed. Both accessory ligaments may be cut when indicated.[17] In very severe cases, the suspensory branches may be transected, but this procedure is done for salvage, as it usually leads to subluxation of the proximal interphalangeal joint.[7]

Carpal flexural deformities are treated with splints and controlled exercise. Early weaning should be considered in these foals. If surgery is necessary, a tenotomy of the flexor carpi ulnaris and ulnaris lateralis in addition to splints may yield good results.

Flexural deformities of the proximal interphalangeal joint are not as common, but can be very serious to the future athletic potential of the horse. Over time, the soft tissues around the joint will fibrose and the proximal interphalangeal joint may undergo degenerative joint disease. At this stage, a pastern arthrodesis may be necessary to achieve a pain-free and potentially sound limb. Desmotomy of the ALDDFT, as well as the tendon of the medial head of the DDFT (level of the chestnut), may benefit affected horses early in the disease process.[7,12]

Tendinitis

Ashlee E. Watts

Definition and Etiology Tendinitis is one of the more common musculoskeletal injuries in athletic horses. Of the two flexor tendons, the SDFT is more commonly injured than the DDFT tendon. SDFT injuries occur in the forelimb far more frequently than in the hindlimb, and most injuries are in the midmetacarpal region. The prevalence of superficial digital flexor tendinitis in Thoroughbred racehorses ranges from 7% to 43%.[1] SDFT injury also occurs in Standardbred racehorses and upper-level event horses and is less commonly diagnosed in other performance horses. Deep digital flexor tendinitis is typically diagnosed in older (ages 9 to 10 years) performance horses. Injury to the distal portion of the DDFT is a major contributor to lameness in horses with foot pain,[2] and DDFT injury also occurs in the fetlock or pastern regions within the digital flexor tendon sheath (DFTS) and infrequently in the metacarpal/metatarsal region.[3,4] Desmitis of the accessory ligament of the DDFT[5] and the accessory ligament of the SDFT[6] are unusual injuries in performance horses.

The function of a tendon is to transfer activity from its associated muscle to its bony attachments on the opposite side of a joint. This allows for joint movement and locomotion. During locomotion, the elastic properties of tendons, particularly those of the SDFT, give them the ability to act like a spring, storing and releasing energy back to the limb to aid in limb advancement during movement. During gallop, substantial elongation of fibers (tendon strain) of up to 16% in the SDFT have been recorded, which is similar to the failure strains of 15% to 17% recorded in vitro, and operating this close to physiologic limits may contribute to injury of the SDFT.[7-9] The DDFT has relatively lower peak forces and strains, contributing more to flexion of the distal interphalangeal joint than to energy storage, and correspondingly has a lower injury rate.[10,11]

Tendon injury occurs when fibers are stretched beyond physiologic limits, which can be due to cumulative and degenerative fatigue failure, as is more common for the SDFT, or to a single, sudden overloading event, as is more common for the DDFT. Factors such as hard or "fast" ground, a rider's weight, and increased load when landing from a jump can also contribute to tendon injury by increasing the peak load on the SDFT. This accounts for the higher incidence of superficial digital flexor tendinitis in Grand Prix jumpers and upper-level event horses than in those competing at lower levels.[12] Response to tendon injury is similar to other tissue healing and includes inflammation, repair, and remodeling. During the acute inflammatory phase, hemorrhage and edema occur, and the degree of the response is determined by severity of the injury. Angiogenesis quickly follows, recruited fibroblasts produce new type III collagen, and a fibrinous scar of weak, haphazardly arranged collagen fibrils is formed. This scar tissue remodels over several months and will slowly increase the amount of collagen type I in the healed area. Controlled loading of the tendon promotes remodeling and alignment of the collagen fibrils in the direction of force (longitudinally). In a severely injured tendon the entire process can take 12 or more months, and it is likely that continued remodeling of the scar may occur over a lifetime. The healed but scarred tendon is permanently stiffer than its original state, thus re-injury is common and usually located at the periphery of the previously injured area.

Clinical Signs The classic appearance of metacarpal/metatarsal superficial digital flexor tendinitis is a convex or bowed profile of the tendon when viewed from the lateral aspect. In acute injury, swelling and heat of the tendon and peritendinous tissues can be noted but may be mild in the earliest stage of injury. A painful response to direct digital palpation can be appreciated and is best performed by holding the leg and palpating the tendon between thumb and forefinger. Unless the injury is severe, most horses with superficial digital flexor tendinitis are only mildly lame initially and rapidly improve to minimal lameness.

Horses with DDFT injuries within the DFTS are moderately lame and more lame after distal limb flexion.[4] Most horses have DFTS distention and thickening, making accurate palpation of the DDFT difficult. Injuries are usually unilateral and occur more commonly in the hindlimbs.[4] Horses with DDFT injuries within the hoof capsule have unilateral or bilateral lameness without any palpable abnormalities.[2] Injuries can be

bilateral and are more frequently found in the forelimbs. Horses with desmitis of the accessory ligament of the DDFT have obvious swelling and are acutely moderately to severely lame.[5] Thickening and effusion in the carpal canal may be noted in horses with desmitis of the accessory ligament of the SDFT.

Diagnosis Ultrasonography remains the technique of choice to confirm the diagnosis and assess the severity of SDFT injuries. The entire palmar/plantar area of the metacarpus/metatarsus should be examined in transverse and longitudinal planes. The commonly measured variables include cross-sectional area, echogenicity, and fiber alignment. The severity of the injury is determined by the length of the lesion, cross-sectional area of the tendon, cross-sectional area of the lesion, lesion echogenicity, and fiber alignment of the lesion.[13] The severity rating score has been correlated with successful outcome. The most common type of SDFT injury is a central core lesion, which appears as an anechoic lesion.[13] Acutely, the core lesion may not be visible, and ultrasound findings may be limited to peritendinous edema with a slight enlargement of the SDFT cross-sectional area. If clinical suspicion of a SDFT injury is high, the ultrasound should be repeated in 5 to 10 days to check for an ultrasonographically visible core lesion.

Diagnostic analgesia may assist the clinician in localizing the tendon injury if clinical signs are subtle or absent. This is particularly true for DDFT injury within the hoof capsule. Pain from DDFT injury in the distal metacarpal/metatarsal region usually improves after intrathecal analgesia of the DFTS.[4]

MRI is the best method of diagnosing deep digital flexor tendinitis within the hoof capsule.[2,14] Injury types include core lesions, sagittal tears, and tearing along the dorsal border; most lesions occur at or near the navicular bone.[2] Transcuneal (through the sole) ultrasonography has been reported but is not easy. Successful imaging requires meticulous foot preparation and clinician expertise.[15] Tenoscopy is the best method for detecting DDFT injury in the DFTS, although ultrasound, contrast tenograms, and MRI can also be useful.[16]

Treatment Proper treatment of tendinitis includes assessment of the injury using ultrasonography, control of the acute inflammatory episode, controlled return to function, and adjunct medical and/or surgical therapy. In acute injury, a combination of systemic NSAIDs (e.g., phenylbutazone, flunixin meglumine) and topical therapy (e.g., cold water hydrotherapy, poultice, distal limb bandage) is recommended. Box stall rest is essential during the acute phase of injury to limit propagation of the injury, especially proximally and distally.

A variety of intratendinous and peritendinous injections have been advocated. Intralesional corticosteroids dramatically decrease the swelling and pain but cannot be recommended due to delayed tendon healing and the risk of continued injury and catastrophic injury in horses that remain in training. For metacarpal/metatarsal DDFT injuries, intrathecal injections of sodium hyaluronan into the DFTS have been beneficial.[17] The therapeutic role of regenerative medicine (e.g., stem cells derived from fat or bone marrow and platelet-rich plasma) in equine tendinitis is not fully understood. Long-term clinical efficacy has yet to be determined, but early clinical results are encouraging.[18,19] Other promising regenerative approaches that target specific pathophysiologic events in tendon injury are being developed and will likely become a standard treatment in the future.[20,21]

The surgical treatment of tendon splitting is no longer recommended due to increased damage to surrounding fibers.[22] Other surgical treatments that are recommended in specific cases are desmotomy of the superior check ligament[23,24] and desmotomy of the palmar/plantar annular ligament.[25] Superior check desmotomy may improve the likelihood that horses return to racing, but it remains somewhat controversial and may predispose horses to desmitis of the suspensory ligament.[26] Annular desmotomy has been successfully performed in horses with signs of annular ligament constriction in addition to flexor tendon injury.[25] Immediate decompression and improved gliding function are presumed benefits.

Other therapies for superficial digital flexor tendinitis that may speed accumulation of collagenous scar tissue include therapeutic ultrasound, low-power laser treatment, and extracorporeal shockwave therapy. Counterirritation (internal or external blisters) and pin firing in combination with controlled exercise or turnout in a large pasture are time-honored treatments, but their effects on tendon healing have not been helpful in studies.[22] These practices can no longer be recommended.

Controlled exercise in combination with the treatments described is of paramount importance in guiding the repair process to produce a functional tendon or tendon substitute. If exercise is excessive or uncontrolled, excess fibrous tissue is produced and remodeling is delayed. If no stress is applied, the tendon will not become well adapted for performance. Therefore a controlled incremental exercise program that is carefully monitored ultrasonographically is advocated. The program should be flexible and adjusted based on the severity of injury and the quality of healing. Typically, stall rest coupled with gradually increasing amounts of hand walking and trotting are recommended. Horses are monitored by regular clinical and ultrasonographic assessment until they have returned to their previous athletic function or have failed to do so. As the tendon heals, its echogenicity increases, and short linear echoes are detected. With continued healing, longer linear echoes and improved fiber alignment appear. Decrease in cross-sectional area is a good indication that the tendon is healing and remodeling. Ideally, complete repair will occur, and the tendon will no longer have a discretely visible area of injury because it has filled in with tissue that is isoechoic with normal tendon and fiber alignment is parallel to normal.

Successful treatment of DDFT injuries within the foot remains a challenge. Without surgery, long-term follow-up indicates a high rate of recurrent lameness despite prolonged periods of stall rest and corrective shoeing.[2] Surgical débridement via navicular bursoscopy appears to be helpful, especially in cases without concurrent severe navicular bone degenerative changes, although long-term follow-up is not yet available in the literature.[14] DDFT injuries within the DFTS also require surgical débridement for the best chance of healing and return to performance. This is because most DDFT injuries within a synovial environment involve the surface and epitenon of the tendon allowing synovial access to the tendon matrix, which limits healing.[27]

Prognosis Prognosis for horses with superficial digital flexor tendinitis depends on lesion severity and the type of athletic work performed. Although many horses treated with appropriate rest and controlled exercise programs will return to work, including racing, re-injury rates are high.[28,29] This is likely because of the permanent change in tendon stiffness due to accumulation of scar tissue in the healed area. Standardbreds, English sport horses, and Western performance horses appear to have a better prognosis. Horses with DDFT injuries remain problematic; prognosis is fair to poor, but as reports on bursoscopically and tenoscopically treated deep digital flexor lesions come out, the prognosis may improve.[2,4,30]

Suspensory Ligament Desmitis

Ashlee E. Watts

Definition and Etiology The suspensory ligament (SL), also known as the *interosseous muscle*, is a strong, flat, tendinous

band that contains a variable amount of muscle fibers.[1] The SL originates from the palmar carpal ligament and the proximal palmar aspect of the third metacarpus (MCIII) and in the hindlimb from the proximal plantar third metatarsus (MTIII). Coursing distally, it descends between the second and fourth metacarpal/metatarsal bones and divides into the medial and lateral branches before inserting on the abaxial aspect of the proximal sesamoid bones. The suspensory apparatus continues distally as the straight, oblique, cruciate, and short distal sesamoidean ligaments, which originate from the base of the proximal sesamoid bones and insert in the palmar pastern. The SL's main function is to prevent hyperextension of the fetlock joint.[1] Its branches also help stabilize the rotational forces on the joint. Injury to the SL occurs when it is overloaded with stress (overstretched) and its structural integrity is compromised. As with tendons, the repair process is characterized by inflammation (desmitis) and resultant fibroplasia. Healing occurs over many months, and repaired tissue is subject to re-injury due to the accumulation of scar tissue. SL desmitis is a common injury in all breeds of performance horses. Both forelimb and hindlimb injuries occur, and bilateral desmitis is not uncommon. Desmitis of the SL can be divided into three regions of interest: the proximal (origin) portion, the body, and the branches. Proximal SL desmitis is likely due to hyperextension of the carpus/tarsus in conjunction with severe overextension of the fetlock joint.[1] Straight hock conformation and hyperextension of the fetlock joint may be predisposing factors or may exacerbate the injury in the hindlimbs. Exercise in deep soft footing may also increase risk of injury.[2] Avulsion fracture, bone sclerosis, and/or enthesophyte formation in the proximal palmar/plantar MCIII/MTIII can also occur. Proximal SL desmitis occurs most frequently in sport horses, racehorses, and Western performance horses.[1] Injury to the body of the SL is less common and occurs predominantly in racehorses, specifically Standardbreds.[1,2] Desmitis of the SL branches is most common in Standardbreds and jumping horses.[1] In the SL branches, injury is frequently associated with fetlock lameness, which suggests that the twisting motion of the fetlock predisposes horses to injury.

Catastrophic traumatic disruption of the suspensory apparatus occurs almost exclusively in the forelimbs of Thoroughbred racehorses and is the most common cause of breakdown injuries.[3] Fatigue and high speed are components of this career-ending injury. Degenerative suspensory ligament desmitis (DSLD) is a disorder characterized by progressive degeneration and enlargement of the SL, resulting in excessive fetlock hyperextension (dropping). Affected horses are generally dropped in both hind fetlocks and variably painful. The condition occurs sporadically in many breeds, usually older horses and broodmares.[1] Peruvian Paso[4] horses may be at risk and often are affected in all four limbs. The pathogenesis is unknown.

Clinical Signs

Horses with proximal SL desmitis frequently have no localizing clinical signs. Heat, swelling, and edema are transient or absent, and lameness is variable. Horses with bilateral injury, especially in the hindlimbs, may have subtle gait abnormalities that are only apparent during ridden work. Lack of impulsion, resistant behavior, and loss of hindlimb activity are frequent complaints. In horses with desmitis of the body and branches of the SL, heat, pain, ligamentous enlargement, and lameness are common. Associated fetlock effusion and concurrent distal splint bone fractures may also be noted. Acute severe traumatic disruption of the suspensory apparatus results in obvious swelling, grade 4 to 5 lameness, and a hyperextended fetlock. Affected horses require first-aid treatment by application of a splint for weight-bearing stability. DSLD is characterized by bilateral chronic lameness, painful and enlarged SLs, dropped fetlocks, prolonged periods of recumbency, and reluctance to move.[1,4]

Diagnosis

Perineural analgesic techniques help localize the site of lameness pain to the SL. For proximal SL desmitis, analgesia of the deep branches of the lateral palmar nerve[1,5] or lateral plantar nerve just distal to the tarsus[1,6] will alleviate lameness in the forelimb or hindlimb, respectively. Desmitis of the SL body and branches is localized using low palmar/plantar analgesia.

Ultrasonography is the imaging modality of choice for all but the proximal SL of the hindlimb, where high field MRI is the modality of choice.[7] Lesion severity is assessed by obtaining cross-sectional and longitudinal views of the ligament and cross-sectional area measurements. Ultrasonographic changes include cross-sectional area enlargement, focal or diffuse areas of hypogenicity, core lesions, loss of normal fiber pattern, and periligamentous thickening. Mild injuries to the SL may be difficult to identify because of the wide variation in its normal ultrasonographic appearance. This is especially true in the proximal SL, since its origin is more heterogeneous than other tendons and ligaments because of variable amounts of fat and muscle tissue. Comparison between the affected and nonaffected limbs in the same horse are recommended because of individual variations and the large variation between breeds.[1]

Radiographic examination should be performed to identify concurrent bony lesions. Subchondral sclerosis, avulsion fracture, and enthesophyte formation have been identified in the proximal palmar/plantar MCIII/MTII regions of horses with proximal SL desmitis.[1,8,9] Axial exostosis along the second and fourth metacarpal/metatarsal bones[10] or fractures can contribute to SL body desmitis. Sesamoiditis and sesamoid fractures may be noted in horses with desmitis of the SL branches. In acute traumatic disruption of the suspensory apparatus, comminuted fractures of both sesamoid bones are common.

Nuclear scintigraphic findings are normal in the majority of horses with SL desmitis.[11] Increased radiopharmaceutical uptake associated with the proximal palmar/plantar MCIII/MTIII can be identified in horses with avulsion fractures and other stress-related bone injuries seen in complex SL desmitis.[8,9] MRI is not necessary but should be considered if no ultrasonographic abnormality is identified, or for the proximal SL in the hindlimb. MRI has identified fibrous adhesions between the SL and the small splint bones.[10]

Treatment

Treatment of acute SL desmitis is aimed at reducing inflammation with systemic NSAIDs, local cold hydrotherapy, limb bandages, and controlled exercise. Initial clinical signs dissipate quickly even when there is significant SL fiber disruption, so it is strongly recommended to assess the ligament using ultrasonography. In uncomplicated desmitis, a controlled graded exercise program is recommended. The duration of rehabilitation will depend on the extent and severity of the desmitis. Fractures of the small metacarpal/metatarsal bones or sesamoid bones should be removed prior to rehabilitation. Horses are confined to a stall and hand walked daily. Ligamentous healing should be monitored every 60 days using ultrasonography. Ideally there should be a progressive reduction in cross-sectional area, improved echogenicity, and fiber alignment. Gradual increase in exercise can be prescribed depending on healing. The reparative process is slow, and return to competition or racing may not be possible for 12 to 18 months.

Damaged SLs have been injected with a wide assortment of therapeutics, and recommendations are similar to those outlined for tendinitis earlier in this chapter. Extracorporeal shockwave therapy[1,12] may be beneficial. The effects of intralesional platelet-rich plasma[13] and autologous stem cells[14] are currently under investigation, and clinical results are promising.

Successful treatment of proximal hindlimb SL desmitis is particularly challenging, and most horses treated conservatively remain lame. Neurectomy of the deep branch of the lateral

VetBooks.ir

plantar nerve,[1,15,16] desmotomy,[17] and fasciotomy[14-17] may be beneficial in these horses. Fasciotomy surgery allows decompression of the compartment-like syndrome that occurs when the damaged proximal SL becomes edematous and swells within the surrounding retinaculum. The deep branch of the lateral plantar nerve within the damaged SL becomes inflamed and damaged, so a neurectomy of this nerve is performed at the same time as the fasciotomy surgery.[18]

For horses with acute traumatic suspensory desmitis, it is crucial to place the affected limb in a protective splint that aligns the metacarpus with the phalanges in a straight column to prevent fetlock bending. Surgical management involves fetlock arthrodesis using a dorsal plate and wires or cables to reestablish the palmar tension band. Treatment for horses with DSLD is palliative, and rest versus turnout or barefoot versus shod does not appear to alter the long-term outcome. When there is deterioration or uncontrolled clinical signs despite treatment, options include surgical fetlock arthrodesis or euthanasia.

Prognosis Prognosis of SL desmitis depends on the location and severity of the injury. Uncomplicated cases with minimal disruption of the ligament can recover, and 90% of horses with acute proximal SL desmitis in the forelimb will return to full athletic function.[2] Complicated, chronic, or recurrent desmitis has been associated with a worse prognosis. Chronic hindlimb proximal SL desmitis has a particularly poor prognosis, and only 14% of horses treated conservatively return to full work.[2] Adjunctive medical and surgical treatments can improve prognosis in these problematic horses. Most horses with traumatic disruption of the SL can be salvaged for breeding after surgical repair. Prognosis for horses with DSLD is extremely poor, although these horses can also be salvaged with surgical arthrodesis of the fetlock joints.

Fractures

Tamara M. Swor

Large animal fracture repair resulting in a successful outcome depends largely on a rapid and correct diagnosis, appropriate first-aid treatment and stabilization of the injured limb, and safe transportation to a referral surgical center. Great advances in large animal orthopedic surgery and anesthesia have allowed successful treatment of several fracture types, but some injuries still retain a poor prognosis for survival. Emergency treatment and stabilization administered by a veterinarian in the field is crucial to preserve the most treatment options and enhance the prognosis. Accurate knowledge of viable surgical and medical possibilities, and the prognosis for various fracture types, is critical during discussions with clients. The referral surgeon should be contacted early in the process by the field veterinarian and involved in decisions regarding limb stabilization, transportation, and owner financial commitments. Various medical and surgical treatment options are discussed in this section; details of specific surgical principles related to fracture repair can be found in surgical textbooks.

Definition and Etiology A *fracture* is defined as a break, crack, or rupture of a bone. In large animals, fractures are usually classified as complete or incomplete; articular or nonarticular; displaced or nondisplaced; open or closed; simple or comminuted; and transverse, oblique, or spiral. Classification by location is also common and includes terms such as *physeal*, *metaphyseal*, and *diaphyseal*.

Fractures in large animals are often associated with an acute traumatic event followed by sudden severe lameness. Horses may have a history of falling or running into a solid object, receiving a kick from another horse, being hit by a car, or flipping over backward (typically young animals). In another common scenario, the owner hears a loud pop or cracking sound while the horse is being lunged or is participating in an athletic activity.

Stress fractures also may occur and are often a result of cyclic loading over time, with corresponding fatigue leading to bone microfracture. Intensive training schedules create a high number of loading cycles with insufficient time to remodel and repair local areas of stressed bone (e.g., racehorse training). Specific locations of stress fractures include the distal end of the scapular spine, caudoproximal humeral head, craniodistomedial aspect of the humerus, medial humeral diaphysis, caudal aspect of the radius, dorsal mid-diaphyseal and distodorsolateral third metacarpal, caudal border of the ilial wing and adjacent to the pubic symphysis, proximolateral tibia, and caudal diaphysis of the tibia.[1]

Less common causes of large animal fractures include nutritional deficiencies, neoplasia, and infectious causes leading to pathologic fractures. Fractures related to difficult parturition events are seen in neonatal foals and calves.

Clinical Signs and Differential Diagnosis An animal with a long bone fracture typically will present with an acute non–weight-bearing lameness of the affected limb. Moderate to severe soft tissue swelling and inability to control the limb often accompany other clinical signs of distress, agitation, shock, and pain. Because of the horse's "fight or flight" reaction to traumatic situations, the patient will often continue attempts to place weight on the fractured limb. Fractures in locations with limited soft tissue coverage are often open (e.g., third metacarpal). Severe hemorrhage or laceration of large vessels is uncommon but may occur (e.g., pelvis).

Complete catastrophic fractures are often easily identified based on limb instability and soft tissue trauma or swelling. Proximal limb fractures may be difficult to palpate but have adjacent severe soft tissue inflammation and edema, crepitus, and difficulties in limb function. Nondisplaced or incomplete fractures may be associated with a wound or may be painful to manual palpation. Focal pain on palpation, a corresponding lameness, and a history of trauma or being kicked by another animal warrants radiographic evaluation in search of an incomplete fracture. An unrecognized incomplete fracture may progress to a complete fracture with time and movement or exercise. Physeal fractures should be considered in young animals.

Stress fractures often present with a history of acute severe lameness followed by a rapid decrease in the degree of lameness. There may also be reports of intermittent lameness that improves with stall rest. Palpation of the limb often reveals a focal area of pain, heat, and/or swelling. The horse may resist manipulation and movement of the limb.

Differential diagnoses should include hoof and sole abscesses, joint subluxation, joint luxation, nerve damage, soft tissue injury, and septic synovial structures.

Clinical Evaluation A complete physical examination should be performed on initial evaluation. Animals that are not immediately identified as having a fractured limb may be in need of systemic support. Fluid therapy, pain control, anti-inflammatory medications, and antimicrobials should be used as necessary.

Definitive diagnosis is made by taking multiple radiographic views; nuclear scintigraphy, ultrasonography, CT, and MRI may also be used (Figs. 38.37, 38.38, and 38.39). Information from imaging studies will provide fracture configuration details essential for determining prognosis. The bone involved, degree of comminution, articular involvement, physeal involvement, risk of infection, and condition of the bone fragments all affect potential repair attempts and long-term prognosis. Incomplete

fractures may not be readily identified at the time of injury, and radiographs should be repeated in 10 to 14 days if a fracture is suspected.

Stress fractures are also commonly diagnosed using radiographic evaluation and may be identified as an incomplete cortical fracture, endosteal sclerosis, or periosteal callus.[1] As with incomplete fractures, it may be difficult to identify a stress fracture by conventional radiography in the acute stages. Radiographs should be repeated in 10 to 14 days if a fracture is suspected. Other imaging modalities, especially nuclear scintigraphy or MRI/CT, may be useful in stress fracture identification.

■ ***Emergency Treatment*** The goals of emergency treatment include preventing further soft tissue damage, stabilizing the injured limb to decrease the patient's anxiety, minimizing further damage to the fractured bone ends, keeping the fracture closed, and preventing further injury and stretching to the surrounding vessels and nerves.[2] A large animal with a fractured limb should be immediately restrained and calmed. Sedatives and tranquilizers should be used with caution, however, because the desired result may be difficult to achieve if the animal is agitated or in shock. The goal of sedation should be to allow manipulation of the limb and placement of external coaptation while keeping the animal standing. Common sedatives should be used with caution to avoid creating additional ataxia; butorphanol should not be used if the horse has sustained a front limb fracture because it will make the horse lean on the forehand. If the animal is in systemic shock, an intravenous catheter should be placed and intravenous fluid support initiated. If a soft tissue wound is present, the veterinarian should assume

TABLE 38.4

Emergency Splinting Techniques for Fractures in Large Domestic Animals

Location	Species/Age	Splint
Distal phalanx	Horses, foals Cattle, calves	No splint needed
Middle phalanx	Horses, foals	Bandage with dorsal (front limb) or plantar (rear limb) splint to proximal metacarpal/tarsal 3 and cast material, Kimzey splint[a]
Proximal phalanx	Horses, foals	Bandage with dorsal (front limb) or plantar (rear limb) splint to proximal metacarpal/tarsal 3 and cast material, Kimzey splint[a]
	Cattle, calves	No splint needed
Distal sesamoid (navicular)	Horses, foals	No splint needed
Proximal sesamoids	Horses, foals	Bandage with dorsal (front limb) or plantar (rear limb) splint and cast material, Kimzey splint[a]
Metacarpal/tarsal 3	Horses, foals	Bandage with dorsal (front limb) or plantar (rear limb) splint and cast material, Kimzey splint[a] if fracture distal
Metacarpal/tarsal 3 and 4	Cattle, calves	Bandage with dorsal (front limb) or plantar (hindlimb) splint and cast, cast
Metacarpal/tarsal 2 and 4	Horses, foals	No splint needed
Olecranon/ulna	Horses, foals	Robert Jones–type bandage with caudal splint to lock carpus in extension
Radius	Horses, foals	Robert Jones–type bandage with lateral splint to withers, second caudal splint if needed
	Cattle, calves	
Humerus	Horses, foals Cattle, calves	No splint needed
Scapula	Horses, foals Cattle, calves	No splint needed
Tibia	Horses, foals	Robert Jones–type bandage with lateral splint to tuber coxae
Femur	Horses, foals Cattle, calves	No splint needed
Pelvis	Horses, foals Cattle, calves	No splint needed

[a]Leg-Saver splint (Kimzey Inc., Woodland, Calif.).

that the fracture is open. The wound should be cleaned, topical antimicrobials used, a bandage placed to prevent further contamination, and the animal started on systemic antimicrobials. Antiinflammatory medications (e.g., phenylbutazone) should be used as necessary. If the prognosis for survival is grave, euthanasia may be suggested to the owner and might be in the animal's best interest prior to attempting transportation.

Appropriate external coaptation and stabilization of the fracture for transport can greatly influence the options available for fracture repair and the prognosis for success. Table 38.4 outlines specific emergency splints for different fractures in large animals.[2,3] Splinting techniques are designed to be placed on the standing horse and attempt to neutralize forces acting on the fractured limb. Splints should be made of a strong, lightweight material like PVC pipe or wooden boards. Bandages over fractures should be placed tightly over the injured area to decrease soft tissue swelling and minimize slippage. A layer of cotton padding should be followed by a layer of gauze or a self-adhering bandage. Multiple layers can be placed if needed (e.g., Robert Jones–type bandage). A recent study suggested that bending forces were equally neutralized with a splint over a small bandage, compared to a Robert Jones–type bandage and splint.[4] The splint should not end at the level of the fracture, should immobilize the joint above and below the fracture when possible, and should have enough padding so that no iatrogenic trauma occurs to the limb. In general, splinting techniques can be divided into categories based on fracture location.

DISTAL LIMB FRACTURES (PHALANGES, DISTAL METACARPUS/METATARSUS). A light cotton bandage should be placed on the affected limb from the carpus to the ground. A splint is then positioned on the dorsal aspect of a forelimb or the plantar aspect of a hindlimb. The toe is pointed toward the ground to align the dorsal cortices and minimize stretching of the palmar/plantar vascular and nerve structures. A second splint should be placed on the medial or lateral side of the limb if any instability is present in those directions. The splint should be secured with inelastic tape. For additional stability, several rolls of fiberglass casting tape should be placed around the entire bandage and splint structure, incorporating the hoof into the cast.

MIDLIMB FRACTURES (MIDMETACARPUS TO DISTAL RADIUS, MIDMETATARSUS TO PROXIMAL METATARSUS). A Robert Jones–type bandage should be placed on the limb from the ground to the elbow in a forelimb or from the ground to the calcaneal tuber in a hindlimb. The bandage should be less extensive in the hindlimb to facilitate splint placement. In the forelimb, splints should be placed on the lateral and caudal aspects of the limb from the ground to the elbow. In the hindlimb, splints should be placed on the lateral and caudal aspects of the limb from the ground to the calcaneal tuber. The splints are secured using inelastic tape followed by several rolls of fiberglass casting tape around the entire structure.

UPPER LIMB FRACTURES (MIDDLE AND PROXIMAL RADIUS, TARSUS, TIBIA). A Robert Jones–type bandage should be placed on the limb from the ground and extend as far proximal as possible. In the forelimb, a splint should be placed on the lateral aspect of the limb from the ground to the withers. For increased stability, a second splint may be placed on the caudal or cranial side from the ground to the proximal forearm if necessary. Horses with olecranon fractures that disable the triceps muscle benefit from placement of a caudal splint to reestablish carpal extension. In the hindlimb, a splint should be placed on the lateral aspect from the ground to the tuber

coxae. Splints placed high in this fashion will help minimize abduction of the limb.

HIGH LIMB FRACTURES (PROXIMAL TO ELBOW JOINT, FEMUR). Fractures in these locations are covered by extensive muscle, and attempts at splinting are usually unsuccessful and unhelpful to the animal. If triceps muscle function is disabled, a splint on the caudal aspect of the carpus, locking it into extension, is beneficial.

TRANSPORT. Transportation of adult horses or ruminants with long bone fractures can be difficult. They should be trailered in a manner that allows them to lean on dividers for support and be tied loosely to prevent them from turning around in the trailer but still be able to use their heads for balance. When possible, horses with forelimb fractures should be transported with the head facing the rear of the trailer, and those with hindlimb fractures should be transported with the head facing the front of the trailer. These positions allow the horse to control its weight most easily with the uninjured limbs during deceleration of the trailer. Foals and calves will often elect to lie down during transport and should be allowed to do so safely in a compartment next to the mare or cow.

Pathophysiology of Bone Healing

Healing of a fracture terminates in the return of the injured bone to its original form. The process of fracture healing involves several biological steps that overlap and interact with each other. Typically, three phases are recognized: inflammatory, reparative, and remodeling.[5,6] The acute *inflammatory phase* occurs in the initial 7 days after bone fracture, and chemical mediators cause chemotaxis, migration of leukocytes, and vasodilation to the injured area. These mediators protect the injury from infection and stimulate angiogenic factors. Cytokines from platelets aid in angiogenesis and mesenchymal cell growth.[5] Granulocytes and macrophages destroy invading bacteria and stimulate cell repair through the release of growth and angiogenic factors. If the inflammatory phase is impaired, fracture healing may be compromised.[5]

The *reparative phase* overlaps with the inflammatory phase and may last for up to 12 months. This phase attempts to reestablish bone union. Interfragmentary stabilization by periosteal and endosteal callus formation begins if the fractured ends are not immobilized.[6] Bony union develops as a result of endochondral and intramembranous ossification.[5,6] In the reparative phase, interfragmentary motion may greatly influence fracture healing.

The *remodeling phase* takes place both during and after the reparative phase. Osteonal remodeling allows for replacement of necrotic regions of bone. When the bone is loaded, the negatively charged concave surface will attract osteoblasts to add new bone, and the positively charged convex surface will attract osteoclasts to remove bone.[5,6] The result is the ability of a fractured bone to straighten itself by creating new bone formation on the concave surface and removing bone from the convex surface.

Repair of a fractured bone with the use of rigid internal fixation will inhibit naturally occurring callus formation and encourage bone to heal through haversian remodeling. *Haversian remodeling* requires that a fracture be rigidly fixed, have adequate reduction, and have an adequate blood supply.[5,6] Haversian remodeling then functions to revascularize necrotic bone at the fragmented ends of the fracture and bridge interfragmentary gaps. This form of remodeling begins 2 to 3 months after injury.

Fractured bones are often described as healing by primary (direct) or secondary (indirect) intention.[5,6] Primary bone healing occurs only with complete anatomic reduction and rigid stability. In large animal fracture repair, this is difficult to achieve because of the size of the animal and micromotion at the repair site. Secondary bone healing (most common in large animals) uses endosteal and periosteal callus formation, and new bone formed at the fracture site develops after initial formation of fibrous tissue or fibrocartilage.[5,6]

The rate of bone healing may be decreased if blood supply is inadequate, infection is present, soft tissue damage is extensive, or stability of the bone fragments is inadequate.

Treatment and Prognosis

Treatment options for fractures in large animals include conservative therapy with stall rest and external coaptation (casts, splints), and surgical stabilization with open reduction and internal fixation. It is important to recognize incomplete and stress fractures and manage them appropriately with conservative therapy, preventing progression to a catastrophic fracture. In cases of incomplete fracture, the adult horse may need to be tied so that it does not cause additional stress to the fracture region by lying down and getting up repeatedly. The majority of fractures require some form of stabilization for the best chance of a successful outcome. Most horses require surgical stabilization for successful fracture repair. Ruminants are more amenable to successful fracture repair with nonsurgical options.

Conservative therapy with stall rest and external coaptation may be successful in some foals, calves, and small ruminants with complete nondisplaced fractures. Young animals have a greater and faster ability to heal bone in a reasonable amount of time, and their body weight is much less than that of a mature animal. In foals and calves, fracture configurations tend to be simpler, and the surgical implants available for repair are of a suitable strength for the animal's size. Unique complications in young animals include premature closure of physes with fractures in these areas, systemic and local infections related to failure of antibody passive transfer, and angular limb deformities from overuse of the contralateral limb. One report described treatment using external coaptation (modified Thomas splint-cast combination) in small equids (median 127 kg) successfully as a salvage procedure.[7]

Irreparable fractures are more common in adult animals because of the greater force required for bone breakage. Proximal limb fractures in adult horses often defy successful treatment because of the severe bone comminution that occurs and because available implants are not strong enough to support the bone until it is healed, adult horses are less likely to protect the limb than foals, and laminitis formation in the contralateral limb results in overuse of the repaired limb. Stall rest with external coaptation alone is rarely associated with a good outcome; most horses need some form of internal fixation for success. Horses are often required to be athletes, and fracture repair resulting in survival but not soundness may be unacceptable. In general, ruminants have a better prognosis for survival than horses because with their less excitable temperament they protect the limb better, and complete soundness is often unnecessary for a positive outcome. In ruminants, external fixation may be a more successful option than just external coaptation because it provides increased stability but costs less than internal fixation. Open fractures in horses greatly decrease the prognosis for survival and may delay the ability to perform internal fixation. In ruminants, open fractures are less common but also carry a poorer prognosis for survival.

Implants used for surgical open reduction and internal fixation methods vary based on the specific bone involved, the animal's age, the strength of the bone fragments used in the repair, and the surgeon's preference. Common implants used in large animals include intramedullary interlocking nails, dynamic compression plates (DCPs), locking compression plates (LCPs), limited-contact DCPs, screws, wires, pins, and dynamic condylar screw plates. Table 38.5 lists specific treatment options and prognoses.

Pelvis	Articular	Medical	Guarded
	Nonarticular	Medical	Guarded to good

[a]Foals, calves, and small ruminants.

SCAPULA. Fractures of the scapula occur most frequently in horses 2 years of age or younger and often involve the supraglenoid tubercle. Surgical removal of the fragment or repair using lag screws, tension band wires, or DCP/LCPs has resulted in limited success. Recently, distal femoral locking plates and transverse LCPs have been used with success in a small number of horses.[8,9] Fractures involving the body of the scapula are often successfully managed conservatively in cattle.[10]

HUMERUS. The humeral fracture is often in a spiral or long oblique configuration. In ruminant and equine species, both conservative and surgical treatments have been used. In foals, surgical repair may include the use of intramedullary interlocking nails, DCP/LCPs, or intramedullary nails. Prognosis for a closed fracture in a foal is fair to good and depends on configuration, age, and weight.[11,12] Humeral fractures in adult horses are not reparable at this time. Recent reports of horses with deltoid tuberosity or greater tubercle fractures of the humerus indicate some successful treatment results.[13,14] Conservative treatment may be successful in adult horses with nondisplaced fractures and has been used in small ruminants and foals with acceptable outcomes. Ruminants have a better prognosis in general than equine species, and calves have been treated successfully using external fixation.[15]

RADIUS. The survival rate for ruminants with radial fractures repaired by external or internal fixation has been reported as 87.5%.[16] Radial fractures in foals and young horses (<1 year of age) repaired with internal fixation have a good prognosis, but in adult horses the success rate is low.[17,18] Prognosis decreases dramatically with an open fracture or surgical site infection. Animals with incomplete fractures that do not progress have a good prognosis for a full recovery with conservative management.[18]

OLECRANON. There are several different fracture configurations, and the olecranon fracture may be articular or nonarticular. These fractures are common in both young and older horses. Surgical and conservative treatments have been used with success, although internal fixation is the preferred treatment method.[19,20] Typically the fracture is repaired with a DCP or LCP applied as a tension band. The prognosis with surgical repair is good, with 75% to 87% of horses returning to athletic use, depending on the fracture type.[19-22] Conservative treatment has been reported to result in a 73% return to soundness.[23]

FEMUR. Diaphyseal fractures are more common in calves, whereas proximal physeal fractures are more common in foals. Femoral fractures in calves may occur during parturition events. In young calves, these fractures have been repaired by internal fixation and femoral head and neck osteotomies with success. It has been found that calves treated surgically for femoral diaphysis fractures had fewer complications than those treated conservatively.[24] In foals, fracture repair with internal fixation gives the best chance of survival, and the use of intramedullary interlocking nails has shown positive results.[25] Third trochanter fractures in horses can heal with conservative management.[26] Complete femoral fractures in adult horses are not reparable at this time.

TIBIA. Tibial fractures in ruminants have been repaired using splints, external fixators, transfixation pin casts, and DCP/LCPs. Fractures repaired with external fixation in adult cattle

VetBooks.ir

had a 64% success rate, whereas conservative therapy yielded a 44% success rate.[27] Internal fixation is the repair method of choice in the equine species. Foals have a fair to good prognosis for survival. Adult horses have a poor prognosis for survival because tibial fractures are often open, have limited blood supply, and are often severely comminuted.

METACARPUS/METATARSUS. In cattle, these fractures are common and have a good prognosis when treated with internal fixation, casts, or transfixation pin casts. Calves may incur distal physeal fractures after forced extraction during a dystocia, and these may be casted with good success. In horses, cannon bone fractures are frequently open because of a lack of soft tissue coverage. Treatment options include internal fixation with DCP/LCPs and screws, or transfixation pin casts. Studies evaluating outcomes in mature horses and foals with complete diaphyseal third metacarpal/metatarsal fractures treated with internal fixation found that 62% survived, although the survival rate was much higher for foals.[28] Another study reported a 67% success rate with surgical repair.[29] In racehorses, catastrophic or condylar metacarpal fracture can occur from preexisting bone injury, and repair may include DCP fixation or lag screw stabilization.[30-32]

PHALANGES. In ruminants, fractures of the proximal or middle phalanx are treated with reasonable success by applying a block to the uninjured claw or by cast application. In horses, proximal and middle phalangeal fractures have been treated by internal fixation with screws and DCP/LCPs. Prognosis for survival is good, but return to athletic function depends on the degree of osteoarthritis that develops after fixation. A recent report of proximal phalanx fractures in nonracing horses found that those treated with internal fixation had a better outcome than those managed conservatively.[33] Reviews of proximal phalangeal fractures in racehorses report that 50% to 75% were able to race following surgery.[34,35] Comminuted middle phalangeal fractures repaired with double plate fixation resulted in 97% of the horses discharged from the hospital and 60% able to return to useful function.[36] Severely comminuted fractures may also be treated successfully with transfixation pin casts or the Nunamaker external skeletal fixator.[37] Fractures of the distal phalanx in horses may be successfully treated with surgical fixation, hoof casts, or modification in shoeing, depending on fracture configuration. One study found that 77% of horses had a successful outcome but did not find that immobilization of the hoof influenced results.[38]

SUMMARY. Animals identified as having incomplete fractures should be treated conservatively with stall rest and tied to prevent them from lying down if the fracture is at risk of becoming complete (e.g., radius). Animals with stress fractures should be treated conservatively with stall rest and a careful rehabilitation program, with ongoing radiographic evaluation.

Many fractures in large animals can be repaired and allow survival of the animal. Despite recent advances in orthopedic surgery and anesthesia, some fractures in large animals are still not able to be repaired. In general, prognosis for survival is improved if the animal is young, weighs 500 pounds (225 kg) or less, the fracture is closed, appropriate emergency stabilization is implemented quickly, and prompt reduction and internal stabilization are performed.

Spontaneous Fractures in Ruminants

Amanda K. Hartnack

Definition and Etiology Spontaneous fractures occur when a pathologic bone lesion weakens bone to the extent that fracture occurs secondary to normal forces. These are also referred to as pathologic fractures. Causes include resorption of bone, reduction of bone mass, insufficient production of bone, or local bone destruction.

Clinical Signs and Differential Diagnoses Clinical signs depend on the affected bones and may include lameness, swelling, postural changes, and angular limb deformity. Physical examination may reveal additional fractures. Commonly affected bones in ruminants include long bones, vertebrae, ribs, and mandible. Differential diagnoses include fractures of normal bones secondary to abnormal forces, septic arthritis or physitis, and osteomyelitis. Diagnosis is confirmed radiographically.

Pathophysiology, Epidemiology, and Clinical Pathology In ruminants, the underlying conditions that can lead to weakening of the bone's composite structure and subsequent fracture include bony destruction secondary to osteomyelitis or neoplasia, osteodystrophy associated with rickets in young animals, osteomalacia associated with nutritional imbalances in adults, and osteoporosis associated with copper deficiency.

Neoplasia and osteomyelitis weaken bone by dissolution of the mineral matrix, resulting in spontaneous fractures of affected bone. A variety of tumor types, including lymphosarcoma, hemangiosarcoma, liposarcoma, osteogenic sarcoma, and osteoma have been reported to cause spontaneous bone fractures in ruminants.[1-5] Radiographically, lesions may have an osteolytic, osteoblastic, osteoporotic, or mixed appearance depending on the tumor or infectious agent involved.[6,7] Localized bone infection can be traumatic or hematogenous in origin and may occur secondary to septic arthritis in calves.[7] Reported cases include vertebral body abscessation, osteomyelitis of the sternum, distal sesamoid bone, mandible, and third phalanx.[7-11] *Trueperella pyogenes* is the most common bacterial isolate,[5,6] although osteomyelitis secondary to infection with *Actinomyces bovis* is also commonly reported in cattle.

Nutritional deficiencies or imbalances can lead to development of osteodystrophy, osteomalacia, and/or osteoporosis. These conditions can lead to spontaneous fracture, particularly of long bones and vertebrae, in some animals. Nutritional deficiencies can be classified as primary or secondary, with primary deficiencies involving inadequate intake and secondary deficiencies involving reduced nutrient absorption. Secondary deficiencies often occur when increased consumption of certain minerals such as iron, manganese, magnesium, zinc, sulfur, and molybdenum impede absorption of other nutrients. Clinically important bone diseases in ruminants are most commonly caused by deficiencies of minerals such as calcium, phosphorus, copper, and vitamin D (1,25-dihydroxycholecalciferol) due to their role in bone mineralization and collagen crosslinking.

In both young and adult animals, development of rickets due to phosphorus or vitamin D deficiency can occasionally result in spontaneous bone fracture.[13] In young animals, rickets affects the developing skeleton, resulting in abnormal endochondral ossification and defective bone formation. In adults, the pathogenesis of osteomalacia-associated disease is similar, although only bone formed during remodeling is affected, and osteoporosis can also be seen.[14] Clinical signs of phosphorus deficiency include loss of body condition, lameness, abnormal stance, spontaneous fractures, reproductive failure, and hypophosphatemia. Primary phosphorus deficiency can occur in ruminants when low levels of phosphorus are available in forage, and secondary phosphorus deficiency can result when significant imbalance exists between calcium and phosphorus concentrations in the ration.[13] Serum phosphorus levels may not reflect the severity of the disease process.[14,15] Gross postmortem findings may include brittle, porous bone and bony callus indicative of healed fractures on the ribs.

VetBooks.ir

Copper deficiency has also been reported as a cause of osteoporosis leading to pathologic fracture in ruminants.[16,17] Although copper deficiency may be caused by low copper levels in the diet (primary deficiency), it is more commonly a result of high dietary molybdemum or sulfur. Deficiency occurs when molybdenum and sulfate form indigestible compounds called thiomolybdates, which bind copper.[18] In addition to spontaneous fractures secondary to osteoporosis, clinical signs of copper deficiency include lameness, achromotrichia, diarrhea, anemia, and poor growth.[19] In cattle, hepatic copper levels are considered the gold standard, with levels lower than 10 µg/g commonly considered deficient. Low plasma copper (<9 mmol/L) or ceruloplasmin levels are suggestive of copper deficiency (<15 IU/L).[20,21]

Other conditions that can cause spontaneous fracture in ruminants include chronic fluoride toxicity (fluorosis)[22,23] and a number of heritable conditions. These heritable conditions include osteogenesis imperfecta in Holstein Friesian calves and Charolais cattle, inherited rickets in Corriedale sheep, and hemochromatosis of Salers cattle.[24-27]

It is important to note that other management and nutritional issues may contribute to abnormal bone composition and lead to spontaneous fracture. A detailed history, physical examination, and diagnostic workup can help identify underlying conditions.

Treatment and Prevention When treating spontaneous fractures, resolution of the underlying disease is essential. The prognosis depends on the severity and location of the fracture, as well as the underlying disease process. Fractures secondary to osteomyelitis or neoplasia carry grave prognoses. However, fractures associated with metabolic bone disease have been treated successfully. As with many other conditions, prevention of spontaneous fractures is aided by proper nutritional management.

Dorsal Metacarpal Disease in the Horse

Travis M. Tull

Definition and Etiology Dorsal metacarpal disease, or bucked shins, is a common problem in the 2- and 3-year-old training horse and is characterized by pain, heat, and periosteal proliferation in the dorsal aspect of the third metacarpal bones. Bucked shins cause lameness resulting in days lost in training, precede dorsal metacarpal stress fracture, and less commonly lead to catastrophic fracture of the third metacarpus (MCIII).[1,2] The development of dorsal metacarpal disease is directly related to the structural changes that race training induces, as the MCIII increases in size, density, and strength.[3-5] Slower gaits or speeds result in tensile strains on the dorsal aspect of the MCIII.[6] According to Wolff's law, the bone initially undergoes modeling and remodeling in response to these changes, resulting in periosteal fibrous bone on the dorsal cortices of the MCIII.[5,7] At faster race speeds, the strain on the dorsal and dorsolateral MCIII rotate, becoming compressive instead of tensile.[6,8] The bone, adapted for tensile forces, incurs microdamage that leads to pain, inflammation, lameness, and in some cases stress fracture.[2,5]

Clinical Signs and Differential Diagnosis Dorsal metacarpal disease occurs in 2- and 3-year-olds that have recently begun race training, typically after the introduction of work at race speeds.[6,7] History is important, as the disease rarely occurs in the nonracing horse and can occur in older racehorses that are changing training surfaces or beginning their career at a later age.[2,9] Affected horses demonstrate inconsistent short-strided lameness, heat, and focal pain over the dorsal cortex of the metacarpus with or without swelling.[2,9] Periosteal swelling can occur anywhere on the dorsal aspect of either limb, but generally both forelimbs or only the left MCIII demonstrate clinical signs.[9,10] Lameness often resolves with rest and NSAIDs. The lameness can be ameliorated with local analgesia such as a high ring block over the proximal dorsal MCIII. Radiographs at early onset may be inconclusive, whereas more chronic cases may have increased dorsal cortical thickness and linear lucencies parallel to the cortex (Fig. 38.40). Nuclear scintigraphic examination yields increased radionucleotide uptake on the dorsal cortex of the MCIII, which must be differentiated from normal uptake in an actively training horse.[11] Dorsal cortical stress fracture of the MCIII has similar presenting signs as bucked shins. Initially there may be lameness after racing or speed work that subsides with rest. There may be focal pain on palpation with variable amounts of swelling or hard periosteal callus. Radiographic signs include periosteal and endosteal proliferation and a 30- to 45-degree oblique linear lucency in the dorsolateral cortex of MCIII, most obvious on the dorsomedial-palmarolateral oblique or

FIG. 38.40 Dorsomedial-palmarolateral oblique radiographic projection of the left third metacarpus on a 2-year-old Thoroughbred racehorse with chronically affected bucked shins. White arrows indicate periosteal bone proliferation. Black arrows indicate linear lucency parallel to the periosteal and endosteal surface.

VetBooks.ir

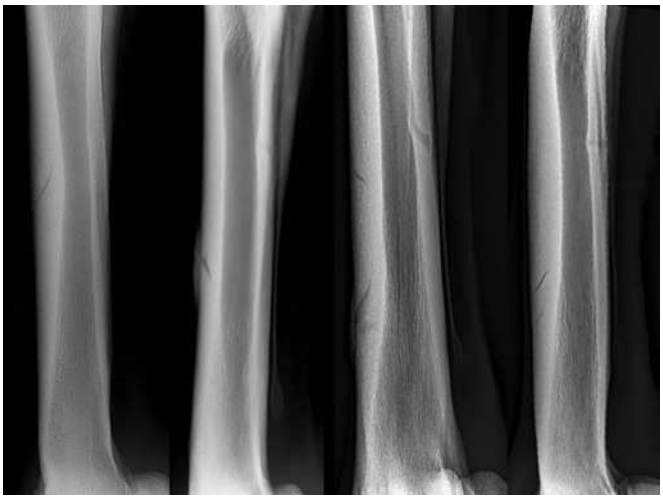

FIG. 38.41 Differing incomplete dorsal cortical stress fracture of third metacarpus configurations. From left to right, fracture line distal to proximal, proximal to distal, saucer type, and multiple fracture lines.

the lateral to medial projections.[12] The fracture line can be oriented from the outer cortex, distal to proximal, proximal to distal, in a true saucer configuration, or on occasion more than one fracture can be present (Fig. 38.41). Nuclear scintigraphy of dorsal cortical stress fracture of the MCIII coincides with moderate to intense focal radionucleotide uptake.[11]

Differential diagnoses include trauma to the dorsal MCIII, exostoses of the second or fourth metatarsal bones, cellulitis, or osteomyelitis. Signalment, a good history of the exercise program, careful physical examination, and radiographic evaluation can readily differentiate dorsal metacarpal disease from other causes of metacarpal swelling.

Pathophysiology The musculoskeletal system of the 2-year-old racehorse undergoes significant changes in response to race training, with measurable changes in the size and geometry of the MCIII, compared to untrained horses.[3,5,13] During training the dorsal cortex of MCIII undergoes fatigue, or repetitive loading, primarily in tension.[2,6] Subsequently the bone adapts by modeling and remodeling, increasing the size of the MCIII through fibrous periosteal bone deposition.[2,6,7,14,15] As training continues with race speed work, the MCIII is subjected to compressive strains in a region adapted to tension, resulting in the clinical signs associated with dorsal metacarpal disease.[2,5,6,16] The primary histologic lesions consist of focal remodeling and periosteal/endosteal bone proliferation with edema in the subcutaneous tissues.[7] After resolution of the clinical signs of bucked shins, horses reenter training. Fibrous bone is weaker than lamellar bone, the dorsal MCIII is poorly adapted for compressive strains, and as with other fatigue fractures, microdamage accumulates under cyclic repetitive loading.[14] Microdamage and microcrack formation occur faster than the ability of the skeletal system to repair the damage through remodeling.[14,15] Microcracks increase in size, and macrocracks form and coalesce, leading to failure or dorsal cortical stress fracture.[14,15]

Epidemiology Dorsal metacarpal disease has been reported to affect up to 70% of juvenile Thoroughbreds at the start of training, 5% to 50% of Quarter Horses, and much less commonly the Standardbred.[1,2,9,17] It has been estimated that between 10% and 12% of horses that develop bucked shins will develop a dorsal cortical stress fracture.[2,9] Catastrophic failure of the diaphysis of the MCIII accounts for 10% of racetrack fatalities.[2] Horses trained on softer surfaces have a delayed incidence of dorsal metacarpal disease.[1,2,10] Standardbreds do not suffer from dorsal metacarpal disease nearly as frequently as Thoroughbreds, which may be related to gait and frequent training at race speeds.[2] Differences in the mechanical properties of the MCIIIs of the two breeds were not observed in vitro.[18] Dorsal cortical stress fractures occur primarily in 3-year-old Thoroughbred horses that have a history of bucked shins in their 2-year-old season.[12,19]

Treatment and Prognosis Treatment for dorsal metacarpal disease involves rest, antiinflammatories, and an altered training schedule.[2,9] The rest period is contingent on resolution of the clinical signs of heat, pain, and swelling. After clinical signs resolve, horses are slowly reintroduced to training. Based on previous research, the training schedule should be changed to incorporate more frequent, shorter, higher speed work and decreased galloping in an attempt to induce remodeling and adaptation of the MCIII for race speeds.[2,20] If clinical signs return, horses are again rested and reevaluated, and training is altered again. Counterirritation (thermocautery, cryotherapy, blistering, and periosteal scraping) and infiltration with antiinflammatories or other products are often applied in conjunction with altered training, although the majority of evidence is from clinical experience, with a paucity of research on efficacy. Extracorporeal shockwave therapy in conjunction with a modulated training regime is also reported to have with a high success rate.[21] There has been some concern that shockwave therapy will induce analgesia and mask pain, predisposing horses to fracture, although current research has not shown significant reduction in pain.[21-24] Other therapies include local and systemic bisphosphonate therapy, although neither of the current products licensed for horses by the U.S. Food and Drug Administration are approved for animals under the age of 5 and therefore cannot be recommended. Although uncommon, if the horse fails to respond appropriately, it should be removed from training for a minimum of 60 days. Surgical intervention is the treatment of choice for mid-diaphyseal dorsal cortical stress fractures. Conservative therapy can be successful but may require a significant amount of time off, and the recurrence rate is thought to be high. Fractures that are very proximal or very distal on the MCIII do not require surgery and typically heal well. Surgical procedures described include cortical drilling (osteostixis), cortical drilling with unicortical position screw, or unicortical lag screw.[12,19,25,26] Fracture healing has been hypothesized to be promoted through the exposure of the damaged bone to medullary constituents, invoking the regional acceleratory phenomenon, or the induction of stress risers leading to osteonal repair.[12,19,27,28] Drilling alone can be performed standing, as there have been some reports of catastrophic failure after general anesthesia with this technique.[19] Methods involving screw placement performed standing require removal of the implant after 60 days.[12,26] All procedures have a similar success rate of greater than 89%, and similar fracture recurrence rates of 4% to 9%.[12,19,26] Screw placement techniques may yield a more predictable convalescence, although there have been no prospective comparative studies to date.[12]

Prevention Current research has demonstrated that the biomechanical properties and structure of the MCIII in the young training racehorse are influenced by training method and that prevention of the disease is possible through alteration of classical training methods.[2,5,10,20] Recommendations include jogging only for the purposes of warming up the horse, limiting long-distance sub-race speed gallops, and implementing more frequent short-distance breezes several times weekly.[2] The full training program has been published and implemented with a lower incidence of dorsal metacarpal disease.[2] Unfortunately,

VetBooks.ir

many trainers are reluctant to alter their methods.[29] Consequently, early identification and intervention are paramount in preventing poor performance and injury.[30] Recently, a prospective study evaluating juvenile Thoroughbred horses found that prophylactic shin scraping, while it did not prevent dorsal metacarpal disease from occurring, decreased the incidence and significantly delayed the onset of bucked shins in treated horses.[29] Future directions in decreasing the incidence of dorsal metacarpal disease should focus on the education and adoption of alternative training programs to allow the MCIII to adapt to racing speeds and pursuing interventions to lessen risk in classically trained horses.

Silicate Associated Osteoporosis

Scott A. Katzman

Introduction Silicate associated osteoporosis (SAO), also referred to as bone fragility syndrome (BFS) or bone fragility disorder (BFD), is a progressive debilitating musculoskeletal disorder with a geographic distribution similar to that of pulmonary silicosis, primarily affecting horses in the region of the Monterey-Carmel peninsula of California, Sonoma and Napa counties, although occasional cases are identified in other regions of California.[1-3] Although SAO, BFS, and BFD tend to be used interchangeably to describe this condition, SAO is preferred, as this most accurately represent the disease process, reflecting its close association with pulmonary silicosis and similar geographic distribution.[1-3] Briefly, pulmonary silicosis in horses results from inhalation of cytotoxic, fibrogenic silicates, with cristobalite being primarily implicated in the development of the condition and geographic distribution related to exposure of horses to Miocene Monterey Shale soil of the Monterey Peninsula region of California, which contains high levels of cristobalite.[4]

Early clinical features associated with SAO include intermittent lameness affecting one or multiple limbs that cannot be localized,[1,2,5] exercise intolerance, and generalized stiffness.[1,2] In the later stages of the disease process, lameness may become severe[1,2]; scapular bowing (Fig. 38.42, *A* and *B*) and lordosis (Fig. 38.42, *C*) are common features,[1,2,5] with a pain response elicited on palpation of the scapulae[5]; and range of motion of the cervical spine may be decreased in both mediolateral and dorsoventral planes.[1,5] Generalized weight loss is also commonly observed, with varying degrees of localized muscle atrophy developing in the shoulder and gluteal regions.[1]

Whether in the early or late stages of the disease process, the cause for progressive musculoskeletal abnormalities observed in SAO-affected horses is secondary to abnormal bone turnover and pathologic fractures affecting primarily the axial and proximal appendicular skeleton. However, clinically significant lesions have occasionally been identified in the radii and tibiae, and changes in bone morphologic and mechanical properties in affected horses have been demonstrated to develop as far distally as the distal metacarpus.[6]

Signs of respiratory tract disease are often identified on physical examination or are a noted as a historical feature and include adventitious bronchovesicular sounds on auscultation,[1] increased respiratory rate,[1] flaring of the nostrils at rest,[1] and coughing.[2] Although a direct link has not yet been elucidated, the signs of respiratory disease observed in several of these instances are suspected to be related to concomitant pulmonary silicosis, which has been confirmed in select cases. In one study describing the clinical features of 16 horses diagnosed with SAO,[1] a definitive diagnosis of pulmonary silicosis was made based on results of bronchoalveolar lavage in 3 of 7 horses for which this diagnostic was pursued, and 4 others had characteristic radiographic evidence of pulmonary silicosis[7] on thoracic radiographs. In another study, 9 of 9 horses diagnosed with SAO on postmortem examination had cytotoxic silica dioxide polymorphs (cristobalite, quartz, tridymite) identified in lung tissue (6 of 9) and/or tracheobronchial lymph nodes (8 of 9).[3]

Treatment of SAO-affected horses is primarily palliative,[1,2] and the most devastating consequence of SAO is catastrophic fracture of an affected bone, necessitating euthanasia.[1]

Etiology and Pathogenesis To date, the etiology and pathogenesis of SAO have not been completely determined, although development of pulmonary silicosis and silicotic tracheobronchial lymphadenitis is attributed to the inhalation of the cytotoxic silicate cristobalite, which is suspected to be the etiologic agent directly responsible for SAO.[1-3] As noted previously, this is due to the similar geographic distribution

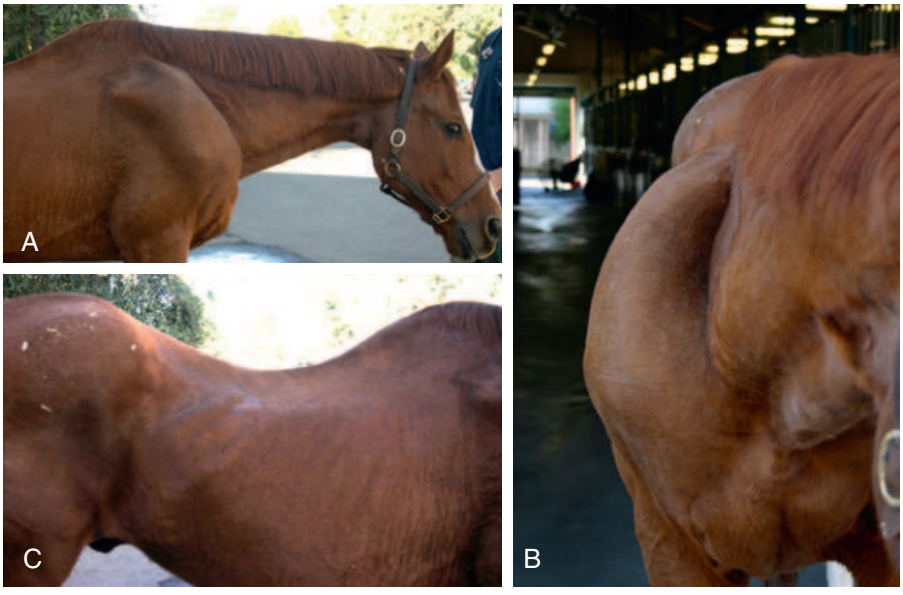

FIG. 38.42 Advanced case of SAO showing phenotypical **(A)** pronounced lateral bowing and **(B)** deformation of the scapula, as well as **(C)** marked lordosis.

between the two conditions, as well as to the diagnosis of both conditions simultaneously, as documented in several instances.[1,3] Proposed mechanisms for development of SAO include exposure to high levels of cristobalite, causing chronic systemic inflammation; dissemination of silicate-containing macrophages to bone marrow secondary to pulmonary silicosis or silicate tracheobronchial lymphadenitis; or abnormal resorption and remodeling of bone due to abnormal osteoclastic activity, comparable to Paget's disease of bone in humans.[2,3] Microscopically, bone lesions are characterized by multinucleate hypertrophied osteoclasts indiscriminately resorbing bone and associated hypertrophied osteoblasts lining bone surfaces.[3]

History and Clinical Signs There does not appear to be a breed or sex predilection for development of SAO, and it has been diagnosed in horses ranging in age from 4 to 22 years, with a mean age of approximately 10 to 14 years.[1-3,5] Due to its geographic distribution, SAO should be considered in the differential diagnosis for horses that reside or have resided in the Monterey-Carmel peninsula of California, Sonoma or Napa counties, and that are presented for any of the previously mentioned early signs of the disease (nebulous persistent or intermittent lameness, exercise intolerance, or generalized stiffness). For the horse older than 10 years that is presented with signs of advanced disease (marked lordosis, severe lameness, scapular deformation, weight loss, decreased cervical range of motion with or without signs of concurrent respiratory pathology), SAO should be a top differential.

It is important to remember the strong circumstantial evidence for a direct association between SAO and pulmonary silicosis and that exposure to cristobalite is responsible for the development of SAO.[2,3] It is unclear how long and at what concentration horses need to be exposed to the aerosolized silicate particles for disease to develop, and it is also unknown at what rate SAO develops following exposure[8]; however, severe multifocal osteolysis associated with SAO has been reported in a horse stabled in an endemic area after a period of only 2 years. In some instances, horses may have no known history of residing in endemic areas or may have spent only short times in these areas. In addition, there are endemic farms from which multiple horses develop SAO, and recent excavation in endemic areas can result in aerosolization of high concentrations of silicates that may be subsequently inhaled by susceptible horses, potentially accelerating the development and progression of disease. Therefore recent excavation in the vicinity of a horse presented with signs attributable to SAO as well as a history of clusters of affected horses in a small geographic area should be noted.

Because much remains unknown about the etiology and pathogenesis of SAO, it can present a diagnostic challenge, particularly in the early stages of the disease process.

Diagnosis Definitive diagnosis is made on postmortem examination. Currently, nuclear scintigraphy is the most reliable antemortem diagnostic test available for making a presumptive diagnosis of SAO.[5] Characteristic multifocal areas of increased radiopharmaceutical uptake (IRU) identified on whole body scintigraphic examination include, in descending order of prevalence, the scapulae (Fig. 38.43, *A*), ribs (Fig. 38.43, *B*), sternebrae, cervical vertebrae, tuber sacrale, ilium, ishium, and tuber coxae.[1] Less commonly, areas of focal IRU are identified in the long bones of the appendicular skeleton.[1,2] It has been established that because the majority of lesions are located from the ribs cranially, hind end scintigraphy is unnecessary in making a presumptive antemortem diagnosis.[2]

Other diagnostic methods that have been investigated to evaluate their efficacy in the diagnosis of SAO include scapular ultrasonography, serum biomarkers of bone turnover, and findings on physical examination.[5] When compared to scintigraphy, it was found that in moderate to severe cases, bowing of the scapulae on physical examination and widening of the scapular spine on ultrasonographic examination were strongly supportive of a diagnosis of SAO and that serum biomarkers of bone turnover were not accurate in supporting the diagnosis.[5] In mild cases, none of these three methods were accurate, and regardless of the severity of SAO, none was as accurate as scintigraphy under any circumstance.

Bone biopsy obtained from regions of focal IRU may reveal osteopenia, fibrosis, and focal regions of bone resorption, but in some cases may be unremarkable.[1] Currently, bone biopsy is not routinely performed in the diagnosis of SAO. In addition, CBC and serum biochemistry are consistently unremarkable in these cases.

Treatment Treatment is palliative and aimed at decreasing inflammation and osteoclastic bone resorption. The most

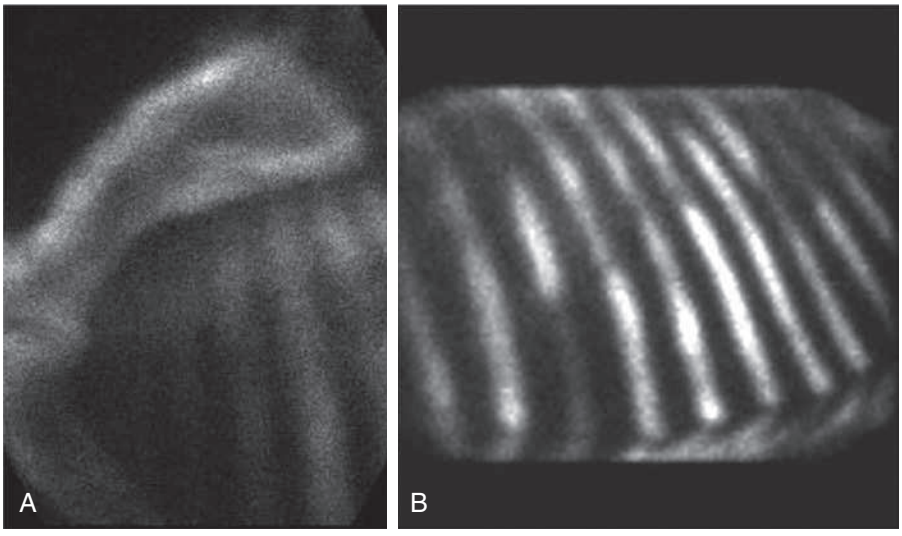

FIG. 38.43 Scintigraphic images of the same horse shown in Fig. 38.42, demonstrating **(A)** lateral bowing of the scapula with increased radiopharmaceutical uptake (IRU) in the regions of the scapular spine and caudal border of the scapula, as well as **(B)** diffuse patchy multifocal IRU noted along the length of several ribs.

VetBooks.ir

effective treatment to date has been intravenous administration of the nitrogen-containing bisphosphonate zoledronate at a dose of 0.057 to 0.075 mg/kg.[2,9] In one study, 9 of 10 SAO-affected horses treated with zoledronate had improvement in lameness scores or resolution of lameness.[2] Eight of ten of these horses also had a subjective decrease in radiopharmaceutical uptake on nuclear scintigraphy performed 6 months after a diagnosis of SAO based on initial scintigraphic examination.

Bisphosphonates are a class of drugs that inhibit bone resorption through osteoclast inhibition.[10] Following administration, bisphosphonates are incorporated into hydroxyapatite, the inorganic component of bone. When released from hydroxyapatite through osteoclastic resorption of bone, they induce osteoclast apoptosis, halting bone resorption. The non–nitrogen-containing bisphosphonate tiludronate has been used in the treatment of SAO, with limited, transient improvement noted after administration.[2]

One third to two thirds of bisphosphonates administered are incorporated into the skeleton, with the remainder excreted through the kidneys. Adverse systemic reactions following bisphosphonate administration are relatively rare in horses. There have been anecdotal reports of horses developing signs of acute renal failure following administration of bisphosphonates, so it is recommended to perform serum biochemical analysis to rule out preexisting renal disease prior to administration. Additional complications that have been reported following bisphosphonate administration include signs of abdominal discomfort and hypocalcemia. For these reasons, it is recommended to administer a single intravenous dose of flunixin meglumine (1.1 mg/kg) 30 minutes prior to zoledronate administration and maintain the horse on a 50% alfalfa diet to promote dietary calcium intake.[2]

In moderate to severe cases of SAO, exercise restriction is recommended to decrease the risk for catastrophic fracture, and judicious use of NSAIDs is often instituted to further reduce inflammation. In mild cases, exercise restriction and further pharmacologic intervention may not be necessary, but this must be determined on a case-by-case basis.

Finally, moving affected horses out of an endemic area may be of benefit, although doing so may not halt the progression of signs or prevent further signs from developing.

Prognosis

Prognosis is fair in the early stages, with return to athletic function possible following diagnosis and treatment. However, the owner must be warned of the risk for musculoskeletal injury secondary to decreased bone strength in these cases.

Prognosis is guarded to poor in later stages, and athletic use cannot be recommended due to the increased risk for musculoskeletal injury. In the advanced stages, SAO can be debilitating, resulting in poor quality of life. Catastrophic fractures frequently occur in these moderate to severe cases, regardless of the treatments used. These two factors, poor quality of life and catastrophic fracture, often necessitate euthanasia in advanced cases of SAO.

Temporohyoid Osteoarthropathy

Tracy E. Norman

Definition and Etiology

Temporohyoid osteoarthropathy (THO) is a disease of bony proliferation at the junction of the stylohyoid and petrous temporal bones. Several etiologies have been proposed for this condition, and the true etiology is likely variable. In some cases, bone inflammation and remodeling may occur secondary to extension of otitis media, otitis interna, or upper respiratory tract infection.[1-5] There is also evidence that many of these cases are due to primary degenerative joint disease.[6] Regardless of the cause, the result is bony proliferation of the tympanic bulla, proximal stylohyoid bone, and petrous temporal bones, often resulting in arthrosis of the temporohyoid joint and subsequent fracture of the stylohyoid and petrous temporal bones.[1-6] These fractures rarely extend into the basisphenoid and basioccipital bones, resulting in meningitis and brainstem disease.[1] Pain and inflammation associated with fracture or altered mobility of the joint and impingement on surrounding nerves result in the observed clinical signs.

Clinical Signs

Horses with THO may not show clinical signs, but two clinical syndromes are associated with THO. Nonneurologic signs may be chronic and include difficulty chewing, nasal discharge, head tossing, ear rubbing, otorrhea, resentment of the bit, head shyness, and pain on manipulation of the head or ears.[1-3] Neurologic abnormalities generally include acute onset of signs of facial and vestibular nerve dysfunction, including ear droop, ptosis, muzzle deviation away from the affected side, corneal ulceration, head tilt toward the affected side, circling, ataxia, nystagmus, and collapse.[1,5,6] Auditory dysfunction is common or ubiquitous in horses with neurologic signs associated with THO but may not be appreciated on standard clinical observation.[5,7] Damage to the parasympathetic portion of the facial nerve may result in reduced lacrimation.[4] Occasionally dysphagia is also observed. Rarely, seizures or sudden death may occur secondary to fractures that extend into the cranial vault.[1] Clinical signs generally have an acute onset and may be associated with manipulation of the head for other reasons (passage of nasogastric tube, etc.).[1]

Diagnosis

Pathologic alterations at the temporohyoid joint may be identified using radiography, guttural pouch endoscopy, CT, or MRI. Otoscopic examination has been reported to identify THO.[8] Radiographs may show evidence of osseous proliferation at the temporohyoid joint on lateral and dorsoventral projections but in general are found to be less sensitive at detecting abnormalities than other diagnostic modalities.[1]

Endoscopy of the guttural pouches has been shown to be sensitive in detecting early, as well as advanced, changes at the temporohyoid joint, including soft tissue inflammation and hemorrhage, osseous proliferation, enlargement of the stylohyoid bone, and previous sites of fractures (Fig. 38.44).[1] The contralateral guttural pouch should always be evaluated, as

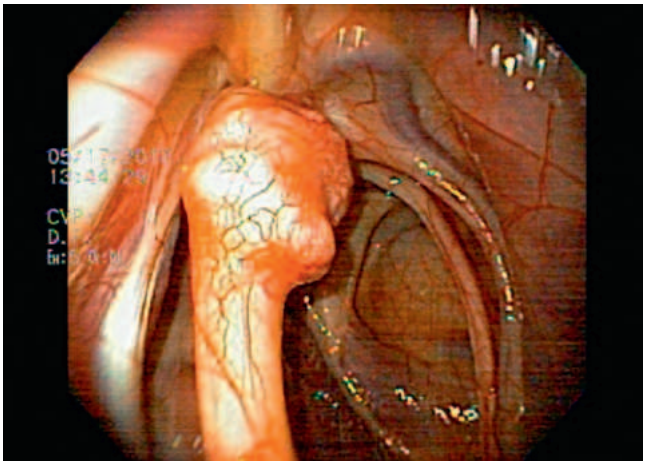

FIG. 38.44 Transendoscopic image of the right guttural pouch demonstrating enlargement of the proximal aspect of the right stylohyoid bone consistent with temporohyoid osteoarthropathy.

VetBooks.ir

some horses have bilateral disease. Evaluation of laryngeal function may be performed concurrently; in a recent study, 61% of horses with THO also had some degree of left laryngeal dysfunction. The association between these conditions was assessed to be most likely coincidental. Awareness of laryngeal dysfunction is important, however, especially in surgically managed cases.[7] Because endoscopy equipment is readily available and evaluations can be performed in the conscious horse, it may be the diagnostic modality of choice.

CT and MRI may be indicated to provide additional information. CT allows exceptional visualization of bony proliferation and can reveal fractures that cannot be detected on plain radiographs because of superimposition of structures. Advancements in this technology and full understanding of the appearance of the topographic anatomy have increased the utility of this modality.[2,3,6]

MRI yields greater soft tissue detail than CT and is useful in documenting fluid accumulations in the middle and inner ear, as well as identifying inflammatory brain lesions.[1] The biggest impediment to the implementation of these imaging technologies is the requirement for general anesthesia and the difficulty of recovering a horse with vestibular abnormalities following the procedure.

Treatment and Prognosis Treatment of THO may include both medical and surgical management. Medical management generally includes antiinflammatory and supportive care. If ptosis and reduced lacrimation lead to exposure keratitis and corneal ulceration, tarsorrhaphy may be beneficial, and intensive medical therapy is required. If otitis is suspected, or if there is a suspected fracture into the cranial vault, the use of broad-spectrum antimicrobials with good penetration of the blood-brain barrier is indicated.

Surgical therapy for THO has been described.[1,9,10] Partial stylohyoidectomy has been used in some cases to reduce the forces on the ankylosed temporohyoid joint and prevent fracture of the petrous temporal bone.[1,9] This procedure risks damage to the adjacent nerves and may result in the formation of a bony union at the stylohyoidectomy site. An alternate technique is ceratohyoidectomy, which eliminates the lever arm that drives movement of and pressure on the temporohyoid joint. Ceratohyoidectomy is technically simpler to perform than partial stylohyoidectomy, avoids the complications of that procedure, and may be performed prophylactically or in cases in which fracture of the petrous temporal bone has occurred.[9,10]

In horses with THO, the prognosis for survival is good and for return to athletic function is fair.[1,7] Surgical management appears to result in better neurologic outcomes and reduced treatment times compared with medical management.[7] Improvement in neurologic function may continue for up to 2 years, but auditory loss appears to be permanent,[7] and facial nerve dysfunction also commonly persits.[1] The most common secondary complication of THO is corneal ulceration on the affected side due to poor eyelid tone and decreased lacrimation resulting in exposure keratitis. The majority of these horses should recover fully, but healing time may be protracted.[1]

Diseases of the Eye

CAROLINE M. BETBEZE and ANNE J. GEMENSKY-METZLER, *Consulting Editors*
MEREDITH L. VOYLES, MARY ELIZABETH LASSALINE, KATHRYN L. WOTMAN, RENEE T. CARTER, CARYN E. PLUMMER, JOHN A. ANGELOS, and KRISTINA R. VYGANTAS

Ophthalmic History and Examination*

Renee T. Carter

A full ophthalmic examination should be conducted for patients presenting with a primary ocular complaint and also as part of a minimum workup for patients with neurologic changes or other unknown systemic disease processes. Prior to conducting a complete ophthalmic examination, basic information including the patient's signalment (species, breed, age, coat color, gender), use, and medical history should be obtained. A complete ophthalmic examination is then conducted in a stepwise methodical pattern to ensure that all aspects of the eye are evaluated and important diagnostic steps are not overlooked.

Reasons for presentation for ophthalmic examination include:

- Abnormal appearance of one or both eyes (i.e., asymmetry or color change)
- Presence of ocular discharge
- Presence of ocular pain
- Reduced vision or blindness
- Change in the performance or behavior of the patient
- Prepurchase examination
- Follow-up of a previously diagnosed ophthalmic condition
- Examinations for inherited ocular disorders

Ophthalmic History

A series of questions regarding the clinical signs observed, the duration and clinical course of the condition, changes in activity or behavior, previous eye problems, and whether other animals have been affected should be asked. The clinician should also obtain information on medications the owner has used to treat the eye (topically or systemically) and the animal's response to therapy. Potential causes for an ophthalmic or visual problem, including any possible relationship to neurologic or iatrogenic (e.g., drug-induced) disease, toxin exposure, or systemic illness, should be explored.

Instruments and Materials

A few basic instruments and materials facilitate an efficient and thorough examination. These include a focused light source (a Finoff transilluminator is preferred), direct ophthalmoscope with a cobalt blue filter, magnifying loupes, and a small pair of fixation forceps. Sterile fluorescein dye strips, Schirmer tear test strips, culture swabs, physiologic saline solution (flushing solution), topical anesthetic (0.5% proparacaine), tonometer, local anesthetic (2% lidocaine), and mydriatic solution (1% tropicamide) are often also necessary. For fundic examination, a direct or PanOptic ophthalmoscope may be used, or indirect ophthalmoscopy can be performed using a handheld lens and light source. To irrigate the nasolacrimal ducts, polyethylene tubing (5-French) should be available.

*Contributions to previous editions by Cecil P. Moore and Erin S. Champagne are acknowledged.

Ophthalmic Examination Procedures

General Inspection

Prior to manual restraint, the animal's activities and movements in its normal environment should be observed. This provides insight into the general well-being of the patient and its visual status. The examiner should study the animal's body condition, attitude, posture, coordination, head carriage, and ability to navigate in its normal surroundings. Animals with vision loss may be noted to spook or exhibit shying behavior on the affected side.[1] As the animal is approached, closer inspection reveals whether facial and ocular symmetry and normal eye movements are present. Signs of ocular pain (e.g., blepharospasm, apparent photophobia, epiphora) are noted, as well as size and position of the globes and the presence of ocular or nasal discharge, opacities, or masses.

Restraint

Adequate restraint is essential to conducting a complete ophthalmic examination in large animal patients. Manual restraint of small ruminants and neonates is usually adequate. For cattle, restraint in a chute with a head catch or in a stanchion with the head pulled laterally by nose tongs or a halter is ideal; restraint of a horse in stocks with a halter is recommended. Chemical restraint may be necessary in cattle, and use of a nose twitch and/or chemical restraint is often needed for horses. The animal's health and duration of the examination should be considered prior to the administration of chemical restraint. Chemical restraint may consist of a combination of injectable sedative (e.g., xylazine or detomidine for horses), with or without an injectable analgesic (e.g., butorphanol for horses). An auriculopalpebral (and occasionally frontal) nerve block using a local anesthetic agent such as 2% lidocaine facilitates examination, especially in patients with a painful ophthalmic condition. Neuro-ophthalmic assessment must be performed prior to administration of sedatives, analgesics, or local anesthetics (see below).

VetBooks.ir

Neuro-Ophthalmic Assessment

An evaluation of the integrity of cranial nerves associated with normal ocular function is conducted (see Chapter 8).

- Menace response (a blink response) may not be present in neonates; use tracking or avoidance behavior to evaluate vision. Assess both the nasal and the temporal visual fields for each eye.
- Evaluate eyelid position and palpebral reflexes. A complete blink response to medial and lateral tactile stimuli should be present in both eyes.
- Direct and consensual pupillary light reflexes.
- Normal ocular motility when the head is moved side to side (oculocephalic reflex).

Detailed Examination

Detailed examination of ocular structures should then be performed in a predetermined pattern (i.e., anterior to posterior).[2-4] A set pattern of examination is recommended to avoid interfering with diagnostic tests that may have to be performed (e.g., Schirmer's test, culture). After evaluation of the animal in its normal environment, it is best to move the patient to an environment that is quiet and well lit for extraocular examination and can be darkened for intraocular examination.

Standing in front of the patient, the clinician should evaluate for alterations in the normal symmetric appearance of the eyes and periocular structures (Color Plate 39.1). Attention should be paid to lash height, pupil size and position, and globe position. If lashes are pointed downward, this may indicate ocular pain, enophthalmos, or ptosis of the eyelid; if lashes are directed upward, this may indicate exophthalmos (orbital disease) or buphthalmos.

Evaluate the size, shape, and symmetry of the pupils by retroillumination using a focal light source in a darkened environment. To perform retroillumination, stand at arm's length distance in front of the patient and obtain the tapetal reflex using a bright penlight or transilluminator. With equal illumination of the eyes, the examiner can evaluate for changes in pupil symmetry. This must be evaluated prior to dilation. Direct and indirect (consensual) pupillary light reflexes (PLRs) should then be assessed. For most patients, due to the lateral position of the eyes, it is often necessary to have an assistant aid in evaluating the consensual PLR. The assistant uses a dim light to determine if pupil movement occurs when the opposite eye is illuminated by a bright light source.[5] The examiner must recall that PLRs are not a test of vision (i.e., abnormal responses may be observed in visual animals, and normal reflexes may occur in nonvisual animals). Pupillary abnormalities that should be noted are inequality in size (anisocoria), abnormal movements (hippus), abnormal location (corectopia), or abnormal shape (dyscoria) (Color Plate 39.2).

At this point, the examiner determines whether ocular cultures or tear measurements are desired, because these procedures must be completed before further manipulations are performed and before topical pharmacologic agents are instilled.[6] Depending on clinical signs, severity of ocular disease, and species being examined, viral, bacterial, or fungal cultures may be indicated. Sterile swabs moistened with saline and appropriate enrichment broth or transport media are applied in direct contact with the tissue surface of interest to be cultured.

Palpation of the boundaries of the orbit for irregularities, asymmetry, masses, or fractures should then be performed. The globe is retropulsed to assess for increased resistance (indicating a space-occupying mass) and to inspect the anterior aspect of the nictitating membrane ("third eyelid") for abnormalities such as trauma or neoplasia. Retropulsion is performed by gently pressing the globe back into the orbit with a finger placed over the partially closed upper eyelid (Color Plate 39.3). Retropulsion should not be performed if the cornea is compromised by a deep ulcer or laceration to avoid rupturing the globe.

It is helpful to use a lighted otoscope head or, alternatively, a direct light source (transilluminator) and wear an Optivisor™ for further examination of the external structures of the adnexa and globe. The eyelids are inspected for integrity, position, and movement. Each eyelid is digitally everted for inspection of the margins, meibomian gland openings, and palpebral conjunctiva. Paresis, malposition (ectropion, entropion [Color Plate 39.4]), defects, masses, inflammation (swelling, ulceration, exudate), alopecia, foreign bodies, and abnormal lashes are noted.

The nictitating membranes are examined for normal position, integrity, degree of pigmentation, and the presence of follicles or masses (see Color Plate 39.3). To inspect for foreign bodies, topical anesthetic solution (0.5% proparacaine or 0.5% tetracaine) is instilled two to three times onto the ocular surface. The nictitating membrane is then grasped and manipulated with small fixation forceps, and both sides are examined for foreign bodies. Care should be taken not to damage the cartilage of the third eyelid with toothed forceps.

Normally the conjunctiva appears moist, glistening, and semitransparent. Signs of conjunctivitis are chemosis (conjunctival edema), hyperemia, and ocular discharge. Color changes of the conjunctiva usually accompany anemia (blanched, pale) or icterus (yellow, amber). Chemosis may indicate severe hypoproteinemia. Conjunctival lesions noted include focal swellings, follicles, adhesions, or masses. The sclera underlying the bulbar conjunctiva is inspected for color, contour, swellings, masses, pigmented areas, or surface irregularities.

Lacrimal system examination entails evaluation of both secretory and excretory components. Normal secretions result in a moist, glistening ocular surface. Although not typically used in large animals, Schirmer tear test strips may be used to quantify aqueous tear secretion (see the Ancillary Diagnostic Procedures section later). Schirmer's tear test is indicated in cases with a lackluster corneal appearance, persistent keratitis, or ocular discharge. To examine the excretory components, the upper and lower puncta and nasal openings of the nasolacrimal system are identified. Any overflow of tears onto the face (epiphora) is noted. Causes of increased ocular secretions (e.g., frictional irritants, foreign bodies, corneal ulcers, ocular inflammation) must be ruled out. Causes for stimulation of lacrimal secretions must be differentiated from causes of outflow occlusion, such as congenital atresia and acquired obstruction of the nasolacrimal system.

Application of fluorescein dye can detect corneal ulceration; a cobalt blue light (available on the direct ophthalmoscope or as a filter for the transilluminator) should be used to assess for stain uptake. In addition, fluorescein dye aids in the assessment of nasolacrimal system patency. Passage of dye from the nasal opening of the nasolacrimal duct confirms patency (positive Jones test). Retrograde irrigation of the nasolacrimal duct by inserting a length of 5-French flexible tubing into the nasal punctum and flushing with saline may be necessary to differentiate insufficient drainage from excessive secretions.

The rest of the ophthalmic examination is performed in a darkened area. The examiner should perform retroillumination as previously described. Opacities will block thenormal tapetal reflex (Color Plate 39.5). Lesions can be roughly localized based on the ability to see the iris. Opacities in the anterior portion of the eye (cornea, anterior chamber) will block the ability to see the iris. Opacities in the posterior portion of the eye (lens, vitreous) will still allow the examiner to visualize the iris. A clear view of the tapetal reflex eliminates anterior chamber, lens, and vitreal opacities as the cause for vision loss in a blind eye.

VetBooks.ir

The cornea is then examined by direct illumination for irregularities and opacities. Direct a focal light source across the cornea (parallel) to highlight corneal irregularities. Localization of opacities to the cornea can be conducted using this technique or alternatively with a direct ophthalmoscope or handheld slit-lamp biomicroscope. The cornea is an avascular structure that is smooth and transparent, with a moist reflective surface. Corneal lesions can often be diagnosed based on their color. Corneal edema appears as a hazy, blue corneal opacity and should be characterized as focalor diffuse (Color Plate 39.6). With severe corneal edema, raised bullae (vesicles) may be noted on the corneal surface.

Infectious keratitis is characterized by suppuration, necrosis, and stromal loss. The cornea becomes more densely opaque and acquires a creamy, off-white or yellow appearance when infiltrate is present; the margins of the opacity will be indistinct, an obvious defect in the corneal contour may be noted, and the eye will typically be painful (Color Plate 39.7). Corneal abscesses occur as focal areas of suppuration within the stroma underlying a nonulcerated cornea.

Corneal opacities may also result from focal or diffuse scarring (flat, gray, with distinct margins), areas of corneal degeneration or dystrophy (white, chalky to refractile with distinct margins), or stretching of Descemet's membrane (Haab's striae) from elevation of intraocular pressure or previous trauma (parallel lines, resemble "railroad tracks" [Color Plate 39.8]). Inflammatory cells may aggregate on the corneal endothelium (keratic precipitates). The color corresponds to the cellular composition, appearing as multiple white, brown, or red foci, usually on the ventral aspect of the corneal endothelium. This finding indicates the presence of anterior uveitis.

Intraocular examination begins with evaluation of the clarity and depth of the anterior chamber. This can be performed using the small spot of light or slit-beam on a direct ophthalmoscope (light source directed perpendicular to the cornea and brought close until in focus); magnifying loupes may be needed. Alternatively, a handheld slit-lamp may be used. The anterior chamber is the space between the cornea and iris that contains aqueous humor. Breakdown of the blood-ocular barrier is known as anterior uveitis and results in opacification within the anterior chamber. Opacities include inflammatory products (cells and fibrin), protein (aqueous flare), red blood cells (hyphema), or white blood cells (hypopyon). (see Color Plate 39.5).

Besides the presence of exudates, loss of anterior chamber transparency may result from lens luxation, vitreal prolapse, anterior synechia, or intraocular masses (neoplasia or foreign bodies). The depth of the anterior chamber should also be evaluated. A shallow anterior chamber may be the result of leakage of aqueous humor, iris prolapse, iris bombé (forward bulging of the iris caused by iris-lens adhesions), anterior lens luxation, and phthisis bulbi. The anterior chamber will appear deep in eyes with cornea globosa, hypermature (resorbing) cataracts, buphthalmos, and posteriorly luxated lenses.

The iris is inspected for altered contour, pigmentation, mobility, neovascularization, pupil size and shape, and the presence of uveal masses (including the normal granula iridica). Granula iridica (i.e., corpora nigra) are normal structures present along the pupil margin. These structures may atrophy with chronic uveitis or become cystic. Transillumination of uveal masses may allow differentiation of solid structures (e.g., melanoma) from uveal cysts, although cysts originating from the corpora nigra in horses typically do not transilluminate (Color Plate 39.9). In animals with lightly colored or spotted hair coats, multicolored irides should be recognized as normal variants. Although uncommon, congenital iris thinning (hypoplasia) may be noted as dark, flat, or translucent areas when transilluminated. The lens-iris interface is best evaluated when the pupil is dilated. Iris membranes, adhesions, or strands should be characterized as congenital (persistent pupillary membranes, or PPMs) or acquired (synechiae or remnants of iris atrophy) (see Color Plate 39.2). PPMs are strands that typically originate from the iris collarette (center of the iris), whereas the edges of the iris are involved with anterior synechia.

Obscuration of the pupil space may occur with severe miosis (from acute anterior uveitis), anterior lens luxation, condensation of anterior chamber exudates (fibrin, cells), and synechiae formation (from chronic uveitis) (Color Plate 39.10). In animals with normal PLRs, complete examination of the lens and structures posterior to the lens (i.e., vitreous and fundus) may be achieved only after dilation with a mydriatic agent such as 1% tropicamide, which usually occurs 15 to 30 minutes after instillation. Once dilated, retroillumination of the ocular media to evaluate for any opacities blocking view of the tapetal reflex (as previously described) is repeated; full evaluation of the lens and fundus can also be performed.

Using a focused light, the lens is inspected for a smooth, transparent, convex anterior capsule and normal position (no part of the equator should be visible). When evaluating for lens opacities (cataracts), the examiner should direct the focused light through the axial part of the lens to establish the presence of a fundic reflex. Cataractous changes are observed as dark areas seen within the area of reflected light or white opacities when the lens is directly illuminated (see Color Plate 39.2). Cataracts may be classified according to the extent to which a fundic reflex is obstructed; a *partial reflex* indicates an incomplete cataract, whereas an *absent reflex* indicates a complete cataract. If the lens profile appears distorted (wrinkled) with numerous refractile particles present, this is typically indicative of a hypermature (resorbing) cataract.

Ophthalmoscopy must be used to examine the vitreous and fundus. The direct ophthalmoscope provides an upright image and high magnification, but it requires a close working distance and provides a small field of view, making it a poor screening tool. Using the direct ophthalmoscope, the vitreous should be in focus with a dioptric setting between +6 and +1, and the fundus is usually in focus between +1 and −2 diopters. Monocular indirect ophthalmoscopy (Panoptic) provides an upright image and moderate magnification and field of view. Indirect ophthalmoscopy provides an inverted virtual image with a less magnified view, making it a better screening tool.

The vitreous is first examined for congenital remnants (retained hyaloid structures) and opacities, including degenerative materials or exudates. Examination of the fundus begins with identifying the optic disk (papilla) and studying its size and shape. The shape, location, and vascular pattern of the optic disk and the appearance of the fundus vary considerably among species. In ruminants the optic disk margin typically appears irregular and fluffy, indicating myelination of axons entering the optic disk. However, it tends to be horizontally elliptical or kidney shaped and located in the tapetal portion of the fundus.[7] An optic disk with extensive myelination may be elevated above the surface of the fundus. In ruminants the major retinal arterioles are large and accompanied by venules that anastomose on the surface of the optic disk. The dorsal arteriole and venule usually intertwine as they course away from the disc over the midtapetum (Fig. 39.1). By contrast, the equine fundus is characterized by a large pink or salmon-colored horizontally elliptical or oval disc located in the nontapetum[7] (Fig. 39.2). Horses are *paurangiotic*, meaning they have vessels that extend only a short distance from the optic nerve head. The small retinal blood vessels extend radially from the margin of the disc, and no anastomotic venules are visible over the optic disk.

In both ruminants and horses, the fibrous tapetum is present in the dorsal two thirds of the eye and is penetrated by choroidal capillaries; thus the fundus in these species is typified by dark, stippled foci called *stars of Winslow* (end-on capillaries).

VetBooks.ir

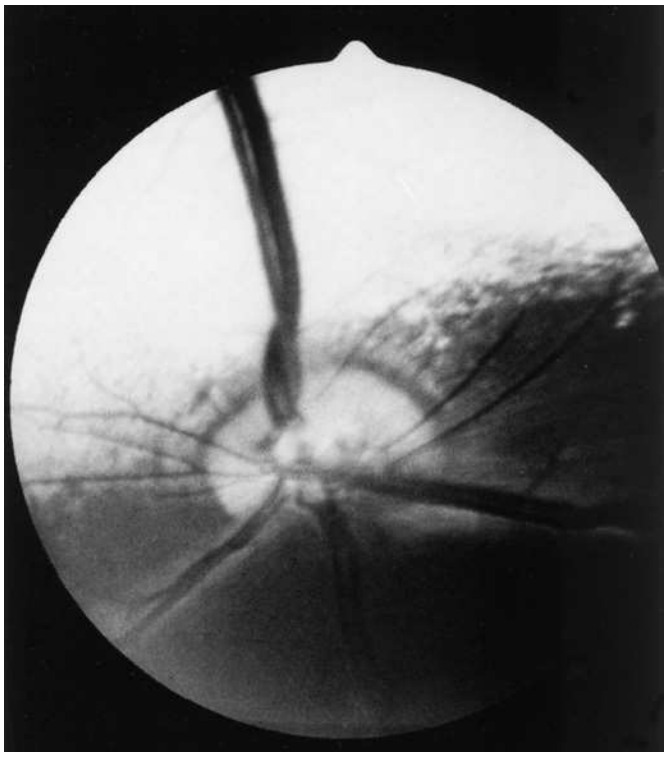

FIG. 39.1 Normal ruminant fundus characterized by a large, kidney-shaped, myelinated optic disk. Note that the large retinal arteriole and venule intertwine as they course dorsally.

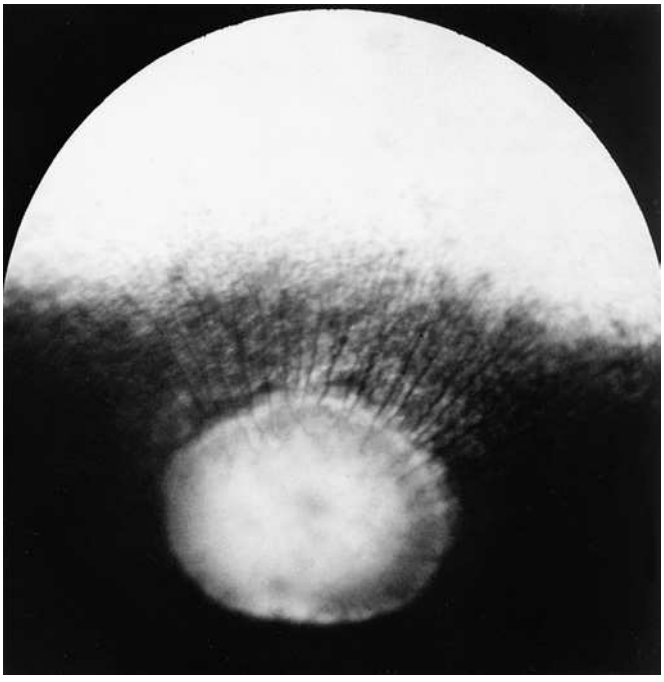

FIG. 39.2 Normal equine fundus characterized by a large, horizontally elliptical optic disk with numerous small retinal vessels entering (arterioles) and exiting (venules) the margin of the optic disk. Note that the optic disk lies in a nontapetal portion of the fundus.

Coloration of the tapeta of large animals also varies considerably and may range from gold to bluish green. In animals with varied coat color, coat color dilution, and/or heterochromia irides (variable iridal color), areas of the fundi may characteristically be devoid of pigmentation and may lack a tapetum. These

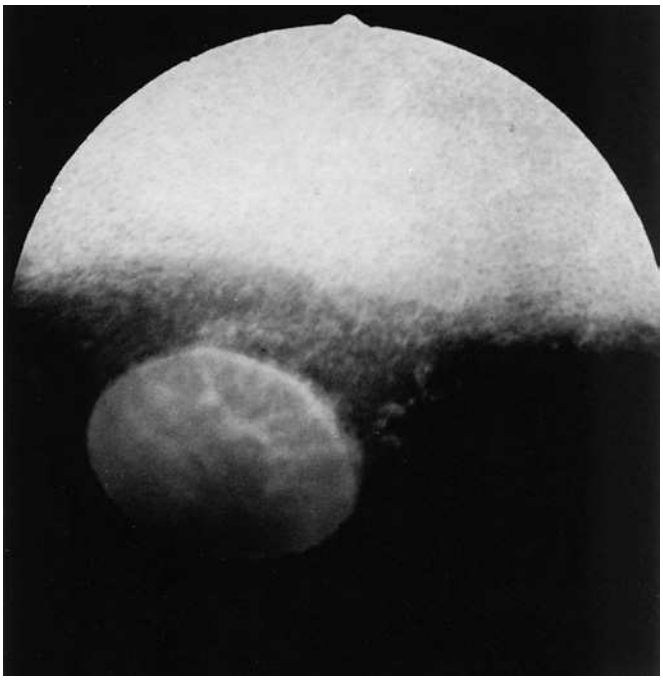

FIG. 39.3 Optic nerve atrophy (equine). Margin of disc is quite distinct because of myelin loss, which is characteristic of optic nerve atrophy. Note absence of retinal blood vessels.

FIG. 39.4 Pigmentary changes after traumatic chorioretinopathy. Irregular linear areas of hypopigmentation and hyperpigmentation are present in the tapetal fundus of a horse after ocular trauma. Pigmentary changes reflect retinal pigment epithelial disturbance from previous hemorrhage and edema. *(Courtesy Dr. K.N. Gelatt.)*

areas may appear orange or red because of direct visualization of the choroidal vasculature.

Abnormalities of the optic disk include hypoplasia (micropapilla), elevation (papilledema), depression (cupping), degeneration (atrophy [Fig. 39.3]), and vascular changes (e.g., congestion, attenuation, hemorrhage). The tapetal fundus is evaluated for clarity, coloration, pigmentation (Fig. 39.4), and integrity

of the retinal vessels (Fig. 39.5). The nontapetal fundus is evaluated for uniformity of pigmentation. Both tapetal and nontapetal areas are assessed for retinal elevations or separations (Fig. 39.6), hemorrhages, degenerations, disorganization (dysplasia), or scleral defects (colobomas).[7]

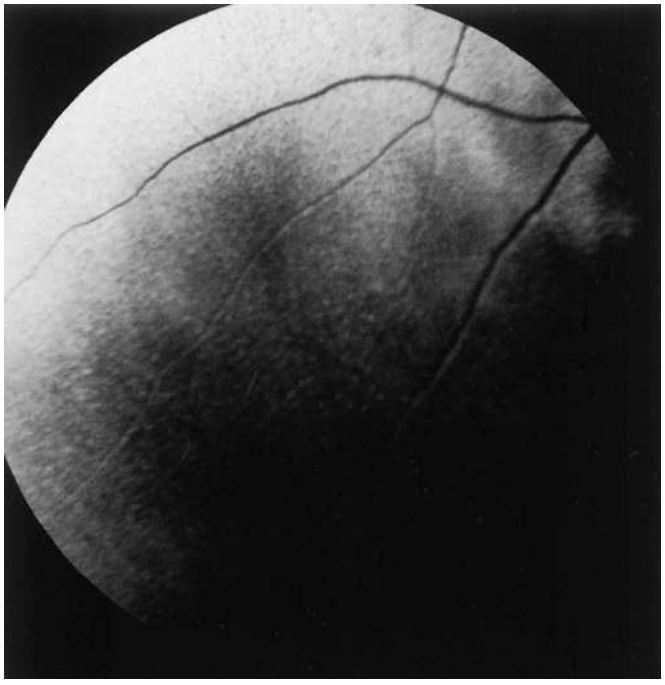

FIG. 39.5 Retinal degeneration (bovine). Peripheral retinal vessels are greatly attenuated near the tapetal-nontapetal junction. Attenuation is accompanied by hyperreflectivity of the tapetal region. These changes are consistent with generalized retinal atrophy.

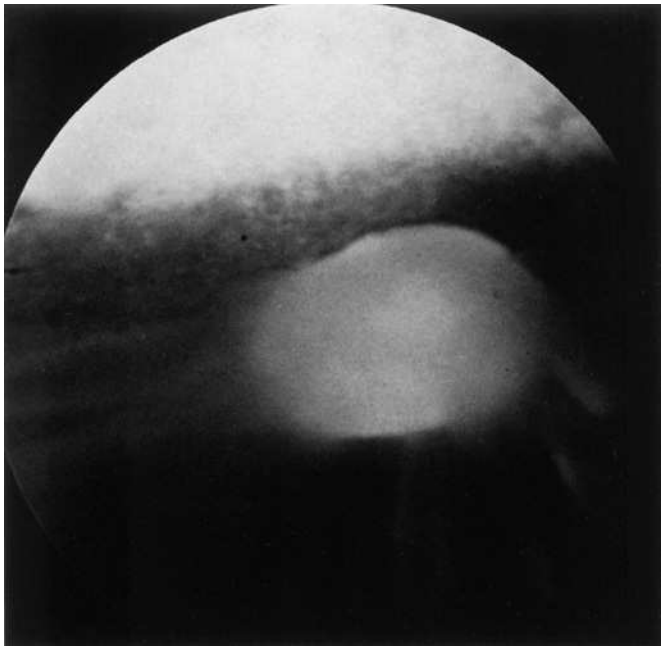

FIG. 39.6 Retinal separation (equine). Gray linear areas radiate from the optic disk into the nontapetal region of fundus. Note that the margin of the disc is quite indistinct in the affected area. Absence of retinal vessels indicates concurrent retinal degeneration.

Ancillary Diagnostic Procedures

Several additional procedures may supplement the complete ophthalmic examination. Although some ancillary procedures require specialized equipment and expertise, many may be performed in general practice.

Fluorescein and rose bengal are ocular surface stains most often used as aids in diagnosing conjunctival and corneal diseases. The tip of a sterile dye strip is moistened with saline or eye-irrigating solution, and a drop of the stain is instilled onto the eye. Fluorescein is a water-soluble dye used to detect exposed corneal stroma resulting from an epithelial defect (erosion), stromal ulceration, or descemetocele and is viewed with cobalt blue light. The pattern of fluorescein staining for a descemetocele is characterized by a donut-shaped area of positive fluorescence, with the perimeter retaining stain and the center or deepest area (Descemet's membrane) not retaining stain. Fluorescein may also be used to evaluate the patency of nasolacrimal ducts because an open duct allows the transmission of stain, which may be observed exiting the duct system at the nasal orifice (Jones test). Rose bengal is retained by devitalized surface cells and is therefore useful in detection of subtle abnormalities like hyperplastic or desquamating cells associated with ocular surface drying, herpetic infection, keratomycosis, or squamous cell carcinoma. Stain uptake appears pink when illuminated with white light. These stains can be performed in any order.

Although tear deficiencies are uncommon in large animals, Schirmer tear test strips may be beneficial to quantify aqueous tear production in selected cases. A sterile filter paper strip (40 × 5 mm with a notched end) is inserted into the lower conjunctival fornix. In large animals it is sufficient to measure the amount of wetting in 30 seconds (≥20 mm is normal). Tear testing is indicated in patients with a dry, lackluster corneal surface; persistent ocular discharge; or keratitis.

Cytologic evaluation of ocular surface scrapings or intraocular aspirates may differentiate between inflammatory and neoplastic diseases or in some cases may provide a definitive diagnosis. Orbital aspirates may be diagnostic in cases of exophthalmos caused by neoplasia (e.g., lymphosarcoma). Immunofluorescent or polymerase chain reaction (PCR) testing of cytologic specimens may confirm viral (e.g., infectious bovine rhinotracheitis) or *Chlamydia* infections.[3] Bacterial cultures taken from the ocular surface or from ocular aspirates, with subsequent antimicrobial susceptibility testing, may be necessary for definitive diagnosis and appropriate treatment of ocular infections. Bacterial and fungal cultures, as well as corneal cytology, are especially important tests when equine ulcerative keratitis is diagnosed. The diagnostic laboratory performing ocular cultures may offer suggestions on culture procedures, including preferred transport media and handling of samples. It is especially important to consult with the laboratory in advance when anticipating culturing for fungi, *Mycoplasma*, *Chlamydia*, or viral agents.

Tonometry, a means of measuring the intraocular pressure (IOP), is useful in diagnosing glaucoma (elevated IOP) and uveitis (low IOP) and in assessing response to therapy for these conditions. Tonometry is indicated in cases with corneal edema, redness, lens luxation, abnormal PLR, and cases with vision loss or a history of glaucoma. Digital tonometry (gently indenting the globe through the upper eyelid) is not considered an accurate measure of IOP; Schiøtz tonometry is not applicable to large domestic species. Applanation tonometry using the TonoPen® provides accurate and reproducible IOP readings in large animals and is routinely performed. In addition, the rebound tonometer, TonoVet®, has been used successfully in horses.[8] The clinician should be aware that eyelid blocks, sedation, and head position can all affect IOP readings.[9]

VetBooks.ir

Biomicroscopy, using a portable handheld slit-lamp, is useful for identifying the location and nature of anterior ocular opacities. Focal irritants (e.g., ectopic cilia, small foreign bodies) and small lesions may only be visible with the magnification provided using biomicroscopy. Alternatively, use of a focal light source with magnification in the form of an otoscope or optivisor may be used for close examination.

Fundic examination may be performed relatively quickly and easily using the technique of indirect ophthalmoscopy. Monocular indirect ophthalmoscopy is performed using a handheld light source and a separate 20- or 14-diopter focusing lens for equine and bovine patients or a 28-diopter lens for smaller ruminants.

Other ancillary diagnostic procedures include electroretinography (to evaluate retinal function), visual evoked potentials (to evaluate visual pathways), and imaging procedures (radiography, ultrasonography, computed tomography [CT]). Although plain skull radiographs and some contrast studies (e.g., dacryocystorhinography) may be performed in general practice, the remaining procedures require techniques and equipment usually available only at referral centers.

Signs of Ocular Disease*

Renee T. Carter

Clinical signs of ocular disease can be grouped into five primary categories at the time of presentation:

- Ocular or periocular asymmetry
- Ocular color change
- Ocular discharge
- Ocular pain
- Visual deficits or blindness

Patients may present with one or a combination of these clinical signs. This section provides a general description of the signs and examples of ocular diseases in which a particular sign predominates. Tables 39.1 and 39.2 summarize common signs of ocular disease in large animals.

Ocular or Periocular Asymmetry

Ocular or periocular asymmetry results from unilateral changes in facial soft tissue or orbital structures, orbital volume, globe size, eyelid position, or pupil size and position (see Table 39.1). Changes in symmetry often involve a reduction or increase in volume of a certain tissue. *Reduction* in tissue volume occurs with congenital hypoplasia, cicatricial shrinkage, atrophy, or dehydration. *Increase* in tissue volume may involve the whole globe (buphthalmos) or be characterized by irregular enlargement, as seen with inflammatory or neoplastic lesions involving the globe, orbit, or eyelids. Asymmetry may also result from a neurologic dysfunction. Common examples include reduced palpebral fissure size (secondary to facial nerve paralysis), strabismus, third eyelid protrusion, and anisocoria (see Chapter 8). This section describes the common signs of ocular disease. It is not the intent to describe in detail each of the diseases that may be noted; these disorders are covered in other sections of this chapter.

Change in Globe Position

Changes in globe position affect symmetry and include exophthalmos, enophthalmos, and strabismus. Forward displacement of the eye (exophthalmos; Fig. 39.7) is often associated with a space-occupying orbital lesion (neoplasia, inflammatory, vascular, cystic) or, less often, a congenitally shallow, underdeveloped orbit. Posterior malposition of the globe (enophthalmos) may result from active globe retraction caused by pain or from loss of supporting retrobulbar soft tissues as seen in cases of muscle atrophy, loss of orbital fat, or denervation. Congenital strabismus is a developmental abnormality that results in ocular asymmetry due to deviation of normal globe position and has been reported in Jersey, Shorthorn, Holstein, and German Brown Swiss cattle.[1,2] Strabismus can occur with exophthalmos and has also been associated with systemic disorders such as polioencephalomalacia and listeriosis.[2] Unequal orbit volume resulting in displacement of the globe or globe malposition may also occur with traumatic orbital fractures.

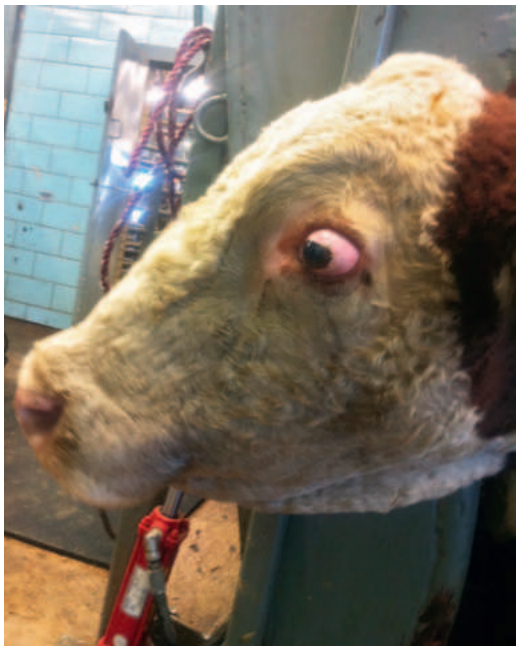

FIG. 39.7 Hereford with marked exophthalmos of the left eye that was present bilaterally.

Change in Globe Size

Unequal globe size can also account for ocular asymmetry. A congenitally small globe (microphthalmia) occurs as a genetic defect in sheep, cattle, and horses[1,3,4] and has also been associated with exposure to infectious agents and teratogens. Microphthalmia is frequently accompanied by multiple ocular anomalies and may be associated with multiple organ involvement or vertebral abnormalities.[2] Acquired variations in globe size usually result from shrinkage of the globe secondary to globe rupture or with phthisis bulbi (Color Plate 39.11) secondary to chronic uveitis; stretching or enlargement of the globe (megaloglobus, buphthalmos) occurs with glaucoma. Cornea globosa has been reported in horses and ponies with multiple congenital ocular anomalies (MCOA) syndrome with the silver mutation and coat color.[5,6]

Changes in Eyelid Conformation

Asymmetry of the upper or lower eyelid may be due to entropion, ectropion, blepharitis, conjunctivitis, or ptosis (facial nerve paralysis or sympathetic denervation). Entropion has been reported in Simmentals[1] and as an inherited trait in sheep.[7] (see Color Plate 39.3) However, entropion most commonly occurs secondary to microphthalmos or enophthalmos (retraction of the eye with pain, reduction in orbital volume, denervation). Trauma with secondary scar formation may result in either entropion or ectropion. Nictitating membrane (third

TABLE 39.1

Causes of Important Ocular Signs in Large Animals

Changes in ocular and periocular symmetry	Eyelid disorder	Ptosis	Facial nerve paralysis
			Sympathetic denervation
			Blepharospasm
		Ectropion	Trauma, scar
		Entropion	Trauma, scar, loss of orbital volume
		Blepharitis	Parasitic
			Viral: pox, bluetongue
			Actinic/photosensitization
			Allergic
			Dermatophyte
			Immune-mediated
		Neoplasia	SCC, sarcoid, melanoma, papilloma, lymphoma, hemangioma, among others
		Third eyelid elevation	Increased orbital volume (space occupying lesion)
			Sympathetic denervation
			Loss of orbital volume:
			Microphthalmos
			Phthisis bulbi
			Dehydration
			Muscle loss
			Loss of orbital fat
			Tetanus
			Retraction of globe: pain
			Hyperkalemic periodic paralysis (flashing of eyelid)
			Neoplasia
	Enophthalmos	Dehydration	
		Loss of retrobulbar fat and/or muscle	
		Congenitally shallow orbit	
		Sympathetic denervation	
		Pain and associated retraction of globe	
		Microphthalmos	
		Globe rupture	
		Compression of globe by periocular tumor	
	Exophthalmos	Trauma: hemorrhage, tissue swelling	
		Orbital neoplasia	
		Inflammatory orbital lesion:	
		Foreign body	
		Cellulitis	
		Abscess	
		Granuloma	
		Cyst: developmental, parasitic	
		Exogenous steroid administration (cattle)	
		CN VI lesion (loss of retractor bulbi function)	
		Vascular lesion	
		Inherited: bilateral convergent strabismus with exophthalmos (B)	
	Buphthalmos	Primary or secondary glaucoma	
	Cornea globosa	Multiple congenital ocular anomalies (MCOA) syndrome (E)	
	Phthisis bulbi	Chronic inflammation or trauma	
	Globe rupture	Trauma	
	Microphthalmos	Viral: bovine viral diarrhea (BVD)	
		Genetic: B, E	
		Teratogenic	
	Strabismus	Extraocular muscle damage: trauma	
		Extraocular muscle denervation: central or peripheral	
		Congenital	
		Inherited: bovine convergent strabismus with exophthalmus (BCSE) (B)	
		Congenital stationary night blindness (E)	
		Otitis media/interna	
	Retrobulbar fat prolapse

eyelid) protrusion is frequently seen secondary to active retraction of the globe in response to ocular pain, enophthalmos caused by loss of orbital contents (dehydration, malnutrition, atrophy), presence of third eyelid masses, orbital space-occupying masses, or neurologic disorders (e.g., Horner's syndrome, tetanus).

Anisocoria

Pupillary asymmetry, or anisocoria, may develop for a variety of reasons that can be grouped into (1) primary iridal lesions, including congenital iridal defects (hypoplasia, aniridia, coloboma, anterior segment dysgenesis, synechia, iris atrophy), (2) neurologic disorders (Horner's syndrome, oculomotor

nerve dysfunction), (3) intraocular diseases (uveitis, glaucoma, unilateral retinal lesions), (4) diseases involving the optic nerve or brainstem, and (5) previous use of pharmacologic agents such as atropine that alter iris sphincter muscle function or exposure to plants containing parasympatholytic alkaloids.

Changes in Tissue Volume

The presence of an ocular mass may be the primary cause of ocular asymmetry. Ocular surface neoplasms are relatively common in horses and cattle. Ocular squamous cell carcinomas usually arise from nonpigmented tissues of the nictitating membrane, the lateral limbal region, or the eyelid margin where ultraviolet (UV) light exposure is highest.[8] They may appear as irregularly raised, papillary surface masses or, less often, as smooth, vascularized lesions that invade the globe (Color Plates 39.12 and 39.13). Ulceration, exudation, and mucopurulent ocular discharge are frequent concurrent findings (see the Ocular Neoplasia section later). Periocular sarcoids are also common in horses; their appearance is variable, ranging from flat foci of alopecia to fleshy or nodular nonulcerative lesions.[9,10] Other ocular tumors occur in large domestic animals but are relatively uncommon. Dermoids and orbital cysts are congenital masses involving the periocular tissues, eye, or orbit. Other nonneoplastic ocular masses seen in large animals include firm parasitic and foreign body granulomas and soft, fluctuant subconjunctival swelling characteristic of prolapsed periorbital fat. Ocular and orbital pseudotumors have also been described in the horse.[11]

Ocular Color Change

Changes in the color of ocular or periocular tissues or the presence of opacities in the clear ocular media (cornea, aqueous humor, lens, or vitreous) are important features of ocular disease. Such changes must be differentiated from normal congenital differences in ocular pigmentation. Developmental color dilution or absence of ocular pigmentation results in light or multicolored irides (heterochromia iridis). Examples of abnormal coloration include hyperemia of conjunctival (superficial) or episcleral (deep) blood vessels associated with ocular inflammation (see Table 39.2), hemorrhage secondary to trauma or coagulopathies, pallor of the conjunctiva (which reflects severe anemia), and yellowing of the sclera and sometimes iris, indicating icterus. A change in the color of the iris may also occur with anterior uveitis.

Opacities of the ocular media may occur as either surface (corneal) or intraocular (anterior chamber, lens, or vitreous) phenomena. Brown discolorations of the cornea are the result of pigmentation, iris prolapse, embedded foreign body, or pigmented fungal plaques. Grayish scars occur from previous episodes of keratitis; infectious keratitis will present with cream- to white-colored infiltrate; corneal degeneration will appear as white deposits of lipid or mineral; vascularization occurs secondary to chronic inflammation or neoplasia; and bluish discoloration is caused by corneal edema. These color changes frequently occur in various combinations in more severe keratitis, especially those of infectious origin such as chronic keratoconjunctivitis caused by *Chlamydia* spp., *Mycoplasma* spp., or *Moraxella bovis*. Cataracts are perhaps the most obvious cause of intraocular opacities in large animals (Color Plate 39.14). Inherited cataracts have been reported in Thoroughbreds, Quarter Horses, Morgans, and Rocky Mountain horses.[12] However, the presence of exudates within the aqueous humor or vitreous, congenital vascular remnants in the vitreous, degeneration of the vitreous, or retinal detachment may also account for intraocular opacities (see Table 39.2).

Ocular Discharge

Ocular discharge can be characterized as serous, mucoid, purulent, or hemorrhagic. The type of discharge may assist in determining the severity and chronicity of the eye disease. Serous discharge generally indicates mild eye disease, whereas mucopurulent or hemorrhagic discharge indicates more serious disorders. A notable exception to this generalization is *equine recurrent uveitis* (ERU), which is associated with serous discharge (see the Immune-Mediated Ocular Diseases section later). The nature of ocular discharge tends to change as the disease progresses or improves. This is most notable in inflammatory or infectious ocular diseases. Initially the discharge is predominantly serous, but it tends to become mucopurulent with chronicity (see Table 39.2).

Epiphora describes facial wetting and results from overflow of tears over the eyelid margin. This may result from excessive secretion of tears (e.g., painful stimulus) or from physical or functional obstruction of the nasolacrimal system. In large animals, reflex lacrimation with an associated overabundance of tears is the typical response to ocular irritation or inflammation (e.g., foreign body, lash disorders, conjunctivitis, keratitis, uveitis). When epiphora is noted, careful digital and visual examination for foreign bodies within the conjunctival fornix or under the third eyelid is indicated. Epiphora is generally one of the earliest signs of conjunctivitis, ulcerative keratitis, or anterior uveitis. In cattle with keratoconjunctivitis caused by *Moraxella bovis*, epiphora is present several days before visible corneal ulceration occurs[13] (see the Infectious Bovine Keratoconjunctivitis [IBK] section later).

If signs of painful stimuli are not noted, the patency of the nasolacrimal system should be evaluated. Developmental defects or malformations of the nasolacrimal duct system (e.g., imperforate puncta) result in epiphora secondary to impaired outflow in neonates. In these cases, the presence of epiphora may be misinterpreted as overproduction of tears. Previously undiagnosed congenital defects may also be the cause of persistent ocular discharge in adult animals. Acquired obstructions of the nasolacrimal ducts may result from infections, foreign bodies, facial trauma, nasal tumors, or sinusitis that involve the duct system. Whether congenital or acquired, simple nonseptic obstructions are characterized by epiphora; septic occlusions result in mucopurulent discharge from the eye or nostril on the affected side. Excessive mucus production is a feature of follicular conjunctivitis, possibly as a result of the rubbing of elevated lymphoid follicles on apposing conjunctival surfaces. Lymphoid follicles are noted in subacute or chronic forms of chlamydial conjunctivitis in sheep and with *Onchocerca* larval migration in horses. Mucoid ocular discharge may be observed concurrently with epiphora in acute ocular surface infections caused by viral or chlamydial agents. Excessive tenacious mucus may also result from inadequate secretion of the aqueous component of tears (i.e., keratoconjunctivitis sicca). Although keratoconjunctivitis sicca (KCS) is not diagnosed as commonly in large animals as it is in dogs, neurogenic KCS due to loss of parasympathetic innervation has been reported in horses, usually as a complication of guttural pouch pathology.[14] KCS has also been reported with locoweed poisoning and hypothyroidism.[15]

Purulent to mucopurulent material is characteristic when bacterial organisms are involved in the ocular disease process. Bacterial conjunctivitis occurs frequently in large domestic species and manifests as red eyes with copious mucopurulent ocular exudate. Ocular foreign bodies and surface masses (e.g., squamous cell carcinoma) may predispose to secondary bacterial infections. Mucopurulent discharge in the absence of ocular inflammation suggests infection of the nasolacrimal sac (dacryocystitis) or ducts, with reflux of exudate from the lacrimal puncta.

Sanguineous or hemorrhagic discharge most often occurs after blunt or penetrating trauma to the eye (see the Ocular Trauma section later). Foreign body penetration may damage the eyelid, conjunctiva, or globe, resulting in bleeding onto the ocular surface. In addition, bloody-tinged ocular discharge has been reported in equine piroplasmosis.[16] Corneal ulcers may rupture and result in uveal prolapse and subsequent hemorrhage on the ocular surface.

Patients with conjunctivitis or ocular surface tumors may develop ulceration resulting in bloody ocular discharge. Whenever blood is noted on the surface of the eye, it is imperative that a thorough ophthalmic examination be performed to determine the cause and evaluate integrity of the globe.

Ocular Pain

Ocular pain can be manifested as blepharospasm, epiphora, photophobia, and periocular hyperesthesia. Animals with severe ocular pain usually resist manipulation of the eyelids or any form of ocular examination by persistently jerking the head away from the examiner and closing the eyelids tightly. In cases of persistent ocular inflammation, discomfort and pruritus may be manifested by rubbing and self-trauma to ocular or periocular structures.

Ocular pain may result from conjunctivitis, trauma, keratitis, uveitis, and glaucoma. Other causes of ocular pain include mechanical irritation from entropion, trichiasis, distichia, ectopic cilia, or foreign material.[17] Foreign bodies that cause ocular irritation in large animals are typically plant materials like seeds, hay stems, straw, twigs, bark, or thorns, although particles of sand or soil can also cause severe ocular irritation. Non-embedded particulate matter is usually entrapped by mucus and washed out of the eye by reflex tearing; it typically results only in transient discomfort. By contrast, embedded foreign material (i.e., between ocular surface layers or within ocular tissues) causes persistent ocular pain.

Blindness

Visual deficits in large animals manifest in a variety of ways. Obvious signs include bumping into objects and lack of response to visual stimuli such as light or hand motions. Another sign of blindness is reliance on stationary objects (e.g., fences, railings, other animals) to maneuver within the environment. Behavioral changes include reluctance to move or to venture into unfamiliar areas, nervousness, and spooking in response to sudden noises or movements.[18] The nonvisual animal is frequently found standing isolated from the group and may experience injury by dominant individuals in the herd and suffer from weight loss.[18] Searching nystagmus is also seen in some animals with congenital blindness.

Nonvisual animals attempt to compensate for loss of vision with their other senses, which may result in an elevated head position or a head tilt. Patients may also exhibit maximum neck extension or snorting or intensive sniffing associated with nervousness. Frequently, blind animals will show exaggerated elevation of the limbs while walking. This must be differentiated from true hypermetria (see Chapter 8). Partial loss of vision may be difficult to determine, and detection depends on observing more subtle behavioral changes such as slight head cocking or tilting, difficulty maneuvering in dim light, or shying and startling from objects on one side or objects present in some specific part of the visual field. Conduction of a maze test will assist the clinician in the detection of partial vision loss. Animals may effectively compensate for congenital blindness or slow diminution of vision, particularly when they remain with other unaffected animals in a familiar environment. Visual disturbance may not be apparent until an affected animal is isolated or moved to an unfamiliar area.

There are numerous causes of blindness in large animals, including those that involve only the visual system and some that involve other nervous system tissues or are multisystemic (Box 39.1). A functional approach to blindness involves anatomically classifying the cause as one of the following:

- Cloudy ocular media (light does not reach the retina)
- Retinal detachment or retinopathy
- Optic nerve or central nervous system (CNS) disorder

BOX 39.1

Guidelines for Inspection (Antemortem and Carcass) and Disposal of Animals, Carcasses, and Parts Affected With Neoplasia

A. Epithelioma of the Eye
   1. Any animal found on antemortem inspection to be affected and the eye has been destroyed or obscured by neoplastic tissue and which shows extensive infection, suppuration, and necrosis, usually accompanied by foul odor, or any affected animal with cachexia, regardless of extent, shall be condemned.
   2. Carcasses of animals with the eye or orbital region affected will be condemned if the affection has:
      a. Involved the osseous structures of the head with extensive infection, suppuration, and necrosis;
      b. Metastasized from the eye or orbital region to any lymph node (including the parotid lymph node), internal organs, muscles, skeleton, or other structure, regardless of the extent of the primary tumor; or
      c. Regardless of extent is associated with cachexia or evidence of absorption or secondary changes.
   3. Carcasses of animals affected to a lesser degree than above may be passed for human food after removal and condemnation of the head, including the tongue, provided the carcass is otherwise normal.

B. Neoplasms
   1. An individual organ or other part of a carcass affected with a neoplasm shall be condemned. If there is evidence of metastasis or that the general condition of the animal has been adversely affected by the size, position, or nature of the neoplasm, the entire carcass shall be condemned.
   2. Carcasses affected with malignant lymphoma shall be condemned.

From Code of Federal Regulations, Title 9, Chapter 3, Parts 309.6, 311.11, and 311.12 (1-1-87 edition).

Assessment of PLRs aids in localization of the lesion. Cloudy ocular media can be identified on retroillumination. Animals with lesions involving the retina, optic nerve, optic chiasm, or optic tracts generally do not have a normal PLR, whereas those with more central ("higher") lesions involving the lateral geniculate bodies, optic radiations, or occipital (visual) cortex are likely to exhibit a normal PLR (see Chapter 8).

Ocular Trauma*

Kristina R. Vygantas

Causes of Trauma

Because the eye is anatomically prominent in horses and food animals, it is prone to blunt and sharp trauma, which can range in severity from a mild abrasion caused by a conjunctival foreign body to a severe corneal laceration with globe rupture and orbital bone fracture. Ocular injuries may result from a variety of causes, including foreign materials such as soil, sand, or stones, which may be thrown into the eye during running or by the wind; trauma from disciplinary action; scratches by vegetable matter such as hay, weed stems, tree limbs, or thorns; exposure to chemical irritants; and sudden, violent head movements during training, working, or grooming. Other sources of ocular injury include stanchions, stall or trailer latches, hooks,

*Contributions to previous editions by R. David Whitley and Elizabeth M. Whitley are acknowledged.

protruding nails, bucket handles, fencing materials, and other animals, particularly horned ruminants.

Recumbent neonates and animals with CNS disease or severe illnesses that cause depressed mentation often suffer eye injuries from abrasion by debris or bedding materials, such as sand, straw, hay, or wood shavings. These injuries may be prevented by protecting the eye from trauma through the use of a padded hood or soft mats under the head or through sedation to prevent thrashing. It is also important to keep the cornea well lubricated in dehydrated animals and/or those with reduced blinking frequency. Following ocular trauma, opportunistic or pathogenic organisms may become established in the wound bed and may cause superficial or deep corneal infections. Ocular flora native to the conjunctiva include potential pathogens that may cause severe infections.[1]

Ocular Examination in Cases of Head Trauma

The goals of examination are to determine the degree of ocular trauma and to offer a prognosis for recovery of vision and preservation of the eye. The history should elicit information as to the cause and duration of the injury, previous ocular and systemic disease or therapy, and a description of any recent sedation, anesthesia, or therapy.

Blunt or sharp facial trauma frequently results in damage to the orbit and globe, including fractures or soft tissue injuries of the orbit, corneal abrasions and edema, corneal or scleral rupture, hyphema, traumatic uveitis, lens luxation, traumatic cataract, vitreal hemorrhage, retinal tear or detachment, or proptosis. Therefore the integrity of the orbit and globe and presence of vision should be determined when evaluating a patient with facial trauma.

Ophthalmic examination can be performed only after adequate restraint of the head (see the Ophthalmic Examination Procedures, Restraint section earlier). Intravenous (IV) sedation, sensory and motor nerve blocks, topical anesthesia, and the use of a halter, twitch (in horses), or nose tongs (in cattle) often are necessary for adequate examination of the traumatized eye.

Trauma to the Orbit

Orbital injuries in domestic animals frequently include fractures of the orbital rim and zygomatic arch and damage to the supraorbital process of the frontal bone.[2] Fractures of the orbit may be identified by palpation, radiography, CT, or magnetic resonance imaging (MRI). Contusions or lacerations of orbital soft tissues and temporary or permanent neurologic dysfunction also may be present.

Radiographic examination of the bony orbit in large animals is technically difficult and often unrewarding with conventional radiography. Standard lateral and dorsoventral views require powerful radiographic equipment for penetration of bony structures in horses and cattle.[1] Large fractures may be identified, but distinct delineation of the bony orbit is difficult because of overlying sinus and nasal structures. An oblique view of the frontal bone is often the most helpful projection.[3] This view may be taken with a portable machine because only minimal radiographic penetration of skull structures is required. Outlining the orbit and surrounding bony structures allows identification of fractures, osteomyelitis with or without bony sequestra, and soft tissue abnormalities, including swelling and radiopaque foreign bodies. If a periorbital sinus is involved in the fracture, subcutaneous emphysema may be present. The use of digital radiography may allow enhanced visualization of the bony structures of the orbit, especially when only subtle changes are present. Digital radiography systems used in conjunction with portable equipment may provide adequate detail in standard as well as oblique projections. CT and MRI are available at many referral centers. Detail of the bony and soft tissue structures is greatly enhanced by the cross-sectional views acquired by CT, as are the structures of the calvarium, sinuses, and teeth. MRI is also beneficial in delineating soft tissue abnormalities within the orbit and sinuses.[4-6] In a recent case report on a periorbital wooden foreign body in a horse, MRI was required to identify the embedded material.[6]

Immediate evaluation for orbital fractures should include careful examination of the globe. In cases with substantial swelling, ice packs applied to the fracture site may reduce swelling. Systemic antiinflammatory therapy (e.g., flunixin meglumine, ketoprofen, phenylbutazone) may also be given. Systemic antibiotics should be used if sinus involvement is suspected. If the fracture fragments are only minimally displaced, surgical intervention may not be required. Surgical repair should be considered if fragment displacement or entrapment of extraocular muscles has occurred or could occur.[3,7] Trauma sufficient to cause fractures may also result in neurologic dysfunction and immobility of the eyelids.

If eyelid movement is impaired, the globe must be adequately protected and lubricated until neurologic function returns. If the globe is only minimally exposed, a sterile ophthalmic lubricant may be used at least three or four times daily. In more severe cases, a nictitating membrane flap or temporary partial tarsorrhaphy may be required. If neurologic dysfunction is permanent and results in significant exposure conjunctivitis or keratitis, partial or complete permanent tarsorrhaphy should be performed.[3] Enucleation with or without placement of an orbital prosthesis may be required for severely affected eyes.

Rupture of the sclera and/or cornea is another potential consequence of blunt trauma to the orbit and globe. A recent study found that eyelid and conjunctival swelling are the most consistent clinical signs of scleral rupture in horses.[8] Other clinical features of this condition are hyphema, subconjunctival hemorrhage, uveal prolapse, and a collapsed anterior chamber (Color Plate 39.15). Ultrasonographic findings include poorly defined scleral margins and echoic or hyperechoic material in the anterior and posterior chambers and in the vitreous.[7] Trauma severe enough to cause corneal or scleral rupture is typically associated with significant intraocular damage such as retinal detachment, uveal avulsion and prolapse, and expulsive hemorrhage. Prognosis for vision and globe salvage is usually poor.

Traumatic puncture wounds of the eyelids and conjunctiva may result in orbital cellulitis and exophthalmos in food animals and horses. Pyrexia and leukocytosis may be present. If a retrobulbar abscess occurs, temporomandibular movement causes extreme pain; the animal may have the eyes partially closed, be off feed, and stand with the neck extended. The client may observe a relatively sudden onset of exophthalmos, eyelid swelling, severe chemosis, and exposure keratitis.[3,9] With time, the cellulitis may organize into a discrete abscess that can be located by palpation or ultrasound. Fine-needle aspiration may be performed to obtain specimens for culture and susceptibility (C&S) and cytology to guide antimicrobial therapy. Therapy should consist of systemic and topical antibiotics and a systemic antiinflammatory medication. Ophthalmic ointments and lubricants should be used on the exposed cornea and conjunctiva to prevent desiccation. In many cases, the wound or abscess should be débrided or drained to facilitate healing, especially if a well-organized abscess is present.

Although traumatic proptosis is uncommon, it may occur in horses and food animals. The prognosis for return of vision is guarded to poor, depending on the extent of damage to the optic nerve and retina. If the globe is ruptured and/or the extraocular muscles are avulsed, the eye should be enucleated. If the extent of the damage cannot be evaluated initially, the globe should be repositioned, a temporary tarsorrhaphy performed, and the globe reevaluated after 7 to 10 days of therapy. Treatment should

include topical broad-spectrum antibiotics, topical atropine, and systemic antiinflammatories and antibiotics. With severe fractures or serious ocular damage, consultation with or referral to an appropriate specialist is advised.

Trauma to the Eyelid

Eyelid trauma is frequently accompanied by injuries to other ocular structures. Careful ocular examination should be part of the evaluation of animals with eyelid trauma. Injuries may range from swelling (blepharedema) or orbital cellulitis to extensive lacerations and avulsion. Blepharedema may be accompanied by hemorrhage and usually resolves quickly without therapy; however, recovery may be hastened by the use of ice packs and systemically administered ketoprofen or flunixin meglumine.

Horses are particularly prone to eyelid lacerations because of the prominence of the eye and their tendency toward sudden head movements when startled. Lacerations may be categorized into those without eyelid margin involvement, those with eyelid margin involvement, and avulsions of part or all of an eyelid. For all types of eyelid injury, several basic principles should be followed. Lacerations should be treated promptly to avoid distortion from excessive swelling, infection, scarring, and loss of function. Lacerated or displaced tissue should not be excised. It is impossible to replace the mucocutaneous junction of the eyelid margin. If eyelid margin is sacrificed, the risk of scar formation and secondary corneal damage is high. The laceration should be thoroughly and carefully flushed with sterile saline and explored to remove all foreign material. In acute trauma, cold compresses may assist in decreasing swelling. When suturing an eyelid laceration, it is essential to preserve the eyelid margin; therefore eyelid lacerations should be repaired with minimal débridement. The vascular nature of the eyelid allows for minimal débridement even if the tissue is severely damaged. In cases of avulsion of part or all of the eyelid, a variety of blepharoplastic procedures may be performed to help restore functional eyelid margin.[10-12] For a more detailed description of the principles of surgical repair of the eyelids, an ophthalmic surgical textbook is recommended.[10,11]

Postoperative care of all eyelid lacerations should include standard wound hygiene, application of fly repellent and topical ophthalmic antibiotics, and prevention of self-trauma. In contaminated wounds, systemic antibiotic therapy is indicated for 5 to 7 days. Tetanus prophylaxis should be administered.

Improper repair of eyelid lacerations can lead to abnormal function and secondary problems, including chronic epiphora and associated dermatitis, exposure keratitis, ulcerative keratitis, cicatricial entropion or ectropion, conjunctivitis, and pigmentary keratitis.

Trauma to the Nictitating Membrane

Lacerations involving the nictitating membrane (third eyelid) should be repaired to avoid irritation and damage to the cornea. This appears to be more important in horses than in ruminants. The margin should be realigned as precisely as possible, and the lacerated conjunctiva should be repaired with absorbable small suture material such as 5-0 to 7-0 polyglactin (Vicryl [Ethicon, Somerville, N.J.]). Topical ophthalmic antibiotics should be used 3 to 6 times daily for 7 to 10 days. The entire nictitating membrane should be excised only if it is irreparably damaged.

Trauma to the Conjunctiva

Conjunctival lacerations result in swelling (chemosis) and hemorrhage. The cornea and sclera should be examined carefully for evidence of lacerations or perforation. A concurrent scleral laceration is probable if the globe is excessively soft on digital palpation, the anterior chamber is shallow or flat, or hyphema or subconjunctival hemorrhage is present.[8]

Chemosis and subconjunctival hemorrhage frequently resolve without therapy. However, if the chemosis is severe enough to cause exposure and desiccation, sterile ophthalmic lubricants or antibiotic ointments are indicated to prevent secondary irritation. Conjunctival lacerations rarely require closure unless they are extensive. Subconjunctival hemorrhage sustained during parturition is common in foals and calves and requires no therapy, although topical ocular lubricants or antibiotic ointments are often prescribed.

Trauma to the Cornea

Corneal injuries in horses and food animals include blunt compressive trauma, foreign body penetration, ulcerative keratitis, and lacerations. Corneal perforation often results in iris (or iris and ciliary body) prolapse. Therapy is dictated by the type and extent of corneal injury, the complications encountered, the intended use and economic value of the animal, and other financial considerations.

Blunt Trauma to the Cornea

Blunt trauma to the globe from lead shanks, whips, and other objects can result in corneal endothelial injury and subsequent edema. Signs of traumatic uveitis also may accompany such an injury. The corneal edema that results from blunt trauma to the globe may be focal, linear, or diffuse. Therapy for blunt trauma includes a topical hypertonic (5%) saline solution or ointment two to four times a day to decrease corneal edema. Flunixin meglumine or phenylbutazone at antiinflammatory dosages may also be used if uveitis is present. A linear keratopathy characterized by a nonedematous, deep, striate, refractile opacity in the cornea may represent a focal thinning or break in the Descemet's membrane in these cases. This type of lesion must be distinguished from Haab's striae, which are linear breaks in the Descemet's membrane that result from elevated IOP in glaucoma.

Corneal Foreign Bodies

Plant matter embedded in the epithelium or superficial stroma is the most frequently encountered corneal foreign body. Foreign bodies usually are easily removed with hydropulsion, a moistened cotton-tipped applicator, or ophthalmic forceps. Sedation, motor or sensory nerve blocks, and topical anesthesia facilitate removal. Culture and sensitivity tests and cytologic examination of corneal samples are recommended to guide antimicrobial therapy. Fluorescein staining helps evaluate the extent of corneal ulceration. While awaiting laboratory results, medical therapy should include a broad-spectrum topical ophthalmic antibiotic (e.g., bacitracin-neomycin-polymyxin three to six times daily) and atropine as needed. In horses, treatment with a topical antifungal agent (e.g., miconazole three to four times daily) may also be warranted. The prognosis is guarded until the cornea heals; the eye should be reevaluated in 24 to 48 hours.

Complications of corneal foreign bodies include bacterial and fungal infection, corneal perforation, and severe corneal scars that may restrict vision. Subpalpebral lavage systems are used in severe injuries when frequent prolonged therapy is needed or when treating intractable animals (see the Infectious Ocular Diseases, Keratitis section later).[13] Originally, the placement of the subpalpebral catheter was described in the middle tolateral fornix of the upper eyelid, although many practitioners place the lavage system in the medial aspect of the inferior eyelid, allowing the third eyelid to protect the cornea from trauma from the lavage catheter itself.[14]

Corneal Ulcers

Corneal ulcers in horses are usually initiated by trauma and should be considered contaminated by bacteria or fungi until

VetBooks.ir

proven otherwise. Trauma may play a lesser role in food animals, in which primary infectious etiologies are more common (see the Infectious Bovine Keratoconjunctivitis [IBK] section later). The conjunctival fornices, third eyelid, and eyelids should be carefully examined for foreign material. Diagnosis is based on cytologic examination, culture and sensitivity testing of corneal samples, and fluorescein staining of the cornea. Material for bacterial and fungal culture is collected from the ulcer with sterile rayon-tipped swabs. Cotton swabs are less satisfactory because cotton exhibits some antimicrobial properties. The eyelid margins and skin should be avoided, and better culture results are obtained if the swab is moistened with a sterile solution (sterile water or saline) before specimen collection. The most reliable results are obtained if the swabs are placed in a transport medium at the time of collection (Port-A-Cul [Becton Dickinson, Sparks, Md.]). Immediately after collection, the swab is replaced in the tube or inoculated onto standard bacterial and fungal agar plates, or blood agar and thioglycolate broth.

Corneal scrapings for microscopic examination are collected with the use of topical anesthesia. The eyelids are retracted, and the margin of the corneal ulcer is gently rubbed with a small brush, a cytology spatula, or the blunt handle end of a Bard-Parker scalpel blade until a small amount of cellular material is collected. This material is transferred to clean glass slides, spread over a 1-cm area, and allowed to air-dry. Slides may be stained in-house with Diff-Quik and/or Gram stain to assess the presence and type of microorganisms and inflammatory cells.

Therapy of corneal ulcers is based on the removal of the cause if it is still present, control or prevention of infection with topical antimicrobials, use of topical atropine for relief of painful ciliary body spasm and prevention of synechia, and, in horses, systemic use of nonsteroidal antiinflammatory drugs (NSAIDs) such as flunixin meglumine or phenylbutazone. The initial choice of topical antibiotic should be based on the results of cytologic evaluation and modified later if necessary, according to the results of culture and sensitivity testing. If gram-positive organisms are demonstrated on corneal cytology, several surveys of bacterial susceptibility suggest that topical chloramphenicol or fluoroquinolones are a good first choice of therapy.[15] If gram-negative organisms are seen, initial empirical therapy should include a topical aminoglycoside or fluoroquinolone antibiotic,[15] but since the ocular flora is primarily gram-positive, use of broad-spectrum combinations such as bacitracin-neomycin-polymixin B should be considered. Susceptibility testing ideally should be performed for every infected ulcer given the increasing resistance seen for bacterial pathogens. If cytology demonstrates fungal hyphae, initial therapy with a topical antifungal agent should be instituted immediately. In a recent study of fungal isolates from equine ulcerative keratomycosis cases, voriconazole was shown to be the most effective antifungal drug for initial therapy.[16] Subpalpebral lavage systems greatly facilitate the delivery of topical medication to the equine eye.[13,14]

Surgical intervention should be considered in cases of deep corneal ulceration and especially when Descemet's membrane is exposed. Surgical procedures most often used for corneal ulceration include conjunctival pedicle flap and keratoplastic procedures. Ophthalmic tissue adhesives and soft contact lenses may also be used as nonsurgical therapy for deep corneal ulcers. Perforating ulcers with iris prolapse and mixed bacterial and fungal keratitis or ulcers present for more than 2 weeks usually have a poor visual outcome.[17]

Corneal Lacerations

Corneal lacerations may be caused by sharp, protruding objects or projectiles. They can occur with or without scleral laceration and, if they are partial thickness, may be treated as corneal ulcers. By contrast, perforating corneal lacerations must be repaired surgically. Preoperative preparation includes tetanus prophylaxis (horses and goats), systemic antibiotics, and sample collection for corneal culture and sensitivity. Ocular ultrasonography is useful in determining the integrity of intraocular structures. However, care must be exercised during ocular examination, ultrasonography, and surgery and anesthesia (especially induction and recovery) because extrusion of the intraocular contents may occur if excessive pressure is exerted on the globe or if the eyelids are forced open. In some cases, complete examination of the globe should be delayed until the animal is anesthetized.

General anesthesia, adequate magnification, proper instrumentation, appropriate suture material and needles, and adequate postoperative care are necessary for successful repair of a corneal laceration. Postoperative therapy must include topical antibiotics and mydriatics or cycloplegics, along with systemic antiinflammatory agents. The prognosis for recovery of vision and preservation of the globe generally is guarded. Complications that may occur after repair of corneal lacerations include phthisis bulbi, corneal fibrosis, synechia formation, blindness, retinal detachment, cataract formation, uveitis, endophthalmitis, bacterial or mycotic keratitis, and wound dehiscence with subsequent iris prolapse.

The prognosis after surgical repair of corneal or corneoscleral lacerations is best when the animal is presented immediately with a small wound in which the cornea or sclera is sealed and the anterior chamber has reformed. Minimal hyphema, clear intraocular media, a clearly visible fundus, and laceration length of less than 15 mm are additional findings that indicate a favorable prognosis.[17] In horses the success rate when only the cornea is involved is about 70% for recovery of vision and 90% for a cosmetically acceptable globe.[18] With corneoscleral lacerations, the prognosis is much worse. In our experience, the success rate in such cases is 20% for recovery of vision and 70% for a cosmetically acceptable globe. Most phthisical globes are not considered cosmetically acceptable. Therefore enucleation should be considered initially with severe corneoscleral lacerations because the prognosis is poor for return of vision and guarded for preservation of the globe. Several surgical procedures have been described in horses to provide a cosmetic appearance to the globe and orbit, including placement of an intraocular silicone prosthesis.[19,20]

Trauma to the Uveal Tract

Trauma to the globe can damage the iris, ciliary body, and choroid. The resulting inflammatory response may range from very mild with rapid recovery to loss of vision and chronic discomfort. Signs of inflammation of the iris and ciliary body include blepharospasm, epiphora, miosis, aqueous flare, corneal edema, fibrin in the anterior chamber, hyphema, hypopyon, low IOP, and synechia formation. Concurrent damage to the corneal epithelium may be present and must be evaluated with fluorescein dye. Damage to the choroid may also affect the retina and lead to retinal detachment or degeneration.

Traumatic uveitis is treated in a manner similar to uveitis of other etiologies. Therapy is directed toward dilating the pupil to prevent synechia formation, cycloplegia to prevent painful ciliary spasm, and controlling the intraocular inflammatory response. Topical atropine is instilled to maintain mydriasis and provide cycloplegia. Topical corticosteroids are used to decrease inflammation of the anterior segment if the corneal epithelium is intact.

The topical corticosteroids of choice are 1% prednisolone acetate or 0.1% dexamethasone. Subconjunctival injection of corticosteroids may also be beneficial in controlling inflammation. Systemic medication should include an antiinflammatory, such as flunixin meglumine, ketoprofen, phenylbutazone, or

rarely, oral corticosteroids. Care must be taken to avoid secondary complications from systemic corticosteroids.

Trauma-induced hyphema usually has a good prognosis if the blood has clotted and fills less than half the anterior chamber. Stall rest, topical 1% atropine, topical corticosteroids, and systemic antiinflammatory therapy should be instituted to control the associated uveitis. If a penetrating wound is suspected, topical and systemic antibiotic therapy should be included with periodic fluorescein staining. Surgical intervention to remove large blood clots is rarely indicated because it may result in additional bleeding or may worsen the uveitis. Dilute tissue plasminogen activator (tPA; Activase [Genentech, South San Francisco, Calif.]), 25 to 50 µg, may be injected into the anterior chamber to disrupt or lyse intraocular hemorrhage and fibrin and to aid in resolution of synechiae. For maximum effectiveness, tPA should be used within 24 to 72 hours of clot formation, although clot lysis by tPA may still occur up to several weeks after the traumatic incident.[21,22]

Chronic uveitis after ocular trauma may be associated with lens damage or the introduction of infectious or foreign agents into the eye and carries a poor prognosis. If the lens is ruptured, its surgical removal is advocated. Ocular perforation is a frequent cause of panophthalmitis in food animals and horses. Although therapy consists of systemic and topical antibiotics, as well as tetanus prophylaxis in susceptible species, panophthalmitis usually necessitates eventual enucleation.

Trauma to the Lens

Blunt or sharp trauma to the eye may damage the lens by causing lens opacity (cataract), by rupturing the lens capsule, or less often by causing a shift in position (subluxation or luxation). Release of lens protein into the eye after lens capsule rupture may induce severe granulomatous uveitis. In such cases the eye should be treated vigorously for lens-induced uveitis with topical atropine and topical and systemic antiinflammatory drugs. If the globe has been penetrated, topical and systemic antibiotics are indicated. The prognosis for preservation of vision is poor. Lens removal may be required to control the inflammatory response.

Cataracts (lens opacities) associated with ocular trauma may occur acutely or develop weeks after the initial injury. The opacity may be focal and not appreciably affect vision, or it may be complete and cause a visual deficit. If the remainder of the eye is normal, surgical removal of the cataractous lens may improve vision.[23,24] In a recent retrospective study of surgical cataract removal in horses, the highest success rate was noted in the removal of traumatic cataract, as compared with cataracts of other known etiology.[24]

Trauma Involving the Vitreous

Trauma to the eye may result in hemorrhage into the vitreous or release of inflammatory products that cause vitreal degeneration. Either circumstance can result in vitreal syneresis (liquefaction), formation of vitreal traction bands, and subsequent retinal detachment. Symptomatic treatment of inflammation is generally adequate, but vitrectomy may be beneficial in the management of vitreal traction bands to prevent subsequent retinal detachment.[25]

Trauma to the Retina

Retinal tears, hemorrhage, edema, and detachment may be caused by trauma.[26] In cases of opaque ocular media, retinal separation may be diagnosed by ocular ultrasonography (Fig. 39.8). Retinal degeneration may follow ocular trauma. Retinal hemorrhage and edema should be treated with systemic corticosteroids. With current technology, surgical repair of retinal tears, lacerations, or detachments in food animals and horses may be feasible in selected cases.

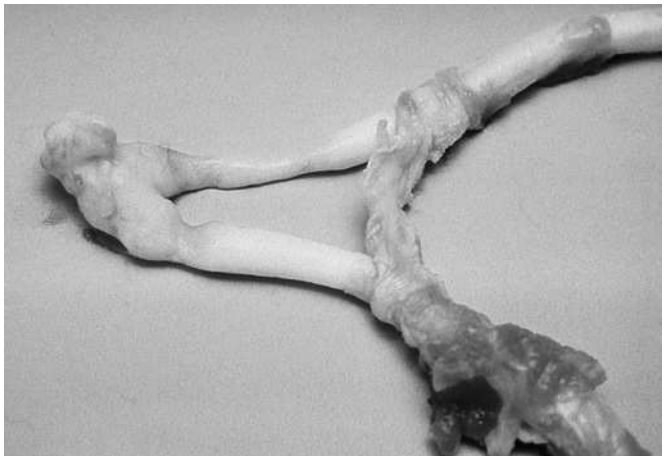

FIG. 39.9 Optic nerves and chiasm of a foal that was blind as a result of head trauma. Note the constrictions of the optic nerves caused by necrosis and degeneration. *(Courtesy Dr. C.L. Martin.)*

Trauma to the Optic Nerve

The pathogenesis of damage to the optic nerve is not well understood. Shearing forces at the optic foramen from displacement of the brain after severe head trauma (Fig. 39.9), direct contusion or avulsion of the optic nerve, or loss of blood supply to the nerve and subarachnoid hemorrhage probably all have roles in optic nerve injury.[27] Early examination may reveal only a dilated pupil that may be partially or completely unresponsive to light. Later, changes may include optic nerve atrophy (Fig. 39.10) and peripapillary retinal pigmentation changes. Therapy with systemic antiinflammatory drugs may be of benefit, but severe damage is usually irreversible.

Traumatic optic nerve atrophy is usually characterized by sudden onset of unilateral or bilateral blindness, dilated fixed pupils, and a lack of menace response. In horses the traumatic episode is frequently characterized by damage to the poll from rearing over backward and striking the back of the head, from rearing up and hitting a ceiling beam, or from blunt trauma (blows) to the side or front of the face. The animal usually stands without loss of consciousness, and the injury is not

considered serious by the owner at the time. Initially, blindness with a normal-appearing ocular fundus is observed.

Within 3 to 4 weeks after the trauma, examination of the fundus reveals a pale optic disk (see Fig. 39.10). Later, loss of peripapillary retinal vessels is usually evident. The optic disk often appears depressed, with increased prominence of the lamina cribrosa. Confirmation of optic nerve or optic tract lesions causing blindness may be made by the absence of a direct PLR with a normal electroretinogram. In some cases, the pathologic lesion is a rupture of the nerve axons from stretching forces produced by movement of the brain.[27] Chiasmal hemorrhage and fractures of the basisphenoid bone may be observed at necropsy. Therapy with systemic corticosteroids (dexamethasone, 2.5 to 5 mg IV or IM) and IV dimethyl sulfoxide (DMSO) has generally not been successful,[27] although the lack of response to medical therapy appears related to the severity of the injury.

A segmental optic nerve atrophy involving one to three quadrants of the optic disk occurs in horses. The appearance is characterized by pallor, loss of normal vasculature, and increased prominence of the lamina cribrosa in the affected quadrants. The etiology is unknown, but traumatic injury is suspected in most cases. Response to medical therapy is poor.

Chemical Injury

Ocular irritation caused by insecticides and disinfectants inadvertently applied to the eye is relatively common in the farm or ranch setting. Chemical burns to the cornea and adnexa may have serious consequences and may warrant a poor prognosis for salvage of the eye. Alkali burns are more severe than acid burns. Corneal burns from acids tend to be sharply demarcated and nonprogressive, whereas alkali burns cause progressive coagulation, melting, and sloughing of the corneal stroma.[3] Chemically induced melting of the cornea must be differentiated from bacterial and fungal infections. Treatment for a suspected or known chemical burn should include lavage of the affected area with copious amounts (500 to 2000 mL) of sterile saline solution. Tap water may be used by the owner until veterinary assistance is available. It may be necessary to sedate the animal. No attempt should be made to neutralize the substance because this may cause precipitation within the cornea. The damage should then be evaluated with the aid of local nerve blocks.

Treatment should include appropriate topical antimicrobials, atropine, and a collagenase inhibitor such as autologous serum or possibly 5% to 10% acetylcysteine (Roxane Laboratories Inc., Columbus, Ohio), which inhibits collagenases and metalloproteinases by binding calcium. Hourly application of serum or acetylcysteine may be needed. Systemic antiinflammatory drugs should be used to control secondary uveitis. Therapeutic soft contact lenses have been used to protect the corneal stroma in patients with extensive corneal ulcerations.

Thermal Injury

Facial burns secondary to barn or stable fires may damage the eyelids, conjunctiva, and corneas. Therapy for minor burns to the eyelids is directed toward keeping the injured area moist with antibiotic dressings and protecting the cornea if eyelid dysfunction occurs. Treatment for injury to the conjunctiva or cornea should include topical antibiotic and systemic antiinflammatory drugs in horses. Full-thickness eyelid burns may require grafting procedures to protect the cornea and minimize scarring. Third eyelid or conjunctival flaps may be required to protect the cornea until eyelid function returns.

Infectious Ocular Diseases

Caryn E. Plummer

This section describes the major infectious ophthalmic diseases of large animals (Table 39.3). Infectious bovine keratoconjunctivitis (IBK), or "pinkeye," the most common ocular disease of cattle, will be discussed in another section. Infectious ocular disease in large animals may be either the result of a pathogen primarily affecting the ocular tissues or an ocular manifestation of a systemic infection, wherein the ocular signs are secondary or concurrent to the systemic illness. As a general rule, surface ocular diseases are often primary in origin, whereas intraocular diseases are either primary or secondary. The first infections described in this section are those with predominantly ocular signs, followed by descriptions of ocular manifestations of systemic disease.

There are many potential ophthalmic manifestations of infectious disease in large animals. Few diseases have pathognomonic or classically distinctive signs, so the combination of signalment, ocular clinical signs, systemic clinical signs, and laboratory diagnostics are necessary to confirm a diagnosis. Clinical signs associated with conjunctivitis are nonspecific to the underlying cause and include conjunctival hyperemia and chemosis. Other clinical signs may include follicle formation (often a manifestation of chronicity) and serous to mucopurulent discharge. Differentiation of primary conjunctivitis from secondary conjunctivitis resulting from other diseases (systemic disease or intraocular disease) is very important. A thorough ophthalmic examination will help with this determination.

In cattle and small ruminants, corneal disease may be initiated by an infectious agent, but infectious corneal disease in horses most often occurs secondary to corneal trauma. It can also be a manifestation of primary ocular disease or systemic disease. Signs of keratitis include pain (blepharospasm, photophobia, epiphora), ocular discharge, corneal edema, variable corneal vascularization, loss of stromal integrity (melting or keratomalacia), and secondary anterior uveitis.

TABLE 39.3

Major Infectious Ocular Diseases of Large Animals

Agent	Common Name/Disease	Major Sign(s)	Cattle	Sheep	Goats	Horses
Mycoplasma conjunctivae	Pinkeye	Keratoconjunctivitis		++	++	
Mycoplasma mycoides subsp. *mycoides*	Pinkeye	Keratoconjunctivitis			+	
Acholeplasma oculusi (oculi)	Pinkeye	Keratoconjunctivitis		+	+	
Chlamydia psittaci	Pinkeye	Keratoconjunctivitis		++		
Branhamella (Neisseria)	Pinkeye	Keratoconjunctivitis		+	+	
Mycoplasma agalactiae		Keratoconjunctivitis		+	+	
Mycoplasma arginini		Keratoconjunctivitis		+	+	
Listeria monocytogenes		Keratoconjunctivitis	+	+		
Bovine herpesvirus type 1 (infectious bovine rhinotracheitis)		Keratoconjunctivitis	++		+	
Colesiota (Rickettsia) conjunctivae	Pinkeye	Keratoconjunctivitis		+		
Equine viral arteritis		Keratoconjunctivitis				+
Equine herpesvirus type 2		Keratoconjunctivitis				+
Mycoplasma bovoculi		Conjunctivitis	+			
Ureaplasma spp.		Conjunctivitis	+			
Equine adenovirus		Conjunctivitis				+
Moraxella spp.		Conjunctivitis				+
Streptococcus equi	Strangles	Conjunctivitis				+
Moraxella bovis	Pinkeye	Corneal ulcer	++			
Equine herpesvirus type 1	Rhinopneumonitis	Keratitis				+
Malignant catarrhal fever		Uveitis, keratitis	+			
Neonatal septicemia		Uveitis	+	+	+	+
Mycobacterium bovis	Tuberculosis	Uveitis	+			
Salmonella spp.		Uveitis				+
Borrelia burgdorferi	Lyme disease	Uveitis				+
Leptospira interrogans		Recurrent uveitis				+
Brucella abortus		Recurrent uveitis				+
Scrapie		Retinitis		+		
Histophilus somni (formerly *Haemophilus somnus*)	Infectious thromboembolic meningoencephalitis	Retinitis	+			
Bovine viral diarrhea		Retinal dysplasia, cataracts	+			
Bluetongue		Chorioretinitis, conjunctivitis	+	+		
Toxoplasma gondii		Chorioretinitis				+
Rhodococcus (Corynebacterium) equi		Panophthalmitis				+
Bovine leukemia virus		Exophthalmos	+			
Cryptococcus neoformans		Exophthalmos				+

Uveitis is inflammation of the uveal tract, which includes the iris, ciliary body, and choroid. Initial clinical signs may include episcleral injection, blepharospasm, photophobia, miosis, aqueous flare, hypopyon, fibrin, hyphema, and corneal edema. Intraocular inflammation can affect the entire eye and may result from direct invasion of the globe by a pathogen or as the result of a systemic inflammatory response. If untreated, uveitis can lead to permanent vision loss, cataract, secondary glaucoma, and phthisis bulbi. Some systemic infections may result in neuro-ophthalmic signs, such as facial nerve paralysis, Horner's syndrome, trigeminal neuropathies, nystagmus, strabismus, or ptosis. Others may cause retrobulbar disease or periorbital swelling.

This section addresses viral-, bacterial-, and fungal-mediated ocular disease; parasitic infections are addressed in a separate section. Many viral diseases affect the eye either directly or indirectly. Those that affect the globes may require direct ocular management. Other infections mediate disease primarily through cranial nerve neuropathy, and management is supportive. Any systemic bacterial infection has the potential to affect the eyes. Certain specific bacterial diseases (e.g., tetanus, botulism) may have their own distinctive ophthalmic signs, but most bacterial infections, especially when sepsis has developed, can be associated with nonspecific ocular inflammation. Fortunately, systemic fungal infections are not common in the immunocompetent animal, although ocular surface infections are common, especially in the horse. For more detailed information on the specific ocular conditions mentioned in this chapter, consult an ophthalmology textbook and the recent literature.

Conjunctivitis and Keratoconjunctivitis

Mycoplasmal Keratoconjunctivitis in Goats and Sheep

Definition and Etiology

Mycoplasma conjunctivae has been frequently isolated throughout the world from epidemics of keratoconjunctivitis, respiratory disease, and arthritis in goats and sheep.[1-4] *Mycoplasma mycoides* subsp. *mycoides* has been isolated from an epidemic of mastitis, arthritis, and keratoconjunctivitis in goats.[5] *Acholeplasma oculusi (oculi)* has been isolated from sheep and goats in epidemics of keratoconjunctivitis.[6,7] *Mycoplasma agalactiae* and *Mycoplasma arginini* have also been described as causing keratoconjunctivitis and systemic disease.[8]

Clinical Signs and Differential Diagnoses Clinical signs of mycoplasmal keratoconjunctivitis include epiphora, conjunctival hyperemia, and occasionally follicular conjunctivitis. In experimental conjunctival inoculation with *M. conjunctivae*,

clinical signs began on day 2 and lasted for 5 weeks.[9] Later in the disease, keratitis with corneal neovascularization (Color Plate 39.16) and occasionally anterior uveitis can be seen.[1,10] One case of choroiditis and hyalitis has been described.[11] Signs can be seen in individuals, as well as in herd or flock outbreaks. The disease is usually unilateral but can be bilateral. Differential diagnoses include other infectious causes of keratoconjunctivitis, such as *Chlamydophila* spp. (sheep), *Branhamella* spp., aerobic bacteria, parasites, and infectious bovine rhinotracheitis (goats), as well as noninfectious causes such as trauma. There may be a slight variation in clinical signs experienced by sheep and goats. Although both will exhibit blepharospasm, conjunctivitis, and keratitis, sheep will occasionally develop a more severe form of the disease associated with mucopurulent conjunctivitis, corneal ulceration, and uveitis with hypopyon (Color Plate 39.17). Goats do not typically ulcerate their corneas, despite the presence of severe and vision-threatening keratitis.

Clinical Pathology In conjunctival scrapings taken early in the disease, many neutrophils are seen; later, lymphocytes predominate. Plasma cells and necrotic epithelial cells are also observed.[12] Organisms can occasionally be found in epithelial cell cytoplasm in coccobacillary or varied forms.[11] Pigment granules can be mistaken for organisms.[6,12,13]

Mycoplasmal organisms can be cultured and identified from conjunctival swabs; serum antibody titers can be measured,[14,15] or PCR can be used to identify *M. conjunctivae* in conjunctival smears.[16,17] Egwu and Faull[18] describe rising serum and lacrimal antibody titers in sheep topically inoculated with *M. conjunctivae*. However, Trotter and colleagues[2] report low serum titers to *M. conjunctivae* in normal animals and no rise in titer in animals subconjunctivally inoculated with *M. conjunctivae* that subsequently developed signs of disease.

Epidemiology Mycoplasmal infections apparently are transmitted directly from animal to animal, as evidenced by herd or flock outbreaks. Subclinical carrier states exist, and *M. conjunctivae* can be cultured from nonclinical animals.[19,20] There is some evidence for vector transmission (flies) as well.[21] Animals can become reinfected, but if they do, their clinical signs are usually more mild than during the initial infection. Keratoconjunctivitis can be induced in sheep with topical inoculation of *M. conjunctivae*.[18,22,23] Clinical signs were identical to natural outbreaks and spread to uninoculated sheep. The organism can be cultured from eyes long after clinical signs abate.[9] Co-infection with other organisms may occur and result in more severe clinical signs.

Treatment and Prognosis In most animals, mycoplasmal keratoconjunctivitis associated with *M. conjunctivae* is transient. Affected animals usually recover spontaneously in 10 days, although some animals seem to have recurring episodes that last for several weeks. In a controlled clinical trial, one dose (20 mg/kg) of long-acting oxytetracycline was given to experimentally inoculated lambs. This treatment seemed to hasten the cessation of clinical signs, although the results were not analyzed statistically.[24] The treatment did not, however, eliminate the *M. conjunctivae* infection and may promote a carrier state. Other drugs recommended for the ocular disease include topical oxytetracycline or oxytetracycline and polymyxin B.[1] Subconjunctival oxytetracycline is not currently recommended because it may cause a severe inflammatory reaction. In vitro antibiotic testing of *M. conjunctivae* shows that florfenicol, tylosin, oxytetracycline, streptomycin, and chlortetracycline are suitable for treatment.[25,26]

Prevention and Control Introduction of new animals into a herd or flock has been implicated in starting an outbreak of keratoconjunctivitis. Therefore isolation and, if necessary, treatment of new animals are important before contact with the herd.[27-29] Transmission between species has been documented, so housing domestic sheep and goats where they might commingle with wildlife is not recommended.[27,28] No other specific recommendations have been made for prevention and control of *M. conjunctivae*.

Bovine Mycoplasmal Conjunctivitis

Mycoplasma bovoculi and *Ureaplasma* spp. have been isolated from cattle with conjunctivitis and IBK. Inoculation of normal calves with *Mycoplasma bovoculi* or *Ureaplasma* isolates produced conjunctivitis characterized by serous discharge and conjunctival hyperemia. Experimentally induced conjunctivitis ran a course of more than 1 month. Cases can be confirmed by culture or PCR performed on conjunctival swabs.[30] Mycoplasmal infection may predispose the animals to development of IBK from *Moraxella bovis*[31,32] (see the Infectious Bovine Keratoconjunctivitis [IBK] section later). Therefore although treatment of mycoplasmal conjunctivitis may not be warranted, it may be advisable in areas where IBK is endemic. Topical oxytetracycline ointment applied three times daily or intramuscular (IM) injection of long-acting oxytetracycline is recommended.

Other mycoplasmal organisms (e.g., *M. arginini*) can be isolated from cows' conjunctiva but are not thought to cause the disease. *Mycoplasma bovis* was found using PCR performed on normal conjunctival samples,[29] but it was not thought to cause conjunctivitis. *Mycoplasma bovigenitalium*, *Mycoplasma bovirhinis*, and *Mycoplasma bovoculi* were isolated from members of two cattle herds with conjunctivitis and bronchopneumonia.[32] However, when viral cultures were performed, bovine herpesvirus type 1 (BHV-1; also called infectious bovine rhinotracheitis [IBR]) was isolated in the same individuals. The mycoplasmal organisms may have contributed to the disease in these herds. In another cattle herd with an outbreak of respiratory disease, keratoconjunctivitis followed, and *Mycoplasma bovis*, *M. bovirhinis*, and *Mycoplasma bovoculi* were isolated in various combinations from affected calves.[33]

Chlamydial Keratoconjunctivitis in Sheep and Goats

Definition and Etiology

Chlamydial agents have been isolated from outbreaks of keratoconjunctivitis in sheep flocks. The agent was originally described as a strain of *Chlamydia psittaci*. The agent was called *Chlamydophila pecorum* for a period of time but is currently designated *Chlamydia pecorum*, which can also cause abortion (see Chapters 31 and 35) and polyarthritis in lambs.[34,35]

Clinical Signs and Differential Diagnoses Early clinical signs consist of epiphora, chemosis, and conjunctival hyperemia. Later in the disease, follicle formation in the conjunctiva becomes prominent. Still later, corneal vascularization may be seen (Color Plate 39.18). Most cases are bilateral and symmetric.[36,37] In some flock outbreaks of keratoconjunctivitis, outbreaks of polyarthritis are also noted. Most lambs that develop chlamydial polyarthritis will also develop conjunctivitis.[36,37] Differentials include other infectious causes of keratoconjunctivitis, such as *Mycoplasma* and *Branhamella (Neisseria)* spp., aerobic bacteria, and parasites, as well as noninfectious causes like trauma.

Clinical Pathology Early in the disease, conjunctival smears show numerous neutrophils and some lymphocytes. Later, there are more neutrophils and fewer mononuclear cells. Cytoplasmic chlamydial inclusions are occasionally seen in up to a third of the eyes scraped and can be definitively identified by fluorescent antibody staining.[34] Conjunctival epithelial cells are often necrotic. Chlamydial organisms can be cultured

from conjunctival scrapings and from blood taken from sheep with polyarthritis and conjunctivitis.[36-38] In one study, titers to chlamydial antibodies were found at 1:16 or higher in a number of the affected lambs, although titers on normal lambs were not reported.[37] PCR can also be used to identify the organism.

Epidemiology Chlamydial organisms are apparently transmitted by direct contact, as evidenced by flock outbreaks. Chlamydial organisms caused conjunctivitis in five lambs inoculated topically.[38] An uninoculated lamb housed with the five lambs also developed conjunctivitis. Lambs subsequently developed follicular conjunctivitis.[38] In another study, chlamydial organisms were injected intraarticularly, intravenously, and intramuscularly and caused polyarthritis and conjunctivitis.[39]

Treatment and Prognosis In uncomplicated cases the disease is self-limiting, and eyes are normal within 2 to 3 weeks.[37] The same treatments indicated for *M. mycoides* subsp. *mycoides* (systemic oxytetracycline and, when possible, a topical tetracycline ophthalmic preparation) are also effective in treating chlamydial conjunctivitis and polyarthritis of sheep.

Branhamella (Neisseria) ovis Keratoconjunctivitis in Sheep and Goats

Branhamella ovis is a gram-negative diplococcus similar to *Moraxella*. This agent has been cultured from the eyes of sheep and goats with keratoconjunctivitis and from normal eyes.[40-42] *B. ovis* has also been cultured from cattle with serous conjunctivitis and, rarely, keratitis.[43] Clinical signs are usually mild and include epiphora and conjunctival hyperemia. Severity of clinical signs is increased when co-infections with other organisms, such as *M. conjunctivae*, are present. Conjunctivitis but not keratitis has been experimentally induced in goats[44] and lambs,[45] and *B. ovis* could be cultured from the eyes of the lambs for up to 20 days after inoculation. Outbreaks of *B. ovis* have been successfully treated with parenteral tylosin, topical neomycin-polymyxin B, and a corticosteroid,[40] or with subconjunctival penicillin.[44]

Moraxella Conjunctivitis in Horses

Two reports have described a *Moraxella* species recovered from several horses in herd outbreaks of conjunctivitis, ocular discharge, and erosions of eyelid epithelium at the canthi.[46,47] The organism was similar but not identical to *Moraxella bovis*, and the disease was reproduced experimentally in horses by instillation of the organism into the conjunctival sac. Huntington and colleagues[47] described successful treatment of the lesions with chloramphenicol ointment, whereas Hughes and Pugh[46] described the lesions as healing spontaneously.

Keratitis

Bacterial Keratitis in Horses

Definition and Etiology

Bacterial keratitis occurs when a traumatic corneal ulcer becomes infected with opportunistic bacteria; no bacteria are known to *initiate* corneal ulcers in horses. The most devastating clinical manifestations are associated with *Pseudomonas aeruginosa* and *Streptococcus equi* subsp. *zooepidemicus*.[48-56] However, any bacteria that have access to the ocular surface may colonize and complicate a corneal wound.[52,53,57]

Clinical Signs and Differential Diagnoses Whether infected or not, corneal ulcers cause signs of pain (blepharospasm, epiphora, photophobia). The conjunctiva is hyperemic, and the ulcerated area of the cornea retains fluorescein stain. Acute superficial ulcers are usually not infected, and the cornea maintains its normal curvature in the ulcerated area. If a superficial ulcer is slow to heal, it should be sampled for microbial C&S, since delayed healing may be a sign of an early or subclinical infection. A deep ulcer (resembling a divot in the corneal stroma) should always be assumed to be infected.

Other signs of corneal infection are rapid progression and white or yellowish infiltrate within the cornea (signifying influx of neutrophils and bacterial colonization within the corneal stroma). An ulcer that is rapidly becoming wider or deeper or begins to melt (corneal stroma softens or begins to dissolve) is highly suggestive of a bacterial infection (Color Plate 39.19). Many corneal ulcers are accompanied by some degree of anterior uveitis (miosis, aqueous flare, hypopyon, anterior chamber fibrin). The uveitis that occurs during a corneal infection tends to be much more severe than that which is present with sterile corneal wounds (see Color Plate 39.7). In cases in which the initially damaged epithelium heals over microorganisms in the corneal stroma, a bacterial stromal abscess may form.[58] Such lesions do not stain with fluorescein, and many topical antibiotics cannot penetrate the epithelial barrier to reach the site of infection. Most stromal abscesses, particularly if they are located in the deep or posterior stroma, are fungal in etiology.[59-61] Fungal keratitis may exhibit similar clinical behaviors and may become secondarily infected with bacteria.

Clinical Pathology A diagnosis of a bacterial keratitis is made via corneal cytology and microbial C&S. Stained scrapings from the ocular surface wound may show intracellular and extracellular bacteria and neutrophils (Fig. 39.11). Bacterial morphology and Gram staining will guide the choice of empirical therapy while the results of C&S are pending. Bacterial organisms are definitively identified after culture of the ulcerated cornea. Aerobic culturing techniques are usually used. Culturing for anaerobic organisms may be indicated if aerobic culture does not reveal an organism and the ulcer fails to respond appropriately to medical therapy. Anaerobic infections are far less common than aerobic bacterial and fungal infections in the equine cornea.[57]

Pathophysiology Bacterial keratitis is the result of pathogenic or opportunistic organisms colonizing a damaged cornea. The cornea is most likely to be damaged by mechanical trauma, but other causes such as chemical injury or corneal exposure are possible. Many different types of bacteria can be cultured from a normal eye, including *Corynebacterium*, *Streptococcus*, *Staphylococcus*, *Bacillus*, and rarely *Pseudomonas* spp. or other gram-negative bacteria.[48,50] Damage to the epithelium enables

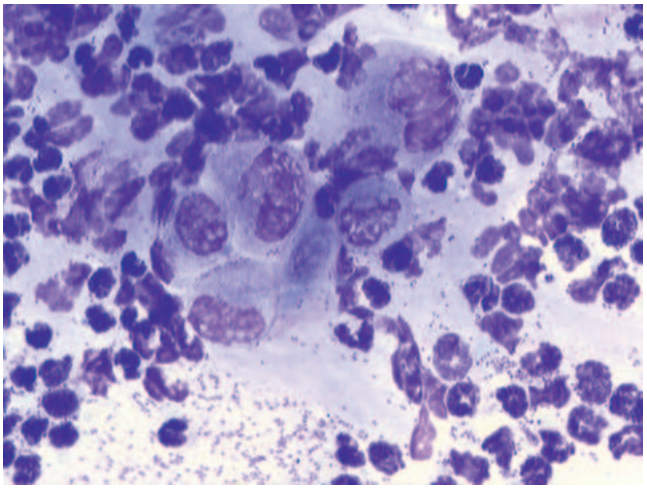

FIG. 39.11 Cytology of bacterial keratitis. Wright-Giemsa, ×100. Note the corneal epithelial cells in the center of field, numerous degenerate neutrophils, and intracellular and extracellular cocci and diplococci bacteria.

bacteria to adhere to the exposed corneal stroma, colonize, and begin replicating.[54] Some bacteria such as *Pseudomonas* elaborate collagenases and other proteoglycanolytic enzymes,[55] which results in corneal collagen destruction. Proteases and collagenases liberated by white blood cells and corneal epithelial and stromal cells also contribute to this "melting" process.[62,63] In this way, what begins as a small wound to the cornea can progress to a corneal perforation within 24 to 48 hours.

Treatment and Prognosis Prognosis is guarded for any corneal ulcer that is rapidly progressing or melting. These ulcers can easily progress to corneal perforation and loss of vision or of the eye despite timely, appropriate treatment. On the other hand, with aggressive therapy many eyes with infected ulcers can be saved and vision maintained, although scarring may be present.

In any ulcer in which a bacterial component is suspected, C&S of the ulcer and a corneal scraping for Gram staining and cytology should be taken. The horse is restrained or sedated and an auriculopalpebral block is performed. A sample for culture should be obtained with a moistened swab before any solutions or medications are applied to the eye. Following culture, a topical anesthetic is applied to the cornea, and the ulcer margins are then scraped gently with a cytology brush, a Kimura spatula, or the blunt handle end of a scalpel blade.

In cases of equine bacterial keratitis, therapeutic goals are to eliminate the bacteria, prevent or slow melting if present, and treat the concurrent uveitis.[64-66] Because this requires very frequent applications of numerous medications to a horse with a painful and often fragile eye, a subpalpebral lavage system is usually required.

PLACEMENT OF SUBPALPEBRAL LAVAGE SYSTEM. The following equipment is necessary:

- Subpalpebral lavage (SPL) kit (MILA International [Fig. 39.12])
- White tape
- Applicator stick (tongue depressor)
- Injectable anesthetic (lidocaine, mepivacaine)
- Topical ophthalmic anesthetic (proparacaine, tetracaine)
- Monofilament nonabsorbable suture on a cutting needle

The horse should be sedated. Additional manual restraint (e.g., twitching) may be necessary depending on the animal's temperament and degree of discomfort and on the handler's comfort and experience. The auriculopalpebral nerve is blocked over the zygomatic arch to paralyze the orbicularis oculi muscle and reduce eyelid movement. If the SPL is to be placed in the upper eyelid, a supraorbital (frontal) block is performed to desensitize the eyelid. This nerve is accessed at its exit from the supraorbital foramen. If the SPL is going into the lower lid, a line block is performed along the ventral orbital rim for regional anesthesia. Topical anesthetic is then applied to the eye by directing a gentle stream onto the globe and into the conjunctival fornix with a small syringe with a 25-gauge needle broken off at the hub. The eyelid and conjunctival fornices should be flushed with a dilute Betadine solution (0.5%).

Once the periocular structures are prepared, a gloved finger or the plastic applicator stick or needle guard from the kit is advanced under the eyelid and used as a guide for the needle to which the SPL tubing is attached. The needle is directed between the eyelid and the guide and then through the skin. In the upper eyelid, it should be placed as high as possible and should grab the periosteum of the orbital rim as it exits, which will help keep the lavage footplate in place and decrease the likelihood of slippage and subsequent irritation of the cornea. While passing the needle through the skin, care must be taken not to inadvertently push the end of the needle onto or against the fragile globe. The needle and Silastic tubing are threaded through the hole in the skin until the footplate is in direct contact with the palpebral conjunctiva. Tape is used to secure the tubing to the upper eyelid, and sutures secure the tape to the skin. The tubing can be braided through the forelock and then run down the neck through several braids to keep it secure. A small catheter is directed into the distal end of the tubing, and an injection port is fixed to the end of the catheter. The catheter and tubing are taped to an applicator stick to prevent kinking. The stick is then taped to a braid of the mane (Fig. 39.13).

Poorly placed lavage tubes or tubes that slip ventrally can rapidly produce a corneal ulcer. A displaced tube footplate can also cause topical medications to leak into the subcutaneous tissues, leading to a swollen and inflamed eyelid. Therefore the tube position should be checked at least once daily by gentle dorsal traction on the exposed tubing to ensure that it has not slipped into the conjunctival cul-de-sac. Excess traction will pull the footplate through the conjunctiva and into the eyelid itself. Most horses tolerate this system well, and well-maintained tubing may be kept in place for up to several months. Occasionally horses try to rub their heads and can damage the tubing; neck cradles or protective eye cups can be used in such horses.

Tubing is woven through braids in the mane, and injection catheter and stopcock taped to a stick applicator (tongue depressor). *(Diagram courtesy Anne Gemensky-Metzler.)*

VetBooks.ir

MEDICAL/SURGICAL APPROACHES AND GOALS. For noninfected ulcers a broad-spectrum preparation (e.g., neomycin-polymyxin-bacitracin, neomycin-polymyxin-gramicidin, chloramphenicol) is appropriate. In a cornea with rapidly developing keratitis or melting ulcer, the clinician should always suspect the presence of an infectious agent. Treatment should be initiated with an appropriate antibiotic, the choice of which should be based on cytologic analysis, administered every 1 to 2 hours. If rods or gram-negative organisms are observed, bacitracin-neomycin–polymixin B, aminoglycoside antibiotics (gentamicin, tobramycin), or fluoroquinolones (ciprofloxacin, ofloxacin)[67] are reasonable choices for treatment. To avoid contributing to bacterial resistance, fluoroquinolones should not be used for bacterial prophylaxis in *noninfected* ulcers. If cocci or gram-positive organisms are seen on the corneal cytology, bacitracin-neomycin–polymyxin B, neomycin–polymyxin B–gramicidin, chloramphenicol, levofloxacin or cefazolin, or penicillin or ampicillin can be used.[56,66] Cefazolin is mixed with artificial tears to a concentration of 55 mg/mL,[61] ampicillin to 10 mg/mL,[49] and penicillin G to 100,000 U/mL. If the ulcer continues to worsen, antibiotics should be changed on the basis of the initial susceptibility results, and the cornea should be recultured because organisms can become resistant to the first antibiotic used or a secondary infection can develop. For resistant organisms, susceptibility testing that gives minimum inhibitory concentration (MIC) may be very useful because higher drug concentrations are more readily and safely attainable in the ulcerated cornea than in the systemic circulation.

Keratomalacia (i.e., "melting") must be treated with collagenase and protease inhibitors, in addition to antimicrobial medications. Autologous serum, oxytetracycline, disodium ethylenediaminetetraacetic acid (disodium EDTA; mixed with sterile water to a concentration of 0.17%), or *N*-acetylcysteine (5% to 10% in artificial tears) can be used topically for their antiprotease and anticollagenase activity, as can systemic doxycycline (10 mg/kg orally [PO] twice daily or 20 mg/kg PO once daily).[49,68] Tetanus toxoid, topical doxycycline, and ilomastat have also been applied to the diseased cornea to decrease collagen dissolution.[69]

Surgical therapy can also be used and may improve prognosis. Conjunctival pedicle grafts can be used to bring a blood supply and conjunctival fibroblasts to deep corneal ulcers, with the goal of slowing progression and aiding stromal reconstruction[56] while still allowing medication to reach the wound. A conjunctival graft allows observation of the cornea so that treatment can be adjusted as corneal health improves or changed if the cornea continues to deteriorate. A nictitating membrane "flap" should not be used in rapidly progressing or deep ulcers because it creates a barrier to topical medications and observation of the cornea such that worsening of the ulcer goes unnoticed, repeated culturing cannot be performed, and appropriate changes in therapy cannot be instituted.

A corneoconjunctival transposition using autologous tissue or a corneal graft (penetrating keratoplasty or deep anterior lamellar keratoplasty) using donor cornea is an excellent treatment to repair very deep ulcers, descemetoceles, and perforations if melting has ceased and the ulcers are sterile.[60,61,70] Other grafting materials, such as porcine small intestinal submucosa,[71] equine amniotic membrane,[72] or bovine pericardium, may be substituted for cornea. Placement of any graft requires microsurgical instruments, techniques, training, and experience. Highly specialized techniques, such as keratectomy with a conjunctival graft, penetrating keratoplasty, posterior lamellar keratoplasty, or deep lamellar endothelial keratoplasty, are necessary to treat stromal abscesses.[53,60,73-76]

The initial desired response to appropriate therapy of a malacic ulcer is simply cessation of worsening of the ulcer. That is, the ulcer does not appear to be healing or shrinking but also is not becoming larger or deeper. This suggests that bacteria have been killed and tissue destruction has halted. Epithelium will then begin to migrate toward the center of the ulcer, covering the stroma or Descemet's membrane if it is exposed, and blood vessels will slowly begin growing into the cornea from the limbus. Once re-epithelialization is complete, new infection with microorganisms is unlikely. If surgery has not been performed, however, the area that had been ulcerated will be thinner than the surrounding stroma. This area will gradually thicken by slow reconstruction of stromal collagen by corneal fibroblasts (keratocytes) or when corneal blood vessels fill the old ulcer bed. This can take weeks to months, and until this happens, the cornea may be susceptible to traumatic rupture.

Another goal of therapy for an infected ulcer is suppression of the trigeminal nerve–mediated anterior uveitis that is associated with any corneal irritation. Topical atropine is used for this purpose because it decreases pain associated with ciliary body muscle spasm and maintains pupil dilation, which reduces the chance of posterior synechia formation. Atropine should be applied to effect (i.e., until reduced pain or pupil dilation is noted). This may be as frequently as every 6 to 8 hours initially but should be decreased after 24 hours and used only to effect once pupillary dilation is maintained.[77] Because topical atropine is absorbed into the systemic circulation and is associated with altered gastrointestinal (GI) motility,[78] small quantities of drug should be applied (1/8- to 1/4-inch strip of ointment or 0.1 mL solution), gut sounds should be assessed frequently, and the patient should be monitored for signs of colic. Systemic NSAIDs also should be used to decrease corneal and uveal inflammation. However, these drugs do slow corneal vascularization to some extent.[79,80] Topical NSAIDs (as with corticosteroids) are contraindicated in infected ulcers. Topical corticosteroids are sometimes recommended by some to reduce corneal vascularization once epithelialization is complete. However, corneal vascularization is a critical means by which corneal stroma (and strength) is reformed, and topical corticosteroids hasten regression of granulation tissue, suggesting that this approach is inadvisable. No evidence indicates that corticosteroid administration decreases the final size of the scar, and steroids may compromise healing and predispose to local immunosuppression, additional or persistent infection, and corneal rupture.

Fungal Keratitis in Horses

Definition and Etiology

Fungal keratitis (or keratomycosis) occurs when an ulcerated cornea becomes infected with a mycotic organism. As with bacteria, no fungi are known to *initiate* corneal ulcers. The most common genera isolated in cases of equine fungal keratitis are *Aspergillus* and *Fusarium* spp., but many other species of other genera have been cultured.[81-86] Horses seem unusually susceptible to fungal keratitis compared with the other domestic species.

Clinical Signs and Differential Diagnoses

Fungal keratitis is very common in the horse, particularly in certain geographic regions (i.e., southeastern United States), but has been reported all over the world. Nonspecific signs of keratomycosis may include pain (blepharospasm, photophobia), serous to mucopurulent ocular discharge, corneal edema, variable corneal vascularization, loss of stromal integrity (melting or keratomalacia), and secondary anterior uveitis (aqueous flare, hypopyon, fibrin, miosis), which may be severe. Fungal keratitis has various clinical presentations ranging from superficial punctate nonulcerative keratitis, to necrotic plaques, to stromal lesions with keratomalacia and furrowing, to deeper stromal defects or deep stromal abscesses.[87,88] A superficial epithelial to subepithelial form presents with microerosions and multifocal, whitish punctate to branching subepithelial opacities that often

VetBooks.ir

retain rose bengal stain.[89,90] This form, if treated promptly, will usually resolve without incident. However, the forms wherein overt ulceration develops are much harder to control. Superficial fungal ulcers often appear with a roughened, gritty ulcer bed and considerable edema (Color Plate 39.20). Often this form develops into a more severe presentation wherein enzymatic destruction of corneal collagen results in a furrow or groove around the margins of the lesion.[91] This furrow is a form of corneal melting and may progress rapidly and lead to corneal perforation. In other cases of keratomycosis, a plaque of tissue that is typically an accumulation of necrotic collagen, degenerating inflammatory cells, and a mat of fungal organisms forms centrally within the ulcer bed (Color Plate 39.21).[88,91,92] A very common manifestation of fungal infection is the formation of a white or yellow deep stromal abscess, typically accompanied by corneal vascularization and edema and moderate to severe anterior uveitis (Color Plate 39.22). Fungi have an affinity for the deep corneal stroma and Descemet's membrane, and in severe cases the organisms may invade through the cornea into the anterior chamber. Fungal involvement should be suspected in any corneal ulcer that is associated with plant or organic material; has been treated with corticosteroids; does not heal as quickly as expected; does not vascularize as expected; exhibits a gritty or pigmented surface; develops a plaque, groove, or deep stromal abscess; or if the uveitis present worsens initially when topical antifungal therapy is initiated. Vascularization is usually necessary for the resolution of fungal lesions in the cornea.

Clinical Pathology A diagnosis of superficial fungal keratitis is made when fungal hyphae or yeast are seen on cytologic analysis or cultured from corneal scrapings (Fig. 39.14). A diagnosis with deep keratitis or a stromal abscess may require a full-thickness corneal biopsy from which the fungus is identified using culture or histopathologic evaluation. Unfortunately, some diagnoses of fungal keratitis are made only after enucleation.[84] Fungal culture with susceptibility testing is recommended, but because results are often pending for prolonged periods, empirical antifungal therapy is required. Recent reports have described the use of confocal microscopy in the standing horse to confirm and assess the depth of fungal keratitis.[93]

Pathophysiology Fungal hyphae do not generally colonize intact corneas. An attachment may be initiated if there is a disturbance in the overlying tear film, but damage to epithelium is usually necessary for pathogenic or opportunistic fungi to begin growth in the corneal stroma. This usually results from a traumatic incident that may or may not be noticed by the owner. Use of antibiotics and corticosteroids alters normal flora and decreases the normal immune response, which may encourage fungal growth.[94] Fungi implicated in keratomycoses are usually present in the horse's environment and can be cultured from more than 90% of normal horse eyes, with *Aspergillus* spp. being the most common isolate.[81,95] There is one report in the literature of keratomycosis caused by *Candida albicans* secondary to disseminated candidiasis.[85]

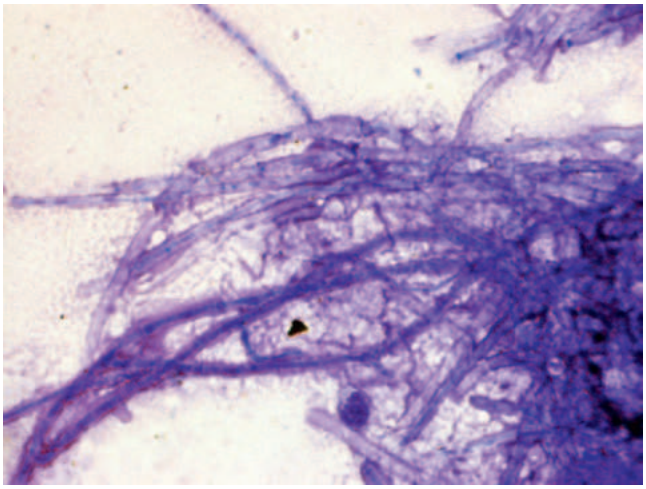

FIG. 39.14 Cytology of fungal keratitis. Diff-Quik, ×100. Note numerous basophilic septate and branching fungal hyphae. A single neutrophil serves as a reference for size of hyphae. *(Image courtesy Anne Gemensky-Metzler.)*

Epidemiology This disease is sporadic, with varying seasonal distribution and worldwide incidence.[81-88,96]

Treatment and Prognosis Keratomycosis in any form typically requires extended medical therapy (generally >6 weeks, sometimes considerably longer), and if stromal loss is detected, early surgical intervention is advisable. Treatment consists of eliminating the fungus from the cornea and controlling secondary bacterial invasion and melting, along with reflex uveitis, as for bacterial keratitis. Subpalpebral lavage systems are usually essential for delivering these drugs. Healing is usually not complete until corneal vascularization has reached the infected area, except when the fungus has reached Descemet's membrane; in these cases blood vessel growth does not always stop fungal growth. Medical therapy is most effective for treating superficial disease. For deep disease, surgical therapy is often necessary in combination with medical therapy. Deep lamellar and penetrating keratoplasty probably carry the best prognosis,[74,75,88,91] although superficial keratectomy with a conjunctival graft can also be used for lesions in the anterior stroma.

A number of antifungal agents are available. Miconazole, used as the undiluted IV preparation, was once the drug of choice for many ophthalmologists. Unfortunately, it is no longer available commercially in this formulation, although it can be compounded. Natamycin (Natacyn) is manufactured as an ophthalmic suspension and is the only commercially available topical ophthalmic antifungal medication approved by the U.S. Food and Drug Administration (FDA). However, natamycin does not penetrate intact epithelium well, and some *Fusarium* spp. may be resistant to the drug.[97,98] Voriconazole administered topically in a 1% solution penetrates intact corneal epithelium and reaches therapeutic corneal concentrations; it has a relatively wide spectrum of action and is efficacious against the common fungal species.[99-101] It is probably the most commonly used antifungal agent presently.

Fluconazole may be used topically or systemically and is generally regarded to have the best penetration of the blood-brain and blood-ocular barriers among the antifungal agents. However, one study reported that fluconazole had lower in vitro activity than a number of other antifungal drugs.[98] The IV preparation is a 2 mg/mL solution, which is used undiluted as a topical preparation. Miconazole and fluconazole do penetrate intact corneal epithelium when given topically, but drug concentrations in the stroma are higher if epithelium is absent.[102] Fluconazole can also be used subconjunctivally, intracamerally, or intravitreally. Ophthalmologists may use fluconazole systemically to treat deep corneal fungal disease because this drug does reach adequate concentrations in the aqueous humor, which may be appropriate for deep stromal or endothelial infections.[103] No toxicity studies have been performed on the horse, but anecdotal evidence does not suggest toxicities, and fluconazole has been associated with resolution of deep disease in some instances. It is not commonly used, however, because of its relatively narrow spectrum.

Compounded formulations of itraconazole/DMSO ointment have also been used for equine keratomycosis. High

concentrations of itraconazole can be achieved in the corneal stroma with this preparation, even when the overlying epithelium is intact, and it has been used successfully in clinical cases.[104] In contrast to fluconazole, systemically administered itraconazole does not penetrate noninflamed equine eyes.[105]

Other drugs have been suggested as treatment for fungal keratitis. Miconazole dermatologic or vaginal creams seem to work for mild superficial disease, but no clinical trials describing their efficacy and safety for ocular use have been reported. Amphotericin B has good antifungal properties but can be very irritating. It is useful for the rare cases in which a yeast is the offending pathogen. In vitro research shows that silver sulfadiazine is fungicidal against isolates from equine patients with keratomycosis.[97] Unfortunately, in vitro results do not necessarily correlate with clinical results in patients with keratomycosis.[106-108] Corneal penetration of the drug, the horse's immune system, and the site and severity of the fungal infection all play important roles in drug choice.[97] The use of newer agents such as posaconazole, caspofungin, and anidulafungin is currently being explored.[109-111]

In addition to topical antifungal agents, therapy should proceed as with any ulcer, with topical antibiotics, antiprotease medications, and atropine, as well as systemic NSAIDs when indicated. Systemic NSAIDs should be used for the secondary uveitis, especially at the beginning of treatment when fungal death can exacerbate uveitis. However, NSAIDs slow vascularization of the cornea, and treatment with these drugs should be decreased as the uveitis is controlled.[79]

Prognosis is guarded to poor in many cases of fungal keratitis. Usually the best possible outcome is a visual eye with some degree of residual corneal scarring. Because no evidence suggests that corticosteroids decrease the eventual size of the scar, and because they will promote the presence of residual hyphae, their use is not recommended in a healing fungal ulcer. Complications of fungal keratitis include perforation of the ulcer with loss of the eye, superinfection with bacteria, and phthisis bulbi.

Viral Keratitis in Horses

Equine herpesvirus serotype 2 (EHV-2) and serotype 5 (EHV-5) have been isolated from eyes in herd outbreaks of keratoconjunctivitis in horses.[112-116] Clinical signs in one outbreak included photophobia, epiphora and corneal neovascularization, color change, and pinpoint ulcerations; eyes healed within 2 weeks.[112] In another outbreak, conjunctivitis and multifocal superficial corneal opacities were seen; eyes healed within 2 weeks on topical idoxuridine.[113] Experimental inoculation of EHV-2 intranasally in two ponies pretreated with dexamethasone caused conjunctivitis, lymphadenopathy, and coughing.[117] Conjunctivae from both ponies was positive for virus by PCR 6 months after inoculation. EHV-2 can also be isolated from the blood of normal horses,[118] and positive PCR results can be obtained from normal eyes as well as eyes with keratoconjunctivitis, making diagnosis difficult.[116] Miller and colleagues[119] confirmed EHV-2 by fluorescent antibody staining after isolating virus from the cornea of a Thoroughbred mare with multiple superficial punctate corneal lesions. The keratitis was successfully treated with topical 1% trifluridine ophthalmic solution.

Acute cases may be moderately painful (blepharospasm, serous epiphora), with chemosis and conjunctival hyperemia. Recurrence is common and is often associated with corneal vascularization. The superficial or punctuate lesions (epithelial, subepithelial, or anterior stromal) of EHV may or may not retain fluorescein stain. Diagnosis may be difficult, and other differential diagnoses should be considered, including fungal keratitis and immune-mediated keratitis. Therapy for EHV keratitis includes topical antiviral and NSAID therapies. Idoxuridine (0.1%) and trifluridine (0.3%) limit viral replication but do not kill the virus; frequent dosing is required (4 to 12 times daily for 3 to 5 days until the condition stabilizes, then 3 to 6 times daily thereafter). A newer antiviral, 0.5% cidofovir, is effective in cats and requires only twice-daily dosing, but its use in horses has not been reported. Topical NSAIDs such as 0.03% flurbiprofen and 0.1% diclofenac are helpful for secondary uveitis and keratitis, but they should be used with caution because they have been reported to cause recrudescence of viral keratitis in human patients. Systemic flunixin meglumine is often helpful to improve comfort. If defects in the corneal epithelium are present, the additional use of a broad-spectrum topical antibiotic agent is indicated to prevent secondary bacterial infection.

Ocular Manifestations of Systemic Disease

Neonatal Septicemia

Neonatal septicemia in calves, foals, lambs, and kids may occur in the first few weeks after birth and may arise from umbilical infection or oral intake of bacteria. Septicemia is especially common in colostrum-deprived neonates. Secondary meningitis, polyarthritis, uveitis, and chorioretinitis may develop. Ocular signs include miosis, aqueous flare with fibrin deposition in the anterior chamber, hypopyon or hyphema, and in severe cases, panophthalmitis. Many different bacteria and fungi are capable of inducing sepsis, particularly in the immune incompetent, but some of the most commonly implicated agents include *Escherichia coli*, *Streptococcus* spp., *Pasteurella* spp., *Salmonella* spp., *Rhodococcus equi*, *Corynebacterium pyogenes*, and *Klebsiella* spp. Therapy should include systemic antibiotics (when possible, based on susceptibility testing) and treatment for uveitis (topical corticosteroids or NSAIDs, topical cycloplegics or mydriatics, and systemic NSAIDs). Prognosis, even for cases treated early, is guarded.[49,120-122]

Bovine Herpesvirus Type 1 (Infectious Bovine Rhinotracheitis)

Etiology

Bovine herpesvirus type 1 (BHV-1) may involve the respiratory or reproductive tracts, nervous system, or conjunctiva or may cause widespread systemic disease (see also Chapter 31). Conjunctivitis is the most common ocular manifestation of the disease, and it may occur as an isolated clinical entity or with involvement of other body systems.[123-126]

Clinical Signs and Differential Diagnoses Although conjunctivitis is frequently bilateral, it can be unilateral. Ocular discharge, initially serous and later becoming mucopurulent, is usually seen without blepharospasm. Chemosis may be severe, especially by 1 week after infection. Both the palpebral and the bulbar conjunctiva are injected, and petechial hemorrhages may occur. Multiple white plaques 0.2 to 0.5 mm in diameter may develop on the palpebral and, to a lesser extent, the bulbar conjunctival surfaces at 1 to 2 weeks after onset of clinical signs. These may coalesce later in the disease (5 to 9 days). Corneal vascularization and perilimbal edema and opacification occur in severe cases. Iridocyclitis (seen as miosis) may occasionally occur in severe cases.

Corneal changes of BHV-1 are differentiated from those of IBK (caused by *Moraxella bovis*) by their peripheral rather than central distribution and lack of corneal ulceration in BHV-1, unless BHV-1 and IBK occur concurrently in the same eye (see the Infectious Bovine Keratoconjunctivitis [IBK] section later). Corneal vascularization and opacification similar to that which occurs in malignant catarrhal fever accompanied by marked signs of anterior uveitis and other signs of generalized vasculitis has been reported occasionally.[127]

Although ocular disease with BHV-1 may occur as an isolated entity, concurrent upper respiratory tract signs, including rhinitis

and dyspnea, are common. Affected animals may be pyrexic, and a fall in milk yield may occur. Abortion in pregnant animals may occur following ocular manifestations of the disease.

■ ***Diagnostic Procedures*** BHV-1 can be recovered from infected eyes during the first 7 to 9 days of the disease but infrequently thereafter. Swabs may be taken for viral isolation in cell culture, which is probably the most reliable means of making a definitive diagnosis. Fluorescent antibody techniques may be used on conjunctival scrapings, and serology may be helpful if blood samples can be collected during the acute and convalescent stages of the disease. PCR is also being used. Histopathology to detect intranuclear inclusions is not likely to allow reliable diagnosis of the disease.[126,127]

■ ***Pathophysiology*** Specific strains of the virus usually cause only one form of the disease (e.g., ocular form) in a herd. Ocular infection results in lymphoid hyperplasia, visible as white plaques. On histology, these are composed of plasma cells and lymphocytes in the conjunctival stroma and subepithelial area. Mild conjunctival epithelial ulceration may occur. During the recovery phase of the disease, diphtheritic membranes secondary to conjunctival necrosis develop on the conjunctival surface.

■ ***Treatment and Prognosis*** Recovery from the conjunctival form of the disease is spontaneous within 10 to 20 days. In certain situations, palliative treatment may be helpful. This is achieved by cleaning the ocular discharge from the lids and applying a topical broad-spectrum antibiotic to prevent secondary bacterial infection. Treatment of the conjunctival form of the disease with topical antiviral agents has not been studied and would rarely be practical or cost-effective.

■ ***Prevention and Control*** Vaccination of susceptible animals is the most effective means to prevent and control the disease. BHV-1 vaccination programs are discussed in Chapter 48.

Bovine Herpesvirus Type 1 (Infectious Bovine Rhinotracheitis) in Goats

Goats are susceptible to BHV-1, which in some cases may result in ocular disease, particularly keratoconjunctivitis. In one goat with ocular signs, conjunctivitis and keratitis with keratoconus were seen 5 days after the onset of severe respiratory illness. BHV-1 virus was isolated from ocular and nasal discharge.[128]

Peste Des Petits Ruminants in Goats and Sheep

Peste des petits ruminants (PPR) is caused by a paramyxovirus of the *Morbillivirus* genus. This highly contagious disease affects both domestic and wild small ruminants and is characterized clinically by fever, diarrhea, depression, polypnea, conjunctivitis, lacrimation, rhinitis, erosive stomatitis, edema of eyelids, photophobia, cutaneous eruption with erythematous areas (especially noticeable in wool-free parts of the body and axilla), and lesions evolving into papules.[129,130] Ocular discharge is initially serous but becomes mucopurulent as secondary bacterial infections, which are common, develop. Goats tend to be more severely affected than sheep, but both can suffer very high mortality rates, especially immune-incompetent juveniles.[129,130] Also known as *pseudorinderpest*, this disease is found mainly in Africa, Asia, and the Middle East.

Scrapie in Sheep and Goats

The scrapie agent causes a degenerative CNS disease in sheep and less often in goats. Barnett and Palmer[131] described two sheep with scrapie that also had multifocal hyperreflective areas in the tapetum, histologically seen as small areas of retina raised by an accumulation of eosinophilic material between photoreceptors and retinal pigment epithelium. The eosinophilic material was characterized as a complex lipid. It was not shown that scrapie had caused the lesions.[131] Subsequently, using a monoclonal antibody, a goat with natural scrapie was found to have the scrapie prion protein in the retina, without any microscopic retinal lesions.[132] A sheep experimentally infected with scrapie was also found to have prion proteins in the retina,[133] as was a sheep experimentally infected with the prion responsible for bovine spongiform encephalopathy (BSE).[134] Prion proteins can also be found in the nictitating membrane,[134,135] which may permit the antemortem diagnosis of scrapie. (See Chapter 35 for more information on scrapie.)

Bluetongue in Sheep and Cattle

Bluetongue is a disease of ruminants caused by an arbovirus that is transmitted by *Culicoides* gnats. Clinical signs include fever and vasculitis that lead to oral lesions, lameness, swollen face, pulmonary edema, and death (see Chapter 32). In pregnant ewes vaccinated with modified live virus (MLV) on day 40 of gestation, fetuses developed cerebral anomalies.[136] These anomalies have also been described in clinical cases in which ewes had been vaccinated with MLV at about 5 or 6 weeks of gestation. In addition, when the fetus was vaccinated with MLV vaccine between days 50 and 75 of gestation, lesions of retinitis and choroiditis that appeared centered around retinal vessels were noted. In some eyes, inflammatory lesions produced persistent areas of retinal dysplasia.[137]

Conjunctivitis and mucopurulent ocular discharge may be seen in cattle chronically infected with bluetongue virus. Although topical antibiotics could be applied to reduce secondary bacterial infection and reduce the ocular discharge, this would rarely be necessary.[138] Systemically ill or congenitally infected animals may have anterior uveitis and corneal edema as a result of this infection.[139]

Bovine Viral Diarrhea

The causative agent, bovine viral diarrhea virus (BVDV), is in the genus *Pestivirus*, a member of family Flaviviridae that, in congenitally affected animals, causes retinal inflammation and necrosis. Cattle infected between days 75 and 150 of gestation may produce calves with cerebellar hypoplasia or ocular lesions. Calves with ocular signs may be blind, and nystagmus may be present. Pupillary light reflexes may or may not be absent. Other abnormalities may include microphthalmia, cataract, leukocoria (as a result of either cataract or dense white inflammatory infiltrate in the anterior vitreous), retinal hemorrhages, chorioretinitis, retinal dysplasia or folds, retinal detachment, or optic neuritis or atrophy.[140-143] The optic disk may appear atrophic, and areas of tapetal color change and hyperreflectivity may be seen, with retinal vascular attenuation. In some cases, inflammatory debris may persist in the vitreous after birth, precluding adequate fundic examination. Congenital cataracts also occur in this disease, and although the pathophysiology is unknown, they probably develop secondary to the intraocular inflammation and necrosis. Cataracts mainly involve the lens cortex.

Transplacental infection may occur when the dam is infected during pregnancy. The severity of the disease is related to fetal age at the time of intrauterine infection. Severe fetal disease and often fetal death occur in cattle infected between 50 and 100 days of gestation. Infected fetuses can also survive and become persistently infected with the virus. In these cattle, viral antigens can be found in neurons of the retina and CNS in the absence of clinical signs.[144] Ocular discharge has been reported in cases of acute or chronic cases of BVD, although the significance of these observations is uncertain.[143,145]

Serum samples collected from affected calves before ingestion of colostrum can be submitted for serologic assessment using

the serum-virus neutralization test, or virus isolation can be attempted from buffy coat cells of a whole-blood sample collected into EDTA (see Chapter 32).

Bovine Leukosis

Lymphosarcoma in adult cattle is usually caused by bovine leukemia virus (BLV), although noninfectious sporadic cases are reported in young animals. Lymphosarcoma is the most common orbital neoplasm in cattle and may result in unilateral or bilateral progressive exophthalmos.[146,147] If undiagnosed, exposure keratitis and chemosis develop. Intraocular involvement can occur, although this is less common than orbital neoplasia. Generalized lymphadenopathy or other signs of generalized lymphosarcoma usually accompany the orbital form. Specific serologic tests for BLV will confirm the diagnosis. Enucleation or exenteration is rarely indicated because of the poor systemic prognosis for affected animals. Differential considerations for progressive exophthalmos include orbital cellulitis, in some instances due to actinomycosis or actinobacillosis, frontal or maxillary sinusitis, or nasal or orbital neoplasia (especially squamous cell carcinoma).

Tuberculosis in Cattle

Tuberculosis caused by *Mycobacterium bovis* may cause granulomatous lesions in the eye of affected cattle. The uveal tract (iris, ciliary body, or choroid) is initially affected, with later expansion of granulomas into other ocular structures. Uveitis, keratitis, and chorioretinitis with retinal detachment are seen clinically.[148]

Malignant Catarrhal Fever

Malignant catarrhal fever (MCF) is a sporadic disease characterized by fever, lymphadenopathy, and generalized vasculitis resulting in inflammation of the mucosal membranes of the mouth, nose, and eye; the skin; and the GI and nervous systems, with variable but usually high mortality. The African form is caused by alcelaphine herpesvirus type 1. The North American form is caused by a similar virus, ovine herpesvirus type 2.[149,150]

Various forms of the disease are described on the basis of clinical signs (see Chapter 32). Ocular involvement is seen in the acute "head and eye" form, which is the most common presentation of the disease. Ocular signs include photophobia, epiphora, episcleral injection and scleritis, severe conjunctivitis, perilimbalcorneal edema and vascularization, anterior uveitis, and exophthalmia. Less significantly, and difficult to diagnose clinically, retinal vasculitis may develop. Corneal edema and anterior uveitis were the most commonly reported ocular signs in a recent report of cows with MCF.[151] The degree of corneal edema at initial examination did not correlate with survival; however, the resolution of corneal edema and uveitis was associated with survival. Corneal edema and uveitis progressed despite supportive care in animals that did not survive. Bullous keratopathy may develop as a result of edema in the anterior cornea, with subsequent rupture of bullae to form painful corneal erosions.[152] The absence of central corneal ulceration distinguishes the disease from IBK, and the severity of the ocular lesions is worse than would be expected with BHV-1, BVDV mucosal disease, or bluetongue. Differentiating this disease from rinderpest could be clinically difficult in areas where both are endemic in cattle.

Serology and PCR are being used to confirm the clinical diagnosis.[153,154] The microscopic ocular lesions are those of a nonsuppurative uveitis and vasculitis. The lesions involve the conjunctiva, cornea, anterior uvea, and retinal blood vessels; the choroid is rarely involved. Serofibrinous and cellular infiltrates develop in the uvea and retina as a result of vasculitis and thrombosis. Perivascular cuffing and optic neuritis may be detected histologically.[155-157]

Prognosis for the eyes and the animal's recovery is poor.[152,158] Most importantly, in endemic areas cattle should be kept away from sheep, which may act as a reservoir for the disease, and affected animals should be isolated.[159]

Thromboembolic Meningoencephalitis

Thromboembolic meningoencephalitis (TEME) is a fatal septicemia caused by infection with *Histophilus somni* (see Chapter 35). Calves and young adult cattle can be affected, but the disease most often occurs in feedlot cattle younger than 1 year of age. The organism is capable of damaging vascular endothelial cells and activating blood clotting. Therefore most of the ocular histologic signs are related to thrombosis of retinal vessels.

Although conjunctivitis may be seen, the main ocular findings are in the fundus. Retinal hemorrhages and exudates may be focal or diffuse. Retinal infiltrates may elevate the retina and involve the vitreous. Retinal edema, hemorrhage and necrosis, vascular thrombosis, and infiltration of the retina and vitreous with neutrophils are seen histologically. Eosinophilic cytoid bodies (swollen axons) are seen in the nerve fiber layer of the retina. Retinal detachments may result from retinal edema. Later in the disease, areas of chorioretinitis result in chorioretinal scars. The anterior segment is less involved in this disease than in MCF, in which keratitis and anterior uveitis are usual.[160,161]

Leptospirosis in Horses and Cows

Leptospirosis is caused by a filamentous bacterium known as a *spirochete*. Disease is seen in most domestic animals as well as humans. Various serovars of *Leptospira interrogans sensu stricto*, *Leptospira kirschneri*, and *Leptospira santarosai* have been shown to affect various organs (e.g., kidneys, liver, spleen, muscles, CNS, eyes) and have been associated with abortions.[162] These organisms primarily cause a vasculitis and endotheliitis in these organs.[163]

Because leptospiral organisms cause vasculitis, it is reasonable to assume that uveitis may be present in an acute infection, and this has been reported in horses during the acute phase of leptospirosis.[164] Uveitis has also been seen experimentally in a calf during acute disease.[165] However, the role of leptospires in uveitis seen weeks to months after the acute disease remains much more controversial. Evidence for such a role is most complete in the horse, in which leptospiral uveitis and its role in equine recurrent uveitis (ERU) or "periodic ophthalmia" have been described.[166-168] ERU is an immune-mediated disorder that is the leading cause of blindness in horses (see the Immune-Mediated Ocular Diseases section later). Although the recurrent episodes of ERU are not directly caused by reinfection with microorganisms or parasites, numerous bacterial, viral, protozoal, and parasitic organisms have been implicated in the initiation of the syndrome. In one outbreak of leptospirosis on a small farm, uveitis was not seen until 18 to 24 months after the acute outbreak of leptospirosis. Treatment with systemic antibiotics did not seem to affect the uveitis. In that study, serum titers to *Leptospira interrogans* serovar *pomona* often remained high for at least 6 years.[166] In another study, uveitis was seen in 22 eyes of 18 ponies experimentally infected with *L. interrogans* serovar *pomona*. The earliest sign of uveitis was seen at 1 year after inoculation. Cataract formation and posterior synechiae were also seen, as were recurrences of overt uveitis.[167]

Recently, leptospiral organisms have been identified using PCR[168] or by culture[168-170] in the eyes of horses with ERU. A study in California using a PCR assay for *Leptospira* showed that 30 of 55 eyes (21 of 30 horses) with ERU had detectable *Leptospira* DNA in their aqueous humor.[168] In other studies, treatment with systemic antibiotics did not decrease the inflammation.[170-172] In Western Europe a total of 618 vitreous and/or aqueous samples were taken from the eyes of 501 horses

with either active ERU or a history of ERU. Leptospires were isolated from 199 (32.2%) of the samples. Most belonged to serogroup *grippotyphosa*, with the rest in serogroup *australis*, *sejroe*, *pomona*, or *javanica*.[169] In contrast, 36 samples of vitreous from 21 normal horses did not grow leptospires.[170] Although leptospires are involved in ERU in many horses with this syndrome, controlling or treating this disease remains a problem. The best means of symptomatic control of ERU at this time appears to be the use of ocular bioerodible cyclosporine A implants that are surgically placed within the suprachoroidal space, with the goal of controlling immune-mediated intraocular inflammation.[173] In the same study, cyclosporine was been shown to be toxic to *L. interrogans* in vitro at the same concentration that was achieved in uveal tissue with the suprachoroidal implant.[173] (See also the Equine Recurrent Uveitis section later.)

Listeria Monocytogenes in Sheep, Cattle, and Horses

Listeriosis in ruminants is manifested mainly as either an encephalitis or a septicemia in neonates, or as a reproductive problem manifested by abortion. Ocular signs with the neural form include facial nerve paralysis and ptosis, often unilateral, on the side of the central lesion; medial strabismus, often on the ipsilateral side because of involvement of the abducens nucleus; nystagmus; and amaurosis.[174] Uveitis with hypopyon has been described in chronic cases.[175]

Listeria monocytogenes has been cultured from conjunctival smears taken from sheep and cattle with keratoconjunctivitis.[176] In most of the sheep, *Branhamella (Neisseria) ovis* was also cultured. Clinical signs included conjunctival hyperemia, epiphora, photophobia, and corneal opacification. Treatment with topical chlortetracycline was curative. Walker and Morgan[177] describe two sheep that developed unilateral anterior uveitis. *L. monocytogenes* was cultured from the conjunctiva of each animal. Both animals recovered after treatment with parenteral ampicillin and topical antibiotics. *L. monocytogenes* has been cultured from the conjunctivae of three cows with keratitis (one with keratitis and uveitis) and from a corneal scraping of one horse with keratitis.[178] *L. monocytogenes* has been cultured from the cornea and conjunctiva of horses with chronic keratitis and keratoconjunctivitis.[179,180] Early treatment with broad-spectrum antibiotics may be effective in some cases.

Rabies

Rabies remains one of the most serious zoonotic diseases today.[181] It can affect any mammal, and reports of rabies disease and death have been reported in all of the large animal species of concern in this chapter.[181,182] Ophthalmic signs of rabies are usually secondary to systemic illness and neurologic impairment and may include prolapse of the nictitating membrane, strabismus, nystagmus, and vision loss.[181-185] Prevention is the best approach to disease control, since affected animals must necessarily be destroyed once affected.[186] Fortunately, preexposure vaccination is highly effective, and postexposure (before the development of clinical signs) prophylaxis (immediate vaccination against rabies, a strict isolation period of 90 days, and administration of booster vaccinations during the third and eighth weeks of the isolation period) may be effective in unvaccinated domestic animals if administered promptly.[186]

Other Bacterial Disease in Horses

Salmonella spp. cause one of the more common and serious bacterial enteritides in foals and adult horses. It is often accompanied by septicemia in foals. Anterior uveitis and hypopyon have been seen in animals with salmonellosis, and *Salmonella* spp. can sometimes be cultured from these eyes.[187]

R. equi is a gram-positive coccobacillus that causes bronchopneumonia in young foals.[187-189] The systemic inflammatory response may result in a fibrinous anterior uveitis. Therapy involves systemic treatment of the pneumonia and topical and/or systemic antiinflammatory treatment for the uveitis.

Strangles is a respiratory infection caused by *Streptococcus equi* subsp. *equi* that can have an accompanying ocular discharge.[190] Chorioretinal depigmentation was noted in the nontapetal fundus of several horses in one group clinically diagnosed with strangles. Because these lesions repigmented with time, it was suggested that they were caused by embolism to the choroid during bacteremia.[191] One case of panophthalmitis caused by *S. equi* in a horse has been described.[192] Ten days after a bout of strangles, this horse developed anterior uveitis that progressed to corneal stromal abscesses and panophthalmitis. *S. equi* was cultured from the eye at enucleation. *S. equi* has also been isolated from infected corneal wounds in horses without systemic signs of strangles. These cases are treated aggressively, as with any bacterial keratitis.

Brucella abortus has been suggested as a cause for ERU,[187] although serum agglutination titers for *B. abortus* in normal horses and horses with ERU are similar.[193] This organism is certainly capable of inducing intraocular inflammation, although its role in recurrence or persistence of uveitis is unknown.

A case of anterior uveitis and bilateral chorioretinitis with retinal detachments has been described in a horse from Denmark as a result of a mycobacterial infection. Acid-fast organisms were seen in both eyes as well as in numerous other organs. *Mycobacterium avium* was cultured from these organs.[194]

Other Viral Diseases in Horses

Equine adenovirus is a DNA virus that causes bronchopneumonia (type 1) or GI signs (type 2) in foals, especially if they are immunodeficient. Mucopurulent nasal and ocular discharge accompanies the respiratory system disease. Histologically, swelling and necrosis of conjunctival cells with intranuclear inclusions are seen, with accumulation of neutrophils in the lumina and adventitia of uveal blood vessels.[195] Treatment of the conjunctivitis is supportive, with lubricants and antiinflammatory medications.

Equine viral arteritis is a rare disease caused by an RNA virus classified as Arteriviridae. Most animals are subclinically infected, but ocular and nasal discharge, rash, pyrexia, rhinitis, leukopenia, edema (palpebral, periorbital, limb, or ventral), and abortions and neonatal death are seen.[196,197] Corneal opacity and photophobia have also been described.[198] The virus characteristically causes a panvasculitis.

Borrelia burgdorferi, the agent of Lyme disease, has been most often described as causing polyarthritis in horses, cows, and dogs. However, one case of ocular disease has been reported in a pony infected with *B. burgdorferi*.[199] Unilateral anterior and posterior uveitis was noted, and spirochetes were found in the anterior chamber. Other clinical signs included arthritis and synovitis of both carpal joints. Some discuss this agent as a potential contributor to chronic immune-mediated uveitis (ERU).

Equine herpesvirus serotype 1 (EHV-1) is a cause of rhinopneumonitis in horses. It has been cultured from cases of superficial punctate keratitis in the horse; the significance of these isolations is unknown.[200] Six foals were experimentally inoculated intranasally with EHV-1.[201] All developed typical mild signs of upper respiratory infection. One foal developed vision problems 1 month after inoculation. Bilateral chorioretinitis was diagnosed. Necropsy findings included chorioretinal degeneration and demyelination of the optic nerve and mononuclear cell infiltrate in parts of the choroid, retina, and CNS.[201] These findings are not surprising in that EHV-1 causes vasculitis and CNS disease in horses.[202] Retinal detachments and optic neuritis are possible as well. Treatment is not usually successful.

African Horse Sickness is caused by an orbivirus that is transmitted by *Culocoides* insects. It results in profound bulging

of the supraorbital fossa, the soft tissue depression above the dorsal orbital rim, which is considered a hallmark of this disease.[203,204] This swelling is due to retrobulbar edema and increased vascular pressure. Chemosis and protrusion of the conjunctiva from between the palpebral fissure is often seen as well. The systemic disease is characterized by either respiratory and/or cardiac impairment and has a high rate of mortality.[203,204] Control of an outbreak in an endemic region (Africa, Middle East) involves quarantine and usually euthanasia of affected animals, vector control, and vaccination of unaffected animals.[203,204]

Equine influenza is one of the most common infectious diseases of the respiratory tract of horses. It is endemic in the equine population of the United States and throughout much of the world. This condition is highly contagious, and the virus spreads rapidly through groups of horses in aerosolized droplets dispersed by coughing. Clinical signs begin abruptly and include fever, serous nasal discharge, submandibular lymphadenopathy, and a harsh, dry, nonproductive cough.[205] Ocular signs are secondary and are usually limited to conjunctivitis with serous to mucopurulent ocular discharge.[205] The severity of clinical signs depends on the degree of existing immunity, among other factors.[206] Younger animals are most susceptible, but immunity in an older horse can be overwhelmed in animals frequently exposed at shows.[205] Vaccination of at-risk individuals is recommended.

Viral encephalitis caused by either Eastern equine encephalomyelitis (EEE) virus, Western equine encephalomyelitis (WEE) virus, or Venezuelan equine encephalomyelitis (VEE) virus is borne and transmitted by mosquito vectors and often has a seasonal presentation.[207] Any and all signs attributable to cortical and thalamic lesions may be seen with these conditions. Neurologic deficits may be asymmetric, since lesions are not necessarily symmetrically distributed. Clinical signs include altered mentation, aimless wandering, head pressing, circling, inability to swallow, irregular ataxic gait, paresis and paralysis, convulsions, and death. Ophthalmic signs include vision loss, nystagmus, strabismus, mydriasis, and abnormalities of PLRs.[207] In contrast, neurologic lesions with West Nile virus (WNV) encephalomyelitis are more prevalent in the brainstem and spinal cord than in the cortical and thalamic regions.[208-210] Thus horses with WNV may present with signs of spinal cord ataxia, hyperesthesia, and muscle fasciculations as well. Ophthalmic signs may include vision loss, facial paralysis (with secondary exposure keratitis), anterior and/or posterior uveitis, and optic neuritis.[208-210] There is no specific therapy for viral encephalitis. Symptomatic support might include fluid therapy, antiinflammatory agents if indicated, and anticonvulsants if necessary. Topical lubricants for the eyes may be necessary.

Cryptococcosis, Histoplasmosis, and Aspergillosis in Horses

Cryptococcus neoformans is a pathogenic fungus that may cause systemic infection in horses and other mammals. Ocular signs are not usually reported in horses with cryptococcosis, although there are reports of frontal sinus granuloma with retrobulbar mass causing exophthalmos, periorbital swelling, blindness, and optic neuritis.[211-212] The chorioretinitis associated with *C. neoformans* seen in other species has not been described in the horse, cow, or small ruminant. *Cryptococcus albidus* has been cultured from the cornea of a horse with chronic keratitis.[213] Diagnosis is based on histopathologic evidence of fungal hyphae in tissue samples or on cytology, as well as a positive culture.

Histoplasma farciminosum, a fungal agent found mainly in Africa, is responsible for epizootic lymphangitis, a disease manifested with nodules and draining lesions of the subcutaneous lymphatic system.[214] A conjunctival form of this disease results from deposition of the organism on the ocular mucous membranes by biting flies. Ocular signs include serous to mucopurulent discharge, blepharedema, and conjunctival papules. Disease progression leads to ulceration of the papules, which may result in secondary keratitis and/or obstruction and erosion of the lacrimal duct. Diagnosis is mainly by cytologic analysis and culture, although serologic assays are also available. Amphotericin B is the treatment of choice, and a vaccine is available for horses in endemic areas. Organisms consistent with *Histoplasma* spp. were seen on cytology of a corneal scraping taken from a horse with chronic keratitis.[215] This horse was successfully treated with topical fluconazole.

Aspergillus spp. are considered opportunistic fungi that rarely cause systemic disease in immunocompetent horses. Aspergillosis may be a cause of guttural pouch mycosis and may also occur secondary to chronic obstructive pulmonary disease.[216,217] Associated ocular signs can include Horner's syndrome, facial nerve palsy, and blindness resulting from ischemic optic neuritis secondary to extension of disease.[216] These organisms are ubiquitous in the environment, and horses are frequently exposed. Treatment with systemic antifungal agents may be attempted, but the prognosis is guarded and dependent on the underlying disease process and severity of the lesions. In contrast to the systemic form of the disease, local *Aspergillus* infections in the cornea are common (see the Fungal Keratitis in Horses section earlier).

Infectious Bovine Keratoconjunctivitis (IBK)

John A. Angelos

Infectious bovine keratoconjunctivitis (IBK), or "pinkeye," is the most common ocular disease of cattle and has been identified in cattle populations worldwide. The clinical signs of IBK include corneal ulceration, corneal edema, photophobia, blepharospasm, and lacrimation (Color Plate 39.23). In less severely affected animals, recovery with or without permanent corneal scarring occurs. In the most severely affected animals, corneal rupture and lens or iris prolapse may occur, causing permanent blindness. IBK is most common in calves, typically affecting one eye, although both eyes may be affected. Estimates of annual incidence of IBK are 5% of all beef cattle, with more than 50% of herds affected.[1] Epizootic outbreaks occur, with case attack rates approaching 90% to 100% of yearling cattle.[2,3] Cattle of all breeds may be affected; however, a higher incidence is reported in Herefords,[4] and a lower incidence is reported in Brahmans and cattle with more pigmentation at the ocular margins.[5,6]

Genetic investigations of cattle affected with IBK have suggested the presence of loci that are associated with IBK.[7,8] Hereford-Friesian crossbred calves with full eyelid pigmentation had a lower incidence of IBK versus calves with less than total pigmentation.[9] Five single nucleotide polymorphisms (SNPs) on bovine chromosome 20 that are significantly associated with IBK have also been identified.[10] A relationship was also reported between a specific SNP in the Toll-like receptor 4 gene and the rate of IBK infection in Angus cattle.[11]

Economic Impact Cattle with IBK have reduced weight gain that results in economic losses to producers. Postweaning 205-day weights of bulls and heifers with IBK showed losses of 36 and 40 pounds (16 and 18 kg), respectively, over unaffected herdmates.[12] In 1169 pasture-raised calves over a 4-year period, the average weight reduction was 11 pounds (5 kg) for calves with IBK in one eye and 35 pounds (15.75 kg) for calves with IBK in both eyes.[13] A study of more than 45,000 health records of weaned calves demonstrated almost 20-pound (9-kg) lighter weaning weights in calves diagnosed with IBK versus healthy calves.[4] A retrospective population-based cohort study of approximately 1800 Angus calves over a 7-year period indicated

that yearlings with evidence of IBK at weaning had reduced twelfth rib fat depth, ribeye area, and body weight versus cohorts without IBK.[14] The economic losses from reduced weight gain along with treatment-associated expenses accounted for annual losses in the United States that many years ago were estimated to be $150 million.[15]

Etiology and Epidemiology

Moraxella bovis is the only organism for which Koch's postulates have been fulfilled with respect to IBK[16]; however, other viruses and bacteria have been associated with IBK, including infectious bovine rhinotracheitis (IBR) virus[17,18] and *Mycoplasma* spp.[19,20] These organisms may increase risk for IBK by enhancing opportunities for corneal injury[21-23] and increasing ocular and nasal discharge, which may facilitate transmission of *Moraxella bovis*. In an outbreak of IBK in young calves, *Mycoplasma bovoculi* and *Mycoplasma bovis* were isolated from affected animals, whereas *Moraxella bovis* was not isolated.[24] In a recent study, IBR exposure as indicated by positive BHV-1 titer was not found to predispose calves to developing IBK in a herd where *Moraxella bovis* was present.[25]

For many years, a role for hemolytic gram-negative cocci in IBK pathogenesis has been suggested from the observations of researchers in the field. In 1966 hemolytic gram-negative cocci were isolated from calves with severe keratitis and corneal ulceration.[26] In Australia, *Neisseria* species were isolated in 24 of 25 outbreaks of IBK; *Moraxella bovis* was identified in only two of these outbreaks.[27] *Neisseria* (*Branhamella*) *catarrhalis* was reported in almost 45% of IBK cases, whereas *Moraxella bovis* was isolated from only 28% of IBK cases.[28] *Moraxella bovis* and *Neisseria* species were also cultured from normal eyes of cattle.[29,30] *Moraxella ovis* and *Neisseria ovis* were also reported from cattle in Israel with IBK.[31,32] *Neisseria ovis* experimentally inoculated into the eyes of calves did not cause lesions typical of IBK, despite previous corneal irradiation.[33] *M. ovis* was reported in mule deer with keratoconjunctivitis, although experimental inoculation of *M. ovis* isolates into eyes of mule deer fawns did not cause IBK.[34] Recently, hemolytic and cytolytic activity from culture filtrates of *M. ovis* isolated from cattle with IBK has been described, suggesting a possible role for bacteria other than *Moraxella bovis* in the pathogenesis of IBK.[35]

During an IBK drug efficacy trial during summer 2002 in northern California, the majority of bacterial isolates from IBK-affected calves were found to be hemolytic gram-negative cocci.[36] Genetic and biochemical characterization of these isolates subsequently identified these organisms as a novel species that was distinct from *Moraxella bovis* and *M. ovis*; it was named *Moraxella bovoculi*.[37] It is likely that *Moraxella bovoculi* has circulated within cattle populations for many years, and until this gram-negative coccus had been shown to be distinct from *M. ovis*, it may have been misidentified by diagnostic laboratories as *M. ovis*, *Branhamella ovis*, *M. ovis*–like, or *B. ovis*–like. A weak causal role for *Moraxeella bovoculi* (as well as for *Moraxella bovis*) was reported in a cohort study that looked for *Moraxella bovis*, *M. ovis*, and *Moraxella bovoculi* DNA in swabs from eyes of beef calves.[38] However, in an experimental challenge study using a corneal scarification model for infection with the type strain of *Moraxella bovoculi*, corneal ulceration could not be demonstrated.[39] A point prevalence study that evaluated ocular flora in animals from herds in varying stages of IBK outbreaks for the presence of DNA from *Moraxella bovis*, *M. ovis*, *Moraxella bovoculi*, *Mycoplasma bovoculi*, and *Mycoplasma bovis* determined that *Moraxella bovoculi* was the only organism that correlated with clinical signs of IBK.[40] In that study, herds with high *Mycoplasma bovoculi* were more predisposed to IBK outbreaks, and authors postulated that there may be synergistic interactions between *Mycoplasma bovoculi* and *Moraxella* spp. in IBK. During 2010 to 2013 *Moraxella bovoculi* was the most frequently isolated organism from IBK-affected cattle in the central United States.[41] When the microbial community in the eyes of a cohort of calves (some of which subsequently developed IBK and some of which did not) were examined using high-throughput sequencing of 16S ribosomal RNA, *Moraxella* was found to be among the top 10 most abundant genera; however, the difference in abundance between calves that never developed IBK and those that did was not significant.[42] Marked genetic differences were determined after whole genome sequence analysis of *Moraxella bovoculi* from cattle with IBK and from nonocular sites in asymptomatic cattle; these data suggest the presence of genetically distinct strains of *Moraxella bovoculi*.[43] In a study of ocular flora from normal goats, *Moraxella bovoculi* was the most common single bacterial species isolated.[44]

In addition to bacterial infection, other risk factors for IBK include flies, solar irradiation, and mechanical trauma from plant awns. *Moraxella bovis* survives up to 3 days on the external surface[45] and 2 days in the gut[46] of face flies *(Musca autumnalis)*. IBK was experimentally induced in cattle that were exposed to face flies that had fed on *Moraxella bovis* cultures.[47] Insecticide-impregnated ear tags or back and face rubbers to reduce fly populations have proved effective in reducing IBK in cattle populations.[48] An association between solar irradiation and IBK has also been documented.[49-51] Corneas of calves exposed to UV irradiation incur corneal epithelial cell degeneration[52] that predisposes eyes to establishment of *Moraxella bovis* and IBK. An experimental model for IBK has been developed in which calves are exposed once daily for 2 or 3 days to UV irradiation using sunlamps held 24 inches (60 cm) from the corneal surface; after the last exposure, animals are infected by instillation of *Moraxella bovis* into the eye.[53-55] Plant awns have been associated with IBK, most likely through direct mechanical damage to the cornea that facilitates infection with *Moraxella bovis* and subsequent development of IBK.

Hemolytic strains of *Moraxella bovis* are considered pathogenic. Nevertheless, nonhemolytic, nonpathogenic *Moraxella bovis* can be isolated from normal cattle,[2,56-58] from cattle exhibiting conjunctivitis,[59] and simultaneously with hemolytic *Moraxella bovis* from cattle with IBK.[58] Outbreaks of IBK typically occur annually during summer months, and such outbreaks were postulated to be caused in part by cattle harboring *Moraxella bovis* subclinically.[58,60]

Pathophysiology of Moraxella Bovis

Moraxella bovis produces many hydrolytic enzymes that may be important in facilitating ocular injury, including C4 esterase, C8 esterase-lipase, C14 lipase, phosphoamidase, phosphatase, leucine and valine aminopeptidases, and gelatinase.[61] To date, however, only two *Moraxella bovis* proteins have been linked to pathogenicity: pili and cytotoxin. Pilin proteins of *Moraxella bovis* are of the *N*-methylphenylalanine type (type IV pili[62-64]) and enable bacteria to adhere to the corneal epithelium and colonize the surface of the cornea.[65-67] *Moraxella bovis* is capable of forming biofilms through formation of type IV pili, and disruption of these pili prevents biofilm formation.[68]

The *Moraxella bovis* cytotoxin (cytolysin/hemolysin) is a pore-forming protein that is also considered necessary for pathogenesis. Broth supernatants of hemolytic strains of *Moraxella bovis* will cause lysis of bovine erythrocytes, neutrophils, lymphoma cells, and corneal epithelial cells in vitro.[69-72] The lytic activity of *Moraxella bovis* cytotoxin occurs through calcium-dependent formation of transmembrane pores in target cell membranes.[73] Ocular lesions induced by a purified hemolytic and cytolytic fraction of *Moraxella bovis* are identical to the ocular lesions observed in naturally occurring IBK; extracts from nonhemolytic *Moraxella bovis* do not cause corneal lesions.[74]

An association between the *Moraxella bovis* cytotoxin and the RTX (***r***epeats in the structural ***tox***in) family of bacterial exoproteins followed the discovery that *Moraxella bovis* cytotoxin

induces the formation of pores in target cell membranes.[73] It was subsequently shown that an approximately 110-kilodalton protein in concentrated culture supernatants from cytolytic *Moraxella bovis* cultures could be recognized by a monoclonal antibody to HlyA, an RTX toxin of uropathogenic *E. coli*.[75] The presence of RTX toxins has been reported in numerous animal pathogens, including *Mannheimia haemolytica*, the agent of shipping fever pleuropneumonia in cattle[76]; *Actinobacillus pleuropneumoniae*, an agent of swine pleuropneumonia[77]; *Pasteurella aerogenes*, an abortifacient in swine and other mammals[78]; and *Actinobacillus equuli*, associated with foal septicemia.[79] Enterohemorrhagic *E. coli* O157:H7 also harbors a plasmid-encoded RTX toxin.[80]

The best-characterized RTX toxin is HlyA of uropathogenic *E. coli*. The gene encoding this toxin is assigned the abbreviation *hlyA* and is contained within a four-gene operon organized 5'-C-A-B-D-3'. The product of the RTX A gene is a structural toxin that must be activated by the RTX C gene product to become hemolytic.[81-83] The activation occurs through fatty acylation of conserved lysine residues.[84,85] After activation the toxin is secreted by membrane transport proteins encoded by the B and D genes and a third protein, TolC.[86,87] The regulation of transcription through the RTX operon in *E. coli* is a complex process and involves the protein RfaH and JUMPStart DNA sequences.[88] As with *E. coli* hemolysin, the *Moraxella bovis* cytotoxin gene *(mbxA)* is contained within an RTX operon (*mbx* operon) that encodes activation and export proteins; this operon is absent in nonhemolytic *Moraxella bovis*.[89] The *mbx* operon defines a pathogenicity island, and acquisition or loss of *mbx* genes may explain the ability of *Moraxella bovis* to change from the hemolytic to nonhemolytic phenotype.[90] *Moraxella bovoculi* and *Moraxella ovis* have also been shown to encode RTX toxins that reside within classical RTX operons.[91] Near-complete identity between the deduced amino acid sequences of cytotoxin genes and geographically diverse *Moraxella bovis* isolates has been reported and demonstrates that there is a high degree of conservation in the gene encoding this important pathogenic factor.[92]

Immunity to Moraxella Bovis

Secretory IgA is the major immunoglobulin found in normal bovine lacrimal secretions.[93] During experimentally induced IBK, tear IgG1 and IgG2 concentrations increase.[94] Early studies suggested that calves with more severe IBK had higher lacrimal IgA titers to crude *Moraxella bovis* antigen preparations than calves with less severe IBK.[95] A subsequent study identified a predominant tear IgG response to a crude, whole-cell *Moraxella bovis* antigen in calves with naturally occurring IBK and concluded that *Moraxella bovis*–specific antibodies in lacrimal secretions did not prevent IBK in calves.[96] Enzyme-linked immunosorbent assay (ELISA) has been used to quantify nonspecific *Moraxella bovis* antigens in tears and has revealed that IgA titers are higher than IgG titers.[97] A study on a small number of calves then suggested that both lacrimal (secretory IgA) and humoral (IgG) antibodies against *Moraxella bovis* whole-cell antigen conferred resistance against IBK, versus a humoral IgG antibody response alone.[98] It was concluded that serum antibodies against *Moraxella bovis* may account for a reduction in the length and severity of clinical signs associated with IBK. Unfortunately, none of these studies adequately controlled for total antibody isotypes present in serum or ocular secretions. In addition, crude *Moraxella bovis* antigen preparations were used in these assays.

Experimental Vaccination

Early studies that reported reduced *Moraxella bovis* infection rates and decreased occurrence of IBK after reexposure to *Moraxella bovis* indicated that vaccination against IBK might prevent disease.[50] Subsequent work showed that calves vaccinated intramuscularly with live *Moraxella bovis* had less severe IBK after challenge.[99] Formalin-killed *Moraxella bovis* was also reported to be as effective as live cultures in preventing experimentally induced IBK[100]; under field conditions, however, a formalin-killed autogenous bacterin was not efficacious.[101]

In an effort to identify other candidate *Moraxella bovis* vaccine antigens, researchers began to examine the use of component or subunit vaccines to prevent IBK. In early studies, *Moraxella bovis* pilin antigens were found to protect calves from homologous challenge.[102] Purified *Moraxella bovis* ribosomes were not protective.[103] Bacterin-containing pili plus corneal-degrading enzymes were protective in field trials, and protection was correlated with the corneal-degrading enzyme level in the vaccine.[104] In that study, however, the exact composition of corneal-degrading enzymes was not reported. In a later study, two commercial *Moraxella bovis* pilus-based vaccines were not protective for calves in a heterologous challenge model.[105] Although pilin is immunogenic, there is marked antigenic diversity between different pilus types because of the presence of two structural pilin genes and variability in the amino acid composition of the pilin molecule caused by inversions within pilin genes.[66,67,106,107] Limited antigenic cross-reactivity was reported between heterologous pili,[108,109] and emergence of novel pilus types can precipitate IBK outbreaks.[110] Such antigenic variability is believed to reduce the overall efficacy of pilus-based vaccines. Nevertheless, more recent work has demonstrated conserved epitopes across different pilus types,[111,112] suggesting a possible future role for conserved pilus antigens in IBK vaccines. In Australia, the prevalence of a limited number of pilus antigens in *Moraxella bovis* suggests that the use of vaccines containing certain broadly represented pilus types may help reduce losses associated with IBK.[113]

Unlike pili, the *Moraxella bovis* cytotoxin is more conserved across different *Moraxella bovis* strains. IBK-affected cattle were shown to develop systemic immune responses to cytotoxin,[114-117] and antihemolysin antibodies to one *Moraxella bovis* strain neutralized hemolysin from 33 different strains of *Moraxella bovis*.[117] A partly purified cytotoxin vaccine also protected calves against IBK after challenge with heterologous *Moraxella bovis*.[114] These reports suggest a role for a cytotoxin-based vaccine to prevent IBK from multiple *Moraxella bovis* strains, which could therefore be superior to traditional pilus-based vaccines.

Methods to partially purify the *Moraxella bovis* cytotoxin have been published,[118] and its efficacy in a vaccine to prevent IBK has been demonstrated.[119] Calves vaccinated with the recombinant carboxy terminus of *Moraxella bovis* cytotoxin had a lower cumulative proportion of ulcerated eyes compared with saline and adjuvant control calves.[120] Along with recombinant *Moraxella bovis* cytotoxin, other recombinant cytotoxin-based vaccines to prevent IBK have been investigated, including recombinant *Moraxella bovis* pilin plus cytotoxin,[121] recombinant *Moraxella bovoculi* cytotoxin,[122] and recombinant *Moraxella bovis* pilin-cytotoxin plus recombinant *Moraxella bovoculi* cytotoxin.[123] Trends for reduced IBK in calves vaccinated with recombinant *Moraxella bovis* cytotoxin suggest promise for such recombinant vaccines, but it is likely that additional protective antigens will need to be included in such vaccines to increase their efficacy against IBK.

Although the vast majority of IBK vaccine trials have evaluated vaccines administered by a parenteral route, the use of mucosal routes of vaccine delivery has been investigated. In one study, aerosol vaccination of cattle with uncharacterized *Moraxella bovis* antigens was reportedly effective against IBK.[124] Intranasal *Moraxella bovis* pilin vaccines stimulated pilin-specific IgA in ocular secretions; the presence of such antibodies, however, could not be correlated with prevention of *Moraxella bovis* ocular infection or the development of IBK lesions.[125] An experimental intranasal recombinant *Moraxella bovis* cytotoxin-based vaccine has been developed[126,127] that appears to reduce severity of corneal ulceration associated with IBK.[128]

VetBooks.ir

Diagnosis, Treatment, and Prevention Diagnosis of IBK is usually based on clinical signs (see Color Plate 39.23). Ocular swabs submitted for bacterial culture can assist practitioners in identifying a specific bacterial species involved in infection and developing more specific therapeutic recommendations based on antimicrobial sensitivity data. When collecting ocular samples for culture, swabbing the periphery of active corneal ulcers and avoiding the subconjunctival cul-de-sac can help reduce contaminant overgrowth and may enhance recovery of *Moraxella* spp. (K. Clothier, personal communication). To culture *Mycoplasma* from ocular swabs, special media and handling may be required, and it is a good idea to consult with your diagnostic laboratory prior to sample collection.

In a recent systematic review of published studies of IBK treatment with antibiotics, most treatments were considered to be effective in IBK, especially during posttreatment days 7 to 14.[129] *Moraxella bovis* is susceptible to penicillin administered subconjunctivally,[130] parenteral oxytetracycline,[131,132] florfenicol administered intramuscularly (two 20-mg/kg injections 48 hours apart) or subcutaneously (40 mg/kg once),[133,134] ceftiofur crystalline-free acid administered subcutaneously (6.6 mg ceftiofur equivalents/kg once) in the posterior aspect of the pinna,[36] and tulathromycin (2.5 mg/kg) administered subcutaneously.[135] The antibiotic sensitivities of 57 California *Moraxella bovoculi* field isolates have been reported and suggest that commonly used antibiotics for the treatment of IBK associated with *Moraxella bovis* should also be effective against *Moraxella bovoculi*.[136] Regional differences in antibiotic susceptibility among *Moraxella bovoculi* and *Moraxella bovis* exist[41,136,137] and underscore the importance of making informed treatment decisions based on antimicrobial susceptibility data. Nonantibiotic treatments of IBK have become increasingly important for purveyors of antibiotic-free cattle. A recent study found that hypochlorous acid spray can reduce pain, infection, and healing time of corneal lesions in calves experimentally infected with *Moraxella bovis*.[138]

Use of an NSAID, such as flunixin meglumine, can help relieve ocular pain and inflammation in severe cases. For individual animals in hospital settings, autologous patient serum applied topically may also assist in healing. Use of denim patches to cover an affected eye is controversial, but it is likely that such patches can relieve ocular pain associated with exposure to bright sunlight and may reduce vector spread of infectious ocular secretions in a herd setting. When applying patches, it is important to allow for ventral drainage; producers should also be advised to check under patches at least once or twice weekly to make sure an affected eye is not deteriorating. Other surgical ocular procedures such as third eyelid flaps may also be considered in severe cases.[139]

Vaccination against *Moraxella bovis* has traditionally been considered to be the foundation of a successful IBK prevention program. As with other multifactorial diseases, however, it is likely that the most effective IBK prevention program will require consideration of a variety of factors, including timing of vaccination (ideally within 4 to 6 weeks of anticipated cases); reducing risk factors (such as plant awns, foxtails, flies, and dust); supplementing trace minerals in deficient areas (e.g., copper and selenium); and reducing iatrogenic spread of potentially infectious material between animals (e.g., contaminated instruments, halters, and hands). To reduce fly populations, insecticide-impregnated ear tags placed on calves and topical insecticides with back and face rubbers are recommended. Clipping mature grasses before cattle are turned out may help minimize risks associated with direct mechanical corneal injury from plant awns. In areas where trace mineral deficiencies, especially of copper and selenium, are prevalent, attention to supplementation of these trace minerals is considered an important aspect of overall herd control and prevention. Neutrophils from copper-deficient calves had lower superoxide dismutase activity versus neutrophils from copper-supplemented calves, but no difference was observed in phagocytic and bactericidal activities of neutrophils from these groups.[140]

For vaccination against IBK, commercially available *Moraxella bovis* bacterins are available, but these are not universally effective. In 2017 a conditionally licensed *Moraxella bovoculi* vaccine was also released.[141] With the increase in reporting of *Moraxella bovoculi* from clinical samples following the initial report of that organism in 2007, producers and veterinarians have also sought to improve vaccination coverage by using autogenous *Moraxella bovoculi* (and/or *Moraxella bovis*) vaccines in prevention programs. While anecdotal reports that support or refute the use of *Moraxella bovis* and/or *Moraxella bovoculi* bacterins are easy to come across on discussion boards of cattle veterinarians, recently published studies investigating the efficacy of autogenous or commercial *Moraxella bovis* or autogenous *Moraxella bovoculi* vaccines reported these vaccines to be ineffective.[142-144] Some authors have also recommended the use of multivalent *Moraxella bovis*, *Moraxella bovoculi*, and *M. ovis* vaccines to prevent IBK.[145]

Immune-Mediated Ocular Diseases

Kathryn L. Wotman • Mary Elizabeth Lassaline • Mary Belle Glaze

This section describes immune-mediated ocular disease in large animals, beginning with a review of ocular immunology, followed by discussion of immune-mediated ocular diseases including immune-mediated keratitis, eosinophilic keratitis, and equine recurrent uveitis.

Except for the conjunctiva, the eye has no lymphatic drainage. Access of antigens to potentially reactive lymphoid tissue is also restricted by the avascularity of the cornea and the presence of selective blood-ocular barriers. As unlikely as immunologically mediated abnormalities may seem under these circumstances, immune-related inflammation remains a leading cause of blindness in the horse. Reports of immune-mediated ocular disease in ruminants are rare.

Ocular Immunology

The conjunctiva represents an extension of the mucosal immune system. A variety of immune cells can be found in the conjunctival epithelium and within the substantia propria, including intraepithelial CD8+ lymphocytes and mast cells, as well as aggregates of CD4+ T-helper (Th) cells and B lymphocytes, CD1+ dendritic cells, and macrophages.[1] The conjunctiva processes ocular surface antigens with the help of regional lymph nodes. Antigen presentation is likely preceded by local tissue damage and release of inflammatory mediators that recruit inflammatory cells to the site. Under the influence of cytokines like interferon (IFN)–α, tumor necrosis factor (TNF)–α, interleukin (IL)–1, and IL-12 released by local and recruited cells, tissue dendritic cells process and carry host and pathogen molecules to regional lymph nodes to activate CD4+ Th cells. Stimulated lymphocytes migrate back to the conjunctiva (T cells) and lacrimal gland (B cells), where they participate in cell-mediated reactions and local production of IgA and to a lesser degree IgG, respectively.[1-3]

Because the globe itself is without lymphatic drainage, intraocular antigens must be processed at a distant site. These antigens pass into the systemic circulation, preferentially stimulating the spleen as well as the bone marrow and other distant lymphoid organs. After 5 to 7 days, sensitized lymphocytes migrate back to the eye and localize within the uvea and limbal conjunctiva. As with those on the ocular surface, these immunologically competent cells are capable of antibody

production and can participate in cell-mediated reactions. Further exposure to the same antigen can provoke an anamnestic response, endowing the uveal and limbal tissues with behavior comparable to that of a regional lymph node.[4]

The intraocular immune response varies from that of a classic immune reaction, presumably to limit excessive inflammation within the eye. Anterior chamber–associated immune deviation (ACAID) is characterized by preferential stimulation of T suppressor cells that inhibit development of both CD4+ and B cells necessary in delayed-type hypersensitivity reactions and production of complement-fixing isotypes of antibody, respectively.[1,5] Cells in the uvea and corneal endothelium also express Fas ligand (FasL), which limits inflammation through apoptosis of activated leukocytes entering the eye.[1]

Each of the four major types of immunologic reactions occurs within the eye.[6] Type I (immediate) hypersensitivity is usually manifested as conjunctivitis, an acute local inflammatory reaction that follows IgE-mediated release of histamine, proinflammatory cytokines and chemotactic mediators from tissue mast cells, and synthesis of cytokines, leukotrienes, prostaglandins, thromboxane, platelet-activating factor (PAF), and kinins.[7] These mediators of the IgE–mast cell inflammatory pathway increase vascular permeability, constrict smooth muscle, dilate blood vessels, and activate leukocyte chemotaxis and the complement cascade. Allergic reactions of the lids and conjunctiva undoubtedly occur in all domestic species.

Type II (cytotoxic/cytolytic) hypersensitivity is an antibody-mediated cytolytic reaction in which the antigen is a cell surface or basement membrane component. Three basic effector pathways lead to cell destruction: (1) opsonization, with increased efficiency of phagocytic destruction; (2) antibody-dependent cellular cytotoxicity, inducing the release of enzymes capable of destroying cells and digesting basement membranes; and (3) lysis of immunoglobulin-bearing cells.[8] Conjunctival damage resulting from autoantibodies directed against epithelial basement membranes is described in equine ocular pemphigoid.

Type III (immune complex) hypersensitivity may share similar effector mechanisms with those described for cytolytic reactions, but antigen locale accounts for dissimilar disease manifestations in these two pathways.[7] This immune complex reaction may explain the clinical signs of pemphigus foliaceus[9] and the intraocular inflammation observed in horses after influenza vaccination or contact with infected animals.[10] Antibody-mediated cell destruction has also been implicated in uveitis.[6]

Type IV (cell-mediated/delayed) hypersensitivity is an important factor in contact allergy of the lids and conjunctiva and may also play a role in ocular toxoplasmosis. The tissue destruction associated with herpetic keratoconjunctivitis in the horse has been attributed to a cell-mediated response.[6] Increasing evidence implicates delayed hypersensitivity in the pathogenesis of equine recurrent uveitis.[11,12] The reaction requires an initial antigen exposure that results in sensitization of antigen-specific T lymphocytes. Reintroduction of antigen induces interleukin production, with subsequent T-cell activation, proliferation, and cytokine production. Once activated by cytokines, recruited leukocytes display increased activity to many antigens.[13]

Allergic Blepharoconjunctivitis

In humans, several forms of allergic conjunctivitis are mediated by IgE, and histamine (H_2) receptors have been discovered on the human ocular surface.[14] The ubiquitous presence of H_2 receptors in domestic animals implies a similar distribution[2] and the potential for immediate hypersensitivity reactions of the eyelids and conjunctiva.

Affected animals demonstrate acute swelling of the eyelids and conjunctiva, accompanied by serous ocular discharge, mild conjunctival hyperemia, and pruritus. If the stimulus persists, multiple subconjunctival aggregates of lymphocytes appear as tiny semitransparent follicles within the conjunctival cul-de-sac. In contrast to bacterial conjunctivitis, crusting and purulent discharge are not typical of allergic conjunctivitis.

Diagnosis of allergic blepharoconjunctivitis is often presumptive, based only on careful and thorough elimination of all other causes of eyelid and conjunctival swelling. Trauma, orbital inflammation, neoplasia, mechanical irritants, conjunctival parasites, and other infectious agents (both ocular and systemic) should be considered. In support of an allergic etiology, conjunctival cytology may reveal eosinophils in response to mast cell degranulation.

The offending allergen may be difficult to identify. Insect stings and toxic plants (e.g., nettle) are possible causes, as are molds and pollens. Allergic conjunctivitis was described in 17 of 187 cows pastured adjacent to a field of blossoming cotton.[15] A group of Angus-Holstein cattle demonstrated excessive lacrimation and ocular pruritus associated with familial allergic rhinitis. Several inhaled allergens have been incriminated, including capeweed, clover, dock, lucerne, pepper tree, paspalum, wattle, ryegrass, sorrel, and fungal extracts.[16] New feeds and certain drugs (e.g., oxytetracycline, penicillin, sulfonamides) may produce generalized urticaria, with accompanying eyelid and conjunctival edema.[17] Similar findings have been reported in cattle with milk allergy. Agents that directly induce mast cell degranulation through osmotic or charge interactions include hypertonic saline, NSAIDs, thiopental, opiates, neuromuscular blocking agents, mannitol, radiocontrast agents, polymyxin B, and vancomycin.[18] Occasionally, allergic conjunctivitis may be associated with a topical medication like neomycin. Clinical signs exacerbate with continued application and diminish when the medication is discontinued.

Ocular signs of hypersensitivity subside with removal of the offending allergen, but this is often impractical. Individual animals may be treated with a topical ophthalmic corticosteroid preparation, such as 0.05% dexamethasone ointment, to hasten resolution of swelling, redness, and discomfort. An agent with antiprostaglandin activity, such as oral or parenteral flunixin meglumine (Banamine®) at 0.5 mg/kg q12h, may be of benefit in the horse. Signs associated with urticaria respond to a decreasing regimen of oral prednisone or prednisolone, initiated at a dosage of 1 mg/kg once daily in the nonpregnant animal.[19] Single parenteral doses of short-acting corticosteroids, epinephrine, or antihistamines have also been used with reported success in food animals.[16]

Ocular Manifestations of Immune-Mediated Dermatoses

Pemphigus foliaceus is the most common of the autoimmune skin diseases described in horses. Lesions are often first noted on the head and lower extremities but spread to other parts of the body with time. Vesicles, bullae, pustules, erosions, and crusting are commonly noted on the skin and mucous membranes, including the eyelids and conjunctiva. Pemphigus foliaceus, bullous pemphigoid, and recently pemphigus vulgaris have been described in the horse.[20-25] Direct immunofluorescence reveals intercellular deposition of IgG and complement (C3) within the epidermis. Histopathology from biopsied lesions is reported to be more reliable, with findings of acantholytic cells with associated neutrophilic inflammation and intraepidermal pustules.[26] In humans, a Welsh pony stallion, and recently in the equine muzzle skin, circulating autoantibodies to epidermal transmembrane proteins desmoglein 3 (Dsg3) and desmoglein 1 (Dsg1) have also been demonstrated, which leads to acantholysis, vesicle formation, and epidermal clefting.[25-27]

Ocular manifestations of pemphigus may include ulceration or crusting of the eyelids, mucoid ocular discharge, and conjunctival hyperemia with erosions. Corneal ulceration may

VetBooks.ir

result from mechanical trauma to affected eyelids and conjunctiva or may be a primary manifestation of disease, as has been reported in humans and a Welsh pony stallion with pemphigus vulgaris.[24,28] Diagnosis is based on clinical findings, cytology, histopathology, and positive immunofluorescence of affected skin. See the discussion of immune-mediated dermatologic disorders for therapeutic recommendations and prognosis in Chapter 53.

Other immune-mediated diseases, such as systemic lupus erythematosus (SLE) or cutaneous lupus erythematosus (CLE), occur infrequently in the horse but can affect the face and eyelids.[29,30] In addition to skin lesions, vasculitis may manifest by hemorrhages in mucous membranes, including the conjunctiva.[20,29]

Eosinophilic Keratoconjunctivitis

Eosinophilic keratoconjunctivitis (EK) is an inflammatory condition of the cornea and/or conjunctiva that can present as unilateral or bilateral ocular disease in the horse. The seasonality typically noted with EK, with a predominance of cases in one study noted during June, July, and August, suggests an environmental etiology, but the specific cause of the disorder is unknown.[31] Studies have suggested contributing factors, including climate variables (temperature, rainfall amounts, humidity levels); sex predisposition, with females being overrepresented in one study; and possible causative effects of certain types of feed.[31] As the name suggests, eosinophils on conjunctival or corneal cytology are diagnostic.[31-35] Recurrence of signs is not uncommon in subsequent years.[35]

Clinical Signs

Clinical signs of mild to severe blepharospasm, epiphora, characteristic caseous mucoid ocular discharge, conjunctival hyperemia, and chemosis are typically noted at the onset of disease. Corneal lesions typically appear as raised white or pink corneal plaques. The plaques may be surrounded by corneal edema, with vascularization extending toward the ulcer and/or plaque from the limbus. Progression to corneal ulceration that extends from the limbus axially is often noted first in the ventromedial cornea quadrant underlying the third eyelid.[31-35]

Diagnosis

Diagnosis is based on clinical signs and cytologic findings of predominantly eosinophils on corneal or conjunctival scrapings and may include segmented neutrophils, mast cells, plasma cells, and lymphocytes. Differential diagnoses include mycotic and/or bacterial keratitis, onchocercal keratoconjunctivitis, neoplasia, foreign body granuloma, traumatic keratitis, squamous cell carcinoma, and calcific corneal degeneration.[36-39]

Pathophysiology

The eosinophilic inflammation found in the cornea and conjunctival surfaces suggests a type I or type IV allergic reaction. Although the inciting allergen has yet to be elucidated, parasites such as *Onchocerca* or *Habronema* spp. are often implicated, but neither has been specifically identified in a case of EK.[31,38] One proposed mechanism for EK is an allergic or inflammatory response to long-term use of ivermectin as an anthelmintic, triggering the complement cascade and cellular chemotaxis in patients with ocular onchocerciasis.[33] A recent case series of a Standardbred broodmare farm with 19 affected mares described environmental management with minimal medical intervention, including specifically fly control, as a key to decreasing incidence of disease, time to resolution of disease, and the number of recurring cases.[34] This suggests that an environmental allergen that may be associated with flies themselves or transferred by flies stimulates the type I allergic reaction. Similarities to vernal keratoconjunctivitis in humans suggest that eosinophil-granule major basic protein may play a significant role in the equine disease, inhibiting corneal epithelial migration and protein synthesis and promoting collagen degeneration.[40] Eosinophil-derived collagenase also has been reported to degrade type I collagen, the predominant collagen in the cornea.[32]

Treatment and Prognosis

Given the mechanism by which EK is believed to persist (i.e., a toxic effect of eosinophilic major basic protein on the corneal epithelium leading to chronic corneal ulceration), the mainstay of treatment of EK should be prophylactic against secondary infection of corneal ulcers, including topical antibiotic therapy with a broad-spectrum drug such as ofloxacin 0.3% solution or neomycin polymyxin B bacitracin ophthalmic ointment, and in areas where fungal keratitis is prevalent, a topical antifungal as well. Treatment with immunosuppressive drugs such as prednisolone acetate or cyclosporine, although historically used to treat EK in horses, is not recommended due to the risk of infection, as well as complications associated with chronic topical steroid use.[31,33,39] Eosinophilic keratoconjunctivitis lesions remodel with minimal corneal scarring, but mean duration of treatment in one series of patients was 64 days (range of 45 to 106 days).[33] Use of topical NSAID preparations may increase the severity of clinical signs of EK in horses because of potentiation of leukotrienes, the primary promoter of eosinophilic inflammation, and thus these drugs are not recommended to treat EK.[32] Medical management and prognosis were recently evaluated in horses diagnosed and treated in the Mid-Atlantic United States and revealed an average time to resolution of 3.7 months.[35] Treatment in some horses included use of tapering doses of systemic dexamethasone starting at a rate of 0.04 mg/kg PO for 1 day, 0.03 mg/kg for 2 days, and 0.02 mg/kg once daily for 3 to 5 days.[35] A group of horses evaluated in the study was also treated with oral cetirizine, an H_1 antagonist that may be useful in decreasing the migration and adherence of eosinophils.[35,41] Horses treated with oral corticosteroids had a shorter time to resolution when compared to horses that were not given oral corticosteroids. This finding, combined with the risk of secondary corneal infection with topical steroids, suggests that systemic rather than topical corticosteroids should be used to treat EK. Treatment with oral cetirizine did not decrease time to resolution of ocular disease, but during the follow-up period these horses were significantly less likely to have recurrence of disease (1 of 13 horses [8%] had recurrence with cetirizine compared to 8 of 14 [57%] without cetirizine).[35] Excision of the corneal plaques by superficial keratectomy appears to enhance healing, attributable to removal of the eosinophil-granule major basic protein.[32,33]

Immune-Mediated Keratitis

Nonulcerative Keratitis

Chronic nonulcerative corneal opacities that vary in color and depth within the cornea without overt signs of discomfort or intraocular inflammation have been described, and they can be a diagnostic and therapeutic challenge due to difficulties in obtaining diagnostic samples from a nonulcerated cornea.[42-45] In a report of 19 horses ages 5 to 11 years diagnosed with nonulcerative keratitis, 11 horses had clinical signs for more than 12 months before referral.[42] Nonulcerative keratitis in this report was described as immune-mediated keratitis (IMK), which comprised three distinct clinical entities classified as superficial, deep/mid-stromal, or endothelial, based on the location of the corneal pathology. *Superficial keratitis* was characterized by a superficial white to yellow infiltrate with diffuse mild to moderate vascularization. *Deep/mid-stromal* lesions were described as more diffuse, with denser cellular and vascular components. A deep cellular infiltrate with mild corneal vascularization and variable degrees of diffuse corneal

edema were typical of *endothelial keratitis.* Intraocular inflammation was not a feature of the disorder, regardless of lesion location.[42] Differential diagnoses include stromal abscess, EK, bullous keratopathy, subepithelial herpes keratitis, nonulcerative keratouveitis, and subepithelial keratomycosis (SEK). The infiltrates seen with SEK lie beneath the epithelial layers and may appear as punctate lesions or more geographic opacities that respond favorably to antifungal treatment.[43] Unlike what is typically noted in the equine eye with lesions due to fungal infections, SEK does not have significant blepharospasm or intraocular inflammation as a feature.[43]

An immune-mediated pathogenesis has been theorized for IMK, based on histopathologic characteristics and response to immunosuppressive therapy. Lesion appearance and description has varied, but typically within the United States, changes are described based on depth: superficial, deep/mid-stromal, and endothelial. Response to treatment and prognosis vary depending on the location of the infiltrate.[44] Regardless of lesion depth, histopathology reveals a predominantly lymphocytic-plasmacytic infiltrate, with stromal fibrosis or necrosis and vascularization. Three of five horses tested were seropositive for *Leptospira* spp. in one study.[42] Presumably the immune system is reacting to a self-antigen, antigens of a foreign protein, or an infectious agent within the cornea. Even though infectious agents have not been consistently documented in this particular disorder, immunologic cross-reaction with self-antigens (i.e., molecular mimicry) may occur, as described with leptospiral organisms or their DNA in the equine cornea.[46,47] Keratectomies from 10 horses diagnosed withsuperficial IMK showed a predominantly cell-mediated inflammation with cytotoxic and Th cells being the most common cells noted.[48] Local immunoglobulin was also identified in the corneal samples, but this could not be directly associated with a systemic humoral response, leaving the role of this arm of the immune system in question as to the pathogenesis of IMK.[48]

Owing to the frequency at which the abnormal equine cornea is afflicted with an infectious agent (bacterial, fungal, viral), diagnostic samples (cytology, culture) should be considered prior to starting therapy with immunosuppressive agents, particularly given that typically no independent confirmation of the diagnosis of IMK, nor microbiological samples ruling out an infectious etiology, are available when the diagnosis of IMK is made. Concurrent therapy with topical antibiotics and antifungals may be warranted. Lesions of superficial stromal keratitis have been described as able to be controlled with long-term topical dexamethasone and/or cyclosporine, with the goal of reducing frequency of the topical glucocorticoid.[42,45] Tacrolimus is a more potent immunosuppressive agent than cyclosporine and could potentially be used topically to aid in decreasing the activity of T cells, but its efficacy as a sole treatment for IMK has yet to be supported with empirical results.[44] Topical ophthalmic NSAIDs (e.g., diclofenac, bromfenac, flurbiprofen) may be a reasonable alternative to topical steroids, particularly for long-term use in some cases. A similar chronic therapeutic regimen may be used in superficial and mid-stromal keratitis[45]; however, topical corticosteroids may be less effective than cyclosporine in the deeper stromal disorder and, when used in combination long-term, may offer improvement in clinical signs.[42] Lesions in 4 of 11 horses with superficial stromal IMK were treated by superficial keratectomy and conjunctival grafting; lesions resolved in all four horses without the need for ongoing medication, suggesting that surgical removal of the inciting antigen in addition to providing a direct blood supply may stop the inflammatory process.[42] Keratectomy followed by a conjunctival graft was curative in one horse with mid-stromal IMK.[42] Response to anti-inflammatory agents varies in patients with endothelial keratitis, resulting from differences in pathogenesis. Only two of four horses were controlled with constant topical dexamethasone and cyclosporine in a retrospective study from Gilger and colleagues.[42] In contrast, horses with endothelial IMK in the United Kingdom usually respond rapidly to a glucocorticoid applied topically 2 to 3 times per day and complete resolution of clinical signs is possible.[43] In general, due to the deep location within the cornea, endothelial IMK carries a poor prognosis for response to treatment and often progresses.[44] Although retention of vision is likely in most cases of nonulcerative keratitis, long-term or even lifelong therapy is required to control the corneal disease.

The therapeutic goal for IMK is disease resolution, or at minimum slowing progression of the corneal changes and decreasing the number of medications and/or frequency of application needed to control the disease. A surgical alternative to a keratectomy of all or a portion of the affected cornea is implantation of an episcleral cyclosporine delivery device, which has shown a positive response in a report of 19 horses with IMK.[49] Keratitis was best controlled (i.e., horses were on no more than one medication) in 14 horses with either superficial IMK or endotheliitis, followed for about 6 months. However, in three horses diagnosed with mid-stromal IMK, keratitis was not controlled without additional medical and/or surgical therapy during the 5-month follow-up period after episcleral implant placement. The episcleral implant appears to reduce and in some cases may eliminate altogether the need for other topical medical therapy in horses that have previously responded to topical cyclosporine. Owners should be counseled that the implant likely lasts 1 to 1½ years and the procedure may have to repeated.[49]

Equine Recurrent Uveitis (Periodic Ophthalmia, "Moon Blindness")

Definition and Etiology Equine recurrent uveitis (ERU) is distinguished by a pattern of intraocular inflammation in which recurring episodes of acute uveitis are separated by periods of clinical quiescence. Inflammation of the iris and ciliary body (anterior uveitis or iridocyclitis) predominates in the early stages; repeated episodes damage the cornea, lens, vitreous, retina, and optic nerve. A more insidious form of ERU characterized by persistent low-grade inflammation occurs in the Appaloosa and Draft breeds of horse.

Equine recurrent uveitis is a leading cause of blindness in the horse and mule. Although the exact prevalence is unknown, estimates as high as 10% to 25% have been reported.[50,51] The financial impact on the equine industry is estimated at US$100 to $250 million annually as a result of the effects on performance and the costs of veterinary care.[52]

Despite extensive clinical research, the specific cause of ERU is still unknown. The pathogenesis is immune mediated, and characterization of T-lymphocyte populations in affected horses documents a delayed hypersensitivity reaction as the basic immunologic mechanism underlying the recurrent inflammatory episodes.[12] Identification of the triggering antigen has proved more elusive, suggesting that the disease does not result from persistence of or repeated exposure to a single antigen, but rather to a variety of circulating antigens or native ocular antigens. *L. interrogans* serovar *pomona* is the most frequently incriminated infectious pathogen,[51] but diversification of T-cell responses to a particular antigen or group of antigens over time may result in evolution of the immune response to encompass endogenous ocular self-antigens.[9,53]

Clinical Signs The ocular lesions observed in ERU vary depending on the severity and duration of the disease.[50,52,54,55] ERU can occur at any age, but the initial uveitis episode frequently occurs in horses 4 to 8 years of age. Acute episodes are painful, characterized by blepharospasm and excessive tearing. Affected eyes are often described by owners as "red"

VetBooks.ir

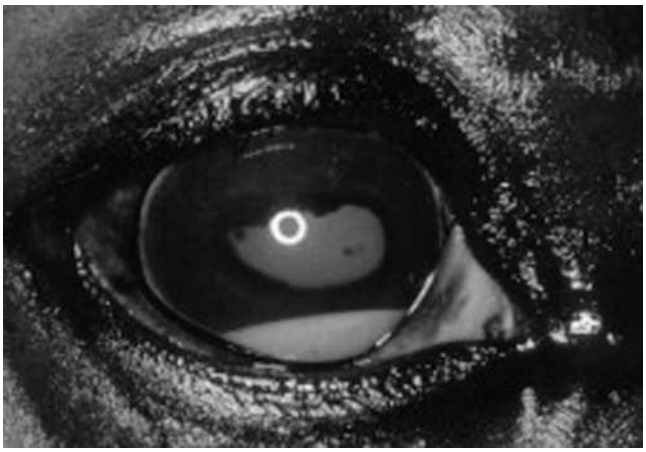

FIG. 39.15 Active uveitis characterized by hypopyon, pupillary irregularities secondary to posterior synechiae, pigment adherent to anterior lens capsule, and a dull tapetal reflection.

and/or "cloudy" because of changes in the conjunctiva, cornea, anterior chamber, or vitreous. Dilation of subconjunctival vessels near the limbus, termed *ciliary flush*, may intensify the generalized conjunctival hyperemia. As corneal endothelial function decreases, diffuse corneal edema gives the eye a bluish-white appearance. The cornea may also exhibit peripheral circumferential vascularization, cellular precipitates on its inner (endothelial) surface, and linear stromal opacities.

Increased uveal vessel permeability causes the aqueous humor to appear cloudy after influx of plasma proteins (flare), inflammatory cells (hypopyon), erythrocytes (hyphema), or fibrin into the anterior chamber (Fig. 39.15). The iris often appears edematous and lackluster or "muddy." A change in iris color may be noted in breeds with lightly colored eyes, changing from blue to yellow or green in response to uveal edema, vascular congestion, and cellular infiltration (see Color Plate 39.10). Prostaglandins and other inflammatory mediators cause pupillary constriction, favoring the formation of adhesions between the iris and lens (posterior synechiae) that distort the pupillary shape. Even without adhesions, the inflamed iris responds poorly to mydriatic agents. IOP is usually decreased because of diminished aqueous production by the inflamed ciliary body, but intermittent IOP elevations can occur.[56] The ciliary body can also deposit cellular exudates within the anterior vitreous, creating an opacity within the pupillary space that may be mistaken for cataract.

Active chorioretinitis causes dullness and loss of detail in affected tissues. Retinal detachment may follow choroidal exudation. Multifocal depigmented or hyperpigmented foci on either side of the optic disk are the sequelae of chorioretinitis ("chorioretinal scars"), commonly referred to as peripapillary "butterfly" lesions (Fig. 39.16).

Intraocular damage increases each time inflammation recurs. Permanent corneal opacity caused by edema results if the corneal endothelium is severely compromised. Chronic recurrent uveitis is characterized by widespread posterior synechiae, iris depigmentation or hyperpigmentation, and iris atrophy. The anterior chamber may appear shallow if aqueous trapped in the posterior chamber by extensive iris-to-lens adhesions causes the iris to balloon forward (iris bombé). Most lens changes occur weeks or months after uveitis begins. Abnormalities may range from pigment flecks on the anterior lens capsule (Fig. 39.17) to dense cataracts (see Color Plate 39.2). Lens luxation often follows degeneration of the lens zonules and vitreous. Retinal detachment may also follow vitreous liquefaction or may result from traction by fibrous tissue bands within the vitreous. If retinal degeneration is substantial, the optic disk atrophies (Fig. 39.18). Permanent hypotony is followed by shrinkage of the globe (phthisis bulbi). Conversely, chronic uveitis may result in secondary glaucoma (see Color Plate 39.8). The combination of these acute and chronic ocular lesions determines the degree of vision loss in the affected animal.

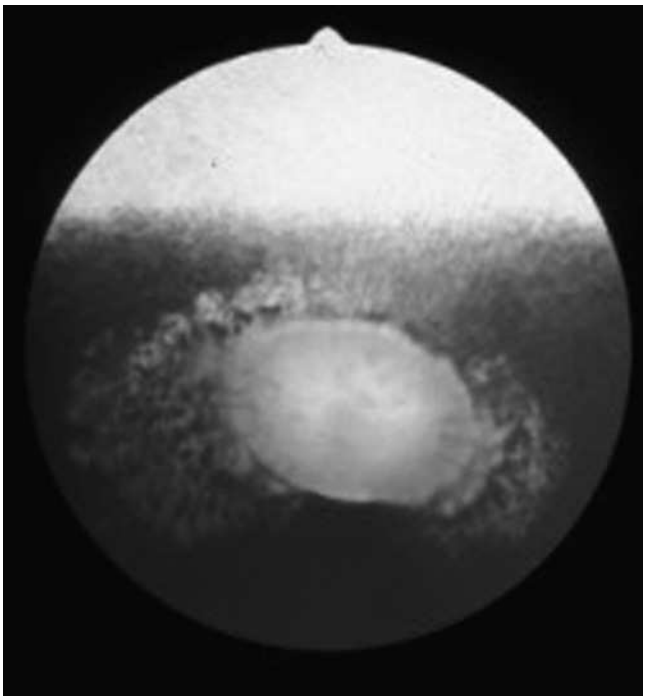

FIG. 39.16 Fundus adjacent to the optic disk takes on a mottled appearance as a result of pigment migration after previous chorioretinal inflammation from recurrent uveitis. Because of the shape, such lesions are sometimes referred to as "butterfly lesions."

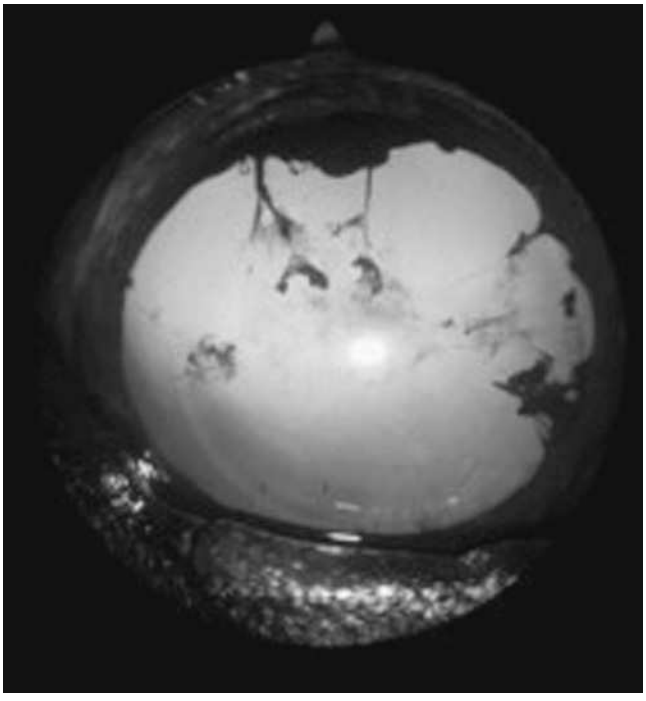

FIG. 39.17 Prior episodes of anterior uveitis are indicated by pigmented remnants on anterior lens capsule and thin adhesions of iris to lens (posterior synechiae). Pupil is pharmacologically dilated.

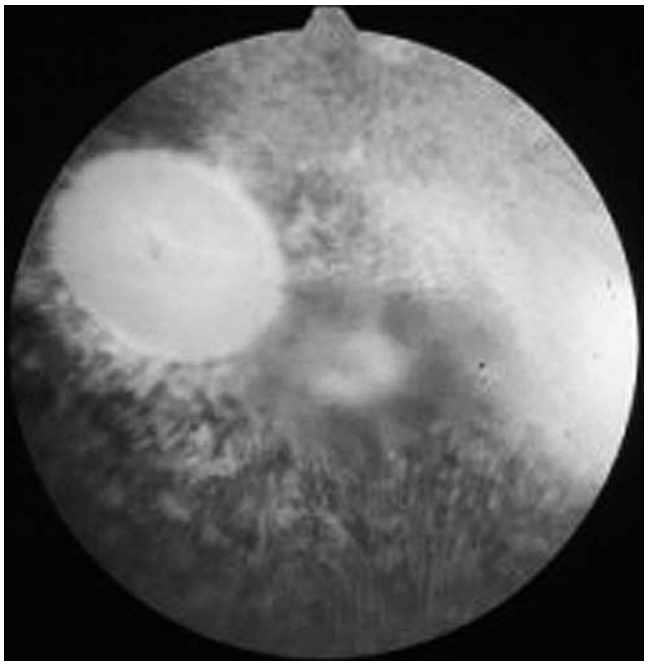

FIG. 39.18 Disk pallor and nontapetal depigmentation accompany an adjacent dark gray preretinal exudate in a horse with chronic active recurrent uveitis. This patient had poor vision.

Equine recurrent uveitis may be accompanied by transient and variable inflammation of the pineal gland.[57-60] Similar pineal inflammation has been reported in experimentally induced recurrent uveitis in laboratory animals.

Diagnosis

Not every case of uveitis in the horse qualifies as ERU. Diagnosis is based on a chronic, recurrent history of intraocular inflammation and the presence of characteristic ocular lesions. In cases where the history is unknown but recurrent disease is suspected, at least several of the following indicators of previous inflammation should be observed before a presumptive diagnosis of ERU is made: corneal edema or vascularization, synechiae (typically posterior), iris color change, corpora nigra atrophy or "polishing," lens capsular pigmentation, cataract, lens luxation or subluxation, vitreous opacities or traction bands, retinal detachment, or peripapillary scarring.[50] Other causes of a red and painful eye that can mimic acute ERU include conjunctivitis, corneal ulceration, corneal stromal abscessation, keratouveitis, and glaucoma.

Serologic testing of paired serum samples for *Leptospira* spp. or other infectious agents incriminated as causes of equine uveitis (see Table 39.2) may contribute to a diagnosis of ERU, but negative titers neither exclude the diagnosis nor eliminate leptospirosis as a contributing factor to the disease.[61,62] Acute leptospiral infections are characterized by high-titer seroreactivity to at least one serovar by the eighth day[63]; the titer usually falls with time, but seroreactivity may persist for many years. Some authors suggest that a leptospiral titer of 1:400 or higher is of clinical importance, particularly for *L. interrogans* serovar *pomona*.[50] A higher titer in the aqueous than in the serum is indicative of intraocular antibody production and further supports a leptospiral cause for the uveitis.[64] *Onchocerca* microfilariae may be identified in conjunctival biopsies, although detection of live microfilariae does not necessarily indicate a causal relationship for uveitis.[65,66] Equine leukocyte antigen (ELA) typing may help determine susceptibility to ERU.[67]

Histopathologic lesions of the ciliary body considered pathognomonic for ERU include the presence of a thick, noncellular hyaline membrane adherent to the nonpigmented epithelium (NPE) and the presence of eosinophilic linear cytoplasmic inclusion bodies within the NPE.[68,69] Clusters of lymphocytes and plasma cells also accumulate in the posterior iris, in the ciliary body, near the ora ciliaris retinae, within the choroid, and near the optic nerve head.[52,70] Dense bundles of fibrils coupled with necrotic cells and mononuclear inflammatory cell infiltrates characterize the changes within the vitreous.[71]

Pathophysiology

Breed has been established as a risk factor for ERU. In a 1988 retrospective study of more than 16,000 equine patients at Cornell University, researchers determined that the Appaloosa had a significantly higher risk of developing uveitis than Thoroughbreds.[72] A subsequent New York field study substantiated the breed predilection, concluding that the Appaloosa was 8.3 times more likely to develop uveitis than all other breeds combined.[51] Within the Appaloosa breed, those with overall light hair coats and focal dark spots are more likely to develop ERU than horses with a dark, basic coat pattern and a light "blanket" over the rump.[52] Trotters and warmbloods were overrepresented in a report of 130 ERU-affected horses in Germany.[73] Of 669 mares included in a serologic study of leptospirosis, significantly fewer positive titers were found in Thoroughbreds and Standardbreds.[74]

In humans, an immunogenetic predisposition to certain types of uveitis has been linked to the major histocompatibility complex (MHC), a closely aligned cluster of genes designated as the human leukocyte antigen (HLA) region located on a single chromosome.[75] Similar genetic loci occur in the horse, and the gene products are referred to as *equine leukocyte antigens* (ELAs). Products of these genes are glycoproteins found either on most nucleated cells (class I antigens) or restricted to accessory cells such as monocytes or macrophages (class II antigens). The immunoregulatory role of the MHC is especially important in discriminating self-peptides from those of nonself origin. Recent studies have shown an increased risk of uveitis linked with the MHC class I haplotype ELA-A9 in a group of German Warmblood horses.[67] As proposed in studies of human HLA-associated uveitis, cross-reactivity between self-antigens and ELA cell surface peptides could explain an inadvertent immunologic attack on normal cells.[76,77]

Experimental findings in ERU patients indicate that a T cell–mediated autoimmune mechanism underlies the recurrent episodes of inflammation. T lymphocytes are the predominant cell type to infiltrate the anterior uvea,[11,70] choroid,[78] and vitreous[79] of horses with ERU, and affected horses demonstrate cell-mediated immunity to retinal autoantigens and peptides.[79-81] B lymphocytes have been reported primarily in retinas from horses seroreactive for *L. interrogans* serovar *pomona*, suggesting that *Leptospira*-associated ocular inflammation may be a distinct subset of equine uveitis.[82] Equine ciliary body epithelium may play a role in recruitment and activation of leukocytes through expression of a chemotactic cytokine (chemokine),[83] although in the normal ocular microenvironment, ciliary body pigment epithelium suppresses T-cell activation by direct cell contact and the action of unidentified molecular mediators.[84] Analysis of messenger RNA (mRNA) collected from horses with uveitis demonstrates elevated levels of IL-2 and IFN-γ, indicating a Th1 response in the disease process.[85] In the absence of bacteria or viruses, this Th1 response by CD4+ uveal T lymphocytes suggests a delayed-type hypersensitivity (DTH) reaction to self-antigens or sequestered antigens in the uveal tract.[12,86] In contrast to the ocular T-lymphocyte population, systemic lymphocytes of ERU-affected horses do not exhibit a Th1 response.[12] The expression of a deviant MHC class II antigen on resident ocular cells (e.g., Muller, retinal pigment epithelial) suggests that aberrant immune regulation may also play a role in ERU.[11,87]

Aqueous and vitreous immunoglobulin levels have been used to characterize immunologic responses within ERU-affected

VetBooks.ir

eyes. Using radioimmunoassay, an early study found that aqueous levels of IgG, IgM, and IgA were 50% to 120% greater in diseased eyes than in normal controls, but that the IgG/albumin ratio suggested leakage of protein through an impaired blood-aqueous barrier rather than intraocular antibody synthesis.[88] Subsequent reports support local ocular antibody production but disagree on the dominant immunoglobulin in ERU-affected eyes. Wagner and colleagues[89] found selectively increased IgA levels in the vitreous of affected horses; Eule and colleagues[90] reported substantial IgM titers in 79.6% of intraocular samples from ERU-affected eyes. In contrast to the intraocular immunoglobulins, there are no significant differences in serum immunoglobulin concentrations between healthy and ERU-affected horses.[89,90]

Both exogenous and endogenous antigens have been proposed as stimuli for these basic immunologic responses. One theory suggests that an infectious agent such as *L. interrogans* (or another, perhaps noninfectious, exogenous antigen) causes the initial iridocyclitis. Sensitized immunocompetent cells enter the uvea during this first inflammatory episode, imparting immunologic memory that is specific for the inciting antigen. Subsequent challenge of these cells by the immunogen causes recurrence of the inflammatory reaction.[6,91] However, although some reports suggest persistent infection as the cause of ERU,[92] the premise of an infectious agent that exclusively induces and maintains ERU through a classic anamnestic response does not fully account for the disorder's clinical course and response to therapy.

The role of leptospiral infection in ERU has been studied extensively in recent years. All major serogroups of *L. interrogans* have been identified in the horse and implicated as initiating factors in ERU.[51,62,93-96] In a report of 130 ERU cases in Germany, 58.8% demonstrated positive serum titers to leptospirosis, an incidence 7 to 10 times higher than the control population.[73] Anti-*Leptospira* antibodies have been found in the serum, tears, aqueous humor, and vitreous of infected horses.[62,94,97-99] Wollanke and colleagues[99] reported positive serum antibody titers to *Leptospira* serovars in 25% (24 of 97) of normal-eyed horses and 22% (50 of 227) of ERU-affected horses, but only the ERU-affected animals had positive antibody titers in the vitreous.[99] Leptospiral organisms have been cultured from the aqueous and vitreous of ERU-affected horses.[61,62,96,100,101] However, in one study, *Leptospira* was not frequently detectable in fixed ocular tissues of horses affected with ERU when using traditional immunohistochemical and real-time PCR techniques.[102] In another study, there were no differences in bacterial DNA detection or in serum or aqueous humor anti-*Leptospira* antibody production between clinically normal horses, horses with ERU, and horses with ocular inflammation not associated with ERU in the southeastern United States.[103]

Horses seropositive to *L. interrogans* serovar *pomona* are reportedly 13.2 times more likely to have signs of uveitis than seronegative horses.[51] Ocular signs during the acute infection are usually subtle or absent, but overt ocular inflammation develops months to years later.[104-107] Risk factors for equine leptospirosis include rodent and wildlife exposure, proximity to ponds and rivers, a dense equine population on site, and increasing age.[74,108,109]

Although direct *Leptospira*-mediated injury to the eye cannot be ruled out in the pathogenesis of ERU, a growing body of evidence instead links leptospiral infection with autoimmune responses to ocular tissue components. Complement-binding anti-*Leptospira* antibodies capable of cross-reacting with equine corneal tissue and lens have been found in the tear film and aqueous humor of horses with leptospirosis.[97,98,110] These antibodies bind corneal epithelial cells, activating complement and initiating tissue damage, a mechanism replicated in tissue culture.[111] A leptospiral protein epitope that shares antigenic determinants with the equine cornea and lens has been found in bacterial homogenates,[46] and a DNA fragment of several serovars of *L. interrogans* was determined to encode a 90-kilodalton protein that cross-reacts with equine corneal proteins.[47,112] Novel leptospiral lipoproteins, identified as LruA and LruB, stimulate local intraocular IgA and IgG production and also cross-react with equine ciliary body, lens, and retina.[113] Immunohistopathologic examination has also demonstrated leptospiral cross-reactivity with iris pigment epithelium and retina from horses with ERU.[82,114] This antigenic relationship between *Leptospira* spp. and equine ocular tissues supports the concept of molecular mimicry as a contributing factor in ERU; exposure to exogenous antigens that share molecular structural sequences with equine self-antigens initiates an autoimmune response.[10]

Toxoplasmosis, brucellosis, salmonellosis, streptococcal hypersensitivity, *E. coli*, *R. equi*, borreliosis,[115,116] intestinal *Strongylus*, and onchocerciasis have also been implicated as causes of ERU, with no consistency in culture or serology results in affected horses.[51] Viruses suspected of a role in ERU include equine influenza virus, equine herpesvirus (EHV-1, EHV-4),[117] equine arteritis virus, and possibly equine infectious anemia.[50,52] More recent studies on vitreous and serum samples from affected horses question the role of *B. burgdorferi*, Borna disease virus, and *Toxoplasma* in ERU.[118,119]

Both humoral and cell-mediated hypersensitivities have been implicated in the lesions of ocular onchocerciasis. Immunoelectrophoretic studies have demonstrated an influx of IgG and complement (C3) into the tears of affected horses in response to larval death.[120] The resulting chemotaxis of mast cells, eosinophils, and lymphocytes perpetuates the inflammatory response and facilitates destruction of the parasite. Human patients with ocular onchocerciasis demonstrate conjunctival infiltration by CD3+ T lymphocytes and increased expression of class II MHC antigens in conjunctiva and iris,[121] as well as deficiencies in suppressor T-cell function that may interfere with the normal regulation of antibody function.[122]

In addition to the role of infectious agents in the pathogenesis of ERU, autoimmunity may occur when a normally sequestered component is exposed to lymphoid cells or when the antigenicity of a component increases as a result of a structural alteration.[123] Several endogenous ocular proteins, including retinal soluble antigen (S-antigen, or S-Ag), interphotoreceptor retinoid-binding protein (IRBP), cellular retinaldehyde-binding protein (CRALBP),[124] and uveal melanin-associated proteins, are known to induce uveitis in various animal models.[125-128] Clinical studies also implicate these potent autoantigens in the pathogenesis of some forms of human uveitis.[129-131] An autoimmune phenomenon in response to damaged uveal tissue has been proposed in the pathogenesis of ERU.[132] The isolation of S-Ag in the horse and the subsequent finding of anti-S antibodies in the aqueous humor and vitreous of horses with uveitis support the theory that this species is similarly capable of local production of antibodies to normally sequestered autoantigens.[79-81,133] Experimental uveitis with features similar to spontaneous ERU has also been induced in horses after injection of IRBP in complete Freund's adjuvant.[78] Autoantibodies to S-Ag and IRBP were found in 72% of vitreous specimens from horses with uveitis.[79] A more recent equine study concluded that retinal S-Ag is a weaker autoantigen than IRBP; T and B cells were activated after immunization with S-Ag, but only one in five horses developed uveitis or demonstrated inflammatory cell infiltration of the uveal tract.[134] Because the retina and NPE of the ciliary body originate from neuroectoderm, it is even possible that ciliary body damage may release an S-like antigen or another uveitogenic substance.[135] Evidence suggests that response to S-Ag is predominantly T-cell dependent.[136]

Verma and colleagues[113] proposed a link between leptospiral cross-reactivity and the release of other ocular autoantigens, based on strong IgG and IgA responses to LruA and LruB

lipoproteins in uveitic eyes but not in companion sera. The early phase of ERU may involve production of non–complement-fixing antibody and non-DTH T lymphocytes specific for LruA and LruB. The antibodies and cells react with the leptospiral lipoproteins, initiating a process that ultimately liberates IRBP and other ocular autoantigens.

The concept of "epitope spreading" has been offered as an explanation for the relapsing character of ERU.[137] The theory proposes that after destruction of an initial target, the immune response spreads from the first autoantigenic determinant to others not previously recognized by the immune system.[138-139] Active uveitis subsides as regulatory cells suppress the inflammation, recurring as the immune response shifts to an epitope of the same autoantigen (intramolecular spreading) or a completely different autoantigen (intermolecular spreading). A recent 22-month study of peripheral T-cell reactions in 8 horses with spontaneous ERU demonstrated intramolecular shifts to different S-Ag–derived (6 of 8) or IRBP-derived (5 of 8) epitopes and intermolecular shifts in all horses, spreading from IRBP-derived to S-Ag–derived peptides (5 of 8) or vice versa (3 of 8).[137] A shift of the immune reaction could be correlated to new uveitic episodes in 10 of 14 relapses that occurred during the observation period. The confounding factor in this theory is the shifts in immune response observed during quiescent stages, perhaps to minor uveitogenic epitopes that fail to result in overt inflammation or as part of an unknown regulatory or protective function of these T-cell clones.

Regardless of etiology, the ocular inflammatory process may attract other reactive lymphocytes to the eye. During primary uveitis, only 10% of the ocular immunoglobulin-secreting cells are specific for the inciting antigen. The remaining cells produce antibodies against immunogens that may not have entered the eye but with which the host had previous contact. As a consequence, the eye may develop recurrent inflammation after systemic exposure to any one of multiple antigens. It is therefore conceivable that subsequent episodes of uveitis may differ etiologically, creating a perplexing clinical picture.[140]

Treatment

ACTIVE INFLAMMATION. Reduction of intraocular inflammation is the primary therapeutic objective in acute uveitis. Preservation of vision depends on successful management at this stage, when sight-threatening sequelae are minimal. If a specific cause for the uveitis is identified, it is also targeted pharmacologically. In most cases, symptomatic therapy combines corticosteroids, NSAIDs, and mydriatic or cycloplegic agents. Nonspecific suppression of T-lymphocyte activation with cyclosporine implants[141] and surgical removal of T cells and, potentially, organisms from the eye by core vitrectomy[142] are recent innovations aimed at preventing recurrence of disease.

No therapy is indicated in nonpainful eyes with lesions of chronic end-stage uveitis. Those eyes that remain painful or do not respond to therapy are candidates for enucleation or evisceration, followed by silicone prosthesis implantation in the orbit or sclera, respectively.

CORTICOSTEROIDS. The severity of the uveitis dictates the routes and frequency of corticosteroid administration. Although topical therapy is most often used, efficacy is limited by the agents' relatively short contact time with the eye. Therefore topical corticosteroids must be applied three or four times daily, even in eyes with mild clinical signs. In more severe uveitis, topical preparations should be combined with other routes of therapy. A subpalpebral lavage system should be considered when frequent application is indicated (see the Bacterial Keratitis in Horses section earlier).

Either ophthalmic solution or ophthalmic ointment is acceptable for topical use in the horse. Prednisolone acetate 1% suspension has excellent intraocular penetration and is considered the drug of choice. Potent dexamethasone preparations, 0.1% solution or 0.05% ointment, are also effective. In general, therapy should be continued for at least 2 weeks after clinical signs have resolved. Ideally, that assessment includes an objective IOP measurement to ensure resolution of ciliary body inflammation and dysfunction.

The subconjunctival injection of a repository corticosteroid preparation is an alternative or supplement to frequent topical therapy. Triamcinolone acetonide 4% suspension is effective for 1 to 3 weeks when injected in a 0.5- to 1-mL volume (20 to 40 mg) beneath the superior bulbar conjunctiva. Subconjunctival injection of methylprednisolone acetate suspension has a comparable antiinflammatory effect but is more likely to cause granuloma formation at the injection site. Duration of effect of either drug depends on the severity of the uveitis. Nonocular use of either drug has been linked to equine laminitis.

Intravitreal triamcinolone injection may provide a safe and effective method to control ERU. In one study evaluating the ocular distribution and toxicity of intravitreal triamcinolone, six horses were injected intravitreally with 10, 20, or 40 mg of triamcinolone. There was no evidence of overt toxicity from intravitreal triamcinolone injection in normal horses, and a single intravitreal injection resulted in ocular levels of triamcinolone for 21 days. However, the risk for bacterial infection after intravitreal injection or anterior chamber aspiration in horses appears to be high.[143]

Evaluation of inflamed eyes should always include topical application of fluorescein dye to rule out ulcerative keratitis. This precaution is especially critical when considering the use of subconjunctival corticosteroids that deliver prolonged and irreversible effects. Topical and subconjunctival corticosteroids are contraindicated in the presence of corneal ulcers because they delay healing, potentiate the destructive effects of endogenous and microbial enzymes, and predispose the cornea to secondary infection.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS. Parenteral corticosteroids may be used when topical and subconjunctival agents are ineffective in controlling inflammation, but NSAIDs are usually preferred in such cases. Use of these antiprostaglandin agents counteracts an important mediator of intraocular inflammation, minimizing the role of parenteral steroids in uveitis therapy and the attendant risk of laminitis. Flunixin meglumine (Banamine) is the NSAID of choice for the eye, administered at a dose of 0.5 to 1.1 mg/kg PO or IV twice daily for 5 days, then 0.5 mg/kg PO once or twice daily. Oral phenylbutazone at 2.2 to 4.4 mg/kg once or twice daily can be used in cases of mild uveitis or in animals that require chronic low-dose oral prophylaxis for recurrent disease. Dosage requirements for aspirin make it less practical in acute cases, but prolonged oral administration of 15 mg/kg twice daily has been used to avert relapses. Frequency of NSAID administration should be reduced as clinical response occurs because antiprostaglandins have been linked to GI ulceration and renal dysfunction with high doses or chronic use.

Topical ophthalmic NSAIDs are generally more costly than corticosteroids and not as potent if used alone. However, an additive antiinflammatory effect can be seen when topical NSAIDs are used in conjunction with topical corticosteroids in horses with acute or resistant uveitis. Although generally considered a safe alternative to topical corticosteroids in the presence of corneal ulceration, topical NSAIDs have been implicated in the development of melting corneal ulcers in humans. Available generic solutions include 0.03% flurbiprofen sodium and ketorolac tromethamine 0.5%. Dosage frequency is empirical, with intervals ranging from every 6 to 12 hours.

MYDRIATIC/CYCLOPLEGIC AGENTS. A parasympatholytic mydriatic or cycloplegic agent must be used if equine

VetBooks.ir

uveitis is to be managed successfully. By dilating the pupil and decreasing iris-to-lens contact, the chance of posterior synechia formation—and secondary glaucoma—is reduced. An adequately dilated pupil may also promote vision during the acute episode. Ciliary spasm is relieved, making the horse more comfortable, and the iridociliary vessels return to a more normal state of permeability, with normalization of aqueous humor constituents.

Topical application of 1% atropine solution or ointment is indicated at a frequency no more than two to four times daily until the pupil dilates. The ultimate goal is to maintain mydriasis with the least frequent application possible, keeping in mind the resistance of the inflamed iris and ciliary body to the effects of atropine. Horses on an intensive parasympatholytic regimen should be strictly monitored for signs of reduced gut motility and colic because systemic effects can occur with frequent topical atropine administration.[144] Pupillary dilation may persist for 4 weeks or more after cessation of therapy.

If mydriasis is slow or incomplete, 10% phenylephrine hydrochloride solution may be used topically in conjunction with atropine.[145] Although a study in the horse suggests that phenylephrine is ineffective when combined with a parasympatholytic agent, investigators did not rule out a possible benefit if dosage or duration of therapy was increased.[146] However, frequently applied phenylephrine has been associated with the development of corneal ulcers, corneal endothelial toxicity with secondary corneal edema, and increased uveal exudation, so response to the drug should be monitored carefully.

ANTIBIOTICS. Because current evidence suggests an immune rather than an infectious basis for recurrent uveitis, antibiotics have assumed a secondary role in ERU management. Although topical antibiotic preparations may discourage opportunistic bacteria during intensive corticosteroid therapy, few will cross the intact cornea and reach therapeutic levels in the anterior chamber or uveal tract. In horses with positive leptospiral titers in serum or ocular fluids, systemic antibacterial therapy with oral doxycycline (10 to 20 mg/kg twice daily for 4 weeks) may minimize recurrences of uveitis.[147] In eyes with mechanical disruption of the blood-aqueous barrier, administration of enrofloxacin IV at 7.5 mg/kg q24h resulted in aqueous humor concentrations greater than the reported MIC for *L. pomona*, suggesting that enrofloxacin may be a good antibiotic choice for horses with leptospirosis-associated ERU.[148]

OTHER THERAPIES. A novel therapeutic approach to management of equine recurrent uveitis was recently described by Fischer and colleagues.[149] Intravitreal injection of 4 mg gentamicin showed promising results in controlling chronic recurrent and persistent uveitis in 71 horses. Complications of the injections were minimal; however, progression of cataract was noted in 5.4% of the horses. Intravitreal gentamicin injections can be performed under standing sedation and may be recommended in horses with uveitis that are refractory to antiinflammatory medication, since a lesser therapeutic effect of a suprachoroidal cyclosporine implant may be seen in such patients.[159]

If leptospiral infection has been well documented in a group of horses with uveitis, vaccination against the disease may be considered. However, although in one study vaccination significantly increased the interval to recurrence (median of 126 days) compared with nonvaccinated controls (median of 86 days), the practice failed to slow the progression of disease in a group of 41 ERU-affected horses.[150] Recently, Zoetis developed the Lepto EQ Innovator® vaccine for *L. pomona* to prevent leptospirosis infection and thereby reduce the risk of abortion, acute renal failure, and development of equine recurrent uveitis. It is not advisable to administer the vaccine to horses that have already developed uveitis, since the immune response to the vaccine could potentially exacerbate the uveitis.

An intracameral injection (25 µg/0.1 mL) of tPA can be used to accelerate fibrinolysis and clear hypopyon in the anterior chamber of horses with severe uveitis. However, tPA should be avoided in eyes with evidence of hemorrhage in the previous 48 hours.

The precise role of *Onchocerca* species in the pathogenesis of ERU is not yet determined, and considerable controversy exists regarding the necessity or benefit of microfilaricidal therapy in cases of ocular onchocerciasis (see the Ocular Parasites section later).

Acupuncture and homeopathic remedies such as poultices of chamomile and oral methylsulfonylmethane (MSM) have been used in the treatment of ERU, but the efficacy of these unconventional modalities is unknown.

Prevention of Disease Recurrence

CYCLOSPORINE. Cyclosporine A (CsA) is a noncytotoxic immunosuppressive drug that blocks transcription of IL-2 and decreases T-cell responsiveness during the initiation of inflammation.[151,152] These properties could block the nonspecific activation of T cells in recurrent episodes of ERU. With its poor inherent antiinflammatory properties, cyclosporine is likely to be more effective in preventing recurrences than treating active inflammation. Unfortunately, topical application of cyclosporine fails to achieve effective intraocular levels in horses and other species.[153] However, reports of sustained intraocular levels of CsA in ocular tissues[154,155] and resolution of clinical signs in experimental uveitis after implantation of a CsA-impregnated device into the vitreous of rabbit eyes[156] set the stage for implantation of a similar device into the anterior vitreous of horses with experimental uveitis. The CsA-containing implant significantly decreased the duration and severity of inflammation, cellular infiltration, tissue destruction, protein concentrations, and the level of transcription of proinflammatory cytokines in the experimental group.[141] The intravitreal device also prevented recurrences in 81% of horses with spontaneous ERU, but overall success was limited by complications from intraocular hemorrhage, cataract progression, and retinal detachment.[157] Because of significant risk of postoperative complications in the face of concurrent inflammation, a horse with active uveitis is not a suitable candidate for cyclosporine implantation until the inflammation is adequately controlled by conventional means.[52] Intravitreal delivery devices containing other immunosuppressive agents such as tacrolimus were also effective in suppressing inflammation after intravitreal implantation in rabbits with experimental uveitis.[158]

To minimize ocular morbidity related to implantation, ongoing studies of cyclosporine have focused on development and evaluation of a deep scleral delivery device.[159] Superficial episcleral implantation failed to achieve substantial intraocular levels of CsA or control inflammatory episodes in ERU-affected horses. Therefore the effects of a bioerodible implant infused with CsA and inserted into the suprachoroidal space beneath a partial-thickness scleral flap 1 cm posterior to the dorsolateral limbus were studied. High concentrations of CsA were achieved in the equine ciliary body, choroid, retina, and optic nerve. In horses with severe ERU, only 15% of eyes were blind a mean of 14.2 months after implantation. In contrast, 90% of patients with severe ERU treated conventionally are blind within 1 year.[52] In vitro studies of CsA also documented a direct inhibitory effect on *Leptospira* growth at concentrations achievable within the uveal tissues after deep scleral implantation.[159]

In one retrospective study evaluating the long-term efficacy, complications, and duration of effect of suprachoroidal CsA implants in horses with ERU, the long-term maintenance of vision of these horses was demonstrated. In 151 eyes of 133 horses from the United States and Europe that had CsA devices implanted with a mean and median follow-up time of 28.9 and 26.3 months (range of 13 to 85 months), respectively,

78.8% of eyes were considered visual at last follow-up.[160] The overall mean frequency of uveitis episodes after CsA implantation was 0.09 ± SD 0.08 episodes per month. Among implanted horses, the most common complications leading to vision loss at last follow-up were persistent uveitis episodes (54%), glaucoma (22%), mature cataracts (16%), and retinal detachment (6%). Persistent uveitis episodes tended to be the highest cause of vision loss in implanted horses with less than 24 months and more than 48 months of follow-up.[160]

CORE VITRECTOMY. Pars plana vitrectomy has been used to remove fibrin, inflammatory cells, and debris trapped in the vitreous and to improve vision and delay progression of clinical signs in affected horses.[12,161,162] Proponents theorize that removal of T cells or infectious organisms like *Leptospira* may reduce adverse interactions between the vitreous and the uveal tract, thereby reducing the recurrence of ERU. The technique appears more beneficial in European warmbloods with ERU than in Appaloosas with ERU in the United States. In one German study, recurrence of ERU was prevented in 85% (29 of 34) of treated eyes followed for 5 months to 5 years, but 45% of horses developed significant cataract formation.[142] A study of vitrectomy performed in the United States was also complicated by postoperative cataract formation and progressive loss of vision, despite some decrease in recurrence of uveitis.[163] More recent reports of vitrectomy performed on more than 1200 eyes at the University of Munich described no further recurrences of ERU in 98% of patients.[164] Cataract formation and retinal detachment were reportedly rare in this group of animals. Investigators explained their success on the basis of improved patient selection and surgical expertise.

Prognosis The long-term prognosis for vision in horses with recurrent uveitis is poor, although statistics of actual rates of vision loss are limited. Dwyer's 11-year study of ERU-affected horses reported that 56% of the 160 study animals experienced blindness in one or both eyes.[52] Appaloosas and *Leptospira*-seropositive horses were at increased risk for blindness over the course of the study. All seropositive Appaloosas (100%) lost vision in at least one eye; 50% were completely blind. Among seronegative Appaloosas, 72% lost vision in one or both eyes, and 29% were totally blind. Seropositive horses of other breeds lost vision in one or both eyes 51% of the time, with total blindness in only 17%. Seronegative non-Appaloosas had the best prognosis, with 34% losing vision in one or both eyes and total blindness in only 6%.

Bovine-Specific Ophthalmia

A recurrent uveitis of cattle has been described and compared to that of the horse.[165,166] As with ERU, its definitive etiology is unknown, although a viral infection was originally suggested. Clinical signs include conjunctival hyperemia, corneal edema and vascularization, inflammatory cells and hemorrhage within the anterior chamber and uveal tract, and retinal and choroidal edema and hemorrhage. The disorder is uncommon and does not share the notoriety of its equine counterpart. Therapy is directed at reducing inflammation, as described for the horse.

Ocular Parasites*

Anne J. Gemensky-Metzler

Parasites are an often overlooked cause of ocular disease in large animals. Ocular parasitic diseases can threaten vision and reduce the economic value of the animal through decreased function, decreased production, or both. The mechanisms by which parasites damage ocular tissues are extremely varied and range from direct tissue effects of aberrant parasite migration to complex immunopathologic responses to parasitic antigens. This section reviews the major ocular parasites of large animals, with reference to the ocular tissue of primary importance. Parasitic eyelid diseases are discussed in Chapter 40.

*Contributions to previous editions by Robert English and Mark Nasisse are acknowledged.

Corneal and Conjunctival Parasitism

Ocular Onchocerciasis

Ocular disease caused by *Onchocerca cervicalis* is the result of aberrant migration of noninfective microfilariae into the palpebral, conjunctival, and corneal tissues.[1] The larvae do not appear to have a predilection for ocular tissues; rather, the eye is involved as part of a generalized subcutaneous migration. Prevalence of onchocerciasis appears to vary with region of the world. One study concluded that 50% of horses with cutaneous onchocerciasis will have ocular involvement,[2] whereas in another study roughly 50% of horses evaluated had dermal microfilariae, and of those 40% had ocular abnormalities consistent with onchocerciasis.[3]

The pathogenesis of ocular onchocerciasis in horses remains unclear, but an immune-mediated inflammatory response to microfilariae has been implicated. In humans, keratoconjunctivitis and uveitis associated with local presence of *Onchocerca volvulus* microfilariae occur only after the microfilariae die. The endosymbiont *Wolbachia pipientis* bacteria are released, inducing an intense host immune response with subsequent dermal pruritus, uveitis, and often blindness.[4,5] Studies of the immunopathogenesis of *O. volvulus* in humans found that much less corneal inflammation occurred when larvae without *Wolbachia* were injected than when larvae containing *Wolbachia* organisms were injected.[6] Because *Onchocerca* microfilariae are commonly found in equine dermal and ocular tissues without evidence of inflammation, a similar mechanism may be involved in horses, but this has not been elucidated.

Ocular onchocerciasis occurs mostly in adult horses.[7] The older the host, the greater the exposure to the vector and the parasite, and presumably the greater the potential for ocular migration of microfilariae. Furthermore, increased immune sensitivity may occur with increased exposure to dead microfilariae.

Clinical Signs Conjunctivitis and keratoconjunctivitis concentrated at the temporal limbus are the most common manifestations of ocular onchocerciasis. Acutely, chemosis and hyperemia of the conjunctiva occur, accompanied by increased lacrimation and blepharospasm. Small, raised, white nodules (0.5 to 2 mm in diameter) in the limbal conjunctiva and similar-sized punctate, subepithelial corneal opacities are often present. Corneal lesions are often wedge shaped, with the base of the triangle at the limbus, and are characterized by varying degrees of superficial and deep neovascularization and cellular stromal infiltrates. Untreated, the lesions progressively enlarge, although the rate of progression and the severity of the disease vary. With chronicity, patches of depigmentation (vitiligo) occur in the perilimbal bulbar conjunctiva. Recurrent episodes of keratoconjunctivitis are common.[1]

Migration and subsequent death of microfilariae in the uveal tract result in uveal inflammation. Both the anterior and the posterior uveal tract may be involved. The clinical signs of *Onchocerca* uveitis include apparent photophobia, epiphora, miosis, aqueous flare, inflammatory cells in the anterior chamber, and globe hypotonicity. However, these signs are not specific for onchocerciasis, and other etiologies must be considered (see Table 39.2).

VetBooks.ir

Chorioretinitis reportedly is a manifestation of posterior segment involvement. Active lesions are recognized ophthalmoscopically by hyporeflective areas representing chorioretinal edema and inflammatory exudates, usually observed around the optic disk in a "butterfly-shaped" pattern.[1,3] However, aqueous and vitreous opacification often precludes accurate assessment of the fundus.

Diagnosis Characteristic clinical signs are highly suggestive of *Onchocerca* keratoconjunctivitis, but definitive diagnosis requires corneal or conjunctival biopsy. Conjunctival biopsy may be collected after topical anesthesia, whereas general anesthesia is typically necessary for partial-thickness lamellar keratectomies to obtain corneal biopsies. A single 3- to 5-mm biopsy is divided into two samples. One sample is placed on a slide with physiologic saline, minced, and warmed to 37° C (98.6° F) to stimulate larvae movement and therefore enhance their detection. Slides are examined repeatedly over the next hour for migrating microfilariae. The organisms are 200 to 240 mm long and 4 to 5 mm in diameter, with a short, unsheathed tail. The other half of the biopsy specimen is placed in 10% buffered neutral formalin for histopathologic examination.

The presence of microfilariae in ocular tissue does not substantiate a diagnosis of *Onchocerca* keratoconjunctivitis unless evidence of a host inflammatory response exists. The cytologic response is usually pleomorphic, with neutrophils, lymphocytes, plasma cells, and eosinophils present. Varying degrees of neovascularization, pigmentation, lamellar disorganization, collagen degeneration, and calcification are present in the cornea. The overlying epithelium becomes thickened and keratinized.[8,9] The presence of eosinophils in corneal and conjunctival scrapings is suggestive of a parasite etiology, but *Onchocerca* microfilariae are rarely found. Definitive diagnosis of *Onchocerca* as the cause of uveitis is rarely possible.

The differential diagnosis for equine keratoconjunctivitis also includes squamous cell carcinoma, habronemiasis, and bacterial or fungal corneal stromal abscesses. Because horses with ocular *Onchocerca* have a generalized larval migration, they may also have dermatitis, especially of the ventral thorax.

Treatment In humans chronically infected with *O. volvulus*, systemic ivermectin therapy decreases ocular microfilaria burden and improves associated ocular disease. Recently, concurrent treatment with doxycycline has been found to improve efficacy of ivermectin therapy by sterilizing adult female worms through elimination of the symbiotic *Wolbachia* bacteria.[10] Furthermore, by eliminating the *Wolbachia*, the subsequent dermal and ocular inflammatory response when microfilariae die is reduced.[6,11]

In horses, microfilaricide therapy has also been associated with increased ocular inflammation. Therefore treatment is directed at first controlling the inflammatory reaction with systemic antiinflammatory medications and then eliminating the parasite.[12] Corticosteroids have been the mainstay of this initial antiinflammatory treatment and may be given topically, subconjunctivally, or systemically, depending on the severity of the inflammation, extent of ocular and dermal involvement, and temperament of the horse. Like ivermectin, moxidectin has been found to be 100% effective in treatment of *Onchocerca* spp. microfilaria-associated dermatitis in horses, but without inducing the dermal edema seen after treatment with ivermectin.[13,14] Systemic NSAIDs or corticosteroids are indicated to treat and/or prevent severe uveitis with concurrent *Onchocerca* dermatitis and before larvicidal therapy. The antiprostaglandin activity of NSAIDs like phenylbutazone (2.2 to 4.4 mg/kg PO q12-24h) and flunixin meglumine (0.5 to 1.1 mg/kg PO, IM, or IV q12-24h) is beneficial, especially when corneal ulceration prohibits topical use of corticosteroids. Prednisolone, at an initial dose of 0.5 to 1 mg/kg PO daily for 5 to 7 days, is tapered as the inflammation decreases. Refractory cases have been treated for extended periods with 0.25 mg/kg PO prednisolone every other day.

When keratoconjunctivitis or uveitis is severe and/or refractory to systemic antiinflammatory treatment, topical application of corticosteroids may be indicated. However, since the corneal infiltrates associated with onchocerciasis are clinically indistinguishable from infectious organisms, extreme caution should be exercised when prescribing or administering topical or subconjunctival corticosteroids in horses. Because of superior solubility, 1% prednisolone acetate and 0.1% dexamethasone sodium phosphate are the preferred topical corticosteroid preparations. Depending on severity, lesions may be treated two to four times daily. Subconjunctival corticosteroids are also beneficial but must be used with caution if corneal ulceration exists. Therapy is tapered as the inflammation is controlled.

Elimination of the microfilariae is recommended once inflammation is controlled (see Chapter 40). Topical antibiotics are also recommended to prevent bacterial infection when corneal or conjunctival epithelial ulceration is present. With uveal involvement, topical mydriatic or cycloplegic agents such as atropine are indicated to relieve ciliary spasm and reduce the risk of posterior synechia formation.

Because systemic ivermectin or moxidectin therapy is not effective in killing adult worms, routine deworming is recommended to eliminate microfilariae and prevent maturation to adult worms.[15] Adult worms may survive in the nuchal ligament of horses for extended periods of time.[7]

Ocular Habronemiasis

Equine ocular habronemiasis occurs when larvae from *Habronema muscae*, *Habronema microstoma*, or *Draschia megastoma* are deposited on ocular tissues. Flies serving as intermediate hosts for *Habronema* are attracted to moist areas of the body for feeding. Periocular sites with ocular discharge, such as the conjunctiva at the medial canthus, and periocular wounds provide feeding sites. As the flies feed, *Habronema* larvae are deposited on the surface of ocular tissues, migrate into the tissues, and produce a local granulomatous hypersensitivity reaction. Equine habronemiasis occurs worldwide.

Clinical Signs Ocular lesions typically consist of raised, proliferative, nonhealing wounds present at the medial canthus or, less commonly, at other periocular sites. The lesions are friable and pruritic and bleed easily. Lesions often contain small (1 to 2 mm), yellow, caseated nodules ("sulfur granules"). Fistulous tracts and subdermal nodules may develop below the medial canthus.[16] Corneal neovascularization, edema, and ulceration can occur as a result of altered lid function and irritation to the cornea from contact with the rough, irregular surface of the lesion. Corneal involvement increases the degree of ocular pain and blepharospasm.

Habronemiasis lesions are typically seasonal, occurring in the warm summer months when the fly population increases. Certain horses appear to be predisposed to developing cutaneous and ocular habronemiasis, and recurrence may be seen in these animals each summer.

Diagnosis Demonstration of the larvae in the granulomatous lesions or fistulous tracts is diagnostic. Biopsies of the affected tissue are directly examined for *Habronema* larvae and may also be submitted for histopathologic examination. Cytologic examination of conjunctival scrapings reveals a mixed inflammatory response, with neutrophils, eosinophils, and macrophages predominating; however, *Habronema* larvae are usually not seen. The differential considerations for these lesions include squamous cell carcinoma, sarcoids, phycomycosis, onchocerciasis, foreign body reaction, eosinophilic granuloma,

and exuberant granulation tissue. Identification by PCR of *Habronema* DNA in the excised tissue may support a diagnosis of habronemiasis.[17]

Treatment Until recently, routine treatment was topical, with systemic therapy reserved for severe or refractory cases. However, oral ivermectin (0.2 mg/kg) and moxidectin (0.4 mg/kg) kill both adults and larvae in the stomach and have become the treatment of choice. Lesions begin to regress in 7 days and are usually healed by 1 to 5 weeks after treatment if reinfestation is prevented.[18,19] Other effective larvicides include trichlorfon and diethylcarbamazine (DEC).

Topical, intralesional, and systemic corticosteroids may be used to decrease the inflammatory response to the larvae, but with ivermectin or moxidectin larvicidal treatment, they may not be needed. Topical antibiotics are indicated, and topical corticosteroids should be avoided if corneal ulceration is present. Débridement and drainage of granulomatous areas and fistulous tracts may increase topical drug penetration, decrease inflammation, and prevent abscess formation. Fly control and prompt treatment of disorders causing ocular discharge or exposure of fresh tissue are important in preventing habronemiasis.

Ocular Thelaziasis

Thelazia spp. nematodes in the conjunctival sac of large animals are considered commensal but can cause clinical ocular disease. *Thelazia* spp. have a worldwide distribution, with *Thelazia lacrymalis* found more often in horses and *Thelazia gulosa*, *Thelazia rhodesii*, and *Thelazia skrjabini* found more frequently in cattle.[20] The infection rate for cattle and horses in the United States is estimated at 15% to 38%, with horses younger than 3 years of age affected more often than adult horses.[21-24] The complete life cycle of the parasite is unknown, but *Musca autumnalis* (face fly) and other *Musca* species serve as the intermediate host or vector.[25]

Clinical Signs Most horses and ruminants infested with *Thelazia* show no clinical signs. However, chronic conjunctivitis, follicular conjunctivitis, conjunctival cysts, and superficial keratitis can occur, especially in the summer months when flies are active.[26] The disease is often mild but can progress to cause corneal neovascularization, edema, and ulceration. Dacryocystitis due to parasite migration in the nasolacrimal system occurs and is more common in cattle than horses. Migration into the lacrimal gland and its ducts is seen and theoretically may lead to keratoconjunctivitis sicca.[24,27]

Diagnosis Direct visualization of the adult *Thelazia* worms in the conjunctival sac or flushing the nasolacrimal system is diagnostic. The parasites are motile unless a topical neuromuscular blocking agent is used. Adult *Thelazia* are 8 to 18 mm long and milky white, and their cuticle contains prominent transverse striations.

Treatment In cattle, both ivermectin and doramectin given systemically at 0.2 mg/kg are effective in eliminating *Thelazia*.[28-30] It is unclear whether ivermectin therapy is effective in eliminating *Thelazia* in horses, and efficacy of newer drugs such as doramectin or moxidectin has not been reported.[28] Alternatively, the parasites may be removed manually with saline flushes or forceps after topical anesthetic is administered, followed by topical ophthalmic organophosphate therapy.[30]

Ocular Elaeophoriasis

Elaeophoriasis, or "sore head," is a disease of sheep that is caused by the nematode *Elaeophora schneideri.* Adult *Elaeophora* organisms are found in the common carotid and internal maxillary arteries of deer, where microfilariae are produced and migrate into the capillaries of the face and head. Biting flies of the genera *Hybomitra* and *Tabanus* transmit the microfilariae to new hosts. The disease is most prevalent in the fall and winter in western parts of the United States where sheep are grazed at high altitudes. *Elaeophora* infections in deer are usually not associated with clinical signs. In small domestic ruminants, bighorn sheep, and elk, however, the migrating microfilariae can cause a hypersensitivity reaction in facial and ocular capillaries.[31,32]

Clinical Signs Migration of *Elaeophora* microfilariae in ocular capillaries leads to local inflammation. Although the uveal tract is affected more often, sheep with elaeophoriasis may develop chronic keratoconjunctivitis evidenced by epiphora, blepharospasm, conjunctival hyperemia, chemosis, and corneal opacities. Clinical signs of anterior uveitis caused by *Elaeophora* are nonspecific and include epiphora, blepharospasm, miosis, clouding of the anterior chamber, and cataract formation. Ophthalmoscopic changes indicative of chorioretinitis and optic neuritis are common and include retinal edema, pigment changes in the tapetal and nontapetal fundus, optic disk edema, and optic disk atrophy.[31]

Diagnosis and Treatment Diagnosis depends on demonstrating the microfilariae in skin or conjunctival biopsies. Treatment of heavily parasitized animals may cause death by occlusion of the carotid arteries with *Elaeophora* adults. Drugs used in treatment include piperazine (100 to 300 mg/kg PO), diethylcarbamazine (100 mg/kg PO), and stibophen (5 to 10 mg/kg IM for 3 to 10 days). The efficacy of ivermectin to treat *Elaeophora* is unknown. Symptomatic treatment of keratitis and uveitis is indicated.

Ocular Manifestations of Nasal Bots

Larvae of the arthropod *Oestrus ovis*, the sheep botfly, can aberrantly migrate up the nasolacrimal duct and enter the conjunctival sac, causing local inflammation. Conjunctival migration is accompanied by epiphora, conjunctival hyperemia, and chemosis. Finding the larvae within the conjunctival sac is diagnostic. Treatment consists of ivermectin, moxidectin, or eprinomectin.[33-35] Visible larvae may be mechanically removed. The nasal botfly *Gedoelstia hassleri* is reported to cause conjunctival and corneal lesions in horses in South Africa.

Ocular Manifestations of Trypanosomiasis and Piroplasmosis

Many species of the protozoal blood parasite *Trypanosoma* can infect horses and ruminants, causing fever, anemia, weight loss, edema of the ventral abdomen and limbs, sudden death, and ocular signs such as conjunctival edema, hyperemia, and petechiation.[36] Sheep and goats experimentally infected with *Trypanosoma brucei* can develop keratoconjunctivitis and panuveitis, including chorioretinitis and optic neuritis.[37,38] Demonstration of the organism in blood smears is diagnostic. Quinapyramine sulfate and chloride has been effective in treating many horses, but persistent or recurrent infections have raised concern about possible drug resistance.[36,39]

Other blood protozoans, including *Babesia* and *Theileria*, can also cause conjunctival edema, petechiation, icterus, swollen eyelids, and blood-stained tears.

Uveal and Retinal Parasitism

Onchocerciasis, Elaeophoriasis, and Trypanosomiasis

Onchocerca cervicalis causes equine parasitic uveitis and chorioretinitis, and *Elaeophora ovis* and *Trypanosoma brucei* cause uveitis in sheep. Ocular manifestations of these diseases are discussed in the Corneal and Conjunctival Parasitism section earlier.

VetBooks.ir

Toxoplasma Iridocyclitis and Retinitis

Although seropositivity for *Toxoplasma gondii* is common in horses and donkeys in some countries, associated clinical disease is uncommon and has not been reported in cattle or horses.[40] However, the intracellular protozoan parasite *Toxoplasma gondii* can cause ocular disease in small ruminants.[41] Invasion and replication in the retina and uveal tract lead to retinitis, chorioretinitis, and anterior uveitis.

Clinical Signs The most common ocular findings with ocular toxoplasmosis are iridocyclitis and retinitis.[40,41] Retinitis is the primary posterior segment lesion, with secondary involvement of the choroid. Retinal degeneration, clumping of pigment in the retinal pigment epithelium and choroid, and optic disk avascularity are seen ophthalmoscopically; however, these lesions are not pathognomonic for toxoplasmosis. Orbital pain and swelling may result from parasitic invasion of extraocular muscles and orbital fat.

Diagnosis and Treatment Toxoplasmosis is most commonly diagnosed by one of a variety of serologic tests for IgG and IgM antibodies or by histopathologic identification through biopsy or necropsy. Antibodies for IgG take more time to develop and may persist for years after an active infection has resolved while IgM antibodies rise and disappear sooner after recovery. Thus, titers for both IgG and IgM should be evaluated and a paired sample taken 2 to 4 weeks later may differentiate past infection or exposure (lower titers with either a decrease or no change) from active infection (a 4-16-fold increase or sustained high titers).[40] Toxoplasmosis may be treated using sulfadiazine and pyrimethamine. Treatment may be beneficial during active infection when organisms are multiplying but is rarely effective in completely eliminating infection or clearing a subclinical infection because of the tissue encystment of organisms.[40]

Miscellaneous Intraocular Parasites

The most common intraocular parasite in horses and donkeys is *Setaria*, with *Setaria digitata* found more frequently within the eyes of horses than *Setaria equina*. Ocular infestation is presumed to result from aberrant migration of the larval stage. Although *Setaria* causes minimal inflammation in the peritoneal cavity, it can cause severe intraocular inflammation, corneal edema and blindness.[42] Diagnosis is made by visualizing the parasite in the anterior chamber and detecting microfilaria in the blood. Treatment involves symptomatic antiinflammatory and ivermectin therapy,[43,44] but surgical removal of larvae from the anterior chamber has also been reported.[45]

Other filarides found free within the anterior chamber of horses' eyes include *Dirofilaria immitis* and *O. cervicalis*.[2] Diagnosis and treatment are the same as for *Setaria*. Severe endophthalmitis resulting from intraocular infection with the free-living nematode *Halicephalobus* has been reported in a horse.[46] The ocular disease was accompanied by a fatal encephalopathy. Diagnosis was based on finding the parasite during microscopic examination of intraocular tissues.

The canine cestodes *Echinococcus granulosus* and *Echinococcus multilocularis* may form intraocular hydatid cysts in humans, but in horses and ruminants subclinical orbital involvement is more common.[47] There is no medical treatment, and surgical removal is often impossible. Diagnosis is made on histopathologic examination of affected tissues.

Coenurus cerebralis, the intermediate form of *Taenia multiceps* and *Taenia serialis*, can develop in the CNS of sheep, goats, and rarely cattle, causing a disease known as "sturdy" or "gid." Besides having abnormal gait and mentation, affected animals are often centrally blind.[48] No treatment exists, and the disease is typically fatal.

Ocular Neoplasia*

Caroline M. Betbeze • Meredith L. Voyles

A wide variety of tumor types may involve the ocular or periocular tissues of food animals and horses. Except for the most common neoplasms, limited information is available regarding treatment modalities, drug dosages, overall prognosis, and prevention or control. The tendency has been to adapt information and methods used in other areas of medicine for use in large animals. Table 39.4 lists potential presenting signs and corresponding ocular neoplastic conditions or related differential diagnoses for horses, cattle, sheep, and goats. Table 39.5 categorizes ocular neoplasms that have been reported in the literature for each of these species. The greatest amount of information pertains to the horse.

Despite the variety of primary and secondary neoplasms affecting the ocular and periocular tissues, most tumors produce similar effects on the eye, with tissue distortion and loss of function being the initial concerns. Strategic therapy and management goals may vary from curative or palliative (e.g., eliminating discomfort by enucleation) for individuals to elimination of the problem (e.g., culling from the herd) for a population. Tumor treatment options are often similar for neoplasms involving a particular ocular region or location. When designing a management plan, however, the specific histologic tumor type is important in determining prognosis. Classification of a tumor as "benign" versus "malignant" or "localized" (e.g., equine sarcoid) versus "systemic" (e.g., lymphosarcoma) greatly influences treatment options and management approaches. The following discussion addresses the major tumors of concern in large animals and briefly surveys miscellaneous tumors that have been associated with ocular signs.

Bovine Ocular Squamous Cell Carcinoma

Definition and Etiology Bovine ocular squamous cell carcinoma (OSCC), commonly called "cancer eye," represents the most economically important neoplasm of cattle. It is the most common tumor affecting cattle in North America, and according to estimates from federally inspected abattoirs in the United States, 12.5% of all bovine carcass condemnations were caused by OSCC.[1] The economic impact includes carcass condemnations, production losses, treatment expenditures, and management costs.

OSCC arises from the epithelial surfaces of the conjunctiva (corneoscleral junction, nictitating membrane, and palpebra) or cornea. The etiology is probably multifactorial, with genetic, environmental, and viral factors being proved or suspected.[1-3] In particular, increasing levels of solar irradiation and decreasing amounts of circumocular pigmentation are linked to an increased prevalence of OSCC.[4,5]

Clinical Signs and Differential Diagnoses The gross appearance depends not only on the anatomic tumor site (because this determines the overall interaction between epithelium and underlying connective tissue elements) but also on the stage of malignancy. In general, premalignant squamous cell tumors are small, white, superficial, and elevated hyperplastic plaques or papilloma-like structures with verrucous surfaces (Fig. 39.19). In contrast, malignant tumors are

*Contributions to previous editions by Steven M. Roberts are acknowledged.

more irregular, nodular, pink, erosive, and invasive in nature (Fig. 39.20). Malignant tumors with accompanying necrosis often have a characteristic foul odor (see Fig. 39.20). Squamous cell carcinomas that invade the orbit may become extensive and eventually invade bone. Often the gross appearance allows a diagnosis to be established, but at times histology is necessary to differentiate among benign tumors, carcinoma in situ, and invasive SCC. Bovine OSCC typically involves (in decreasing order of frequency) the lateral limbus, eyelid margins (especially the lower), nictitating membrane, and medial canthal regions.[1,2] (See Color Plate 39.12) Clinical signs resulting from metastatic lesions are not common, although regional lymph nodes may become infiltrated with neoplastic cells.

Despite the characteristic appearance of lesions, differential considerations include conjunctival follicular hyperplasia, dermoid, fibroma, fibrosarcoma, granulation tissue, infectious bovine keratoconjunctivitis, lymphosarcoma, and mastocytoma (see Tables 39.4 and 39.5).

Pathophysiology The tumor in all species develops through a series of premalignant stages (i.e., hyperplastic plaques or epidermal plaques and papillomas) to progress over months and years to a carcinoma in situ and finally to an invasive squamous cell carcinoma. Neoplastic lesions may arise without notable precursor stages. It is unlikely that tumors arise in the cornea unless previous vascularization has occurred.[6] Spontaneous regression of 30% to 50% of bovine precancerous lesions may occur,[1] and in rare cases early OSCC may regress spontaneously. Tumors arising at the limbus are confined by the dense

and poorly vascularized sclera and cornea, thus hindering metastasis to extraocular sites. Nictitating membrane tumors extend to the base of the membrane and cartilage more rapidly, with spread into the orbit and surrounding bones occurring much sooner than with tumors involving the globe. Although metastasis may eventually occur, extensive extraocular spread is limited in cattle by the practice of sending most affected animals to slaughter.

Epidemiology

Although OSCC has been reported in a wide variety of cattle breeds, the Hereford breed (either purebred or crossbred) is most often diagnosed with this tumor as a result of the common use of this breed as a range animal and the strong genetic trait for a white face. Thus selective breeding for partially to fully pigmented periocular skin greatly reduces the occurrence of this tumor.[1] The tumor is more common in older cattle, with the peak age prevalence being 7 to 8 years. Exposure to increasing levels of actinic radiation raises the prevalence of bovine OSCC.[4] The prevalence of ocular squamous cell tumors, including nonmalignant tumors, involving Hereford herds in regions with abundant sunlight can range from 20% to 40%. Research performed in cattle herds suggests that a high plane of nutrition or a lower-than-normal body weight in cows for the first 2 years acts to increase the prevalence.[1] The possibility that bovine OSCC may be induced by viruses (e.g., papillomavirus) warrants further research.

Clinical Pathology and Necropsy Findings

Definitive diagnosis is achieved by cytologic samples obtained with a spatula after topical anesthesia[1] or specimens excised for biopsy and fixed in formalin. Benign lesions typically contain superficial anucleated, keratinized squamous cells and deeper epithelial cells with enlarged nuclei and coarse chromatin clumping. Biopsies of these lesions show that the basal layer or basement membrane has not been invaded. Malignant OSCC lesions are composed of pleomorphic cells with bizarre shapes, large hyperchromatic nuclei containing large clumps of chromatin, and prominent nucleoli. Invasion across the basement membrane is noted, and keratin-pearl formation or marked anaplasia is usually present.[6] In the event of regional lymphatic involvement, fine-needle aspiration or preferably a biopsy may demonstrate neoplastic infiltration.

Depending on the extent of tumor invasion, gross changes may be noted that involve the globe, conjunctiva and nictitating membrane, orbit, bones of the orbit, sinuses, and regional lymph nodes. In rare instances, metastasis to thoracic and abdominal organs can occur.

Treatment and Prognosis

Numerous modalities are available, and applications depend on availability of instrumentation, location and extent of the tumor, and value and intended function of the animal. Choices include radiofrequency hyperthermia (RDM Hypertherm [RDM International, Phoenix, Ariz.]), cryonecrosis, intralesional injection of biologic response modifiers (BRMs) such as allogeneic OSCC extract, mycobacterial cell wall fraction (Normagen [Fort Dodge Laboratories, Fort Dodge, Iowa]), *Propionibacterium acnes* (ImmunoRegulin [ImmunoVet, Tampa, Fla.]), intralesional chemotherapy with cisplatin (Platinol [Bristol-Meyers, Wallingford, Conn.]) with or without initial debulking,[7,8] radiotherapy (cesium-137, cobalt-60, gold-198, iridium, strontium-90), and surgical removal (local excision, enucleation, and exenteration with or without salivary gland and lymph node resection). Intralesional use of cisplatin (1 mg/cm^3 of tumor volume) is highly effective, but multiple injections are necessary (four times at 2- to 3-week intervals). Handling of the drug and animal after treatment must adhere to U.S. Occupational Safety and Health Administration (OSHA) guidelines,[9] and animals must not be used for food consumption. Appropriate precautions should be followed with off-label use of cytotoxic drugs. Surgical debulking with adjunctive cryonecrosis or radiofrequency hyperthermia is an effective and affordable treatment modality. Cryonecrosis is achieved with liquid nitrogen, using a probe or spray delivery system to freeze the tissues to –30° C (–22° F) twice, with complete thawing between freeze cycles. Cryotherapy is not

recommended for lesions larger than 0.5 cm in diameter. Massive tissue necrosis and loss of the eyelid can be seen if the lesion is too large.

Radiofrequency hyperthermia is performed with piercing or surface probes to heat the tissues to 50° C (122° F) for 30 seconds.

Because recurrence rates range between 30.4% and 42.4%,[3,10] owner compliance to return the animal for follow-up treatment is a significant determinant in overall survival. Financial constraints are the most common reason for cessation of treatment. Many animals that die as a consequence of OSCC are euthanized at the owner's request. The overall prognosis is determined by the degree of neoplastic involvement of normal tissue, but a guarded prognosis is usually warranted. If treatment is undertaken, intervention should begin at the earliest stages of tumor development. In animals destined for slaughter, the guidelines for condemnation of bovine carcasses affected with OSCC shown in part A of Box 39.1 should be considered.

Prevention and Control In cattle, factors such as genetics, UV light, and environmental factors (e.g., wind, dust) are known to be involved in OSCC. Ocular viral infection may also be contributory. If possible, affected animals should be culled as soon as possible because most production situations preclude environmental factor modification.

Equine Ocular Squamous Cell Carcinoma

Definition and Etiology Equine OSCC is the most prevalent equine ocular neoplasm (followed by equine sarcoid) and typically occurs in horses with nonpigmented eyelids.[3,11] Horses with two or more coat colors (Appaloosa, Quarter Horse, Paint) may have minimal ocular and periocular pigmentation. These breeds are at an increased risk of developing equine SCC. Thoroughbreds, Haflingers, and Draft horses (Clydesdale, Belgian, Shire) also have increased prevalence of SCC, even with adequate ocular pigmentation.[12] The amount of perilimbal and nictitating membrane pigmentation represents another important causal factor in cattle and horses that has received little attention but should be considered on prepurchase and health examinations (see Chapters 1 and 2).

Clinical Signs and Differential Diagnoses Similar tissues are involved in horses as in cattle. These sites include palpebra (eyelids), limbus (corneoscleral junction), conjunctiva, nictitating membrane, and cornea (Color Plate 39.24). Some reports suggest that the nictitating membrane is more frequently involved than the corneoscleral junction.[3,11] In addition to the traditional sites, horses also are affected by corneal stromal invasive SCC. The tumor in this location appears as a nonraised mass lesion that grows directly deep into the corneal stroma (see Color Plate 39.13). The smooth appearance may lead to clinical underestimation of the greater underlying tumor invasion.[13,14]

Differential considerations for OSCC in the horse include adenocarcinoma, adenoma, angiosarcoma, basal cell tumor, conjunctival follicular hyperplasia, dermoid, fibroma, fibrosarcoma, granulation tissue, habronemiasis, lymphosarcoma, mastocytoma, plasma cell tumors, sarcoid, and schwannoma (see Tables 39.4 and 39.5).

Pathophysiology Horses demonstrate multiple tumor locations and local invasion in up to 50% of cases.[6,10] The tumor has high rates of local infiltration and recurrence.[15] Metastasis beyond extraocular sites is rare in horses but has recently been reported in local tissues, such as nasolacrimal duct, regional lymph nodes or maxillary sinus, and more distant sites, such as mediastinum. These metastases occurred without evidence of local recurrence in a delayed fashion, 18 to 42 months following initial therapy.[16,17]

Epidemiology Equine OSCC in North America demonstrates an increased prevalence with increasing longitude (°W), altitude, and mean solar irradiation.[11] Breeds with a greater risk of developing OSCC include Draft breeds, especially the Belgian (odds ratio [OR] = 21.7), Appaloosa (OR = 7.9), Paint and Pinto (OR = 4.5), and grade horses (OR = 3.1). Coat colors showing an increased risk include white (OR = 26.7), cremello/palomino (OR = 13.7), gray (OR = 6.7), red/white and strawberry/white (OR = 4.7), buckskin (OR = 4.4), and chestnut/sorrel (OR = 3.8).[11] Prevalence increases with age, with the mean age of affected individuals between 9 and 13 years. Bilateral involvement may be as high as 20%.[3,10]

Treatment and Prognosis Surgical excision with adjunctive therapy as described in the Bovine Ocular Squamous Cell Carcinoma section earlier is used in horses. Surgical resection is most effective early in the disease process when clean margins can be obtained. Excision of corneolimbal or corneal SCC via keratectomy followed by adjunctive therapy, such as radiation therapy or cryotherapy, is recommended over surgical excision alone because it is difficult to obtain clean margins in the periocular area.[13,15] The most common adjunctive therapies for periocular SCC in horses include cryonecrosis (liquid nitrogen), radiofrequency hyperthermia, intralesional cisplatin or carboplatin, and radiation therapy (cesium-137, cobalt-60, gold-198, strontium-90, iridium).[18] Currently the carbon dioxide (CO_2) laser is being used for both surgical removal and adjunctive therapy following removal.[19] Photodynamic therapy (PDT) can be used alone or in conjunction with surgical removal.[20] Recurrence rates were lower following surgical debulking and PDT in comparison to surgical debulking and cryotherapy in a study by Giuliano and colleagues; however, the photosensitizer verteporfin has become increasingly difficult to obtain for veterinary use.[20,21] Recurrence rates for ocular and adnexal SCC is high (44.1%). This can be reduced to 11.9% with adjuvant radiation therapy. The anatomic site in horses with the highest recurrence rate was the limbus (corneoscleral junction) or bulbar conjunctiva.[14] Medical therapy alone is ineffective as sole treatment for ocular SCC, but it may be an effective adjunctive therapeutic modality. Mitomycin (0.4%) and 1% 5-flourouracil (5-FU) can be used as ophthalmic preparations to treat corneal and eyelid SCC.[18,22-24] When applied in an alternating regimen of 7 days on and 7 days off for the cornea, tumor regression was reported for small carcinoma in-situ masses.[12]

Prevention and Control Specific preventive measures have not been systematically evaluated in horses, but recommendations include reducing UV light exposure, using fly masks with UV protection in horses (to decrease solar irradiation and environmental irritants), and avoiding breeds thought to have an increased risk of tumor development. Tattooing of lightly pigmented periocular skin has been performed in hopes of reducing the risk of UV light–induced SCC. This procedure has no deleterious effects, but true efficacy in prevention of SCC is unknown.[25]

Ovine and Caprine Ocular Squamous Cell Carcinoma

Although rarely reported, SCC of the eye and eyelids has been described in both sheep and goats. Invasive OSCC has been reported in twin goats, but etiology was not elucidated.[26] In another study of ovine and caprine cutaneous tumors, ocular tumors (SCC) comprised 11.2% and 13.3% of tumors detected, respectively.[27]

FIG. 39.21 Orbital lymphosarcoma. Diffuse orbital involvement causing exophthalmos and secondary exposure keratitis of the right eye.

Ocular Manifestations of Lymphosarcoma

Definition and Etiology Lymphosarcoma is a fatal systemic neoplastic disease of the lymphoreticular tissue. The adult or enzootic form of bovine lymphosarcoma is likely the most devastating and common neoplasm of dairy cattle. This is a systemic disease with ocular manifestations rather than a primary ophthalmic problem. (See Chapter 37 for specific information regarding bovine lymphosarcoma and the bovine leukemia virus.) Lymphosarcoma represents the most common cause of orbital neoplasia in cattle,[28] excluding OSCC that involves the orbit by local extension. Lymphosarcoma may also affect horses[29] and goats. The etiology in horses and goats is unknown.

Clinical Signs and Differential Diagnoses Clinical signs in cattle are usually associated with exophthalmos caused by orbital invasion of neoplastic lymphoid cells, subsequent exposure keratitis, and eventual proptosis[15] (Fig. 39.21). One report documented intraocular lymphosarcoma in a Holstein cow as the presenting sign of generalized lymphosarcoma.[30] Subtle exophthalmos is often overlooked because of the natural exophthalmic state of some dairy breeds. Clinical signs associated with the exophthalmos and exposure keratitis include corneal edema, vascularization, ulceration, epidermalization, conjunctival hemorrhage, chemosis, and ocular discharge. These signs may develop, progress, and change quickly once corneal protection is compromised. Other physical examination findings are discussed in Chapter 37. Differential considerations for exophthalmos include orbital cellulitis, trauma, retrobulbar hemorrhage, retrobulbar soft tissue masses, chronic sinusitis, and sinus neoplasia (see Tables 39.4 and 39.5).

Equine lymphosarcoma involving the eye is usually an ocular manifestation of multicentric lymphoma. Other systemic manifestations are discussed in Chapter 37. In one study, ocular lesions were reported in 27% of horses with multicentric lymphoma.[31] Ocular manifestations of equine lymphoma include uveitis, nictitating membrane masses, chemosis and conjunctivitis, and neoplastic infiltration of the eyelids and orbit.[29,31,32] Several cases of primary ocular lymphoma have also been reported, including one horse with anterior uveitis that was attributed to solitary uveal lymphoma and a horse with corneal lymphoma associated with IMK that had been chronically treated with antiinflammatory medications.[33-35] Differential considerations should include conjunctival pseudotumor[36] or follicular conjunctivitis,[37] any chronic inflammatory disease, equine infectious anemia, equine piroplasmosis, and infectious causes of uveitis (see Table 39.3).

Clinical Pathology and Histopathology Definitive diagnosis of lymphoma is based on cytologic and histopathologic findings. Equine malignant lymphoma is often composed of a heterogenous cell population consisting of B and T lymphocytes.[38] Histologic characteristics of lymphoma include compression of normal architecture, a single cell population without organized chromatin pattern, and variable nucleoli size. Tissue samples can also allow for immunophenotyping lymphoma into B- or T- cell origin.[39] More information on diagnosing equine lymphoma is available in Chapter 37.

Necropsy Findings As with the clinical signs, necropsy findings are variable. In cattle, orbital involvement is common, with lymphoid tumors being firmly attached to the periorbita and walls of the orbit. Extraocular muscles are frequently infiltrated with tumor cells. The globe itself is typically not involved.[6] Ocular lesions occur less often in horses than in cattle. In the horse, the globe (uveal tract) can be involved in addition to extraocular tissues. As with other systemic neoplastic diseases, multiple organ involvement is usually expected with lymphoma.

Treatment and Prognosis This systemic disease may be treated palliatively or definitively in an attempt to achieve remission for a time. Enucleation provides palliative treatment, and chemotherapy with corticosteroids, vincristine, and L-asparaginase may induce remission. Off-label use of these cytotoxic drugs must be approached with extreme caution, and treated animals must not be used for food consumption. Most cattle with orbital lymphosarcoma either die or are euthanized in terminal stages of disease within 6 months of diagnosis.[28,29] Horses can have a much more protracted disease course, with many presenting because of chronic illness of up to 12 months' duration.[18] A recent investigation of extraocular lymphosarcoma in 26 horses found that prognosis for remission was fair to good when complete tumor excision could be achieved and there was no eyelid or cutaneous involvement.[40] The overall long-term prognosis is unfavorable, regardless of the species involved.

Prevention and Control Control of bovine lymphosarcoma depends on efforts to eradicate bovine leukemia virus, a monumental task in most cases. In other large animal species, prevention and control recommendations for lymphosarcoma are not possible until the etiology can be identified. If animals are destined for slaughter, the guidelines for condemnation of bovine carcasses affected with lymphosarcoma as shown in part B of Box 39.1 should be followed.

Ocular Manifestations of Equine Sarcoid

Definition and Etiology Equine sarcoid is a locally aggressive, nonmalignant, fibroblastic tumor of equine skin (see Chapter 40). It appears to be the most common equine cutaneous neoplasm, with 14.7% of ocular and adnexal tumors in the horse being sarcoids (all involving the eyelids), making it the second most common eyelid tumor of horses, behind SCC.[41] This neoplasm develops more frequently in sites predisposed to trauma and areas that come into contact with existing sarcoids, and it does not metastasize to internal organs. There appears to be a genetically fixed predisposition, which is probably viral induced. Bovine papillomavirus (BPV-1 and BPV-2) DNA was detected in 88% to 100% of sarcoids examined in several studies.[42,43] Breed, family, and genetic predispositions have also been identified. Quarter Horses,

Appaloosas, and Arabians are at the highest risk, followed by Thoroughbreds. Standardbreds seem to have the lowest risk.[44,45]

■ ***Clinical Signs and Differential Diagnoses*** Sarcoids involving the eyelids are classified according to the scheme used for cutaneous lesions: verrucous, fibroblastic, mixed, or occult. Tumors of the eyelids may appear smooth and nodular, crusted and nodular, ulcerated, or pedunculated (Figs. 39.22, 39.23, and 39.24). Regardless of their appearance, the tumors are nonregressing. Periocular sarcoids are subject to trauma; thus the verrucous type frequently transforms into the fibroblastic type with surface ulceration. It is difficult to differentiate sarcoid from fibroma, fibrosarcoma, neurofibroma, neurofibrosarcoma, schwannoma, or nonneoplastic granulation tissue (see Tables 39.4 and 39.5).

■ ***Treatment and Prognosis*** Problematic tumors can be treated by a variety of modalities, none of which is uniformly successful. Often multiple treatment sessions are required for tumor control. Treatment modalities that have been reported include surgical excision (50% success rate), cryonecrosis (30% success rate), radiofrequency hyperthermia (RDM Hypertherm), intralesional injection of a BRM (bacille Calmette-Guérin),[41] chemotherapy with intralesional cisplatin or carboplatin (with or without initial debulking),[6,7] radiation therapy (cesium-137, cobalt-60, gold-198, iridium, strontium-90), and chemotherapy (cisplatin or 5-fluorouracil) combined with surgical excision.[46] An available commercial *Mycobacterium* product (TheraCys®) can be used successfully, but the reported clinical efficacy is variable. If the sarcoid is static, flat, and hairless, it may be best left alone because any trauma—surgical or otherwise—could increase the lesion's growth rate and invasiveness. Topical therapy with the antiviral/antitumor drug imiquomod (Aldara®) may induce regression in flatter periocular sarcoids, but care should be taken to avoid contact with the conjunctival or corneal surfaces, as the preparation can induce significant ocular irritation.

Intratumoral use of cisplatin is highly effective (see Chapter 40). Response to therapy varies on the basis of tumor location, duration, severity, and previous therapeutic measures.

Although all of these treatment modalities have been used for periocular sarcoids, it is prudent to investigate product availability when developing a treatment plan, as some products vary in their accessibility. Prognosis is favorable for equine periocular sarcoid if a complete treatment protocol is followed. As with any neoplastic disease, at the first evidence of recurrence, the animal should be reevaluated

FIG. 39.22 Equine sarcoid. Upper eyelid exhibits a smooth nodular mass typical of many periocular sarcoids.

FIG. 39.23 Equine sarcoid involving medial aspect of eyelid. At examination or during treatment, sarcoids may become ulcerated. This tumor became ulcerated after one injection of a *Mycobacterium* cell wall preparation but subsequently resolved.

Miscellaneous Tumors With Ocular Involvement

The tumors previously discussed represent the most significant ocular or periocular neoplasms of large animals. However, to the individual animal or owner, any tumor type represents a significant problem, even if it is rare. Thus clinicians must remember that numerous primary and secondary neoplastic processes can involve the eye and surrounding tissues. Secondary tumors may be either metastatic masses or locally invasive masses extending from sites near the eye. The greatest variety of ocular neoplastic disease has been reported in the horse (see Table 39.5).

Miscellaneous Adnexal Tumors

Adnexal tumors that have been reported include adenoma, adenocarcinoma, basal cell carcinoma, fibroma, fibrosarcoma,

FIG. 39.24 Multiple equine sarcoids extending from the lateral canthus into periocular tissues.

VetBooks.ir

hemangioma,[47] hemangiosarcoma,[48] lymphoma, melanocytoma, melanoma,[49] papilloma, plasma cell tumors, mast cell tumor,[50] hemangiosarcoma,[51] and schwannoma. Depending on their location, many of these tumors are amenable to excision and adjunctive therapy, such as cryonecrosis or local chemotherapy.[49,50]

Surgical excision of small lesions, cryosurgery, radiation therapy, and intralesional cisplatin[7,8] have been the mainstay of treatment for various periocular tumors in the horse. Periocular melanomas have been reported in the horse and are usually seen in older, gray horses (Color Plate 39.24). Most of these masses are benign, and surgical excision is curative, but eyelid reconstructive procedures for larger excisions can be challenging in the horse. A malignant third eyelid melanoma in a gray horse was successfully treated with excision and local chemotherapy.[49] Oral use of cimetidine has been reported to shrink dermal melanomas,[52,53] but this has not been as successful in other studies,[54,55] so is not currently recommended. A recent retrospective study of equine ocular and periocular hemangiosarcomas suggests that early intervention and complete excision yields a good prognosis, whereas in past case reports recurrence was more common and euthanasia of affected horses often resulted. Adjunctive therapies, such as Mitomycin C 0.04% or cryotherapy, were used in most cases in this study.[51]

Miscellaneous Ocular Tumors Involving the Globe

Reports of neoplasia involving the globe, all in horses, describe the clinical, histologic, and treatment aspects of hemangiosarcoma,[51] epibulbar melanocytoma,[56] intraocular melanoma,[57,58] medulloepithelioma,[59] and lymphangiosarcoma.[60,61] Intraocular melanomas are rare in horses and are unlikely to metastasize, but secondary glaucoma usually results in enucleation. Ocular melanocytic tumors are more prevalent in horses with a gray coat.[58,62,63] Other than vascular tumors, most primary intraocular tumors in horses do not display a severe metastatic threat. Although enucleation may be curative, histologic evaluation of excised tissues and long-term patient follow-up are necessary if accurate epidemiologic and prognostic data are to be available. Once an accurate diagnosis has been made, the clinician and owner must determine, in light of all available medical information and the proposed use of the animal, whether treatment should be curative or palliative or whether elimination of the problem from the herd should be of greater concern than care of the individual animal.

Miscellaneous Orbital Neoplasia

Orbital neoplasia usually present as gradual exophthalmos with or without blindness and mydriasis. Neuroendocrine tumors are the most frequently reported primary orbital tumor in the horse. They rarely metastasize and tend to grow slowly. Exenteration is usually curative, but care must be exercised because there is a large risk for hemorrhage.[64,65] Optic nerve tumors include neuroepithelial tumors[66] and meningioma.[67] An optic nerve neuroepithelial tumor that presented with exophthalmos displayed metastatic spread as a result of extension into the brain through the optic foramen, causing brain compression 2 months after enucleation.[66] Other tumors previously documented in the equine orbit include multilobular osteoma (chondroma rodens),[68] fibroma,[69] angiosarcoma,[70] hemangiosarcoma,[51] medulloepithelioma,[71] malignant rhabdoid,[72] and adenocarcinoma.[65]

Any tumor involving the nasal and paranasal cavities has the potential to involve the ocular structures as the result of orbital spread. Enzootic adenocarcinoma in sheep is an example of this type of process. Although infrequently noted, exophthalmos secondary to orbital invasion of this tumor has been reported.[73]

Central blindness has been reported in a mule with an ependymoma, but could be caused by any type of neoplasia affecting the CNS, diencephalon, or occipital cortex.[74] Other forms of intracranial neoplasia can secondarily involve the eye as a result of cranial nerve dysfunction. For example, an intracranial schwannoma caused exposure ulcerative keratitis in a cow that presented with left facial paresis.[75]

VetBooks.ir

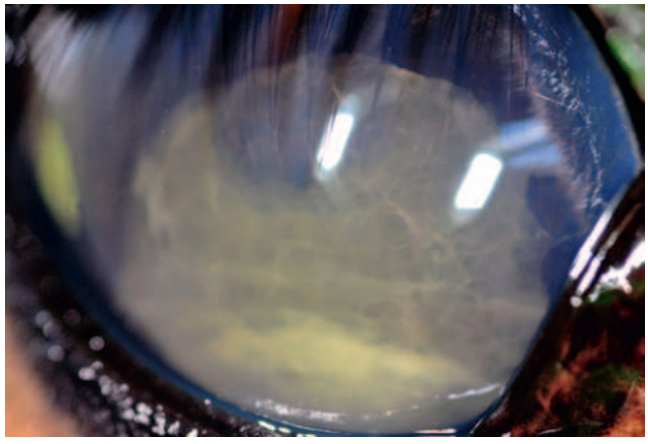
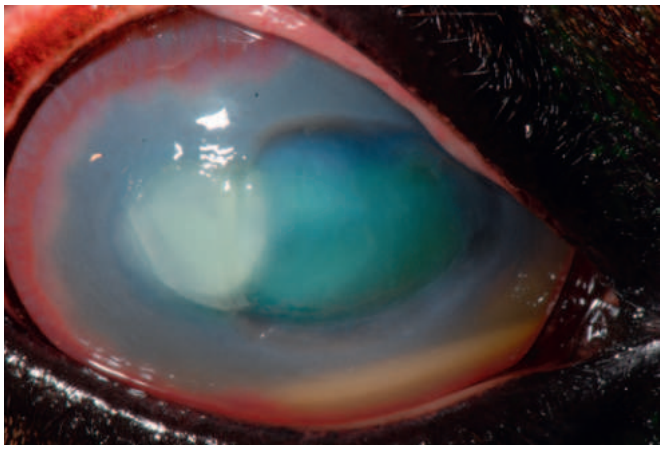
Color Plate 39.1 Marked asymmetry present when standing in front of this equine patient. Left eye is buphthalmic, with elevated lashes and diffuse corneal edema secondary to glaucoma. Right eye is developing phthisis bulbi, evident by increased scleral show and decreased lash height secondary to reduced orbital tissue volume.



Color Plate 39.2 Dyscoric pupil secondary to posterior synechia and corneal scarring with a hypermature cataract in an equine patient with equine recurrent uveitis.

Color Plate 39.3 Entropion in a bovine patient; note the trichiasis present. Patient presented with blepharospasm and epiphora.

Color Plate 39.4 Third eyelid elevation is noted on retropulsion of the globe. The nictitating membrane can now be thoroughly examined.

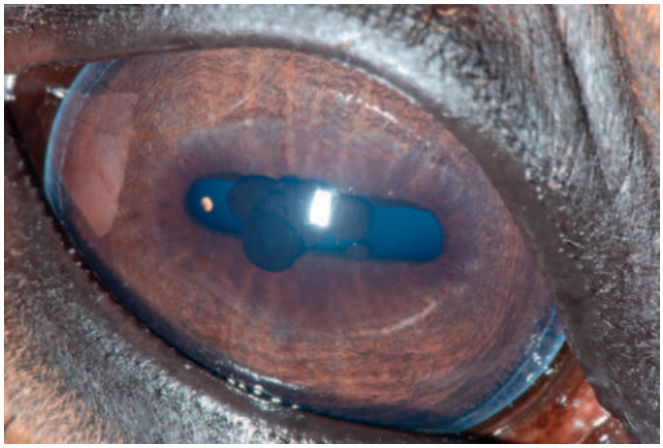


Color Plate 39.5 Fibrin in the anterior chamber of a patient with anterior uveitis. Opacity is blocking the fundic reflex. Opacities in the cornea or anterior chamber will also obscure visualization of the iris.

Color Plate 39.6 Diffuse corneal edema in an equine patient. Diffuse patterns of edema, which are fluorescein negative, indicate endothelial dysfunction.

VetBooks.ir

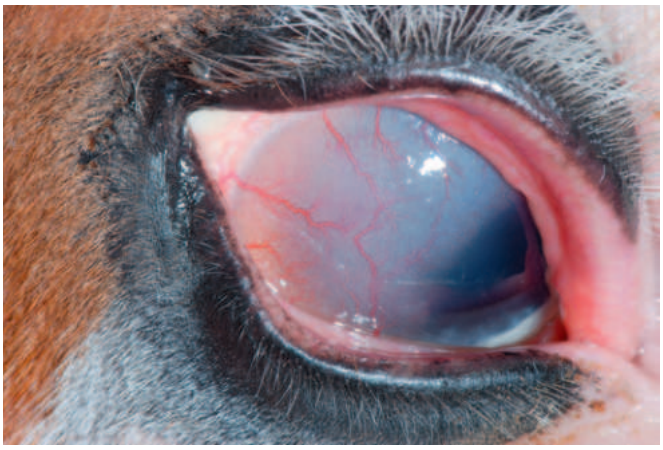
Color Plate 39.7 Cellular infiltration of the cornea is prominently associated with this large corneal ulceration, resulting in stromal loss. Corneal vascularization, diffuse corneal edema, and hypopyon are also present.



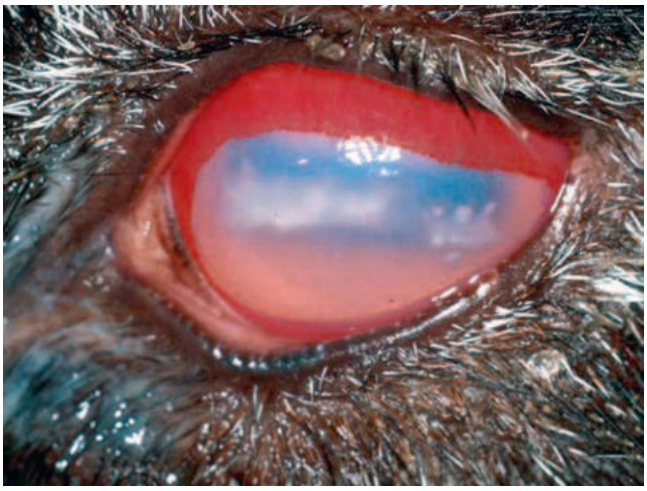
Color Plate 39.10 Iridal color change, swelling, and miosis with blood (hyphema) and fibrin in the anterior chamber of a patient with anterior uveitis.

Color Plate 39.8 Haab's striae in an equine patient with glaucoma.

Color Plate 39.11 Phthisis bulbi secondary to chronic equine recurrent uveitis.

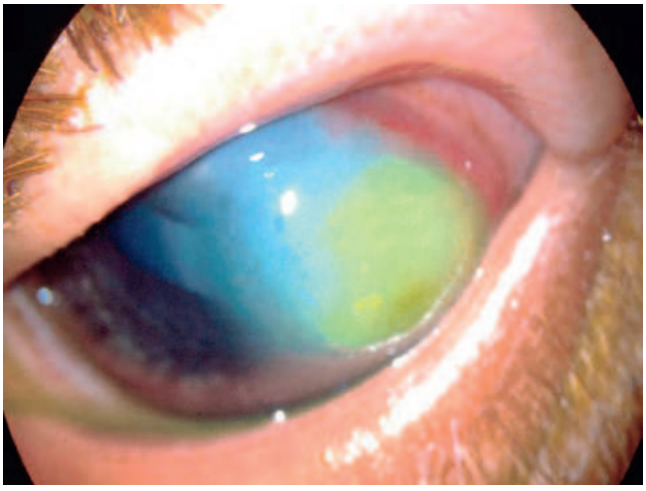


Color Plate 39.9 Corpora nigra cyst in an equine patient. Cysts can become large enough to obstruct vision in horses.



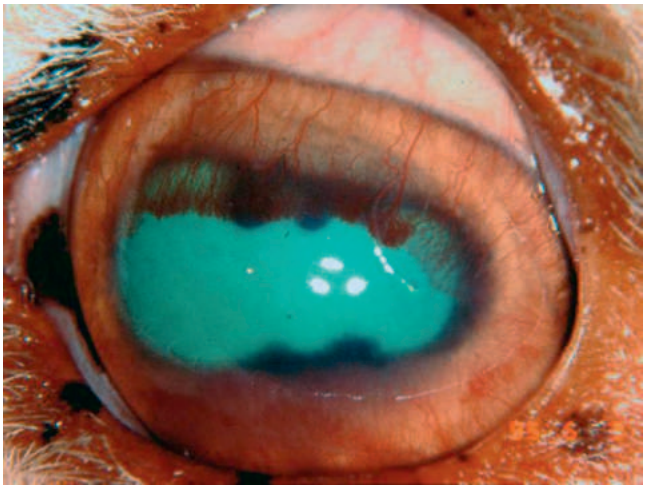
Color Plate 39.12 Bovine squamous cell carcinoma of lower eyelid and medial canthus with secondary corneal ulceration.

VetBooks.ir



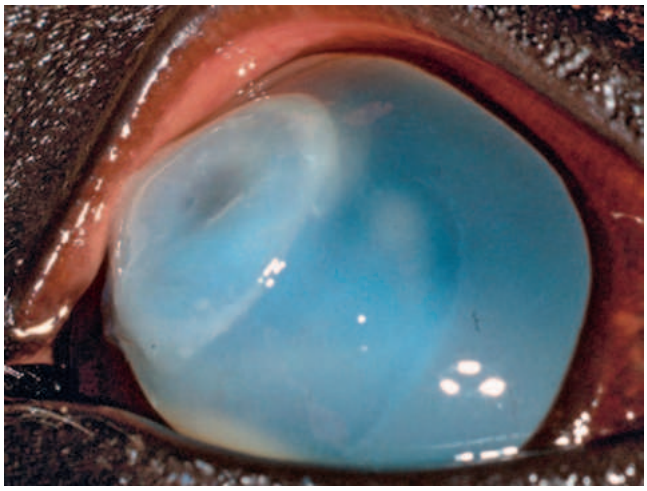
Color Plate 39.13 Corneal stromal invasive squamous cell carcinoma in the horse. Note the vascularized infiltrative mass with smooth epithelial surface.

Color Plate 39.16 *Mycoplasma* keratoconjunctivitis in a goat. Note the 360-degree superficial corneal vessels, diffuse corneal edema, a linear accumulation of white cellular infiltrates of the axial cornea, and miosis.

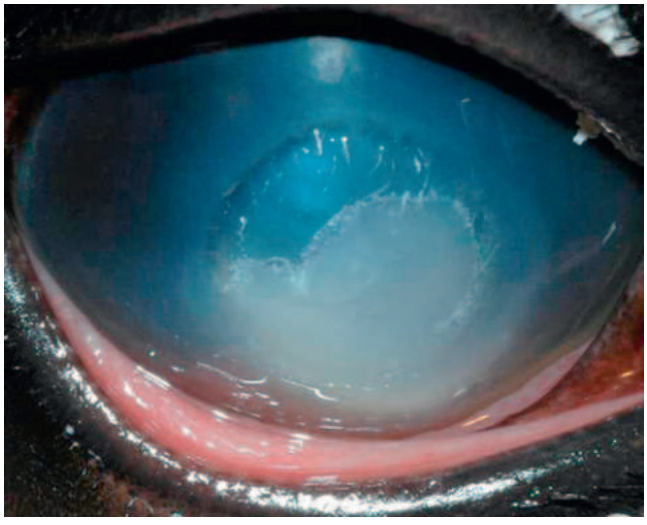


Color Plate 39.14 Congenital cataract in a Thoroughbred colt.

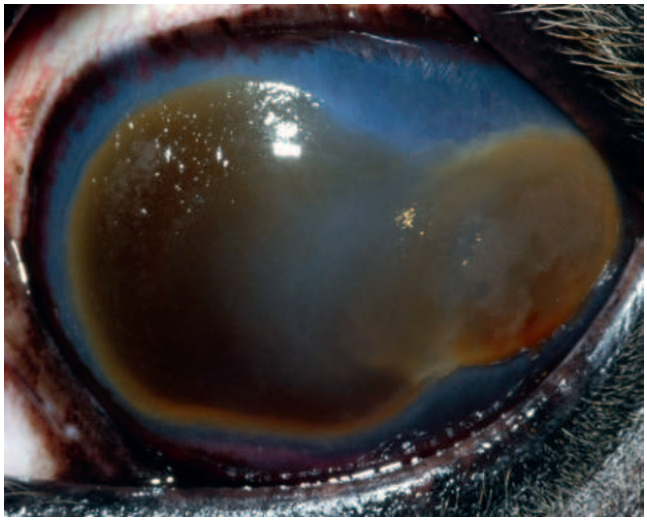
Color Plate 39.17 *Mycoplasma* keratoconjuntivitis in a sheep. Note the miosis, focal corneal edema, and superonasal corneal vessels extending to the margins of a superficial corneal ulcer that has been stained with fluorescein dye.



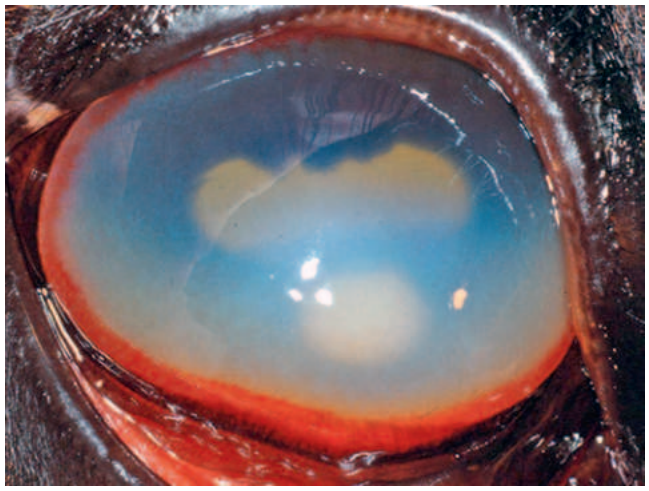
Color Plate 39.15 Severe corneal laceration in a horse. This laceration was large and fibrin, iris, and intraocular contents were expelled. Lacerations such as these require enucleation.



Color Plate 39.18 *Chlamydia* keratoconjunctivitis in a sheep. Note the mild diffuse corneal edema, miosis, and 360-degree superficial branching corneal vessels.



VetBooks.ir



Color Plate 39.19 Melting corneal ulcer, *Pseudomonas* infection. Note the diffuse corneal edema, hypoyon, and a large superonasal ulcer with cellular infiltrate around the margins and malacic corneal tissue protruding from the surface.

Color Plate 39.20 Fungal keratitis with a granular white cellular infiltrate and a surrounding groove or gutter. Note the corneal vascularization inferiorly.

Color Plate 39.21 Fungal keratitis with a pigmented necrotic axial plaque surrounded by active dense corneal vascularization.

Color Plate 39.22 Fungal corneal stromal abscess. Note the 360-degree deep stromal corneal vessels, diffuse corneal edema, yellow cellular infiltrate of the inferior cornea, a paracentral foci of white deep stromal cellular infiltrate, and miosis.

Color Plate 39.23 Infectious bovine keratoconjunctivitis. Deep corneal vascularization, cellular infiltration, ulceration, and diffuse corneal edema are noted.

Color Plate 39.24 Pigmented mass of the superior eyelid in a horse that was diagnosed as having eyelid melanoma after excisional biopsy.

Autoimmune Skin Disorders

Stephen D. White

Pemphigus Foliaceus

Definition and Etiology The term *pemphigus* is derived from the Greek word for "blister" and is used to describe a group of autoimmune vesiculobullous disorders characterized histologically by intraepidermal acantholysis and immunologically by intercellular deposition of immunoglobulin. Pemphigus foliaceus is the most common of this group of autoimmune diseases; in large animals it has been reported in horses,[1,2] goats,[3,4] sheep,[5] and a donkey.[6] In small animals pemphigus foliaceus has been putatively associated with drugs,[7] but this has not been identified in large animals. The factors precipitating the development of pemphigus foliaceus in large animals are unknown. The clinical lesions recognized in horses and goats are primarily scaling and crusting.

Pathophysiology Pemphigus foliaceus is characterized by the production of autoantibodies. In humans and dogs these are directed against transmembrane proteins (desmoglein-1 in humans and a minority of dogs; desmocollin-1 in most dogs[8]). The pemphigus autoantibody binds to the transmembrane protein, resulting in release or activation of one or more proteolytic enzymes. These enzymes destroy the attachments between adjoining epidermal cells. The result is *acantholysis;* the epidermal cells assume a rounded shape and separate from one another, leading to the formation of intraepidermal clefts and vesicles.[9]

Clinical Signs Pemphigus foliaceus is characterized clinically as a generalized exfoliative dermatitis (Fig. 40.1, Color Plate 40.1). Ventral or peripheral limb edema and crusts are the most common clinical signs.[1] In one study, no age, breed, or gender predilection was noted, although 80% of affected horses first exhibited signs between September and February.[1] In the horse, lesions are usually first noted on the head, limbs, or ventrum. Initial lesions also may be associated with fever, depression, or rarely urticaria. The disease usually progresses to involve the entire body over days to weeks. The primary lesion is a pustule, but these are fragile and transient lesions. Pustules rupture soon after formation, resulting in erosions, epidermal collarettes (rings of exfoliating superficial epidermis), scale, and crust. The lesions may or may not be associated with pruritus or pain.[1,2]

In the goat, pemphigus foliaceus also presents as a generalized exfoliative dermatitis. In the limited number of cases described, lesions initially were noted on the limbs, perineal region, and ventrum. The lesions consisted of crusting and scaling resulting from rupture of vesicles and bullae. Pruritus and malaise appear to be variable findings.[3]

Diagnosis Diagnosis of pemphigus foliaceus in large animals is typically based on biopsy of lesions submitted for routine histopathology. Characteristic histologic findings include intragranular to subcorneal cleft and vesicle formation associated with acantholysis. Both follicular and surface epithelia are frequently involved. Neutrophils tend to predominate in the inflammatory infiltrate, although eosinophils may also be present.[1-3] Because certain strains of *Trichophyton* species of dermatophytes may also cause acantholysis, any histology suggestive of pemphigus foliaceus must be stained for fungi.[10] Direct immunofluorescence or immunohistochemistry as an aid in the diagnosis of pemphigus foliaceus in horses and goats has also been reported but is somewhat limited to research and academic institutions.[3,9,11] Indirect immunofluorescence testing (for pemphigus antibodies in serum) is reported to be unreliable for the diagnosis of pemphigus foliaceus in horses, although this may be due to variability in the substrate used.[9,12]

Therapy Treatment is corticosteroids at immunosuppressive doses, such as prednisolone at 1 mg/kg orally (PO) every 24 hours (q24h) or dexamethasone at 0.08 to 0.1 mg/kg PO q24h, then tapering. Oral prednisolone is preferred to prednisone because some horses are unable to metabolize prednisone into the active metabolite of prednisolone.[13] Injectable gold (Solganal [Schering, Kenilworth, N.J.]) was also used successfully, but this product is no longer available. There are anecdotal reports of benefits using another gold salt, aurothiomalate (Myochrysine [Sanofi-Aventis, Bridgewater, NJ]), 1 mg/kg intramuscularly (IM) every 7 days. Gold salts take 1 to 3 months to reach effectiveness, after which dosage frequency can be tapered to every 14 to 30 days. Adverse reactions of gold salts, although rare in the horse, include thrombocytopenia and glomerulonephropathy.

There are also reports of azathioprine (1 to 3 mg/kg PO q24-48h) being used for various autoimmune skin diseases in horses.[14,15] A potential side effect is thrombocytopenia because horses have low levels of the enzyme thiopurine methyltransferase (TPMT),[16] which is responsible for the metabolism of

*Contributions to previous editions by Anne G. Evans are acknowledged.

VetBooks.ir

FIG. 40.1 Pemphigus foliaceus in a horse; note the generalized crusts.

azathioprine in other species, including humans. However, the author has administered azathioprine (1 to 3 mg/kg PO once daily for 1 month, then q48h) to eight healthy horses with no deleterious effects.[17] Azathioprine is used as a steroid-sparing drug with corticosteroids, eventually decreasing the amount of steroid needed. Approximate cost of daily azathioprine for a 500-kg horse is $300/month.

Goats have also been treated successfully with corticosteroids (dexamethasone, prednisolone) and aurothioglucose.[3,4,11] Dosages approximate those for the horse.

Prognosis The response to treatment in equine pemphigus foliaceus varies from patient to patient. Many horses require lifelong administration of medication to control the clinical signs; others may be weaned from medication gradually without further relapse. In one study where follow-up information was available for 13 horses, 4 were euthanized because of complications of the disease or its treatment. The reported cases of caprine pemphigus foliaceus are insufficient in number to establish a reliable prognosis.

Pemphigus Vulgaris

Pemphigus vulgaris is a rare autoimmune skin disease anecdotally reported[9] in horses and recently definitively diagnosed in a Welsh pony.[18] In that report, the diagnosis was confirmed with both direct and indirect immunofluorescence and immunoprecipitation studies, the latter identifying circulating immunoglobulin G (IgG) directed against the epidermal transmembrane protein desmoglein-3, similar to the pathogenesis in humans and dogs. Clinical signs are vesicles and ulcerations seen in mucocutaneous and cutaneous areas. Initial corticosteroid treatment improved the clinical signs, but onset of laminitis necessitated a dose decrease with a recurrence of lesions and development of oral ulcers. Despite successive adjunctive treatment with azathioprine, gold salts, and dapsone, the disease progressed, and the pony was euthanized. Necropsy showed additional lesions of the cardia of the stomach.[18]

Bullous Pemphigoid

Bullous pemphigoid is an autoimmune vesiculobullous and ulcerative disorder that affects the cutaneous basement membrane zone (BMZ). It has been rarely noted in horses.[9,19] Initiating triggers for the disease in the horse are unknown.

The pathophysiology of bullous pemphigoid in horses is assumed to be similar to that described in other mammals. Complement-activating anti-BMZ antibodies bind to a glycoprotein antigen in the lamina lucida of the BMZ. In horses this has been shown to be bullous pemphigoid antigen II (also called collagen XVII). Complement activation results in degranulation of mast cells and chemotaxis of neutrophils and eosinophils. Eosinophils release tissue-destructive enzymes with resultant injury to the BMZ, loss of dermoepidermal adherence, and subsequent blister formation.[9]

Equine bullous pemphigoid is characterized clinically by painful, crusted, or ulcerative lesions of the skin (face and axillae), mucous membranes, and mucocutaneous junctions. Bullae are rare.[9,18] Ulceration may involve the gastrointestinal (GI) tract. The diagnosis is based on histopathologic and, when available, immunofluorescent findings. Treatment is the same as for pemphigus foliaceus; the few cases reported have not had favorable outcomes, but the author has seen a case that initially responded well to corticosteroids.

Alopecia Areata

Alopecia areata is a disease of horses and cattle typified by areas of nonpruritic alopecia.[9,20,21] One horse has been described with severe hoof dystrophy on all four legs.[22] In one report the median age was 9 years, with an age range of 3 to 15 years. Alopecia was the primary dermatologic abnormality in all horses and most commonly affected the mane, tail, and face, although any part of the body could be affected (Color Plate 40.2).[23] Histologically, a lymphocytic infiltrate surrounding the base of the hair follicle is seen, but in long-standing cases this infiltrate may not be present.[24] A mare with a T-cell lymphocytic infiltrate causing a mural folliculitis of the isthmus (central section) of the hair follicles was described.[24] Antibodies targeting the hair follicle itself have been documented.[25] Most horses regrow the hair, but this may take up to 2 to 3 years, and the disease may wax and wane, worsening most commonly in the spring and summer months.[23] Corticosteroids *may* hasten hair regrowth. Mane and tail "dystrophy" of Appaloosas and other breeds may in fact be a form of alopecia areata. Because of the circular nature of the alopecia, this disease is often mistaken for ringworm.

Hypersensitivity Disorders

Stephen D. White

Atopic Dermatitis

Definition and Etiology Atopic dermatitis can be defined as an abnormal immunologic response to environmental allergens like pollens, barn dust, and molds. It is increasingly being recognized as a cause of pruritus in horses. The disease may be seasonal or nonseasonal, depending on the allergens involved. Age, breed, and gender predilections have not been extensively reported. A familial predisposition may be present.[1]

The presumed etiology is a type I (immediate) hypersensitivity response mediated by IgE. Evidence indicates that atopic horses do produce allergen-specific IgE[2,3]; the IgE is presumed to be directed against specific allergens. When that allergen is bound to two or more IgE antibodies on the surface of a mast cell, the mast cell releases granules containing various substances that cause erythema, vascular leaking, and pruritus.

Clinical Signs Pruritus, often affecting the face, distal legs, or trunk, is the most common clinical sign. Alopecia, erythema, urticaria, and papules may all be present. Urticarial lesions may be severe but nonpruritic. In one study of 54

horses with atopic dermatitis, 28 horses had urticaria, 8 had pruritus, and 18 had both.[3] Horses may have a secondary pyoderma typified by excess scaling, small epidermal collarettes, or encrusted papules *(miliary dermatitis)*. Diagnosis of atopic dermatitis is based on clinical signs and exclusion of other diagnoses, especially parasite *(Culicoides)* allergy.

Diagnosis Diagnosis is based on clinical signs and exclusion of other pruritic skin disease. Confirmation to formulate allergen-specific immunotherapy (ASIT [hyposensitization]) is based on either intradermal testing (IDT) or serum allergy tests. IDT involves a series of intradermal injections of aqueous allergen extracts along with a positive (histamine) and negative (saline) control. Injections are usually performed over the lateral cervical or thoracic region, and the sites are then observed for 30 minutes to 24 to 48 hours for evidence of wheal formation. A positive reaction does not necessarily mean that the horse's clinical signs are caused by the reacting allergen, but rather that the horse has antibodies to the allergen that, on intradermal exposure, cause wheals to form. False-negative IDT reactions may occur, the most important cause of which is the use of corticosteroids, antihistamines, or phenothiazine tranquilizers before testing, especially within the previous 14 days.[4]

Horses with atopic dermatitis generally have a higher incidence of positive reactions than healthy horses, but the diagnosis (as in other species) cannot be solely made based on the IDT or serologic test alone. Such tests should be interpreted by considering the history of the disease. For example, a horse with seasonal signs is more likely to have an allergic response to seasonal allergens (pollens in summer, barn dust in winter). This interpretation will help the clinician determine which allergens might be relevant in hyposensitization, should the owners choose that treatment.[2,3,5-7]

IDT and available serologic tests look for allergen-specific IgE in the animal's blood,[8] but the latter's use on horses and other domestic species is not without controversy. One study showed no statistical difference in the efficacy of hyposensitization between horses tested with IDT and those tested with serology.[3] Preferentially, IDT and/or serologic testing are performed on horses with atopic dermatitis that have owners interested in pursuing hyposensitization. It should be remembered that, in regard to food allergy, neither serologic testing nor IDT likely has any relation to reality. Clinical research is ongoing to determine the most important allergens, their testing dilutions, and effective control substances.[9,10]

Therapy Corticosteroid treatment is usually effective in the control of pruritus or urticaria due to atopic dermatitis. The usual oral medication used is prednisolone (1 mg/kg PO q24h), although dexamethasone (0.05 mg/kg PO q24h) can also be used. The injectable dexamethasone solution may be used orally, although the clinician should remember that the bioavailability is 60% to 70% of the injectable route.

Corticosteroids in horses may cause various adverse effects, including steroid hepatopathy, laminitis, and iatrogenic hyperadrenocorticism. Therefore other modalities of treatment may be used, such as the antihistamine hydroxyzine pamoate (200 to 400 mg/500 kg PO q12h) or cetirizine (0.2 mg/kg PO q12h); doxepin, a tricyclic antidepressant with antihistaminic effects (300 to 600 mg/500 kg PO q12h); or diethylcarbamazine syrup (6 to 12 mg/kg PO q24h). Hydroxyzine, cetirizine; and doxepin may cause either drowsiness or nervousness, although these adverse effects are uncommon. Cetirizine is expensive; because it is the active metabolite of hydroxyzine, if the latter is ineffective in an individual horse, cetirizine probably will be as well. Pyrilamine maleate, though often used in the horse, in fact has poor oral bioavailability.[11] Some clinicians have noted improvement when an essential fatty acid (EFA) product is added to the feed. Platinum Performance (Platinum Performance Inc., Buellton, Calif. [Dr. W. Rosenkrantz, personal communication, 2004]) has been used successfully in some atopic horses as an adjunctive treatment.

In general, hyposensitization injections for any manifestation of atopic dermatitis in the horse should be evaluated for efficacy for at least 12 months. The veterinarian should maintain consistent communication with the client to monitor the progress of treatment and encourage the owner to continue with the injections for the full year. Although most horses will need to be maintained on injections for life, if hyposensitization is successful, perhaps as many as 25% may be able to discontinue the treatment without recurrence.[3] Experience at the University of California, Davis, School of Veterinary Medicine (UCD-SVM) shows that about 65% to 70% of atopic horses improve with hyposensitization[3,12]; other researchers have reported even better results but in a noncontrolled study.[13]

Urticaria

Definition and Etiology Urticaria is characterized by transient focal swellings in the skin or mucous membranes called *wheals*, which represent localized areas of dermal edema. Angioedema is essentially identical but involves the subcutaneous tissues. The swelling of angioedema is diffuse, often involving the entire face and neck of the animal.

Urticaria is more frequently recognized in the horse than in ruminants. *Allergic urticaria* is usually caused by atopic dermatitis (environmental allergens like pollens),[1,6,7,14] drug eruptions (especially from antibiotics[15] and nonsteroidal antiinflammatory drugs [NSAIDs]), contact allergies, and food allergies (rarely).[16]

Physical urticarias are less common and involve a nonimmunologic pathogenesis. The three most important categories are mechanically induced, such as dermatographism, essentially a "pressure" urticaria; cold urticaria; and exercise-induced urticaria. Miscellaneous diseases that can cause urticaria include dermatophytosis (initial lesions),[17] pemphigus foliaceus, "stress" (sometimes seen in racehorses immediately before a race), and vasculitis (Box 40.1). Urticaria is a recognized manifestation of milk allergy in cattle.[18]

Pathophysiology The wheals result from vasodilation and transudation of fluid from capillaries and small blood vessels. Both immunologic and nonimmunologic factors can trigger release of mediators from mast cells and blood basophils that will ultimately produce the characteristic wheals (Fig. 40.2). The most frequently cited immunologic mechanism of urticaria is type I hypersensitivity (IgE). Non–IgE-dependent, immune-mediated urticaria may be induced by either type II (cytotoxic, involving antibody and complement) or type III (immune complex) hypersensitivity reactions. Complement-activated urticaria may involve either immunologic or nonimmunologic mechanisms and may occur through either the classic or the alternative pathway. Urticariogenic materials can induce wheal formation without involving immunologic mechanisms by being ingested, injected, or contacting the animal. Physical agents, including mechanical injury, thermal changes, and solar radiation, may induce urticaria. An example of mechanically induced urticaria is *dermatographism* (whealing after blunt scratch injury to the skin). Local or generalized exposure to heat or cold may induce urticarial lesions in certain individuals.

Clinical Signs and Differential Diagnosis Wheals range from 1 to 10 cm (0.4 to 4 inches) in diameter and tend to involve the cervical and craniolateral thorax (Fig. 40.3). The animal may or may not be pruritic. Alopecia is not usually a feature of urticaria. The most important factor in distinguishing urticaria from other nodular diseases is that the individual lesions pit with pressure. This is easily demonstrated in the

BOX 40.1

Possible Causes of Urticaria in Horses and Ruminants

Allergic Urticaria

Inhalants

Pollens, animal danders, mold spores, feather down, aerosols, smoke, dust, and volatile chemicals

Injectants

Drugs, diagnostic agents, vaccines, insect stings, serums, and blood

Ingestants

Drugs, various food items, beverages, and occult additive materials found in foods

Infections

Foci of bacteria, fungal, viral, and parasitic infections

Contactants

Animal products, plant materials, cosmetics, plastic, and other chemicals

Drugs

Penicillin, aspirin, quinine, sulfonamides, insulin, and many others

Milk Proteins

Milk retention (cattle)

Urticaria Caused by Urticariogenic Materials

Drugs

Cocaine, morphine, codeine, atropine, quinine, thiamin, pilocarpine, polymyxin B, D-tubocurarine, dextran, dehydrocholate sodium (Decholin), and other drugs

Foods

Certain citrus fruits, strawberries, and certain fish

Toxins

Cobra venoms, jellyfish toxin, and certain plant and insect toxins

Physical Urticaria

Dermographic (induced by blunt-scratch injury)
Heat
Cold
Light

Miscellaneous Urticaria

Erythema multiforme
Pemphigus foliaceus
Infections
Collagen vascular disease
Neoplasia
Psychogenic

early stages of wheal formation, when the lesions consist primarily of dermal edema. In the later stages, when there is cellular infiltration into the dermis, the pitting is less apparent.

Diagnosis Urticaria is usually a clinical diagnosis; the diagnostic dilemma is to determine the *cause* of the urticarial eruption. A skin biopsy not only will lend support to the clinical diagnosis of urticaria but also may show evidence of pemphigus foliaceus, dermatophytosis, or vasculitis. Initiation of ectoparasite control, IDT or serologic tests for atopic dermatitis, fungal culture, skin biopsy, and feed trials may all be used to determine the underlying disease.[14]

Therapy Avoiding the allergen or initiating factor or treating the underlying disease is the best therapy. When this is not possible or when the allergens cannot be identified, medical therapy should be used, as described in the Atopic Dermatitis section.

Milk Allergy

The principal cutaneous manifestation of milk allergy is urticaria and is usually seen in cows during the drying-off period. Increased intramammary pressure presumably causes milk proteins to gain access to the circulation, where they induce a type I hypersensitivity reaction.[19] The disorder is believed to be hereditary and familial, with cattle of the Channel Island breeds demonstrating increased susceptibility.

The urticarial reaction can be localized or generalized. Other clinical signs that may be noted include muscle tremors, respiratory distress, restlessness, ataxia, dullness, and even maniacal behavior. Diagnosis is made by observing an edematous swelling at the site of an intradermal injection of the cow's milk or the milk protein casein diluted 1:1000, in combination with the appropriate clinical signs.[19,20]

Treatment involves the use of antihistamines early in the disease. Prevention requires avoiding milk retention. An affected cow is likely to suffer recurrences of milk allergy, so culling is usually recommended.

Erythema Multiforme

Erythema multiforme (EM) has been recognized clinically in the horse and in one bull (Fig. 40.4). This is an immunologic reaction in the skin, and programmed keratinocyte cell death (apoptosis) is the prominent change seen on biopsy. The keratinocytes may be killed specifically by killer lymphocytes. The many possible etiologic factors include infectious diseases, drugs, systemic disease, and neoplasia. In horses, drugs are probably the most frequent inducers of EM, although in many cases an underlying disease is undiagnosed.[21,22] In one bull the EM may have been caused by a pyelonephritis found on necropsy.[23] Clinical lesions are characterized by macules, papules, urticarial lesions, or vesicular bullous lesions. Individual lesions may expand peripherally, leading to formation of target-like lesions. Scaling and crusting are usually not a feature of equine EM unless the disease is characterized by erosions or ulcers. Individual lesions can persist for several days, unlike urticarial lesions. Pruritus and pain are variable but not usually seen. Lesions may occur in association with or after an infection or drug administration. The late Dr. A.A. Stannard of UCD-SVM had theorized that reticulated and hyperesthetic leukotrichia may also represent a type of EM in the horse,[22] although a recent article demonstrated histologic differences between hyperesthetic leukotrichia and EM.[24] One report associated EM in a horse with equid herpesvirus 5.[25] Interestingly, a similar disease, toxic epidermal necrolysis, has rarely been reported in cattle.[26]

Differential diagnoses include urticaria, amyloidosis, and other nodular papular diseases. The diagnosis is made based on history, physical examination, and skin biopsies. Histologic changes are distinctive and often include a lichenoid pattern with keratinocyte apoptosis. Vesicular lesions may be present and can include more confluent areas of keratinocyte destruction with massive spongiosis and subepidermal and intraepidermal edema.

Treatment should be directed toward the underlying cause if one can be found. A drug eruption should be high on the list, and searching the history for recent drug administration is important. Although some cases of EM are self-limiting and may resolve within 1 to 3 months,[21] corticosteroid treatment as for pemphigus foliaceus may be tried. In our experience, reticulated leukotrichia does *not* resolve spontaneously and does not respond to corticosteroids.

Vasculitis

Vasculitis is a histopathologic term that implies the presence of inflammatory changes in the walls of blood vessels, and it is associated with a broad spectrum of disorders. *Cutaneous vasculitis* is recognized in horses and is most often seen as a feature of photoaggravated dermatitis, drug reactions, or purpura hemorrhagica.[27] Mules and donkeys may also be affected.[27] Affected vessels may be limited to the skin or may involve other organs, resulting in systemic disease. The cutaneous lesions are characterized by crusts, scales, edema, purpura, necrosis, and ulceration, most often affecting the legs (Fig. 40.5, Color Plate 40.3).

As a clinical entity, *photoaggravated vasculitis* seems to be more common (if poorly understood) in California and the western United States. Although previously termed *leukocytoclastic vasculitis*, the most common histologic finding is cell-poor and lymphocytic/histiocytic vasculitis.[27] It generally affects mature horses and produces lesions confined to the lower extremities that lack pigment, although pigmented legs may also be affected. Lesions are multiple and well demarcated, with the medial and lateral aspects of the pastern the most common sites. Initially, erythema, exudation, crusting, erosions, and ulcerations develop, followed by edema of the affected limbs. Some lesions may have a "punched-out" appearance. Chronic cases may develop a rough or "warty" surface. Pathogenesis is uncertain; an immune complex etiology has been suggested, and when lesions are restricted to nonpigmented areas this suggests a role for ultraviolet (UV) radiation. Drug reactions may be a potential cause.[22] One report also implicated *Staphylococcus intermedius*.[28]

It must be emphasized that cutaneous vasculitis can occur anywhere on the body and may become generalized.

The differential diagnosis is photosensitization, particularly that caused by contact. The diagnosis is confirmed by skin biopsy, which demonstrates vasculitis, often with vessel wall necrosis and thrombosis involving the small vessels in the superficial dermis. These changes may be difficult to demonstrate.

Treatment involves corticosteroids at relatively high doses (prednisolone at 1 mg/kg PO q12h or dexamethasone at 0.08 to 0.2 mg/kg PO q24h) for 2 weeks, then tapered over the next 4 to 6 weeks. Reducing UV light exposure is helpful, by bandaging affected legs, stabling inside during daylight hours, or both. In some cases, topical corticosteroids (e.g., betamethasone valerate cream 0.1% or triamcinolone spray 0.015%) may enable the horse to be weaned off systemic corticosteroids. Pentoxifylline (8 to 10 mg/kg PO q12h) may be an effective adjunct treatment. Another alternative (but more expensive) is 0.1% tacrolimus ointment q24h (Protopic [Astellas Pharma US, Northbrook, Ill.]). This disease recurs in approximately 25% of cases.[27] These horses are prone to secondary bacterial infections, and a month of antibiotic treatment (usually trimethoprim-sulfamethoxizole) is often indicated if the horse has fever or its legs are extensively swollen.

Cutaneous vasculitis seemingly is rare in ruminants; one report in calves describes lesions on the forelegs and ear tips occurring within a month on one farm. Histology showed a fibrinous-necrotic or leukocytoclastic vasculitis. Glucocorticoid (prednisolone) therapy was effective.[29] A recent article describes systemic vasculitis (polyarteritis nodosa) in four flocks of sheep.

VetBooks.ir

Clinical and histologic signs involved several organ systems, including the skin.[30] Vasculitis and purpura hemorrhagica are discussed in more detail in Chapter 37.

Drug Eruption

A drug eruption is a cutaneous reaction to any agent that enters the circulation by ingestion, injection, inhalation, or percutaneous absorption. Drug eruptions may or may not be associated with systemic signs. Many drug eruptions are thought to be immunologically mediated hypersensitivity reactions, although on occasion they may occur with the initial administration of a drug and therefore without any prior sensitizing exposure, characteristic of an immunologic reaction. Drug eruptions may also occur after years of repeated asymptomatic exposure to a drug, although this is probably less common than formerly supposed. Any medication can cause a drug eruption, but the compounds most frequently incriminated include antibacterial agents (especially semisynthetic penicillins and the sulfas), phenothiazine tranquilizers, NSAIDs and antipyretics (especially phenylbutazone), local anesthetics, and anticonvulsants. In general, the more recently a drug has been given, the more likely it may be the cause of a skin disease. The clinician should try to determine a temporal association between administration of the drug and the skin disease.

FIG. 40.6 Drug eruption in a horse; note pruritus.

Because drug eruptions can result in a wide variety of cutaneous manifestations, they must be considered in the differential diagnosis of all skin disorders. Certain clinical symptoms are more often associated with drug eruptions. Urticaria and angioedema, diffuse erythema, papular rashes, intense pruritus that responds poorly to corticosteroids (Fig. 40.6), sharply demarcated ulcers secondary to vasculitides, vesicular and bullous eruptions, and photosensitization should arouse clinical suspicion of a drug eruption. Typically, cutaneous lesions are noted 24 to 48 hours after drug administration, although there may be a longer lag interval. The eruption usually subsides within 24 to 48 hours after exposure ceases, although lesions may persist for up to 6 months after the offending agent is eliminated.[22]

A diagnosis of drug eruption is based on clinical suspicion associated with an incriminating history of drug administration and by ruling out other possible causes. In a suspected case, all medications should be discontinued. If life-saving medications are being administered, a chemically unrelated compound with similar pharmacologic effects should be substituted. Administration of corticosteroids may provide some relief, but drug eruptions respond variably to corticosteroids. Although development of a cutaneous reaction after readministration of the suspected agent would support a diagnosis of drug eruption, readministration is not advisable because it can be fatal as well as unethical. Future exposure to any implicated compounds and chemically related substances should be avoided.

Contact Dermatitis

Definition and Etiology Contact dermatitis is recognized in both horses and ruminants and can be subdivided into irritant and allergic contact dermatitis. *Irritant contact dermatitis* occurs more often and is defined as a cutaneous reaction to an irritating concentration of an offending agent. The substance chemically damages the skin without immunologic mediation.

VetBooks.ir

The reaction may occur after a single contact with a strong irritant or after repeated contacts with a milder irritant. *Allergic contact dermatitis* represents a cutaneous reaction in a sensitized animal to a nonirritating concentration of the offending agent. Tissue damage is immunologically mediated by delayed-type hypersensitivity (type IV), so prior exposure is required to sensitize the skin to the material eliciting the dermatitis.[16,18] It may be difficult to differentiate between the two types of contact dermatitis, and it may not be clinically important. In our experience, the vast majority of contact dermatitis cases are iatrogenic, caused by topical products placed on the skin by veterinarians or owners.

Clinical Signs The clinical lesions associated with allergic and irritant contact dermatitis are very similar. Predisposed areas include the muzzle, extremities, and areas contacted by tack. Early lesions include erythema, edema, and vesiculation that progress to erosions, ulcerations, and crusting and ultimately to lichenification and hyperpigmentation. A gravity-induced drip pattern may be evident when the irritant is a liquid.[31]

Diagnosis A detailed history is very important—the bedding, all topical products and blankets, and other potential environmental antigens and irritants should be noted. Certain woods release various irritant oils and have been implicated when incorporated into the bedding.[32] Patch testing is possible but usually impractical. Provocative exposure is the most useful test for diagnosis of contact dermatitis, although it does not reliably distinguish between allergic and irritant contact dermatitis. It requires avoiding contact with all suspected agents for 7 to 10 days to permit clearing of the skin lesions. The patient is then reexposed to these agents on an individual basis at 7- to 10-day intervals while being observed for recurrence of the dermatitis. When a positive reaction is observed, challenge with the suspected agent should be repeated to confirm the diagnosis. The process is time consuming, requiring owner patience and cooperation.

Therapy An animal with a suspected or confirmed diagnosis of acute or irritant contact dermatitis should be placed in an environment where there is negligible chance of exposure to agents that might have produced the dermatitis. Symptomatic treatment pending spontaneous resolution includes gently washing the affected regions with water. Pentoxifylline at the dose noted earlier for vasculitis may be helpful in horses.

Bacterial Diseases

Stephen D. White

Dermatophilosis (Streptothricosis, Rain Scald, Lumpy Wool, Strawberry Foot Rot)

Definition and Etiology Dermatophilosis is caused by an actinomycete bacterium, *Dermatophilus congolensis*. The organism is a gram-positive, non–acid-fast, branching, filamentous, aerobic bacteria that divides longitudinally and then transversely to form parallel rows of coccoid zoospores. Dermatophilosis affects horses, cattle, sheep, and goats, as well as a wide range of other mammals.[1-4]

Three conditions must be present for *Dermatophilus* to manifest: a carrier animal, moisture, and skin abrasions. Chronically affected animals are the primary source of infection, but they become a serious source of infection only when their lesions are moistened, which results in release of zoospores, the infective stage of the organism. Mechanical transmission of the disease occurs by both biting and nonbiting flies, ticks, and possibly fomites. Because normal healthy skin is impervious to infection with *D. congolensis*, some predisposing factor that results in decreased resistance of the skin, especially prolonged skin wetting by rain, is necessary for infection to occur. The organism has been isolated from the environment of affected animals. Distribution is worldwide, but frequency of occurrence of dermatophilosis varies with geographic location; areas with increased rainfall are predisposed. There is no apparent age, breed, or gender predilection.

Clinical Signs Dermatophilosis is usually seen during the fall and winter months, with the dorsal surface of the animal most often affected (Fig. 40.7, Color Plates 40.4 and 40.5). In horses, this association with the wetter months of the year has led to the term *rain scald*. Occasionally the lesions involve the lower extremities when animals are kept in wet pastures ("dew poisoning") or if horses are left in the stall while the stall is cleaned with high-pressure water hoses. In the early stages of disease, the lesions can be felt more easily than they can be seen. Thick crusts can be palpated under the hair coat. Removing the crusts and attached hair exposes a pink, moist skin surface, with both the removed hair and the exposed skin assuming a paintbrush shape. The undersurface of the crusts is usually concave, with the roots of the hairs

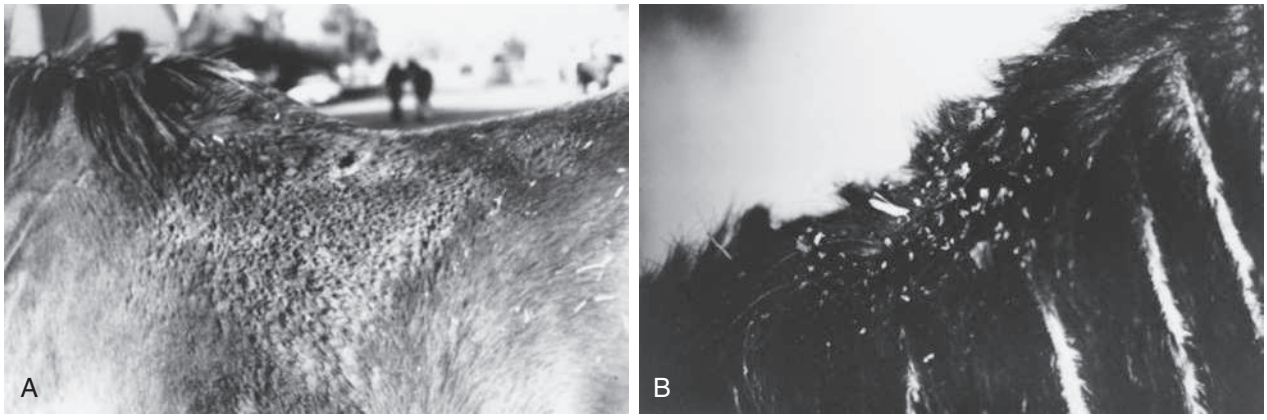

FIG. 40.7 Dermatophilosis *(Dermatophilus congolensis)*. **A,** Horse with suppurative crusts and matted hair on the back. **B,** Scaling and crusting over withers and neck of a bovine.

protruding. In cattle and goats the older term *cutaneous streptothricosis* is sometimes still used. In sheep the condition is referred to as "lumpy wool" or "mycotic dermatitis" when wooled areas are affected and as "strawberry foot rot" when distal extremities are involved.

Body areas predisposed to infection include those that are most susceptible to maceration and trauma. The distal extremities, muzzle, and entire length of the dorsum are frequently the initial sites of infection. Nonpigmented skin is also reported to be more susceptible to infection. Horses develop lesions in areas rubbed by tack, and cattle often have involvement of the udder and scrotum. Goat kids may have a tendency to develop lesions on the pinnae and under the surface of the tail. Sheep may develop a form of dermatophilosis that begins as an encrusted proliferative dermatitis at the coronet region; removal of the external crusts reveals a pink-red granulation bed that resembles the surface of a strawberry. Lesions can extend from the hoof to the hock; with loss of the crusts, ulceration occurs. Under appropriate conditions, dermatophilosis can become generalized.

Diagnosis Diagnosis is made by demonstrating the "railroad-track" cocci on impression smears. A portion of one of the crusts should be minced and mixed with a few drops of sterile water on a glass slide, Gram stained, and examined microscopically. Alternatively, bacterial culture or histopathology may be used for diagnosis, particularly in chronic cases. A thick crust composed of alternating layers of parakeratotic stratum corneum, dried serum, and degenerating neutrophils is the most characteristic change. A superficial folliculitis may be a prominent feature of the disease.[1] In Gram-stained sections, the branching filamentous organisms can be observed in the crusts and follicles. A recent report showed the efficacy of using real-time quantitative polymerase chain reaction (RT-qPCR) in the diagnosis of this organism.[5]

Therapy The animal should be removed from the wet environment if possible. Careful removal of possibly painful crusts, washing with iodophors or lime sulfur, and administration of antibiotics (for horses, 22,000 units/kg procaine penicillin G IM twice daily or 30 mg/kg trimethoprim-sulfamethoxizole PO twice daily) for 7 to 10 days.[4] Long-acting oxytetracycline given as a single 20-mg/kg IM dose has been reported to be effective for bovine and ovine dermatophilosis. The crusts are important in contagion, so they should be disposed of rather than brushed to the ground. Reduced tick control has been associated with increased incidence of the disease.[6]

Folliculitis, Furunculosis, and Impetigo

Definition and Etiology Bacterial *folliculitis* (superficial pyoderma) is defined as inflammation of the hair follicles secondary to a bacterial infection. *Furunculosis* is the term used to describe a follicular infection that breaks through the follicular wall ("boil"). Bacterial infection that causes subcorneal pustules but does not involve hair follicles is called *impetigo*. Folliculitis and furunculosis are often seen in horses[1,4] and goats[3] but are an uncommon problem in cattle and sheep. Impetigo is relatively common in cattle and goats.

Bacterial folliculitis is usually caused by a coagulase-positive *Staphylococcus* species. Both *Staphylococcus aureus* and *Staphylococcus pseudintermedius* (formerly *S. intermedius*) have been isolated.[7,8] In one study in horses, *S. aureus* accounted for twice as many isolates as *S. pseudintermedius;* the same study isolated some strains of *Staphylococcus hyicus* as well.[9] *Staphylococcus delphini* has also been isolated from horses on occasion. Many isolates are resistant to penicillin G.[9] Occurrence of pyoderma has been linked to poor nutrition and husbandry in some cases.[10]

Clinical Signs Clinical signs of staphylococcal pyoderma are most often crusts, usually in a circular pattern suggestive of dermatophytosis (this may be why equine pyoderma is underdiagnosed), epidermal collarettes (circular skin lesions with an exfoliative border, as seen in dogs with superficial pyoderma), or encrusted papules similar to the miliary dermatitis reaction pattern in cats.[7] These infections tend to vary in intensity of pruritus. Histology often shows folliculitis and furunculosis, but bacterial colonies are not always seen. A truncal form of bacterial folliculitis (contagious acne, contagious pustular dermatitis, Canadian horsepox) is often associated with poor grooming and trauma from tack and saddle; warm, wet weather; and heavy work. It is painful and interferes with working and riding. It is usually caused by a coagulase-positive *Staphylococcus* species but may also be due to *Corynebacterium pseudotuberculosis*[11] (more often a cause of deep pyoderma, as discussed later). In horses, folliculitis often develops in the saddle and lumbar region, particularly in the summer. The affected area may initially be swollen and sensitive, followed by formation of follicular papules and pustules. These may become confluent or rupture, forming plaques and crusts. Deep pyoderma followed by ulceration may develop over large areas of the body, especially the neck, sides of the thorax, inner surface of the thighs, and prepuce.

A pastern bacterial infection (pastern folliculitis) is often seen. Again, the causative agent is usually a coagulase-positive *Staphylococcus* species. As with most primary pyodermas, the mechanism by which the organism gains its foothold is unknown; it is not necessarily contagion or poor sanitary conditions. The lesions are usually limited to the posterior aspect of the pastern and fetlock regions; one or more limbs may be involved. Initial lesions consist of papules and pustules. If left untreated, they coalesce and may produce large areas of ulceration and suppuration that may be quite painful. The disease is usually not associated with systemic signs, and the general health of the horse is not affected.

A relatively uncommon nodular disease termed *botryomycosis* mimics actinomycosis or a deep fungal infection but is most often caused by *Staphylococcus* spp. in the horse. These may require surgical excision as well as long-term antibiotics.

Public Health Considerations In a 2000 study, methicillin-resistant coagulase-negative staphylococcal species were cultured from healthy horses in Japan. The authors concluded, "These organisms must be considered a potential threat to horses and veterinarians who care for them."[12] In a 2006 study from the Netherlands, methicillin-resistant coagulase-negative staphylococci were found frequently.[13] The organism was usually *Staphylococcus sciuri* rather than *Staphylococcus epidermidis*, which was found in the humans in close contact with these horses. No methicillin-resistant *S. aureus* (MRSA) was found in healthy horses. A more recent article reported *S. sciuri* from a horse's skin infection.[14]

There is little public health concern about methicillin-resistant *S. pseudintermedius* (MRSP) or *S. delphini* because clustering of equine cases does not appear to be important, and zoonotic disease potential seems to be limited.

In contrast, a single strain of MRSA was isolated from *both* humans (13%) and horses (4.7%) on horse farms in Canada and New York state.[15] In looking at horses admitted to a university teaching hospital (Ontario Veterinary College), MRSA was isolated from 120 (5.3%) of 2283 horses. Of these 120 horses, 50.8% were positive at admission, and clinical infections due to MRSA were present or developed in 14 animals. Horses colonized at admission were more likely to develop clinical MRSA infection. Administration of ceftiofur or aminoglycosides during hospitalization was the only risk factor associated with nosocomial MRSA colonization. Another strain of MRSA was isolated from a small number of horses

at the Veterinary University in Vienna, Austria.[16] Of further concern is the finding of nasal carriage of *S. aureus* in cattle.[17]

Of most concern is the finding of humans reporting skin lesions after contact with a community MRSA-positive affected foal, despite short-term contact with standard protective barriers. Isolates from the foal were indistinguishable from those affecting humans.[18] In another study, MRSA was isolated from 15.6% of veterinarians or technicians in large animal practice, as opposed to from only 4.4% of small animal personnel; large animal practice was the only statistically significant variable associated with colonization of MRSA.[19] On two horse farms with endemic MRSA, active screening and strict implementation of infection control protocols resulted in a rapid decrease in the number of colonized horses. Most horses eliminated MRSA without antimicrobial treatment.[20]

Therapy The antibiotic usually used for bacterial skin infections in the horse is oral trimethoprim-sulfamethoxazole (TMS [30 mg/kg PO q12h for 2 to 6 weeks, longer for deep infections]).[7] Interestingly, dosing intervals for intravenous (IV) administration of TMS in horses may not be appropriate for use in donkeys or mules. Donkeys eliminate the drugs rapidly compared with horses.[21] In cases of staphylococcal resistance to TMS, enrofloxacin or doxycycline may be used. Doxycycline is less expensive but associated with a higher incidence of colic. Dosage is usually 10 mg/kg PO q12h. Off-label use of oral enrofloxacin formulations for poultry, ruminants, or swine has been suggested. The formulation for poultry may be used; the dose is 7.5 mg/kg PO once daily. Use of enrofloxacin in young horses (<2 years old) should be avoided because of concerns about damage to the articular cartilage.[22] One report of use of an oral gel formulation of enrofloxacin (100 mg/mL of gel) showed good clinical efficacy for infections in several organs, but almost one third of the horses had some diarrhea, and 10% had oral lesions.[23] It was hypothesized that this latter side effect could be overcome with a tap-water rinse of the oral cavity after administration; however, we have seen oral lesions and a swollen tongue, suggestive of a contact reaction, develop in a horse receiving the oral water rinse. Interestingly, enrofloxacin binds to melanin in equine hair, although the clinical implication is unknown.[24] Ceftiofur sodium (2.2 mg/kg IM or IV q12-24h) may also be used for pyoderma in horses, although its usefulness over a long period is limited by its parenteral route. In one report of 15 horses, vancomycin was used, alone or in combination with an aminoglycoside, to treat MRSA and enterococcal infections. The average vancomycin dosage was 7.5 mg/kg IV q8h over 30 minutes. The antibiotic, alone or in combination with an aminoglycoside, was safe and effective. Because of the problems with emerging resistance, we recommended that vancomycin use in horses be limited to cases where culture and susceptibility indicate effectiveness and no reasonable alternative treatment exists.[25]

For localized lesions, mupirocin ointment 2% or silver sulfadiazine cream (Silvadene) may be effective. Recently a gel with 0.4% stannous fluoride (MedEquine Gel [Dolphin International Inc., Camdenton, Mo.]) was reported as resolving bacterial skin infections in horses.[26] As shampoos, ethyl lactate (Etiderm [Virbac, Fort Worth, Tex.]) or a *tris*-EDTA/4% chlorhexidine combination (Triz-Chlor 4 [Dechra, Overland Park, Kan.]) is helpful.

Pyoderma in ruminants has not been studied as much as in horses. In goats, lesions (often pustules that progress to crusts) usually begin on the udder and spread to the abdomen, thigh, perineum, and face. Pruritus is variable. Stress from parturition is also an important predisposing factor in goats. In sheep, a generalized staphylococcal scalded skin–like disease has been reported in lambs.[27] Staphylococcal infections associated with *Psoroptes ovis* infestation have also been noted.[28,29]

In cattle, furunculosis caused by *C. pseudotuberculosis* manifests as a locally extensive, raised, raw lesion that is frequently hemorrhagic. The lesions are almost constantly covered with a serosanguineous exudate, and palpation of the lesions usually elicits a pain response. Treatment is similar to treatment of dermatophilosis, taking into consideration culture and susceptibility results as well as withdrawal times for food animals.

Equine Staphylococcal Cellulitis

Cellulitis is a severe deep, suppurative process in which a poorly defined area of infection tends to dissect through tissue planes. Although many organisms are capable of producing cellulitis, staphylococcal cellulitis has been recognized as a specific disease entity in Thoroughbred racehorses.[30] Coagulase-positive staphylococci have been isolated from all reported cases, and, when speciated, the isolates were classified as *S. aureus.*[31] Other studies of pathogenic *Staphylococcus* spp. from horses have suggested that *S. aureus* and *S. (pseud)intermedius* are the major cutaneous pathogens,[31,32] with no significant difference in their susceptibility patterns.[31] In a retrospective study of limb cellulitis in 44 horses, coagulase-positive *Staphylococcus* spp. were cultured from 33 of 36 horses from which specimens were obtained. Horses that were febrile at admission or developed laminitis were significantly less likely to survive.[33]

The cause of staphylococcal cellulitis is uncertain. Management practices may be associated with the condition because bathing, grooming devices, or handlers can be a source of the organism.[32]

The initial symptom is acute swelling and lameness that involves one or more limbs. Lesions progress rapidly by dissection along tissue planes. The overlying skin becomes devitalized and frequently sloughs. Accompanying systemic signs include increased rectal temperature and heart rate. Laminitis of either the affected or the contralateral limbs, osteomyelitis, and bacteremia are possible sequelae.[30] Diagnosis is based on the results of bacterial culture and biopsies for routine histopathology.

Treatment must be aggressive and initiated early in the course of the disease. Pending the results of bacterial culture and sensitivity, treatment should include broad-spectrum antibiotics like TMS. To decrease edema, promote weight bearing, and reduce the chance of laminitis, therapy should include NSAIDs, hydrotherapy, and support wraps.[30] The prognosis for complete recovery is guarded.

Equine *Corynebacterium pseudotuberculosis* Cellulitis

Solitary or multiple abscesses or nodules with many draining tracts that progress to diffuse cellulitis are often caused by *C. pseudotuberculosis;* when it affects the pectoral region it is called "pigeon fever" in the United States. This type of deep *Corynebacterium* infection may occur where caseous lymphadenitis is common in sheep or goats (although proximity to small ruminants is not a requirement), and it also may be seen seasonally when insect populations and activity are maximal. This may occur in the dry seasons, giving rise to another vernacular name, "dry land distemper", when the process affects the inguinal region. Insect vectors seem probable, especially stable, horn, and house flies.[34] The frequency of this disease is increasing in the United States.[35] Draining nodules or abscesses are especially common in the pectoral region and occasionally affect the face, neck (Color Plate 40.6), axilla, groin, and limbs; they begin deep and enlarge, often with much edema, and rupture in 1 to 4 weeks, discharging viscid creamy pus, a major source of contamination. Abscesses most often rupture externally. Diagnosis is by clinical signs, with the infection readily identified by bacterial culture of aspirate samples from abscesses.

VetBooks.ir

VetBooks.ir

The synergistic hemolysis inhibition test is useful for diagnosis of internal abscesses but unreliable for external abscesses.[36] Recent molecular studies of various strains of *C. pseudotuberculosis* have not shown definitive relationship between an individual strain and the location of the abscess.[37,38]

Treatment depends on location. If the abscess is in the axilla and thus painful on movement or prevents locomotion, establishing drainage is important, and antibiotics are indicated.

The antibiotics most commonly used are ceftiofur (2 to 4 mg/kg IM q12-24h), enrofloxacin (7.5 mg/kg PO or IV q24h), procaine penicillin (20,000 to 50,000 IU/kg/day), rifampin (3 to 5 mg/kg PO q12h), and TMS (30 mg/kg PO q12h).[36,39] Interestingly, there have been no changes in the minimum inhibitory concentrations of effective antibiotics over time.[40] Treating with TMS and rifampin concurrently can lead to a greater incidence of colitis and is to be avoided. If the decision is made to use antibiotics but drainage cannot be easily established (e.g., axillary abscess, with owner unwilling to allow veterinarian to use trocar and drain), antibiotics *must* be used for a minimum of 1 month. If the abscess is solitary and not causing pain or fever, antibiotics are usually unnecessary, but bringing the abscess to a head with hot packs or heat-inducing agents (ichthammol) is important. Once an abscess has drained, gentle cleaning with tamed iodines or chlorhexidine is indicated.

Early diagnosis and long-term antimicrobial treatment are important for a successful outcome in horses with internal *C. pseudotuberculosis* infection. Ultrasonographic imaging is an important technique for identifying specific organs affected, aiding in obtaining samples for a definitive diagnosis, and monitoring response to treatment. Pregnant mares with internal infections are at risk for fetal loss. Preexisting chronic organ disease may be associated with a poor prognosis.[41]

Digital Dermatitis (Papillomatous Digital Dermatitis, Bovine Digital Dermatitis, Foot Warts, Heel Warts, Hairy Foot Warts, Hairy Heel Warts, Mortellaro's Disease, Strawberry Heel Warts, Verrucous Dermatitis)

John A. Angelos • Muhammad Muzafar Makhdoomi

Digital dermatitis (DD) of cattle is an infectious, contagious, painful dermatitis of the digital skin and is a major cause of lameness in dairy cattle. Economic losses in affected animals are attributable to decreased milk production and reproductive performance, increased costs for treatment and management, and increased culling rates.[1-4] Primarily a disease of housed dairy cattle, DD was first described in Italy in the mid-1970s[5]; however, since the mid-1990s this condition has increased in prevalence throughout the world. It has been reported in many countries, including several in Europe, the United States, Japan, Chile, Canada, Mexico, and New Zealand.[6-9] Digital dermatitis has also been found in feedlots and pasture-based dairies. Although it is difficult to assign costs to specific diseases, DD is thought to be of lower cost than sole ulcers or foot rot; however, prevalence of DD can be much higher than that of other lesions, so the total cost can be high.

Clinical Signs

Roughly 80% of DD lesions occur on the plantar aspect of the hind foot, immediately proximal to the heel bulbs and adjacent to or extending into the interdigital space.[8] A 2017 study of dairy cattle in New Zealand reported that approximately 75% of affected cows were infected on one rear limb and 25% were infected on both rear limbs.[10] Less commonly, lesions occur on the plantar aspect of a forefoot and the dorsal aspect of any foot.[8] Lesions are confined to the digital skin below the level of the dewclaws.[8]

The gross appearance of lesions and the predilection for hind limbs and skin-hoof wall junctions, especially those bordering the heel bulbs and interdigital space, distinguish this disease from other causes of bovine dermatitis. The clinical appearance of DD has been classified into five stages, advancing from acute to chronic and in some cases to regression and healing.[11] The first stage describes small (~1 to 2 cm) focal lesions with a reddened circumscribed area (hence the name "strawberry heel warts") that are extremely painful and have hairs on the periphery of each lesion that are erect and matted in exudate. The second stage has larger (2 to 6 cm) ulcerated lesions with peripheral hairs that are two to three times longer than surrounding hairs. In the third stage healing lesions have a rough, encrusted surface and are often gray in color. The fourth stage (often referred to as the "hairy" or "papillomatous" stage) consists of chronic proliferative lesions with varying degrees of hyperkeratosis characterized by black papilliform projections that vary in length from 1 mm to 3 cm. If the fifth stage is reached, it is characterized by healing of the lesion.[11] Washed surfaces are characteristically extremely painful and either red and granular, or they may appear as white-yellow, gray, brown, or black papillary areas with red, granular areas interspersed. Lesions bleed easily if traumatized. The time required for lesions to progress to a mature ("hairy" or papillomatous) state varies. DD lesions involving the interdigital space often occur in association with a previous interdigital fibroma. Lesions may have a foul odor[12,13] attributed to secondary anaerobic bacterial growth in exudate material (most likely *Fusobacterium necrophorum* and/or *Porphyromonas levii*).[14] Swelling of the pastern and fetlock regions is not typical in uncomplicated cases. Lameness is characteristic on dairies where DD has a high prevalence, but lameness is not consistently related to lesion size or chronicity. As such, animals can appear much lamer than one might expect given the size of the lesion. If affected digits go untreated, those with plantar or palmar lesions may become clubbed when a cow preferentially bears weight on toes while the heels overgrow.

Differential Diagnoses

Differential diagnoses for an individual case of DD include interdigital necrobacillosis (foot rot; foul in the foot; interdigital phlegmon), interdigital hyperplasia (corns; interdigital fibroma), interdigital dermatitis, and traumatic injury with granulation tissue. For herd problems of lameness localized to the digit, differentials should include DD, interdigital necrobacillosis, interdigital dermatitis, laminitis, excessive sole wear from caustic or abrasive flooring, and improper or no hoof trimming. If signs of polysystemic disease exist, coronitis from viral diseases (e.g., bovine virus diarrhea, vesicular stomatitis, foot-and-mouth disease) should be considered.

Epidemiology

Digital dermatitis typically spreads rapidly among adult cows, often affecting a majority of adult animals within a year after introduction. Once established in a herd, lameness is more typically seen in first and second lactation cows, commonly after entry into a milking string.[15-17] Lesions are typically seen in older cows; however, lameness in older animals is less common compared to younger cows. Bulls and yearling heifers can be affected, but these groups generally comprise a small proportion of clinical cases. Freestall herds tend to be more commonly affected than stanchion (tie stall) housed cattle or pastured cattle. DD is almost exclusively seen in dairy cattle, with no breed predilection. In endemic herds it is unlikely that eradication is possible.

Retrospective epidemiologic studies in the United States identified two significant risk factors in high-prevalence herds: muddy or wet conditions and purchasing replacements from off premises.[3,16] Experimental transmission of DD was demonstrated when homogenates of DD lesions were applied to

VetBooks.ir

the feet of calves subjected to moisture and low oxygen tension.[18] Conditions of moisture and low oxygen tension are present on confinement dairies if manure management and hygiene are inadequate. Other risk factors include use of outside hoof trimmers and not washing hoof-trimming equipment between cows.[3]

Pathogenesis A variety of anaerobic organisms have been associated with DD.[6,19-25] *Treponema* spp. spirochetes have been identified most consistently and form the majority of the colonizing bacterial flora on active lesions; these organisms also can invade the epidermis and dermis.[23,25-29] These spirochetes induce a humoral antibody response in cattle with active lesions.[30] Although DD lesions can exhibit gross and histologic similarities to viral papillomas, bovine papilloma virus has not been found in lesions.[2,8,31]

Evidence suggests that DD is a multifactorial disease involving environment, microbial, host, and management factors.[3,8,15-17,25] Rough flooring; inadequate drainage; fecal and urine accumulation on floors; dirty, wet, or uncomfortable bedding areas; and overcrowding can adversely affect digital skin health and increase the risk of DD. Transmission among cattle and between herds may be facilitated by contact between clinically and subclinically affected cows, fomites such as foot-trimming instruments, and livestock trailers and farm equipment.

Chronic and recurrent cases in otherwise healthy adult cattle are reported; immunity to DD, if it does develop, may be incomplete or temporary. Recurrence is common in individual cows following antimicrobial treatment.[11,32] Spontaneous regression of lesions and resolution of lameness, while possible, occurs rarely.

Pathologic Findings Histopathologic criteria to establish a diagnosis of DD are[8]:

- Circumscribed plaque of eroded acanthotic epidermis attended by parakeratotic papillomatous proliferation profusely colonized by spirochete-dominant bacterial flora
- Loss of stratum granulosum
- Invasion of stratum spinosum by spirochetes
- Infiltration of neutrophils, plasma cells, lymphocytes, and eosinophils into the dermis.

If performed, biopsies should be full-thickness 4- or 6-mm punch biopsies, washed off with sterile saline and placed in buffered formalin. Although helpful in confirming a diagnosis, histopathology is not necessary to make a diagnosis because DD lesions typically exhibit a characteristic appearance and occur in specific locations in cattle.

A biopsy study on treatment and recurrence of DD showed that clinical and histopathologic diagnoses were in agreement for active lesions before treatment.[32] Histopathology on day 28 post treatment with lincomycin or oxytetracycline, however, demonstrated that more than half of the lesions that appeared clinically resolved still had microscopic evidence of infection.[32]

Treatment and Prevention The most common methods for treating DD involve application of topical antibiotics.[8,11,32,33] There are no antibiotics currently labeled for treatment of DD in the United States; therefore adherence to extralabel drug-use regulations and observance of scientifically established withdrawal times is imperative when risk of drug residues exists.

The most commonly used therapy for DD is topical oxytetracycline or lincomycin applied in spray or powder form. To apply it topically as a spray, oxytetracycline or lincomycin is mixed with deionized or distilled water in a 2- to 4-L agricultural sprayer (25 g/L oxytetracycline, 8 g/L lincomycin) and applied directly to the heels of DD-affected cattle daily for 5 to 14 days. For topical powder treatment, 2 grams of oxytetracycline or lincomycin powder are placed on a cotton pad, applied to the affected area with an elastic bandage, and changed daily for 5 to 10 days. Both treatments elicit a rapid response consisting of dramatic lameness regression and reduction in wound size. The recurrence rate is high enough that topical treatments may need to be repeated after 45 to 60 days for more effective control. There have been no reported antibiotic residue violations resulting from topical application of antibiotics.[34] Parenteral penicillin and ceftiofur have been reported to be efficacious[8] but may require milk withholding. Given the current restrictions on extralabel use of ceftiofur in the United States, practitioners should be mindful of following all label directions related to dose, route, frequency, and duration of therapy.

Footbaths containing a variety of products, including 5% formalin, oxytetracycline (1 to 4 g/L), lincomycin (1 to 4 g/L), copper sulfate (0.25 to 1 g/L), zinc sulfate (20%), or sodium hydroxide,[12,31,35-38] can assist in controlling the disease in infected herds; however, low-prevalence herds (<10%) may have better responses. Some authors believe that individual treatment should precede foot-bathing on contaminated farms.[37] When there is a high prevalence of DD, individual topical treatment is likely to be more effective at reducing prevalence. Contamination of footbath solutions with feces and urine can reduce effectiveness, and constant vigilance by farm workers to maintain footbath solutions is important. This problem can be reduced by placing two footbaths in tandem and spaced several feet apart, with the first containing water or a mild detergent solution for cleaning the feet and the second containing the antiseptic solution. Footbath solutions should be changed every 150 to 300 cow passages. Footbaths should be a minimum of 8 feet long and 2 to 3 feet wide, with a depth of 5 to 6 inches. The baths should be covered to limit dilution by rain and placed in an exit alley out of the milking parlor to avoid splash contamination of teat ends before milking. Additional footbaths can be placed in other locations to treat bulls, dry cows, and heifers. Footbath treatment frequency should be based on empirical evidence of efficacy every 2 to 7 days. Laws regulating the use and disposal of chemicals vary; therefore consultation with local regulatory agencies is prudent before initiating a control program on a dairy.

Improving environmental hygiene, providing dry and comfortable bedding, and improving ventilation to allow drying of stalls and alleys may reduce the incidence or severity of clinical cases. Foot-trimming equipment, mobile tilt tables, and livestock trailers should be thoroughly cleaned and disinfected to prevent potential transmission of the agents of DD between dairies. Use of iodine disinfectant containing 2.5% (weight per volume) available iodine reduced detection rates for *Treponema* spp. on hoof-trimming equipment.[39] Published vaccination studies with *Serpens* spp. or *Treponema* spp. bacterins have not reported efficacy against DD.[33,40,41]

Interdigital Dermatitis, Heel Horn Erosion, and Heel Cracks

Interdigital dermatitis (ID) is a condition of acute or chronic inflammation confined to the epidermis of the interdigital skin. It is characterized by small circular ulcers in the interdigital epithelium, and severe cases are often characterized by ulceration, necrosis, and underrunning of the hoof horn.[42,43] It can cause varying degrees of lameness, which may be absent to moderate in severity, and can be associated with a distinct odor. A moist, white to gray serous exudate is often present. In many cases, skin irritation results in hypertrophy and may increase the growth rate of the axial hoof wall along with excessive horn production along the axial wall and sole. It is one of the most commonly diagnosed foot conditions, with

prevalence running as high as 50% in affected herds.[44] Prevalence is most common on dairies with intensive stocking rates and moist, filthy conditions. In tied systems the hind digits are more commonly affected. In freestall systems lesions are observed equally between the front and hind digits. Diffuse epidermal erosion in the interdigital cleft may be seen in early cases. More chronic cases exhibit hyperkeratosis leading to a roughened appearance to interdigital skin and dorsal and palmar commissural skin folds. Chronic cases are frequently accompanied by cracks in the heel (heel horn erosion, "slurry foot," "slurry heel"), with potential underrunning of the heel horn and subsequent severe lameness.

Some investigators have hypothesized that ID and DD are forms of the same disease complex. *Dichelobacter nodosus* may be a primary or contributory pathogen[36] along with *Treponema* spp.[45] ID and DD share certain histologic characteristics suggesting contribution or involvement by spirochetes *(Treponema)*, and both can be successfully treated and prevented with the same topical antibiotics or footbaths. However, ID can persist on dairies that practice regular foot-bathing. Slatted, rather than solid, floor systems may reduce incidence of the condition. Causative organisms may survive within deep heel cracks, which should be trimmed to reduce accumulation of debris and allow exposure to foot bath solutions.

ID differs from interdigital necrobacillosis (foot rot), in which infection extends into the dermis, leading to fissure formation, infection of deeper structures if left untreated, and cellulitis of the pastern and fetlock regions.

In sheep, ID and virulent foot rot (VFR) are considered two different stages of the same disease complex,[46,47] with ID classified as a less severe form.[48] The same disease state is also classified as benign foot rot in Australia. Some authors designate the more severe form of disease as VFR in sheep, whereas others classify it simply as foot rot. In the UK, ID and VFR are the main causes of lameness in sheep[49] and major animal welfare issues.[50] The primary pathogen is *D. nodosus*, a gram-negative, rod-shaped anaerobic bacterium.[51-53] In sheep, ID is characterized by inflammation of the interdigital skin, resulting in lameness and loss of body condition.[54] In ID the interdigital skin appears pink and moist and is sensitive to touch, whereas VFR is characterized by underrunning of the hoof horn leading to separation of the hoof from the underlying soft tissue. The underrunning of the hoof horn begins at the junction of the skin fold with the heel that spreads anteriorly to the abaxial wall. This causes separation of the hoof horn from the laminae of the foot.[55] It is often accompanied by discharge of a grayish exudate that has a characteristic fetid odor.[51] Some authors have suggested a role of the host's acute inflammatory response to *D. nodosus* infection in leading to the development of clinical signs.[56]

The occurrence of ID is influenced by local climatic conditions.[57] In Australia a mean daily temperature greater than 10° C and a wet pasture are required for transmission of the disease. In the UK the disease can occur throughout the year and can be transmitted between sheep even when daily mean temperatures are greater than 10° C.[58] A study reported mini epidemics of ID during the spring in the UK, with increasing temperature and rainfall favoring spread of disease.[59,60]

In the UK, ID in sheep is treated with topical oxytetracycline spray (25 mg/mL) on the interdigital skin for 3 days. The use of topical antibiotic spray is highly effective at combating the disease[61,62] and leads to more than 95% recovery within 3 to 4 days.[61,63] Foot-bathing has also been used, but topical therapy is generally considered a more effective method of ID control. VFR can be difficult to treat with antibiotics, and recurrent cases of VFR can occur after 2 weeks of antibiotic treatment. VFR can be effectively controlled and eliminated from sheep flocks by vaccination with a *D. nodosus* serogroup-specific vaccine.[64]

Control and elimination programs for ID and VFR in the United Kingdom are based on empirical evidence that *D. nodosus* cannot survive off the host for more than 7 days.[51] Survival off the host (pasture) is dependent on moist conditions, and some authors have reported that *D. nodosus* does not survive on pasture for more than 2 weeks under warm and damp conditions. Therefore, under these conditions, sheep are not at risk of ID and VFR once pastures have been rested for 14 days. However, a recent study using qPCR reported that viable *D. nodosus* can survive for at least 40 days in soil microcosms, and the rate of survival is affected by soil type, moisture, and temperature, with lower temperatures (41° F) and clay soil favoring survival of higher loads of *D. nodosus*.[65] This is a step change in our understanding of the ability of *D. nodosus* to survive off a host. Aggressive treatment of infected sheep and preventing access of healthy sheep to *D. nodosus*–contaminated pastures for at least 40 days can potentially aid in controlling ID.

Viral Diseases

Stephen D. White

Papillomas (Warts, Fibropapillomas)

Definition and Etiology Cutaneous papillomas or warts occur (in decreasing order of frequency) in cattle, horses, goats, and sheep.[1-4] The growths usually occur in young animals,[4] as well as on teats of mature cattle and goats, and are white, tan, or gray firm, protruding masses with a dry, horny surface. They vary in size from 1 to 500 mm and may be single or multiple. Species-specific papillomaviruses (subgroup of papovavirus) are responsible for causing warts.[5-7] It is now accepted that parts of the bovine papillomavirus (BPV) genome are found in naturally occurring equine sarcoids.[8] There are at least 10 BPV strains, designated BPV-1 through BPV-10 (Table 40.1),[9] and probably more. At least two strains of virus are currently recognized in horses.

Clinical Signs Warts are usually small, benign growths that appear on animals younger than 2 years, persist for 3 to 12 months, and then spontaneously regress without causing clinical signs (other than a blemish). In cattle, warts on the teats, penis, or interdigital skin[10] or in the alimentary tract may produce clinical signs of pain or occlusion. Warts usually develop in the ears of young cattle after tagging or tattooing, especially if instruments are not disinfected between individuals; these are not age related. Teat warts also predispose to environmental mastitis. Occasionally individuals with (presumed) defective cellular immunity may develop multiple extremely large warts that may result in weight loss.

In horses, warts on the face are rather common but rarely cause a significant problem (Fig. 40.8). The previously reported congenital wart in young horses has now been more properly termed a *hamartomatous lesion* (epidermal nevus) and has been shown not to be virus induced.[11]

Warts are relatively rare in goats. They occur mainly on teats and may spread throughout the herd. A 1936 report described a herd outbreak involving the head, neck, shoulders, and forelegs in milking goats.[12] Does without adequate pigmentation on the udder develop persistent mammary gland warts that may undergo transformation to become squamous cell carcinomas.[13] There are probably at least two different strains of goat papillomavirus (head/neck and mammary).

Warts are rare in sheep but may occur on the face or legs. Differential diagnosis in sheep and goats includes contagious ecthyma (orf), ulcerative dermatosis, dermatophilosis, and sheeppox and goatpox.

VetBooks.ir

TABLE 40.1

Distribution and Appearance of Bovine Warts by Type of Virus

Virus Strain	Usual Site	Appearance	Comments
BPV-1	Nose, teats, glans penis	Filamentous or frondlike	Can prevent breeding when on penis
BPV-2	Head, neck, brisket, occasionally alimentary tract	Pedunculated or broad-based mass	Most common typical warts
BPV-3	Atypical warts, head, neck, possibly interdigital[a]	Nonpedunculated protruding growths, delicate fronds with hair between	Persist for years
BPV-4	Alimentary tract, urinary bladder	Pedunculated mass	See Chapters 32 and 34
BPV-5	Teat	Smooth, white	Persist for years; other types may also occur on teats
BPV-6	Teat	Round and either flat or frondlike	Similar in appearance to BPV-1 when frondlike

[a]Suspected, but BPV-3 has not yet been isolated from interdigital warts. Some authors speculate that interdigital warts may be caused by yet another new BPV strain.

BPV, Bovine papillomavirus.

Modified from Hunt E: Infectious skin diseases of cattle. *Vet Clin North Am Large Anim Pract* 6:163, 1984.

FIG. 40.8 Typical warts (papillomas) on the nose of a yearling horse.

FIG. 40.9 Aural plaques on inner surface of pinna of a horse's ear.

Treatment and Control Small warts can be crushed, pinched off, or surgically removed. Cryosurgery can be used on larger warts. Many regress spontaneously within a few months, even without treatment.

When show animals are involved or when animals have multiple large papillomas, tissue can be removed and made into crude autogenous vaccine (2 mL intradermally 3 times weekly) by homogenizing, grinding, freezing and thawing twice, filtering, and killing virus with 0.5% formalin. Autogenous wart vaccines are variable in their efficacy, as are commercial vaccines.[14-16] The latter rarely seem to result in effective regression of existing warts but may prevent development of new lesions if the same BPV strain is involved. Autogenous vaccines can prevent new lesions caused by the same BPV strain in a herd. There is no indication that cattle vaccines have any efficacy in other species. No wart vaccines for horses, sheep, or goats are currently marketed.

Because the viruses can be transmitted directly or via fomites, prevention involves isolation; preventing animals from rubbing on each other; and not sharing halters, brushes, and other equipment. Dipping of dehorning, tagging, and tattooing instruments in a viricidal solution between animals will also slow spread of the virus.

Aural Plaques

Aural plaques is a form of viral papilloma that often affects the inner pinna (Fig. 40.9). Nonpruritic, these plaques may also occur on the genitalia and mammary glands. The color varies from pink to grayish-white. Plaques do not resolve spontaneously, as do the "classic" papillomas seen in young horses. Biopsy or "shaving off" aural papillomas may stimulate reduction or resolution of the masses, although in some horses this may only be temporary (6 to 12 months). This has been theorized to be due to the release of "papilloma antigens" into the bloodstream during the surgical procedure, prompting an immune response against the tumor. Imiquimod (Aldara-3M, Minneapolis, Minn.), a nonsteroidal local immune response–modifier cream, has been helpful in some cases when used 3 times weekly, every other week, for 2 to 4 months.[17] Owners should wear gloves and should be forewarned that there is frequently an impressive inflammatory reaction to the cream in the initial weeks of treatment.

A papillomavirus has been demonstrated in aural plaques on electron microscopy and with immunohistochemical techniques.[18]

Pseudocowpox

Pseudocowpox is a common parapoxvirus of cattle related to the viruses of contagious ecthyma (sore mouth) of sheep and goats and bovine papular stomatitis (see Chapter 32 for these diseases). All three parapoxviruses may cause nodular lesions on humans. The lesions of pseudocowpox are usually confined

VetBooks.ir

to the teats of cattle, and the disease is common worldwide. Cyclic waves of reinfection occur in a herd, where it causes minor teat lesions characterized initially by a small papule 2 to 3 mm in diameter, followed by crusting and circular spread of the lesion. Approximately 10 days later, the 15- to 20-mm lesion appears as a ring or horseshoe-shaped scab.[19] Lesions occasionally involve the udder, medial thighs, or scrotum. Deep ulceration is rare. There are no systemic signs of illness. The major problem associated with the teat lesions is an increased incidence of mastitis. The most important and common differential diagnoses are bovine herpes mammillitis and viral papillomas. Rare viruses involving the teat include vaccinia and cowpox.[19] Cowpox is a rare disease of cattle in Europe that causes ulcers and may also produce lesions in humans. Vesiculation is rare in pseudocowpox, in contrast to bovine herpes mammillitis, vaccinia, and cowpox. Recent advances in PCR technology have improved diagnostic sensitivity[20,21]; advances in vaccine technology have been reviewed elsewhere.[22]

Bovine Herpes Mammillitis (Bovine Herpesvirus, Bovine Ulcerative Mammillitis)

Bovine mammillitis teat lesions are caused by bovine herpesvirus 2 (BHV-2), which is widely disseminated in most cattle populations.[23,24] The disease may be epidemic or endemic. The virus may also cause oral lesions, udder lesions, or generalized skin disease in cattle. The teat lesions start as swollen, tender, edematous teats. Vesicles may appear in some lesions, whereas others ulcerate almost immediately. The teats become painful, and ulcers require 3 to 10 weeks to heal.[23,24] Mastitis is increased because the scabs on the teats are laden with bacteria. Diagnosis may be confirmed by isolation of the virus, the BHV-2 serum neutralization tester, or histologic demonstration of herpesvirus particles.[23,24] Therapy consists of segregation of affected animals from the rest of the herd, and affected cows should be milked last. Milkers should wash hands between cows. In severe cases, secondary infection may be controlled by topical antibiotic creams or parenteral antibiotics, with proper residue avoidance precautions in place.

Sheeppox and Goatpox

Sheeppox and goatpox are caused by capripoxviruses.[25] Both occur in Africa, Asia, and the Middle East; goatpox also occurs in parts of Europe and the United States. The two diseases are clinically similar, although sheeppox has the most severe systemic signs of the animal pox diseases. Studies have shown that the viruses are phylogenetically distinct and can be differentiated by molecular tools.[26] The diseases affect all ages, causing pyrexia, anorexia, conjunctivitis, rhinitis, and skin lesions. Prophylaxis using attenuated vaccines is the preferred control measure because the immunity is long lasting.[25,26] Morbidity is high. Mortality may reach 80% with sheeppox but usually is low with goatpox. Humans may develop skin lesions from goatpox.

Fungal Diseases

Stephen D. White

Dermatophytosis (Ringworm)

Dermatophytosis refers to infections of the keratinized tissues of the skin (stratum corneum layer of epidermis, hair, claws, hoof, and horns) by *Microsporum* and *Trichophyton* spp. Dermatophytosis is relatively common in the horse and in cattle, less common in goats, and rare in sheep.

Etiology and Pathogenesis The most common dermatophyte species isolated from horses are *Trichophyton equinum*, *Microsporum equinum*, *Trichophyton mentagrophytes*, and *Trichophyton verrucosum*.[1-3] *T. verrucosum* infections in humans caused by transmission from horses have been reported.[4] In ruminants the majority of dermatophytosis lesions are caused by *T. verrucosum* and to a lesser extent by *T. mentagrophytes*.[5] Transmission of the disease is usually from animal to animal by direct contact or indirectly through fomites such as grooming instruments, tack, housing, fencing, or feed bunks. The incubation period may range from 1 to 6 weeks.

Several factors may influence the susceptibility of an animal to dermatophyte infection. Age is probably most important, with younger animals more susceptible to infection. The susceptibility of young animals is most likely related to lack of prior exposure or infection and thus no immunity, as well as crowding of young animals and conditions that decrease resistance to infection (e.g., poor nutrition). Environmental factors like warmth and humidity also may play a role. Calves kept indoors or exposed to foggy weather with little or no sunlight have an increased incidence.

Under normal circumstances, dermatophytes only invade fully keratinized, nonliving tissues.[1] This results in weakened hair shafts, leading to alopecia.

In many cases, dermatophytosis is theorized to be a self-limiting disease, with the duration of infection ranging from 1 to 4 months. The spontaneous regression is at least partly related to the development of immunity, of which cell-mediated immunity is the more important. The immunity that develops is probably not complete, and its duration is unknown.

Clinical Signs The lesions are often circular; usually appear first on the face or in the axillary/girth area; and may spread over the trunk, rump, neck, head, and limbs (Fig. 40.10). Occasionally in the horse, dermatophytoses may be limited to the pastern region. Rarely, dermatophytes may be a cause of coronary band disease in horses. The mane and tail are rarely involved. Cattle and goats are frequently affected around the eyes and face (Fig. 40.11, Color Plate 40.7).

Lesions may be superficial or deep. Superficial infections are much more common and manifest with development of thick crusts or more generally a diffuse moth-eaten appearance with desquamation and alopecia, sometimes in a ring pattern. A small crust may form over the follicle, and the hair is lost. Occasionally the initial lesions may be urticarial, progressing to multifocal, sharply demarcated areas of alopecia and scaling. The degree of pruritus varies but is usually mild or absent. Erythema is usually absent or obscured by pigmented skin.

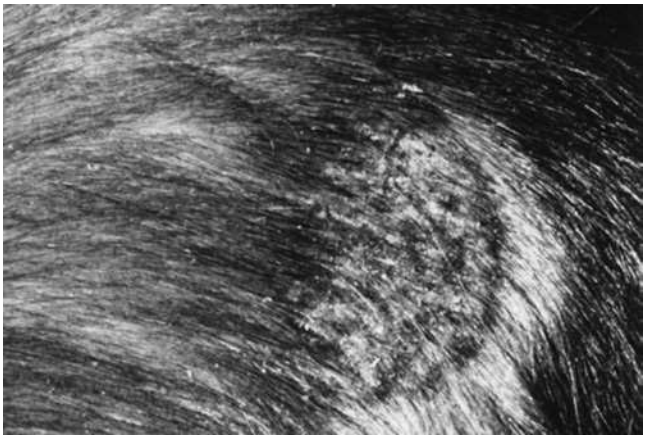

FIG. 40.10 Ringworm lesion (due to *Trichophyton* spp.) in a horse's flank area.

VetBooks.ir

FIG. 40.11 Ringworm lesions (due to *Trichophyton verrucosum*) around a calf's eye.

The lesions in cattle are usually characterized by excessive crusting, taking on an almost wartlike appearance.

Dermatophytosis must be considered in the differential diagnosis of any dermatoses characterized by multifocal alopecia or scaling and crusting. For a solitary lesion in horses, the occult sarcoid is the primary differential diagnosis. The two most important differential diagnoses of more extensive lesions are dermatophilosis and pemphigus foliaceus.

Diagnosis Direct microscopic examination of infected hairs is of value, but in general the most common and reliable method of diagnosing dermatophytosis is fungal culture (see Chapter 11). Broken hairs at the periphery of lesions are most satisfactory for this purpose. Large crusts should be avoided. The use of specialized indicator media is preferred. On occasion, dermatophytosis is diagnosed histopathologically. Interestingly, *Trichophyton* spp. occasionally may cause acantholysis, mimicking pemphigus foliaceus on histopathology.[6] As with other infectious diseases, the role of PCR is being investigated for diagnostic accuracy.[7]

Therapy Although 50% captan (2 tablespoons powder in 1 gallon water) has been recommended in the past and is certainly safe for tack, its effectiveness on the animal has been questioned. Lime sulfur (LymDyp [IVX Animal Health, St. Joseph, Mo.], LymDyp DVM [Bayer, Shawnee Mission, Kan.], LimePlus dip [Dechra, Overland Park, Kan.]), 1 cup to 1 gallon of water, and bleach 1:10 with water are both effective but messy, odiferous, and staining. Shampoos containing miconazole, ketoconazole, and/or 3% to 4% chlorhexidine may be effective. In Europe and Canada an enilconazole rinse (Imaveral [Merial, Baie d'Urfé, Canada]) approved for horses and cattle is highly effective.

Systemic treatment is occasionally needed. The efficacy and proper dose of griseofulvin in horses has not been thoroughly researched, but we have advocated and used a dosage of 100 mg/kg PO daily for 7 to 10 days on a small number of horses. Griseofulvin is a teratogen and should not be used in pregnant mares. Alternatively, 20% sodium iodide (NaI) may be given IV (250 mL/500-kg horse once or twice every 7 days) but is also contraindicated in pregnant mares because it may cause abortion.[2]

Vaccinating cattle against *T. verrucosum* has long been successful in Eastern Europe and Scandinavia. Effective control of ringworm in cattle has been achieved in regions implementing systematic vaccination.[8] Vaccination against *T. equinum* in horses may reduce the incidence of new infections and protect a high percentage (>80%) of vaccinates from infection. These data are based on results with an inactivated vaccine containing both conidia and mycelial elements.[9] In cattle, newer vaccines consisting of recombinant protein and deoxyribonucleic acid (DNA) derived from heat shock protein 60 of *T. mentagrophytes* have shown success experimentally.[10] Such vaccines are not yet available in the United States.

Malassezia Dermatitis

The exact species of the yeast *Malassezia* growing on large animals' skin is just beginning to be investigated.[11] In one study of horses and livestock, the *Malassezia* spp. isolated were identified as *Malassezia furfur*, *Malassezia slooffiae*, *Malassezia obtusa*, *Malassezia globosa*, and *Malassezia restricta*.[12] We have examined several mares with a *Malassezia* infection between their mammary glands that was intensely pruritic. The mares rubbed their tails and ventral abdomens. Physical examination showed a dry, greasy-to-the-touch exudate. Cytology of the exudate showed numerous yeast organisms, which were identified on culture as *Malassezia* spp. Treatment with a topical 2% miconazole/chlorhexidine shampoo was curative. We are aware of other similar cases. However, healthy nonpruritic mares may also have large numbers of yeasts in the intramammary area.[13]

Sporotrichosis

Sporotrichosis is caused by the yeast *Sporothrix schenckii*, which is most common in vegetation. The yeast becomes pathogenic in animals because of its dimorphic ability to convert from a yeastlike form at tissue temperatures between 35° and 37°C (95° and 98.6°F) to a mycelial phase (with branching, septate hyphae) at environmental or laboratory temperatures of 25° to 30°C (77° to 86°F).[14] The disease has been reported in many species of domestic animals.

The initial lesions are nodules, which frequently ulcerate, and the disease may progress to a lymphatic-cording disease. Rarely, the fungus will eventually spread to the lungs. In a retrospective study from UCD-SVM, equines were the second most common species affected, after cats.[15] Diagnosis is made by demonstrating the organism on histopathology, immunofluorescent antibody testing on affected tissues, impression smears, and culture.[15,16] This is a zoonosis, so care should be taken when handling suspected samples.

Successful therapy with a number of different systemic iodine preparations (NaI, KI) has been reported. Organic iodides have proved to have superior efficacy to inorganic iodides in treating equine sporotrichosis, with ethylenediamine dihydroiodide (organic iodide powder [Neogen Corp., Lexington, Ky.] or EDDI 20 Gr. Dextrose base [Vedco, St. Joseph, Mo.]) being a commonly used preparation. This product is in the form of a feed additive and can be mixed with a small amount of grain and administered at 1 to 2 mg/kg of the active ingredient once to twice daily for the first week, then 0.5 to 1 mg/kg once daily for the remainder of the treatment. In general, lesions will begin to regress during the first month of treatment, and therapy should be continued for *at least 1 month* beyond complete resolution of all cutaneous nodules and healing of any ulcerated lesions. Prematurely discontinuing therapy will invariably result in an unnecessary relapse of the disease. During treatment, the horse should be closely observed for any evidence of iodide toxicity (iodism), which includes excess scaling and alopecia, a serous ocular or nasal discharge, excess salivation, anorexia, depression, coughing, nervousness, or cardiovascular abnormalities. Should any of these signs develop, the treatment should be discontinued for 1 week, then resumed at three quarters the dosage at which the iodism was noted. In most cases the treatment is subsequently well tolerated.[17] Although both itraconazole and terbinafine have been shown to be effective in vitro against the organism isolated from a horse,

there is an absence of clinical reports of their use.[18] Successful management of an infected donkey with both KI and fluconazole has been reported.[15]

Histoplasmosis

Histoplasma capsulatum var. *farciminosum* ("farcy," the cause of equine epizootic lymphangitis in East Africa) infection has been reported in donkeys, where it can have considerable economic impact.[19] Cutaneous lesions resemble those seen in sporotrichosis. Treatment has not been well established but may be similar to the treatments for *S. schenckii*.

Phaeohyphomycosis

Phaeohyphomycosis is caused by a number of ubiquitous fungi that are either saprophytes or plant pathogens. These include *Alternaria*, *Drechslera*, *Cladophialophora*, *Cladosporium*, *Phialophora*, and *Stemphylium* spp. The correct terminology currently depends on the histologic appearance of the organism, as follows[20]:

- *Chromomycosis:* any pigmented fungi
- *Chromoblastomycosis:* pigmented fungi, primarily yeast
- *Phaeohyphomycosis:* pigmented fungi, both hyphal elements and yeast
- *Hyalohyphomycosis:* nonpigmented fungi, mainly hyphal elements

Cutaneous lesions arise from either trauma to the skin or disseminated disease. Animals with disseminated disease probably have a deficient immune system. Similar to the other deep mycoses, these lesions present as expanding nodules and draining tracts. Diagnosis is by biopsy or occasionally cytology. Histopathology shows foamy or epithelioid macrophages, and special stains will show the organisms. Veterinarians and their staff should be careful in handling material from infected animals, because the inadvertent inoculation of these organisms can cause human infections.

Treatment has generally included surgical excision or amputation if practical. Potassium iodide, as for sporotrichosis, and (if the owners can afford it) fluconazole per os at 5 mg/kg may be effective.

Zygomycosis

Similar to phaeohyphomycosis, zygomycosis is caused by a number of related fungal species that are ubiquitous saprophytes. GI and respiratory tract involvement is possible. Cutaneous lesions are thought to be caused by wound penetration. The disease typically occurs in tropical and subtropical areas. The two orders of Zygomycetes that cause disease are Mucorales, including the genera *Rhizopus* and *Mucor*; and Entomophthorales, including the genera *Conidiobolus* and *Basidiobolus*. Most cutaneous reports are in horses, although ruminants may have other organ systems affected.

The skin disease is ulcerative, nodular, and generally found on the trunk and neck. Generally, only one large nodule is present. Diagnosis is by histopathology and culture; a serum agar immunoprecipitation test has been useful in diagnosing conidiobolomycosis. Surgical removal, if possible, is preferred for treatment. Medical options include the iodides (not effective against the order Mucorales) and possibly the azoles or amphotericin B.[1]

Pythiosis

Pythium insidiosum is considered to be the causative agent of *swamp cancer*, also known as *Florida horse leech*, *bursattee*, and *kunker*. This organism is termed a *protista* and is found in tropical and subtropical areas worldwide, although its range may be expanding; it recently has been reported in a horse in northern California.[21] The pythiosis lesion occurs most often on the limbs, abdomen, neck, and lips and consists of dense granulation tissue containing masses of yellow-gray necrotic tissue, which sometimes are calcified and often are present as cores in fistulae and are removable intact. Such masses are known as *leeches* or *kunkers*. The granuloma ulcerates and extends peripherally and may reach a very large size in a short time. The overlying and adjacent skin is destroyed by both the inflammatory reaction and the self-mutilation by the horse. Important differential diagnoses are systemic fungal infections, habronemiasis ("summer sore"), and neoplasia. Although most reports in large animals are in horses, cattle, sheep, and goats may also be affected.[22-24]

Histopathologic examination of affected tissue reveals pyogranulomatous inflammation directly surrounding the organism. Isolation of organisms from the lesions is necessary for further identification and study, but histologic demonstration of the protozoa within tissues reacting to its presence is critical in establishing the causal relationship in an individual lesion. In obtaining culture, the kunkers are preferred to the actual tissue. For samples that cannot be processed immediately, acceptable handling techniques include storage at room temperature for up to 3 days, refrigeration for up to 5 days, shipping on cold packs, and storage in antibiotic solution, each combined with subsequent inoculation on selective media.[25] Recent advances in enzyme-linked immunosorbent assay (ELISA) or molecular techniques offer better potential for organism detection and identification.[26] Wide surgical excision combined with or without immunotherapy has been effective in some cases.[26-28]

Parasitic Skin Diseases

Stephen D. White

Pediculosis

Lice are obligatory ectoparasites that are generally host specific. Adults and nymphs are seldom able to live for more than a few days away from their host. Large animals suffer from infestation with several species of lice that belong to the orders Mallophaga, the biting lice, and Anoplura, the sucking lice (Table 40.2).[1]

Clinical infestations are most apparent during the winter months and reflect efficient louse reproduction during the late fall and the fact that summertime temperatures on body

TABLE 40.2

Lice Associated With Large Domestic Animals

Host	Mallophaga (Biting)	Anoplura (Sucking)
Horse	*Bovicola (Damalinia) equi* *Werneckiella equi equi*	*Haematopinus asini*
Cattle	*Bovicola (Damalinia) bovis*	*Haematopinus eurysternus* *Haematopinus quadripertusus* *Haematopinus tuberculatus* *Linognathus vituli* *Solenopotes capillatus*
Goats	*Bovicola (Damalinia) caprae* *Bovicola (Damalinia) limbatus* *Bovicola (Damalinia) crassipes*	*Linognathus stenopsis* *Linognathus africanus* *Linognathus vituli*
Sheep	*Bovicola (Damalinia) ovis* *Bovicola (Damalinia) caprae*	*Linognathus pedalis* *Linognathus ovillus* *Linognathus africanus*

areas exposed to sunlight are too high for lice. Apparent carrier animals within a herd maintain populations during the "off" season and serve as a source for reinfestation of the herd during the fall.[1] The hallmark of infestation is pruritus, and many clinical changes result from self-trauma. The neck and tail are typically affected first,[2] but infestation and clinical signs may become generalized. The coat becomes dry and scaly. Patchy alopecia and crusted ulcerations result from excoriation. A heavily infested animal may become anemic. Significant hide damage occurs as a result of excoriation, and hairballs may accumulate in the GI tract from self-grooming. Reduced productivity and weight loss result from decreased feed intake associated with restlessness. Diagnosis is usually by examination; a hand lens is useful (e.g., otoscope without cone). Interestingly, when a horse is exercised and becomes warm and sweaty, the lice will climb out toward the tip of the hair and are easier to find.[3]

Several treatment approaches exist. Ivermectin at 200 µg/kg every 14 days SC for 2 applications is effective for sucking lice but not biting lice. Application of an appropriate topical insecticide to infested animals and to all contact animals at 2-week intervals for 2 or 3 treatments is usually curative for both types of lice. Repetition of treatment is necessary to break the louse life cycle because eggs are not killed by insecticides and will hatch despite therapy. Effective topical agents include pyrethroids, permethrins, selenium sulfide, imidacloprid, phoxim, and fipronil.[3,4] Development of resistance is also possible.[5] Appropriate attention should be paid to withdrawal times in food animals. Cleaning of fomites like blankets, brushes, and rope halters is probably indicated, although lice do not live long off the host.

Trombiculidiasis

Trombiculidiasis is caused by the larval stages of mites commonly called "harvest mites" or "chiggers." The most common species affecting large animals are *Eutrombicula alfreddugesi* (North America) and *Neotrombicula autumnalis* (Europe). The adults and nymphs are free living. The larvae feed on mammalian hosts, secreting substances in their saliva that hydrolyze the epidermis and allow extraction of tissue fluids. The individual larval stage is short, but the infestation may be ongoing with the acquisition of new larvae from the environment. In the northern hemisphere, *E. alfreddugesi* is active from late spring through early fall, whereas *N. autumnalis* is more common in late summer to mid-fall. The mites may be found in wooded areas, grass, and hay.[3,6]

The clinical signs of trombiculidiasis are crusts and papules, especially on the face, neck, and extremities. Pruritus is variable.[6] Rarely, this parasite has been implicated in headshaking in horses.[7] Diagnosis may be made early in the course of infestation by careful inspection (e.g., hand lens) and finding the minute red-orange larvae in the center of a papule. The six-legged larvae have round bodies and may be identified specifically on skin scrapings or acetate tape preparations.[3] Although the larvae remain on the animal host for only several days, clinical signs may persist longer, so trombiculidiasis should be suspected even in the absence of mites in an animal with appropriate signs in the summer and fall.

The disorder is in theory self-limiting because of the short time of attachment of the parasite. However, if the pruritus is severe, corticosteroid administration is indicated.[3] Various products have been used on the horse to eliminate the larvae; 5% lime sulfur, fipronil, and permethrin are generally the safer parasiticides to use.

Mange

Mange is a general term for infestation by any mite species.

Psoroptic Mange

Psoroptic mange has been recognized in horses, cattle, sheep, and goats (and rabbits). The host specificity of *Psoroptes equi*, *Psoroptes ovis*, *Psoroptes natalensis*, and *Psoroptes cuniculi* is controversial; two reports state that the mites are all genetically homogeneous with little or no host specificity,[3,8] whereas another report documents an inability to transfer *P. ovis* to goats.[9] The mites do not affect people. Psoroptic mange is common in cattle but has been eradicated from horses and sheep in the United States; it is still a concern for sheep production in the United Kingdom and elsewhere in the world. The mites have a 2-week life cycle on their host but can live away from the host for up to 3 weeks. *Psoroptes* mites live on the surface of the epidermis and do not burrow. Symptomatic infestation tends to be more prevalent during the cooler months.

The hallmark of infestation in all species is pruritus. In cattle, crusted papular lesions are typically first apparent on the withers but then generalize, resulting in weight loss, secondary infections, and decreased production.[10] Horses develop papules, crusts, and alopecia most often at the base of the mane, tail, ears, and intermandibular area, with subsequent spreading to the trunk.[3] An otitis externa may be present, seemingly with *P. cuniculi*.[3] In sheep, typical lesions include papules and crusts in wooled areas, and secondary infection with *S. aureus* may occur.[11] The intense pruritus can be debilitating. Certain sheep (Merino) and cattle (Belgian Blue) breeds are more susceptible to infestation than others.[9,12] The immune response in sheep has been studied extensively, with early innate and longer-term adaptive cutaneous immunoinflammatory responses as well as mite antigen–directed IgE being reported.[10] Goats usually have lesions restricted to the ears, although infestation and symptoms may spread to the neck and body.[13,14]

Diagnosis is based on demonstrating mites in skin scrapings and ear swabs from affected animals. Psoroptic mites are recognized by their round bodies and long, segmented pedicles.[13] Recently, serologic assays have been useful in diagnosis, especially in identifying subclinically infested animals.[15]

A number of topical insecticides have been recommended for treatment and should be applied to all affected and contact animals according to the manufacturer's guidelines. These include deltamethrin, coumaphos, diazinon, malathion, toxaphene, and lime sulfur.[6,13,16] The contaminated environment should also be treated. Ivermectin, doramectin, and moxidectin have been used for *Psoroptes* spp. in large animals at 0.2 mg/kg,[6,17-19] usually for two to three times, given subcutaneously but treatment does not always eliminate live mites from all animals. There may be lesser efficacy when using generic formulations of ivermectin.[20] It has been recommended that *P. ovis*–infested cattle be isolated for a minimum of 14 days after treatment to prevent transmission to susceptible contact cattle.[18] *Psoroptes*-infested ears in horses should not be treated topically because of the resulting discomfort; reliance is on systemic treatment. Psoroptic mange is a reportable disease in the United States.

Chorioptic Mange

Chorioptic mange, also known as *leg mange*, is common in cattle and sheep, uncommon in goats, and seen with variable frequency in horses, depending on geographic area. Draft horses may be more susceptible than other breeds. *Chorioptes* spp. are relatively host specific and include *Chorioptes bovis*, *Chorioptes texanus*, *Chorioptes ovis*, *Chorioptes equi*, and *Chorioptes caprae*.[6,13,21] The mites do not penetrate the epidermis[6] and do not affect humans.[18] They have a life cycle that spans 2 to 3 weeks and can live off the host for only a few days.[16]

This disease is variably pruritic, more so in ruminants than in horses, and less so than infestations with *Psoroptes* or *Sarcoptes* mites. Lesions consisting of papules, erythema, scaling, crusting, ulceration, and alopecia result from self-trauma. In cattle the

lower aspects of the hindlimbs, the perineum (particularly the perianal fossa), tail, and scrotum are usually affected. Sheep typically demonstrate involvement of the lower limbs and scrotum. Goats have involvement of the lower limbs. Horses typically have lesions on the pasterns, although the ventral abdomen may become involved in severe cases. In all species, infestation can become generalized.[3,6,18]

Mites are often numerous and readily demonstrated with skin scrapings. Cattle may be asymptomatic.[18] Chorioptic mange will respond to treatments described for psoroptic mange, although ivermectin and related compounds are more effective in ruminants than horses; in horses, lime sulfur or fipronil applied once weekly for at least 1 month is recommended.[3,22-27] One study in horses showed efficacy using a single dose of moxidectin 2% oral gel (Equest [Fort Dodge Animal Health, Fort Dodge, Iowa]) at the manufacturer's recommended therapeutic dose of 0.4 mg/kg body weight.[26] Other studies have not found it to be effective in eliminating the parasite in a multihorse situation.[28] Chorioptic mange is a reportable disease in the United States.

Sarcoptic Mange

Sarcoptic mange is an uncommon contagious disease of horses, cattle, sheep, and goats. The etiologic agent is *Sarcoptes scabiei;* several subspecies are relatively host specific but can be transmitted to humans. The mite burrows into the epidermis, where the egg is deposited, and its life cycle is complete in 10 to 17 days. Transmission is usually by direct contact, but the mite has a variable survival time off the host, so environmental and fomite transmission are possible.[3,6]

Clinical signs are all referable to the severe pruritus caused by the mite. Lesions include papules, scaling, crusting, ulceration, and alopecia. The head (especially the ears) and neck are usually the initial areas of involvement, although lesions become generalized.[3,6,16] Horses in areas frequented by infected wild foxes may have lesions affecting the legs and ventral abdomen.[3] Dairy cattle may have an associated udder cleft dermatitis.[29] Sheep tend to have initial involvement of the nonwool areas. The ears should always be scraped for mites; the mite is identified by its rounded body, terminal anus, short legs, and long unsegmented pedicles.[3,6,16]

Because mites may be present only in small numbers, negative skin scrapings do not rule out the disease. Diagnosis should be based on clinical suspicion and response to therapy.[3,6,16,30]

Topical acaricides have been recommended for treatment and are applied to all affected and contact animals at 10- to 14-day intervals for 4 to 6 treatments. These include lindane (not recommended owing to toxicity in humans), coumaphos, diazinon, malathion, toxaphene, and lime sulfur.[3,6,16] Ivermectin 0.2 mg/kg SC at 2-week intervals for 2 to 4 injections (ruminants) or orally (horses) has been shown to be effective, as has injectable moxidectin and topical doramectin. The contaminated environment should also be treated. It is recommended that the state regulatory agency for livestock disease control be consulted for methods of treatment and products to use because sarcoptic mange is a reportable disease.

Demodectic Mange

Demodectic mange is a rare disorder, although it has been recognized in all large domestic species. The mites live in hair follicles and sebaceous and sweat glands and are host specific. They are not contagious between members of the same species, but *Demodex* spp. are presumably transmitted from mother to offspring during the first few days of life by direct contact with the dam. Little else is known about the life cycle of the mite.[3,6] Two species of *Demodex* are recognized in the horse.[3,30] *Demodex caballi* is a normal inhabitant of the pilosebaceous apparatus of the eyelids and muzzle and may be found in skin scrapings of these areas on horses in the absence of skin lesions. *Demodex equi* inhabits the pilosebaceous apparatus of the remainder of the body and on horses is the species that has been associated with disease. The species found on cattle, sheep, and goats are *Demodex bovis* and *Demodex ghanesis*, *Demodex ovis*, and *Demodex caprae*, respectively.[3,6,16,18,31]

Clinical signs are variable depending on the species affected. The disease is quite rare in horses, which may develop alopecia of the head and trunk; we have seen one case of concurrent demodicosis and chorioptic mange on the legs of a draft horse. Underlying pituitary dysfunction of the pars intermedia has been seen in some horses.[3] Pruritus and secondary pyoderma are variable. Goats and cattle usually develop nodular lesions that involve the face, shoulder, and neck.[32,33] In goats the nodular contents are white and caseous; microscopic examination for mites differentiates the lesions from *C. pseudotuberculosis.*[33] Sheep tend to develop periocular nodular lesions.

Diagnosis is based on recognizing mites with microscopic examination of skin scrapings or exudates obtained from nodular lesions. The mites are elongated and have short, stubby legs.[3,6,16]

No treatment has proved to be consistently effective in large animals, although relatively few case reports exist in the literature. Amitraz has not been successful in the treatment of caprine demodicosis.[33] Horses sprayed with 0.025% amitraz developed somnolence, depression, ataxia, muscular weakness, and progressive large intestinal impaction, suggesting that amitraz is contraindicated in equids.[34] Daily ivermectin has been suggested as a successful treatment for equine demodicosis, but dosages have not been codified. Oral ivermectin (0.67 mg/kg once weekly for 12 weeks) and pour-on eprinomectin (0.5 mg/kg) each successfully treated one goat with generalized demodicosis.[35] A combination of ivermectin injections of 200 µg/kg body weight twice weekly and amitraz dip once weekly has been reported as successful in cattle.[36]

Culicoides Hypersensitivity

The females of various *Culicoides* fly species ("no-see-ums," "punkies") may feed on either the dorsal or the ventral surface of the horse, affecting the mane, saddle, and rump or causing a ventral midline dermatitis in a diffuse pattern. Alopecia, papules, crusts, and erythema may all be present (Fig. 40.12). The insects induce a hypersensitivity response through salivary antigens; this condition is termed *Culicoides hypersensitivity* (Queensland itch, sweet itch) and is recognized in various areas of the world. Evidence indicates a hereditary predisposition to develop the hypersensitivity. Histopathology of lesions frequently reflects a hypersensitivity response.[37] Although many species of *Culicoides* exist, the three most commonly suspected of causing the allergic response are *Culicoides variipennis*, *Culicoides obsoletus*, and *Culicoides nubeculosus*.

FIG. 40.12 Severe *Culicoides* hypersensitivity in a horse, showing typical distribution of withers, shoulders, and head (not visible).

VetBooks.ir

Numerous studies have attempted to define the nature of the hypersensitivity response. One study found serum antibodies to *Culicoides* salivary glands in both healthy horses exposed to *Culicoides* bites and horses with insect dermal hypersensitivity.[38] In contrast, no antibodies were detected in serum from native Icelandic horses that had not been exposed to *Culicoides*. Anti–salivary gland IgG antibodies were detected in both groups of horses, whereas IgE antibodies were detected only in clinically affected horses.[38] Another study compared two groups of affected Icelandic horses: those born in Iceland (no previous exposure to *Culicoides*) and transported to Europe, where they were then exposed to the flies, and those born in mainland Europe. The former had IgE and IgG antibodies to a greater number of the insects' salivary proteins.[39] Further investigation of immunoglobulins in relation to *Culicoides* found significantly more IgE-bearing cells in the dermis and epidermis of acute and chronic lesions than in skin biopsies from healthy horses.[40] Further evidence for a hypersensitivity response was demonstrated in a study in which intradermal injection of a *Culicoides* antigen extract induced T-lymphocyte and eosinophil accumulation in the skin of affected horses.[41] Other studies have supported the immunologic nature of this disease.[42-46] Two recent reports have shown some linkage between insect bite hypersensitivity (IBS) and airway disease.[47,48]

The hallmark of disease is pruritus. Although no gender predisposition has been noted, Icelandic horses may have a higher incidence of allergic reactions to the *Culicoides* insects than other breeds. The disease is uncommon in horses younger than 1 year of age, with an onset usually between 2 and 4 years. *Culicoides* hypersensitivity may be seasonal, at least during the first few years of life, in temperate climates. Diagnosis is primarily by clinical signs. *Culicoides* antigens (commercially available in the United States by Greer, Lenoir, N.C.) seem useful in both diagnosis and treatment,[49-51] but this must be documented in large case studies.

Therapy is aimed at insect control, especially the following:

1. Stabling horses at sunrise and sunset, peak *Culicoides* feeding hours.
2. Ultrafine setting or screens placed in windows (60 squares to the square inch).
3. Fly control, especially keeping horses away from standing water and using permethrin repellents, usually 2% permethrin sprays. Frequently, sprays must be applied more often than the label recommends (i.e., daily, at least at first). We have had success using a nonpesticide herbal spray or roll-on (MedZone [VetShield & Sheen, Sun City, Ariz.]).
4. Overhead or stall fans (drafts interfere with insects' flight).
5. "Dresses" that physically obstruct the insects from reaching the skin.
6. Hyposensitization is controversial; success may vary with the presence of an adjuvant or the actual antigen used.
7. Oral prednisolone to manage the pruritus.

Ventral Midline Dermatitis of Horses

This is a reaction pattern in horses to ectoparasites, and not necessarily specific to any one arthropod. *Culicoides* hypersensitivity, *Onchocerca cervicalis* infestation, and black flies (Simuliidae) may cause generalized ventral midline dermatitis, whereas horn flies *(Haematobia irritans)* cause a focal dermatitis. Severe chorioptic mange may also involve the ventral midline. In all cases the lesions have variable alopecia, pruritus, and crusts. Treatment is based on eliminating or repelling the causative organism.

Other Flying Insects

Stable flies *(Stomoxys calcitrans)*, black flies (Simuliidae), horn flies *(H. irritans)*, horse flies (*Tabanus* and *Hybomitra* spp.), deer flies (*Chrysops* spp.), houseflies *(Musca domestica)*, face flies *(Musca autumnalis)*, and mosquitoes are commonly associated with irritant and allergic skin disease, as well as being vectors of many parasites (Color Plate 40.8). They must be controlled by limiting breeding areas and by repellents; 2% permethrins are often used. It is important to remember the relationship of these various flies to the environments they favor or require for breeding and when they feed, as follows:

Horse flies, deer flies	Vegetation and water	Daytime feeders
Horn flies	Cattle	Daytime feeders
Stable flies	Manure and decaying bedding	Daytime feeders
Black flies	Running water	Morning and evening
Culicoides	Standing water, manure and decaying vegetation	Twilight to dawn
Mosquitoes	Water	Dusk to 2 hours after sunset

Screwworm Infestation

Screwworm flies cause primary myiasis; the species of importance in the Americas is *Cochliomyia hominivorax (Callitroga americana)*. The fly was formerly found throughout the American tropics and subtropics from the southern United States to northern Chile.[52,53] It is no longer found in the United States or Mexico because of state, federal, and international eradication efforts.[54]

The adult fly is about three times the size of a housefly, with a metallic bluish or blue-green color.[52,54] Females are attracted to fresh wounds (castration, dehorning, branding, and shearing sites), abraded body orifices, areas soiled by discharges or excretions, and navels of newborns. They lay batches of 150 to 500 white eggs on the margin of damaged tissue in rows that overlap like shingles. Eggs hatch within 24 hours, and the larvae begin to feed in a head-downward position. Larvae are obligate parasites that require living tissue as feedstuff. They cannot develop in carrion. Larval development continues for 4 to 10 days, and at the time of their maturation they may have created a cavity 10 to 12 cm (4 to 5 inches) in diameter.[53] Mature larvae are about 2 cm in length, pink, pointed anteriorly and blunt posteriorly. The larvae then drop to the soil and pupate. The life cycle averages about 21 days and is favored by hot, humid weather.

Screwworms do not have a dormant stage in their life cycle and cannot overwinter in cold climates.[52] Thus the susceptible stage of development is the pupae, which will not survive soil temperatures below 15° C (59° F). The feeding larvae burrow deeply, creating a cavernous lesion characterized by liquefactive necrosis, profuse brownish exudate, and an objectionable odor. The syndrome is self-perpetuating in that wounds infested by screwworm larvae become increasingly attractive to gravid females. The end result is often death of the host from secondary bacterial infection, toxemia, and fluid loss.[53]

Treatment of wounds requires clipping and cleansing, as well as destroying all larvae. Dressings containing larvicides and antiseptics should be applied. Preparations containing lindane or organophosphates have been used in an ointment or gel base. The treatment is repeated twice weekly. When large numbers of animals are affected, a 0.25% solution of coumaphos, chlorfenvinphos, or fenchlorphos may be applied to herds with a power sprayer. Calves may become ill from the spray; thus applications should be restricted to the ventral abdomen.[53] Another study showed that the curative efficacy of fipronil 1% against *C. hominivorax* larvae infestation in castration wounds was 100%.[55] Even more impressive, doramectin as a prophylactic treatment was 100% effective in prevention of *C. hominivorax* infestations.[56]

Control of screwworm flies in the United States has been achieved largely through the release of sterile males, because of the single mating tendency of the female fly. The eradication program has proceeded through Mexico south to the 21st parallel.[52] Screwworm myiasis is a reportable disease in the United States, and suspect larvae should be preserved in 70% alcohol for positive identification.[57]

Blow Fly Strike (Fleeceworms, Woolmaggots, Secondary Screwworms)

Blow flies are found throughout the western hemisphere. The species of importance include *Cochliomyia macellaria* (secondary screwworm), *Phaenicia sericata* (green bottle fly), and *Phormia regina* (black blow fly). The flies tend to be most common in the warmer regions, with the exception of *P. regina*, which is widespread throughout the cooler parts of North America and Europe.[52] Blow flies cause serious loss of sheep and wool in many countries.[54] Female flies are attracted to decaying animal matter, such as wounds infested by primary screwworms, infected sores, carcasses, and fleeces that are dampened with feces, urine, or bloody fluids.[52] They lay eggs in batches of up to 300, which hatch within hours. The larvae feed on necrotic tissue but may invade healthy tissue. Larvae develop for 3 to 5 days and, when fully mature, are white and 6 to 12 mm in length. The larvae then drop to the ground for pupation. As soil temperatures fall, larvae fail to pupate and may overwinter until the following spring. The entire life cycle is generally complete in 2 to 4 weeks under ideal conditions of warm temperatures and high humidity.[53]

Unlike primary screwworms that feed in pocket-like aggregations, secondary screwworms tend to be dispersed throughout the infested tissue. In wool infestation the larvae may remain on the skin surface, feeding on the decomposing wool, or may penetrate the skin through small abrasions. The most common site of involvement is the breech. Infested tissue attracts more ovipositing females, and thus the syndrome is perpetuated.[52] Affected sheep are restless and do not feed. They move with their heads close to the ground, bite or kick at their wounds, and continually wriggle their tails. Affected wool is moist and brown with an obvious odor. Animals may become systemically ill and die.[57]

Treatment of individual wounds is as described for screwworms. Control involves management practices that decrease the incidence of wounds or skin irritations. Sheep are often clipped below the tail and between the hindlimbs ("crutched"), where wool is likely to become saturated with urine or feces. Castration, shearing, docking, and lambing are avoided during the summer season.[52]

Cutaneous Onchocerciasis

Definition and Etiology Cutaneous onchocerciasis in horses is a common filarial dermatitis with a worldwide distribution. Its incidence in the United States has decreased dramatically since the introduction of ivermectin for routine deworming. In a report from South America, *O. cervicalis* microfilariae were detected in midventral skin biopsy samples in 215 (17.9%) of 1200 horses examined, and the adult worms were recovered from 200 (16.6%) ligamentum nuchae from the same animals.[58]

The disease is caused by the microfilaria of *O. cervicalis* and is seen primarily in adult horses.[59,60] Adults typically are found coiled in the funicular part of the ligamentum nuchae, where they produce calcified nodules. Viviparous females may live for up to 5 years and produce large numbers of microfilariae that migrate through connective tissues to the superficial layers of the dermis. Preferential areas of microfilarial localization include the ventral midline, lower eyelid, and lateral limbus of the eye.[59] The infection is transmitted by *Culicoides*, which act as an intermediate host. The larvae are ingested by the vector and undergo development into the third-stage (L_3) larvae in approximately 2 weeks. The L_3 larvae enter the animal host through lesions created by the feeding vector.[61] Many horses are infected with the parasite without demonstrating clinical disease.[59,61] A form of cutaneous onchocerciasis seen in donkeys in Africa and possibly in other nearby areas causes severe ulceration in the withers and neck region; it is the adult parasite (sometimes extractable by the handful) that causes this problem. This is possibly caused by the species *Onchocerca raillieti*.

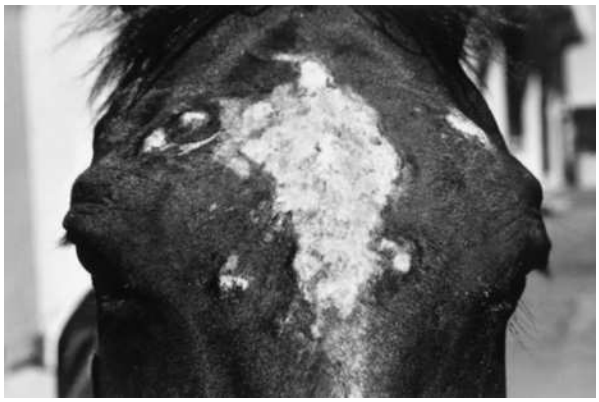

FIG. 40.13 Cutaneous onchocerciasis in a horse.

Pathophysiology Pathogenesis is believed to involve a hypersensitivity reaction to antigens released by dying microfilariae.[59,61] This theory has support because not all infected horses demonstrate disease, neither the presence nor the severity of the dermatitis is correlated with the number of organisms present, and treatment with filaricides often causes a temporary exacerbation of clinical signs.

Clinical Signs Clinical signs occur most often in older horses and can include both ocular and cutaneous lesions.[59,61] Ocular lesions include uveitis, conjunctivitis, keratitis, and depigmentation of the lateral limbus.[62] Cutaneous lesions include diffuse or patchy alopecia, erythema, and scaling. Focal cutaneous depigmentation is common. Lesions tend to occur in regions where microfilariae are typically present in highest concentrations, such as the ventral midline, face (Fig. 40.13), base of the mane, anteromedial proximal forelimbs, and anterior pectoral region. An inflammatory, alopecic, or hyperpigmented area in the center of the forehead is highly suggestive of the disorder.[62] The dermatitis is generally reported as being nonseasonal and nonpruritic.[61,63]

Diagnosis and Histopathology Because many normal horses have microfilariae without disease, the finding of microfilariae does not prove that they are the cause of the cutaneous lesions. In addition, because microfilariae tend to "nest" in the dermis, there is a tremendous difference in the number of microfilariae recovered from adjacent skin samples.[60,64] Thus although the absence of microfilariae makes cutaneous onchocerciasis unlikely, it does not definitively exclude it as a diagnosis. Differential diagnoses should include ventral midline dermatitis caused by the horn fly *H. irritans*, hypersensitivity reaction to *Culicoides*, dermatophytosis, and infestation with mange mites.

Ultimately diagnosis should be based on history, supportive clinical findings, exclusion of other differential diagnoses, and most importantly, response to treatment.

A positive *Onchocerca* microfilarial saline preparation demonstrates slender, delicate microfilariae that are approximately 8 × 220 µm. Typical histopathologic changes include an eosinophilic and lymphocytic perivascular dermatitis, a finding that is nonspecific and common to many other equine parasitic dermatoses (see Chapter 11). Aggregations of microfilariae may be found in the superficial dermis or perifollicular region.[59,61,64]

Therapy

Ivermectin or moxidectin are the treatments of choice and are administered at 0.2 mg/kg PO.[65,66] Most horses improve within 2 to 3 weeks. Minor adverse reactions, including fever and swelling of the periorbital, facial, and ventral midline regions, may occur in up to 25% of infected horses treated with ivermectin; moxidectin did not cause posttreatment dermal reactions in one study.[66] Severe reactions may benefit from treatment with corticosteroids, but most reactions resolve within 24 to 72 hours. Because there is no effective adulticide, recurrence may be noted as soon as 2 months after therapy. Most animals remain free of clinical signs for 6 to 12 months.[63,65] Re-treatment is recommended at 4-month intervals. Interestingly, ivermectin has been reported as having both greater and lesser GI absorption in donkeys than in horses. This awaits more clarifying studies.[67]

In cattle, onchocerciasis has been caused by the microfilariae of *Onchocerca gutturosa* and *Onchocerca lienalis* and, in Africa, *Onchocerca ochengi*.[68,69] Flies of Simuliidae are the vectors. The disease causes nodules and crust on the skin, including the teats; adult worms surrounded by neutrophils were detected free in the teat canal.[70] Ivermectin and moxidectin are effective treatments.[68]

Stephanofilariasis

Cutaneous stephanofilariasis is a filarial dermatitis of cattle. The disease is caused by organisms of the genus *Stephanofilaria* and has been observed in cattle in many countries.[71,72] Within the United States the disease is most prevalent in the western and southwestern regions, where it is caused by *Stephanofilaria stilesi*.[57,62,72] Adults and microfilariae inhabit the epidermis. The parasite is transmitted by the female horn fly *(H. irritans)* when it feeds on lesions on the ventral midline.[62] The microfilariae are ingested and develop to infective L_3 larvae in 2 to 3 weeks. The L_3 stage is introduced into the animal host on subsequent feedings.[72]

Clinical signs of cutaneous stephanofilariasis include a ventral midline dermatitis initially associated with a papular eruption. The scrotum may also be affected.[73] The lesions progress to nodules, alopecia, and crusted ulcers. There may be mild pruritus.[53] Diagnosis is based on history and appropriate clinical signs, excluding differential diagnosis and demonstration of the nematode. Biopsies may be taken as described for equine onchocerciasis, or the crust can be removed from an acute lesion and deep skin scrapings performed to recover the parasite. The tissues should be minced in isotonic saline and then examined microscopically. Multiple skin scrapings may be required to demonstrate the parasite. Either adults or microfilariae may be found. The adult male is about 3 mm in length, and the adult female is about 6 mm in length.[70] Microfilariae are 50 µm in length.[70] Characteristic histopathologic findings include a perivascular dermatitis associated with an eosinophilia. Microfilariae may be noted in the dermis, and adults in epithelial-lined cysts at the base of the hair follicles, although both may be difficult to find.[70]

There is no approved treatment for stephanofilariasis, although approved topical organophosphates have been suggested.[60] Some authors have not recommended treatment, because clinical signs are relatively mild in many animals.[72] Cattle with zebu ancestry may be more resistant.[71]

Hypoderma (Warbles)

Definition and Etiology

Infestation with the larvae of *Hypoderma* spp. is a common and serious economic problem in cattle and is recognized sporadically in horses that are pastured near cattle. Occurrences have also been reported in sheep, goats, and humans.[74] Warble flies are present in the northern hemisphere between 25 and 60 degrees latitude in more than 50 countries of North America, Europe, Africa, and Asia. *Hypoderma* spp. are not established south of the equator.[60,74] The U.S. cattle industry loses millions of dollars annually because of cattle grubs.

Two species of *Hypoderma* parasitize cattle: *Hypoderma bovis* and *Hypoderma lineatum*. The latter prefers warmer climates and is the only *Hypoderma* species present in the southern United States. Each of the species occurs in the northern United States and Canada.[60] *H. lineatum* and *H. bovis* have very similar life cycles, but the stages of *H. lineatum* tend to occur 3 to 8 weeks earlier than those of *H. bovis*. Timing of the life cycle also varies with local geographic and climatic factors.[60,74]

The adult flies are beelike in appearance, covered with dense chin bristles (hair), and are 12 to 188 mm in length, and they have nonfunctional mouthparts.[75] They have a short life span, only 1 week. Adult flies are active in the spring to early summer, with *H. lineatum* appearing 3 to 4 weeks before *H. bovis*. Female *H. lineatum* flies deposit eggs on the hairs of the legs or lower body, whereas *H. bovis* tends to deposit eggs on the rump or upper parts of the hindlimbs. Total egg production by a single female has been estimated to range from 500 to 800.[75] The eggs hatch in 3 to 7 days, after which the larvae penetrate the skin and begin their migration through the connective tissues. *H. lineatum* larvae migrate to the subcutaneous connective tissues of the esophageal wall, whereas *H. bovis* larvae migrate toward the spinal canal. The first-stage (L_1) larvae remain in this location for 2 to 4 months during autumn and early winter. Between January and February the larvae begin a final migration through the connective tissues to the subdermal tissue of the back of the host, where they form a breathing hole through the skin. Cysts (warbles) develop around L_1 larvae. Within the cyst the larvae undergo two molts over a 4- to 6-week period. The L_3 larvae (grubs) emerge from the breathing pore, fall to the ground, and pupate. Adult flies emerge from the pupae in 1 to 3 months, and emergent adults are ready to mate almost immediately.[57,75] The life cycle is complete in 1 year. Most larvae fail to reach normal size and complete their life cycle in the horse.[74,75] A recent study suggests a humoral response from the host against the larvae while they are intact. Once the larvae are destroyed, cellular response occurs, isolating and destroying the remains of the larvae.[76]

Clinical Signs

CATTLE. During the spring and summer when adult flies are active, "fly worry" may be a serious problem. Cattle exhibit a stampeding behavior called "gadding" when chased by ovipositing females, even though the flies do not bite or sting. This fear reaction results in self-injury and decreased feeding and milk production.[75] Diagnosis of warble flies in goats by ELISA has been reported, but it is not known whether this is applicable to cattle.[77]

Clinical lesions are not usually observed in association with migration of L_1 larvae unless the larvae die along the migratory path.[74] Lesions that have been associated with infestation of L_1 larvae of *H. bovis* include fat necrosis and inflammation of the connective tissues surrounding the spinal canal. Secondary periostitis, osteomyelitis, and rarely paralysis or other nervous disorders may occur. Similarly, infestation with L_1 larvae of *H. lineatum* in the submucosa of the esophagus may cause inflammation and edema in the surrounding tissues. Swallowing and eructation may be hindered, resulting in bloat and subsequent respiratory failure.[74]

VetBooks.ir

Lesions most often observed with *Hypoderma* infestation are attributed to L_3 larvae. Warbles occur along the back from the shoulders to the tailhead and from the dorsal midline to a point about one third the distance down the sides. The lesions may be firm to fluctuant, raised, and painful to the touch. They measure approximately 3 cm in diameter and contain a breathing pore that usually exudes a yellowish serum. Excisional biopsy of a nodular lesion reveals the larvae within a cystlike structure that contains yellow fluid. The surrounding tissue is necrotic. Secondary infection of the cysts can result in large suppurating abscesses. The number of warbles in an infested animal may range from 1 to 300. Infestations are most serious in younger animals and become progressively less severe with age. Emergence of the grub results in healing, although carcasses retain evidence of infestation and are devalued at slaughter.[60,74] Diagnosis is usually by direct clinical examination, but immune diagnosis using pooled serum and/or milk sample is also possible.[78]

HORSES. Most horses have only one or two grubs, but heavy infestation is present in rare cases. Lesions associated with L_3 larvae include small nodular swellings that develop dorsally and frequently in the region of the withers. Most lesions have a breathing pore.[57] Differential diagnosis is most often eosinophilic granuloma (nodular collagenolytic granuloma, nodular necrobiosis), but mastocytoma, sterile nodular panniculitis, and amyloidosis should also be considered. Posterior paralysis associated with involvement of the spinal cord has been reported in both horses and cattle.[75]

The season, location of the lesions, and presence of a breathing pore are usually diagnostic. Larvae can be recovered by enlarging the breathing pore with a scalpel and extracting the grub.

Therapy When small numbers of cattle are affected with just a few grubs, manual removal of the grubs is possible by simply enlarging the breathing pore. This is usually the preferred treatment in horses as well if only one or two lesions are present. Care must be taken to remove the larvae in their entirety, because breaking the larvae and rupturing the cyst during removal can result in a severe systemic reaction.[60,74]

Systemic insecticides are the only means of eliminating the migrating larvae. Organophosphates or the macrocyclic lactones (doramectin, eprinomectin, ivermectin, moxidectin) have been used for this purpose and are applied on the midline of the back.[74,79,80] Administration of insecticides should be timed to provide treatment in early autumn after all eggs have hatched and larvae are in the early stages of their connective tissue migration. L_3 larvae are less susceptible to insecticides, and destruction of larvae in later stages of migration increases the risk of serious secondary illness. It is advisable not to administer systemic insecticides later than 8 to 12 weeks before the anticipated first appearance of grubs along the back.[60,74] In the northern United States and Canada, treatment of cattle with systemic insecticides is not recommended from October 1 to March 1; this is when *H. bovis* larvae are in the epidural space and *H. lineatum* larvae reside in the esophagus.[60]

Sheep Keds

The sheep ked, *Melophagus ovinus*, is a wingless fly approximately 6 to 7 mm in diameter with a ticklike appearance. Sheep keds have a worldwide distribution. They primarily parasitize sheep and occasionally goats that are kept under poor management conditions.[60,81] Recently the sheep ked has been shown to be a vector of *Rickettsia raoultii* and *Rickettsia slovaca* (of the spotted fever group of organisms).[82]

The entire life cycle is spent on the host. Females live 4 to 5 months, individually laying 10 to 15 larvae that are cemented to the wool or hair. The larvae pupate in 12 hours, and the adult emerges 3 weeks later. Adults feed on blood and do not survive longer than a few days off the host. Transmission is by direct contact, and infestation is more common in the winter months.[60,61,81]

Clinical signs of infestation include pruritus with subsequent self-trauma, wool stains from the flies' fecal material, and, in severely parasitized animals, anemia. Multiple firm nodules (cockles) develop because of repeated puncture of the skin as the keds feed.[60,61] Infestation results in economic loss from a reduction in dressed carcass weights of lambs, reduced clean dry weight of fleece, wool staining, and reduced value of sheep skins because of nodular defects.[60,81,83] Diagnosis is based on demonstration of the parasite.

Therapy involves shearing all sheep in the affected flock, followed by two topical applications of malathion, diazinon, or coumaphos at 14- to 21-day intervals to kill emerging adults.[60] Because the larvae are attached to the wool or hair some distance above the skin surface, many larvae and pupae are removed by shearing.[61,83] Imidacloprid has been shown to be effective in killing the parasite.[84] All new animals should be isolated and treated before introduction to prevent reinfestation. A control program includes annual treatment of the entire flock.

Cutaneous Habronemiasis (Equine Summer Sore)

Habronemiasis ("summer sore") is a granulomatous disease caused by the deposition of *Habronema microstoma*, *Habronema muscae*, or *Draschia megastoma* larvae by flies at the site of wounds or natural body moisture (sheath, eyes).[85,86] Adult parasites normally reside in the stomach, where they cause little tissue reaction, with the exception of *D. megastoma*, which produces gastric nodules of varying sizes near the margo plicatus. Females are viviparous, and larvae are passed in the feces, where they are then ingested by the larvae of flies acting as intermediate hosts. *H. muscae* and *D. megastoma* develop in the housefly, *M. domestica*, and *H. microstoma* develops in the stable fly, *S. calcitrans*.[60] The L_3 larvae are then deposited around the horse's mouth and swallowed to pass to the stomach, where they mature to adults. Cutaneous lesions occur when the larvae are deposited in damaged skin or areas of natural body moisture. The larvae cannot penetrate normal healthy skin.[61] In these aberrant locations, they are unable to mature to adults, and the resulting proliferative lesions are thought to represent a hypersensitivity reaction to the dead or dying larvae. In temperate parts of the world, habronemiasis is a seasonal disease, occurring in warm, wet weather.

Arabians, gray horses, and horses with a dilute hair coat seemingly have a predilection for this disease. The medial canthus of the eye, male genitalia, nictitating membrane ("third eyelid"), and distal extremities are the most common parts of the body affected.[85] Lesions consist of ulcers and nodules. Diagnosis is based on clinical signs, history, and the presence of calcified concretions (sulfur granules) and is confirmed by biopsy. The nodular lesions may take on the gross appearance of neoplasia. Alternatively, the larvae may infest a preexisting tumor, especially squamous cell carcinoma of the male genitalia, and a biopsy is crucial for accurate diagnosis. Characteristic histopathologic findings include granulation tissue with a diffuse infiltration of eosinophils and an ulcerative epithelial surface. The granulation tissue usually contains focal areas of coagulation necrosis surrounded by a dense eosinophilic infiltrate. Cross-sections of larvae can often be identified within some of the necrotic foci.[85] Rarely, larvae are found in scrapings from the lesions.[60] Larvae are not always found in the biopsy sections[85]; in these cases, if neoplasia has been ruled out, presumptive treatment for habronemiasis should be performed. A PCR assay for diagnosing habronemiasis has been developed and

may hold promise in the future for cases where larvae are not found on biopsy.[87]

Treatment in the past has been either corticosteroids or organophosphates, topical or systemic. Ivermectin (0.3 mg/kg PO) has been shown to be effective and is considered the treatment of choice by many clinicians. Moxidectin (0.4 mg/kg PO) may also be used. These medications may be used once to twice in treating this disease. Systemic corticosteroids (e.g., prednisolone 1 mg/kg PO once daily for 10 to 14 days, then tapered over 2 weeks) or intralesional or topical corticosteroids are often used because of the hypersensitivity-reaction nature of the disease process. In severe cases, surgical removal or debulking of the lesion should be considered.[86]

Habronemiasis has been seen in horses routinely given ivermectin as part of their deworming program.[86] Prompt removal and disposal of manure and soiled bedding are important to eliminate vector breeding habitats. Insect repellents should be applied to affected horses. Face guards (fly masks) will also prevent infection. In general, the prognosis for resolution of individual lesions is good if the therapeutic goals are achieved.

Besnoitiosis

Donkeys have a higher reported incidence than horses for infections with the protozoal parasite *Besnoitia bennetti*.[88-91] This organism is the same species that afflicts cattle and is closely related to *Besnoitia tarandi*, which afflicts reindeer *(Rangifer tarandus)*.[89] The mode of transmission has not been determined. Skin lesions affect the nares, skin, and sclera. Males and younger animals may be at greater risk.[91] Diagnosis may be from histopathology, serologic testing, and PCR. Unfortunately there is no known treatment.

Bovine besnoitiosis, due to the cyst-forming organism *Besnoitia besnoiti*, is widespread in Africa, Asia, and southern Europe, although its range may be expanding.[92] Economic losses result from decrease in cattle and milk production, transient or definitive sterility of bulls, laminitis, and mortality.[92-94] Goats are also affected by this parasite. Lesions are reported as warm and painful edema progressing to excessively folded skin, primarily on the legs, udder or scrotum, and head.[95] The mode of transmission is unknown, although flying insects have been suspected.[96] Diagnosis is as with donkeys; the skin of the rump may be the best place to biopsy.[97-99]

Tumors and Cysts

Squamous Cell Carcinoma

Stephen D. White

Squamous cell carcinomas (SCCs) are tumors composed of squamous epithelial cells. They occur in all domestic species and are the most common bovine ocular tumor (see Chapter 39) and the second most common tumor recognized in the horse.[1] Although their gross appearance may vary, these tumors are usually slightly raised, broad based, and white to pink and have a cobbled or cauliflower-like surface (Color Plate 40.9). SCCs frequently occur on the penis and sheath of aged stallions and geldings (see Chapter 43). They also occur on the lips, nose, eyelids, eyes, and ears of horses. SCC often accompanies cutaneous papillomas of the udder and teats in Saanen milk goats, as well as female Angora goats in South Africa. The ears, base of the horns, perineal region, and prepuce may also be affected.[2,3] SCC is reported as the most common cancer of the ear of sheep; an outbreak primarily affecting the eyelids in 15% to 18% of a sheep population has been reported.[4] Diagnosis is by biopsy. There is increasing evidence that SCC in horses and sheep is associated with papillomavirus infection.[5-8]

The treatment of choice is wide surgical excision.[2,9,10] Solar elastosis (aggregates of thick, wavy, interwoven elastic fibers mixed with areas of degenerated collagen), when seen histologically with SCC, may lend a more favorable prognosis after complete surgical removal of lesions.[11] Other treatment modalities reported as successful include cryosurgery, radiofrequency hyperthermia, and radiation therapy.[2,12] Another study showed that topical application of 5-fluorouracil (5-FU) and intralesional cisplatin were effective in horses with SCC.[13-16] Piroxicam was successful in the long-term control of SCC with metastases in one horse.[17]

Equine Sarcoid

Alain P. Théon

Sarcoids

EPIDEMIOLOGY. The equine sarcoid was first reported by Jackson in 1936.[1] It is the most common tumor in Equidae (horses, donkeys, and mules), affecting between 1% and 3% of Equidae across the world.[2] Various sources report that histologically confirmed equine sarcoids constitute between 30% and 70% of all tumors and 70% and 90% of all skin tumors.[1,3-5] Because most estimates of incidence and prevalence are established from veterinary referral hospital data with high caseloads of affected horses, the true population base is unknown.

Sarcoids are locally aggressive, nonregressing, fibroblastic tumors of the dermis and subcutis with a variable proliferative epithelial component. This dual involvement of the epidermis and the dermis is the hallmark of sarcoids and explains the multiple and evolving clinical appearances of the tumor. The epidermal component of sarcoids shares features of a benign papilloma, and the fibroblastic component is consistent with a low grade fibrosarcoma.[6] These characteristics lead to an incorrect diagnosis of fibrosarcoma or nerve sheath tumors when the surrounding skin is not included in the tissue analyzed.[3]

Despite numerous clinical reports on sarcoids, the clinical and epidemiologic data are still puzzling. The inconsistent and sometimes conflicting data do not support any gender, breed, age, and genetic predispositions or any anatomic predilection.[2] However, paradoxical findings between studies may simply reflect the lack of histologic confirmation of the disease in most reported studies, but they may also represent regional or national variations of the clinical characteristics of sarcoids.

It is widely accepted that bovine papillomavirus (BPV) types 1 and 2 are associated with the pathogenesis of sarcoid disease. Although papillomaviruses are strictly species specific, an equine papillomavirus has not been identified in sarcoids. As opposed to other species, equine sarcoid is the only documented infection of a heterologous host by papillomavirus.[7] While BPV1 has been shown to be more prevalent in sarcoids from horses in Europe, the eastern United States, and Australia,[8-10] BPV2 has been more commonly reported in lesions from horses in the western United States and Canada.[11,12] Recently, sarcoids collected in Brazil were found to be associated with BPV13, which is genetically more than 90% homologous to BPV1 and BPV2.[13]

BPV1 and BPV2 genomes and transcripts have been found consistently in equine sarcoids.[11,14-18] Sequences of early-expressed genes of the viral genome including *E5*, *E6*, *E7*, and occasionally *E2* are consistently detected in sarcoid tumors and surrounding normal cutaneous margins but not in other tumor types.[19-21] Both the epithelial and the fibroblastic components of the tumor contain differential viral gene sequences that are actively transcribed.[15,17]

However, the role of BPV in the etiology of sarcoids continues to be questioned. Although equine fibroblasts can be transformed in vitro following BPV1 infection,[22,23] experimental

transmission studies of sarcoids have been unsuccessful. Inoculation of sarcoid cell–free extract in cows does not induce warts, nor does it induce sarcoids in unaffected horses.[3] Experimental cutaneous infection with BPV induces fibropapillomas that are clinically similar to sarcoids. The lesions, however, regress spontaneously with production of neutralizing antibodies to the virus and presence of viral DNA sequences in white blood cells.[24,25] In contrast, histologically confirmed, naturally occurring sarcoids do not regress and are not associated with detectable serum antibody responses to BPV.[26]

The infection in horses is considered nonproductive because BPV cannot replicate in horses nor be serially passaged from BPV-induced fibropapillomas.[17,25] Full viral life cycle has never been demonstrated in Equidae, and viral particles have never been detected in lesions. Hence the disease is currently accepted as the result of an abortive cycle, dead-end infection where only early BPV gene sequences persist episomally[27,28] or are integrated in host DNA.[29]

The mode of transmission of the disease is unknown and does not require contact with cows. Intradermal injection of primary sarcoid fibroblasts containing viral episomes,[24] naked full-length BPV1 genome,[24] or transforming genes (*E5* and *E7*)[30] does not induce sarcoids in horses and donkeys. Supporting evidence for an equine-to-equine infectious cycle that maintains BPV without the need for bovine host is missing. The finding that the majority of sarcoids collected in Austria, Switzerland, the United Kingdom, and Poland harbored equid-specific BPV1 variants, and that bovines lack these variants,[31-35] further strengthens the theory that BPV is not transmitted from bovines. This is confirmed by a study where BPV DNA sequences were detected in healthy skin of horses not known to have ever been in contact with bovines.[36]

An epidemiologic BPV DNA analysis of a sarcoid outbreak in donkeys and mules in a rescue sanctuary revealed that donkeys were not the victims of an epidemic but had accidently developed sarcoids associated with different BPV variants and were assumed to have acquired infection before their rescue.[37] In addition, evidence of a transmissible infectious cell line has not been found.[38] Because only complete BPV virions can induce transformation, contamination cannot occur by casual contact with contaminated fomites or affected horses[36] or by BPV-infected insect bites[39] or blood samples.[40] As a result, horses are considered to be nonpermissive hosts for BPV,[41] and horizontal BPV transmission remains to be documented.

The presence of viral genetic material appears to be directly associated with tumor development. However, BPV DNA sequences have also been detected in healthy skin[36] and in some cases of dermatitis.[42] In addition, the presence of viral DNA sequences has also been reported in skin swabs of unaffected horses and in peripheral blood mononuclear cells of horses with unrelated skin lesions (abscess, carcinoma, and hoof canker).[40,43] As a result, intracellular persistence of BPV transforming genes is not sufficient to produce the disease, and the role of BPV in the etiology of sarcoids continues to be questioned.[22,23]

Molecular Biology The mechanisms of cellular oncogenesis are similar to those of other transforming papillomaviruses. Cell transformation is associated with episomal or genomic integration and expression of the three transforming genes *E5*, *E6*, and *E7*. The gene products, *E5*, *E6*, and *E7*, are cell cycle regulators necessary for host cell proliferation and viral genome replication. In sarcoids, overexpression of these genes associated with persistent infection underlies cell transformation and progression into tumor cells. *E5* is always found and expressed in sarcoids. *E5* binds to and activates the platelet-derived growth factor beta receptor (PDGFβR),[44] which triggers several downstream effectors pathways controlling cell proliferation, cell survival,[44] and invasion.[45] *E6* and *E7* proteins bind to cell cycle control gene products, blocking their activity. They specifically promote cell cycle progression and prevent apoptosis and therefore immortalize the transformed cells.[33] *E6* is a transcriptional activator that inactivates the apoptotic and cell cycle arrest functions of the tumor suppressor gene *p53*. Loss of functional activity of tumor suppressor *p53* has been confirmed in sarcoid cells in culture and in tumors.[14,19,23,46,47] *P53* loss of transactivation function without *p53* mutation has been confirmed in sarcoids.[48] *E7* cooperates with *E5* as well as with *E6* in cell transformation.[49] Although *E7* lacks the binding domain of the tumor suppressor retinoblastoma protein (Rb),[50] it still inhibits apoptosis in a Rb-independent pathway, which provides transformed cells with a survival advantage.[51] The mechanisms by which *E7* and its cellular targets contribute to cellular transformation in sarcoids are not fully understood.[52]

The presence of inflammatory cells of the innate and adaptive immune system that infiltrate sarcoids provide evidence of an antitumor immune response that could eliminate abnormal cells before they can become tumorous in BPV-positive unaffected horses. Although there is evidence that the inflammatory and immune response may inhibit the development of cancer, BPV1- and BPV2-infected equids seem to lack an effective antiviral immune response to BPV and BPV-infected tumor cells. As a result, sarcoid lesions persist and progress despite the presence of cytotoxic T cells and T-helper cells in lesional and perilesional tissue.[53] It is speculated that *E5* and *E7* downregulation of the immune response may contribute to successful viral infection and allow cells to evade immune surveillance. *E5*-dependent downregulation of the surface expression of major histocompatibility complex class I (MHC I), by reducing transcription of the MHC I heavy chain gene and blocking transport of the MHC I complex to the cell, has been shown to depress adaptive immune response and allow persistence of infected cells.[54] In addition, BPV *E7* along with *E5* have been shown to block the innate immune antiviral response by downregulation of Toll-like receptor 4 (TLR4) expression.[55] Further evaluation of the defective host antitumor response ruled out a recruitment of actively immunosuppressive inflammatory cells such as regulatory T cells (Tregs). Tregs' cell density was not different in sarcoids compared to normal skin.[53]

Although the interplay between BPV *E5*, *E6*, and *E7* and their downstream targets is critical to immortalize and transform cells as well as to conceal them from the immune system, epidemiologic and experimental data indicate that persistence and overexpression of viral transforming genes are not a sufficient cause to induce sarcoid. The initiation of sarcoid appears to be due to a viral-induced inhibition of apoptosis rather than uncontrolled cell proliferation, as the markers of cell proliferation, such as cyclins and their respective kinases, are not different from those of normal skin[19,56] Additional genetic events are required for tumor cells to acquire the traits that enable them to become malignant. These events are sustained by several mechanisms, including loss of function of tumor suppressor genes, and driven by the host genomic instability that expedites additional mutations leading to malignancy.

Genomic instability is a hallmark of cancer progression[57] and plays a central role in sarcoid development. Increased genomic instability in sarcoids has been demonstrated by an abnormally high number of genomic aberrations found in tumor cells compared with normal unaltered skin tissue samples.[58] Similar genomic instability has been found in cultured sarcoid-derived fibroblasts, suggesting that BPV may directly stimulate genomic instability through DNA replication stress due to loss of *p53* function or through oxidative stress due to shifts in energy metabolism to support rapid proliferation.[59]

Genomic instability in sarcoids has been shown to allow accumulation of mutations of genes engaged in biological pathways common to other cancers. Growth factor signal transduction pathways, including PI3-AKT (phosphoinositide

3-kinase v-akt murine thymoma viral oncogene homolog 1)[44] and *p38* mitogen-activated protein kinase (MAPK),[45] have already been identified. Whole genome scan has been used to identify genetic variants associated with sarcoids.[58] The study confirmed an increased genomic instability already detected in tissue culture.[59,60] Aberrations of genes involved in immune response (cytokines), generation of metabolites and energy, intracellular signal transduction (PI3-AKT and MAPK pathways), and cell proliferation were identified. In addition, aberrations of common cancer genes, including *VEGF*, *Kit*, and *Ras*, were detected.[59]

There is good evidence that genomic instability driving progression to malignancy could be promoted by inflammation, viral integration, and epigenetic modifications. The presence of leukocytes within sarcoids provides evidence of a link with inflammation.[17] If inflammation can retard or eliminate the tumor, it can also contribute to tumor growth and survival by supplying factors that sustain proliferation and limit cell death and enzymes that facilitate invasion.[57] BPV is commonly found in inflamed equine skin conditions.[61] Although skin trauma, wound healing, and chronic irritations have been suggested as important mechanisms to allow BPV access to the dermal fibroblasts,[43] they are not required, and inflammation alone may be sufficient to allow BPV access to the dermal fibroblasts.[61] The inflammation itself may be partly a result of BPV infection, and the inability of some horses to resolve the inflammation in these areas may promote sarcoid formation.[61] The inflammatory response may play a role in providing survival and proliferative signals to initiated cells, thereby leading to tumor promotion. One effector mechanism by which the host fights microbial infection is the production of reactive free radicals that leads to oxidative damage of all cell components and induces host DNA damage actively mutagenic for nearby cancer cells, accelerating their genetic evolution toward states of heightened malignancy, which promotes genomic instability.[57-60]

Epigenetic events are emerging as an important additional mechanism whereby the BPV transforming genes promote development of sarcoids. Epigenetic events are those that can alter phenotype without changing the genotype. Epigenetic mechanisms of silencing or activating expression of nonmutated genes involving DNA methylation and regulatory noncoding ribonucleic acids (RNAs) have been identified in sarcoids. BPV-induced aberrant DNA methylation has been associated both in vitro and in vivo with genomic instability, activation of cell proliferation genes, and silencing of genes involved with immune function.[60,62] Further, microRNA deregulation in equine sarcoid tissues resulting in abnormal expression of messenger RNA (mRNA) at the posttranscriptional level has been shown to be engaged in cancer-related pathways, including regulation of cell proliferation, apoptotic pathway, and genomic instability.[63]

The role played by BPV in the development of sarcoids may be conceptually similar to the role of a genetic predisposing mutation that favors the appearance of the tumor in affected cells. Therefore in the pathogenesis of sarcoids one can identify at least two factors. The first one is related to the effects of transforming genes' proteins, which lead to an environment of genomic instability and local immune suppression. The second factor is the accumulation of cellular genetic damages not related to BPV, needed for tumor development. In humans, viral DNA integration is another factor that plays a critical role in the deregulation of key cellular genes by insertional mutagenesis. Although integration of human papillomavirus (HPV) DNA into the host genome has been shown to positively correlate with the severity of the tumors in humans, there has been no investigation of the role of viral integration in sarcoids.

Biological Behavior

Sarcoids represent a wide spectrum of fibroblastic tumors ranging from indolent, apparently benign lesions to aggressive and invasive tumors. Clinically, many sarcoids behave initially as benign lesions because they are slow growing, giving the false impression that the lesion is inactive. In addition, sarcoids are frequently classified as biologically benign tumors because they do not metastasize to distant organs and regional lymphatic metastasis is rare and usually associated with multiple unsuccessful treatments.[64] However, the equine sarcoid is not a benign tumor because it is a progressive disease that invades and destroys surrounding normal tissue, does not regress spontaneously, and recurs predictably after surgical mass removal.[3,33,65] Early lesions are restricted to the dermis and epidermis, but advanced lesions commonly invade the subcutis and may extend through fascia into deeper muscular structures. Considering sarcoids as benign tumors leads to inappropriate management early in the course of the disease and thus to multiple recurrences and also results in unsatisfactory cosmetic and functional outcomes as well as unnecessary expenses to control the disease.

Molecular understanding of the different pathways leading to sarcoids may explain why some lesions remain quiescent for many years and eventually undergo progressive transformation to the aggressive fibroblastic type, whereas other lesions arise de novo as aggressive fibroblastic tumors.[3,6,66] The variable presence, type, and location (episomal vs. integrated) of BPV DNA and expression of BPV transforming genes in tumor cells[47] as well as the status of the host immune response, may explain the variable appearance, location, and behavior (growth rate, local invasion) of sarcoids. However, clinical manifestation of the disease is not in a simple linear correlation with BPV activity, and the correlation between viral load and disease severity remains controversial.[46]

Sarcoids share common features with soft tissue sarcomas, particularly the propensity for local invasion of surrounding tissues and infiltration of tissue planes. Tumor invasion of surrounding normal structures is believed to require matrix proteases and metalloproteases (MMPs) to allow cell migration and invasion. It has been shown that the overexpression and activation of MMPs is induced by BPV transforming proteins in equine sarcoid fibroblasts, and recently MMP overexpression by epidermal and dermal cells has also been confirmed in vivo.[47,67,68] Identifying signaling cascade controlling invasiveness may provide therapeutic targets against the most aggressive sarcoids.[44,45]

Diagnosis

Sarcoids are recognized as having different multiple clinical manifestations, including occult, verrucous, and nodular clinical types (Fig. 40.14).[3] In addition, approximately one third of affected horses have multiple sarcoids at different clinical stages at the time of diagnosis.[2] The different clinical aspects represent stages of tumor progression and reflect the relative predominance of the dermal or epidermal component. Lesions with a predominant epidermal component include occult and verrucous sarcoids. Occult sarcoids appear as an almost circular area of alopecia with a gray, scaly surface. Verrucous sarcoids may be sessile (flat variety) or pedunculated (warty variety); the skin is thickened with a dry, rough surface, with partial or total alopecia. Nodular sarcoids, also called *fibroblastic sarcoids*, range in appearance from a dermal or subcutaneous nodule to a large exophytic mass with a skin surface that eventually ulcerates. The nodular type is locally invasive, destroying adjacent tissues, and ultimately may infiltrate lymphatic vessels and nerve sheaths and disseminate to form regional metastases.[64] Mixed forms represent a transition from one type to another. The multiplicity of recognized clinical forms confirms the equivocal and progressive nature of the disease.

The polymorphic appearance of sarcoids and the diverse list of differentials make the clinical diagnosis of sarcoids unreliable. The diagnosis and treatment of sarcoids require a biopsy because they are often overdiagnosed clinically. In a review of 681 horses referred to the Equine Oncology Clinic at the University of California, Davis Veterinary Medical Teaching Hospital

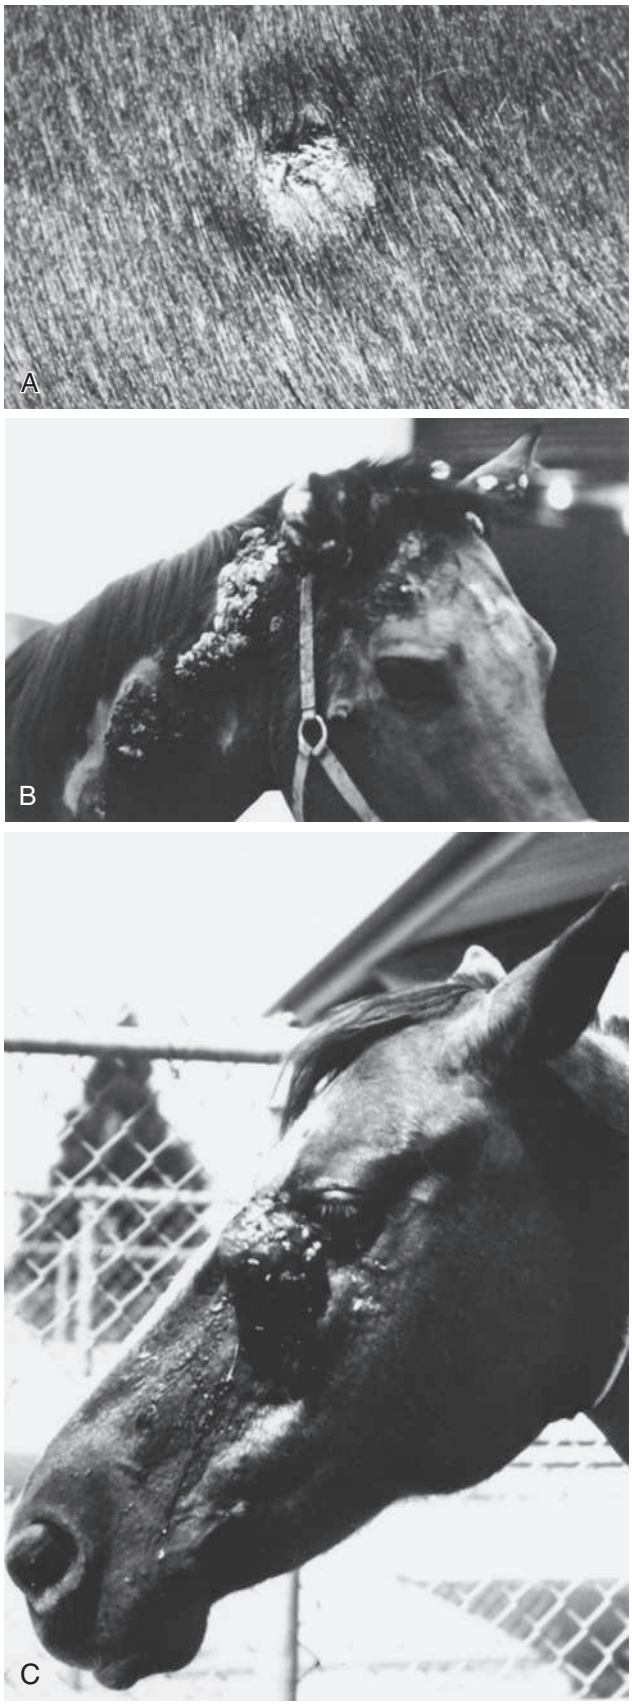

FIG. 40.14 Equine sarcoids. **A,** Small occult sarcoid. **B,** Multiple verrucous sarcoids. **C,** Fibroblastic sarcoid.

for evaluation and treatment of clinically diagnosed sarcoids, 31% of lesions were found to be nonneoplastic dermatologic conditions.[69] After ruling out a nonneoplastic skin condition, any clinically suspicious lesion should be biopsied.[70] As with any tumor, early recognition and treatment of a small lesion is always associated with a better prognosis. It is important to keep in mind that any large and invasive sarcoid associated with a poor prognosis was, earlier in its evolution, an apparently inactive small lesion that was not recognized or was neglected. There is no contraindication for a biopsy of a suspicious skin lesion as long as definitive and effective treatment is instituted immediately after the diagnosis is made. There should be no fear about performing a biopsy of a suspected sarcoid because very effective treatments are available. However, a biopsy, like any trauma, can increase proliferation of a previously slow-growing tumor and may accelerate tumor progression. As a result, a biopsy should not be recommended if the owner is not willing to pursue treatment, if needed, because the process of biopsy without subsequent treatment has the same effect on overall prognosis as an unsuccessful attempt at treatment.

Treatment Sarcoids are low-grade fibrosarcomas and share common features of soft tissue sarcomas. They are locally invasive and tend to infiltrate into surrounding normal tissues through and along fascial planes 2 to 4 cm from the palpable tumor mass. Treatments that are used can be broadly grouped into ablative (surgery, laser vaporization, cryotherapy, hyperthermia, caustic ointments), cytotoxic (radiation therapy, chemotherapy) and biologic (immunotherapy) modalities. The overall treatment goals are (1) to destroy all tumor cells in the gross tumor and also in the normal-appearing surrounding tissues and (2) to minimize damage to healthy tissues. These goals are difficult to achieve with ablative treatment methods because they are not selective against tumor cells. A cuff of surrounding normal tissue containing microscopic disease must be ablated to remove all tumor cells. Early complete surgical resection has a central role in the treatment of sarcoid. Alternate ablative modalities have no oncologic benefits over a well-planned conventional surgery and do not allow histopathologic evaluation of surgical margins to assess the quality of the procedure. Topical applications of escharotics with zinc chloride–based caustic ointments[*,†,‡] or 5-FU cream[§] are used empirically for treatment of sarcoids. Unfortunately, to date, no evidence-based data have been published documenting treatment efficacy against histologically confirmed sarcoids. As a result, no evidence-based information on treatment protocol, efficacy, prognosis, and toxicity is available.

Because tumor size and previous unsuccessful treatment attempts are the most important prognostic factors,[65,75] early and histologically complete surgical resection is the mainstay of treatment of sarcoids.[70] Failure to eliminate the disease results in regrowth of a tumor that is histologically and biologically more aggressive and requires wider excision than the primary lesion. As a result, it is critical to submit the resected tissue specimen for histopathologic examination to determine the status of the surgical margins. As a rule, grossly or histologically incomplete resection (i.e., positive or close pathologic margins [≤5 mm]) must be followed by a re-resection if possible or by effective adjuvant treatment. For noninvasive sarcoids resected with a pathologic margin greater than 5 mm and for invasive sarcoids resected with a pathologic margin greater than 1 cm, the risk of recurrence is low and no further treatment

other than observation at regular intervals for at least 1 year is recommended. For invasive sarcoids resected with surgical margins between 5 and 10 mm, the risk of recurrence is high and adjuvant treatment may be recommended, particularly when tumor recurrence may be difficult to manage because of unfavorable anatomic location. Access to molecular techniques (PCR and RT-qPCR) designed to detect BPV *E5* or *E6* in pathologic margins will help assess the risk of recurrence and determine the need for adjuvant treatment.[76,77]

Among the nonsurgical treatments, radiation therapy and intratumoral chemotherapy with a viscous-fluid, slow-release formulation of cisplatin have well-documented efficacy against biopsy-confirmed sarcoids of all clinical types and in any location.[75,78,79] The selective effects of these treatments have the advantage of controlling the disease while avoiding disruption of anatomic structure and preserving function. When compared to radiation therapy, intratumoral chemotherapy with cisplatin is as effective but does not have long-term side effects and does not require any special license. The overall cure rate (all stages and clinical types combined) after treatment with intratumoral cisplatin therapy used alone or as adjuvant to surgery has been reported to be as high as 96%.[75] Treatment includes a series of four intratumoral administrations of cisplatin (approximately 1 mg/cm^3 of tissue) given at 2-week intervals. Widely available and inexpensive compounded crystal is formulated in a water and sesame seed oil emulsion stabilized with sorbitan monooleate (Span 80).[75] Treatments are done on an outpatient basis under sedation, and the methods of administration and safety precautions have been described.[80] Although other antineoplastic drugs[81-83] and drug formulations[65,80,82,84] for intratumoral chemotherapy have been evaluated, cisplatin in sesame seed oil emulsion remains the most effective drug.[75] In an effort to increase duration of tumor exposure to cisplatin, cisplatin-containing biodegradable beads implanted intraoperatively[84a] have been used but have not shown any therapeutic benefit when compared to conventional intralesional cisplatin administration.[75] Attempts to increase cisplatin uptake in tumor cells by applied electroporation[85] called electrochemotherapy also failed to show any therapeutic benefit when compared to conventional intralesional cisplatin administration.[75] Further, electrochemotherapy requires general anesthesia for each treatment due to painful pulses of electric current as well as expensive equipment and complex procedures.

Systemic chemotherapy with doxorubicin* has shown preliminary evidence of efficacy for fast-growing fibroblastic sarcoids but not for indolent verrucous sarcoids.[87]

BPV-associated equine sarcoids are distinct from other equine tumors in that they express viral foreign antigens necessary to maintain the cancerous phenotype that could be targeted by the host's immune system. Because sarcoid tumor cells have the potential to be highly immunogenic, immunotherapy has been evaluated for treatment of sarcoids. Nonspecific cell-mediated immunotherapy has been used for sarcoids with inconsistent results. Treatment involves the use of immune stimulatory agents that act nonspecifically to elicit both innate and adaptive immunity and results in the induction of proinflammatory cytokines, chemokines, and other immune mediators. This in turn leads to the generation of a type 1 helper cell (Th1)–biased cell-mediated immune response and a concomitant generation of cytotoxic effector cells against antigens in the tumor. Bacillus Calmette-Guérin (BCG) cell wall derivatives† and imiquimod‡ are two nonspecific immunostimulants that have been reported for treatment of sarcoids. BCG cell wall derivatives† administered intralesionally[90] have been shown to be effective only for periocular sarcoids.[65,91,92] The number of treatments depends on the rate of tumor regression, and the treatment schedule depends on normal tissue toxicity; most sarcoids require two to nine treatments over several weeks.[65] Encouraging results have been reported with a biological response modifier used topically (5% imiquimod cream[89]). The ointment is recommended for the treatment of viral warts and basal cell carcinomas in humans. It was applied as a thin layer to the surface of sarcoids three times a week on nonconsecutive days for up to 32 weeks until resolution.[93] However, in our experience, imiquimod treatment was effective only for treatment of persistent cutaneous papillomas in adult horses that have an appearance similar to verrucous sarcoids and a small percentage of occult sarcoids. Treatment did not prevent progression of verrucous or fibroblastic sarcoids. In all cases treatment was associated with severe and painful inflammation of the treated area.

The continued expression of the *E5*, *E6*, and *E7* proteins by equine sarcoid tumor cells makes them excellent targets for specific immunotherapy.[17,18] Therapeutic humoral immunization has not been found effective for treatment of affected horses. Immunization against BPV1 virus-like particles in sarcoid-bearing horses[30] and donkeys[94] resulted in BPV1 neutralizing antibodies but was not therapeutically effective. Cell-mediated immunity is critical for the control of papilloma-associated tumors.[95] Therapeutic vaccines aim to control tumors by activating the patient's own cellular immune response to recognize and kill cancer cells. In humans, trials with therapeutic vaccines that target the *E6* and/or *E7* proteins using peptide or protein-based vaccines, live vector vaccines, cell-based vaccines, and DNA vaccines have been disappointing for treatment of HPV-associated tumors.[95] Although *E5* is uniformly expressed by sarcoid tumor cells, no attempt at targeting the *E5* protein has been made in veterinary medicine. The renewed interest in *E5* protein as a target for therapeutic vaccine in human medicine[96] may provide a biological rational for targeting *E5*-expressing sarcoid cells. Dendritic cells are the central players in the initiation of the adaptive immune response and play a key role in the antitumor T-cell responses. A preliminary study with autologous monocyte-derived dendritic cells (MoDCs) isolated from horses with sarcoids and loaded with tumor lysates showed that the treatment was safe and prevented tumor recurrence after surgery in 13 of the 21 treated horses.[97] Although the data are preliminary and need to be confirmed in a larger study, they underscore the need for an increased understanding of dendritic cell biology, which will lead to further development of innovative strategies to optimize vaccine-elicited T-cell antitumor immune responses.

Although therapeutic vaccines aim to develop a strong cellular immune response to BPV antigens that are expressed in transformed cells, prophylactic vaccines aim to prevent a putative BPV infection by inducing a neutralizing antibody response. In humans, prophylactic HPV vaccines act by inducing neutralizing antibodies against the late capsid protein L1 of HPV16 and HPV18. This has led to attempts to establish a vaccine for protection against BPV1- or BPV2-associated sarcoids. Although natural or experimental infection of the skin by wild-type BPV1- or BPV2-associated sarcoid does not induce a measurable antibody response,[24] intramuscular immunization of horses with BPV1 L1 virus-like particles has been shown to elicit high titers of BPV1-neutralizing serum antibodies.[98] Virus-like particle late protein vaccine proved highly effective in protecting horses from BPV1-induced pseudosarcoid formation (short-lived papules) but not from BPV2 challenge.[99] This provides a rationale for developing a preventive vaccine that would benefit naive horses exposed to BPV1 and BPV2. However, immunization of previously exposed latent BPV1- and BPV2-carrier horses would require a vaccine that could stimulate cell-mediated immune responses to specifically target and kill the infected cells. Because it would be impossible to test horses for prior exposure to BPV prior to vaccination and horses need to be protected against both BPV1 and BPV2, the ideal vaccine would have to generate both humoral and cell-mediated immune response to BPV1 and BPV2.

Mastocytosis

Stephen D. White

In horses, mastocytosis (mast cell tumors, mastocytomas) occur in animals 1 to 18 years old (average, 9 years), with no breed predilection. A predilection for males has been proposed but is not always sustained.[1,2] In addition, multiple mast cell tumors resembling urticaria pigmentosa of humans may occur in newborn foals; these occur spontaneously and regress.[2,3]

Equine mastocytosis is usually solitary and occurs most often on the head and trunk, although occasionally multiple tumors may be seen.[4] Lesions are 0.5 to 20 cm in diameter, well to poorly circumscribed, firm to fluctuant, dermal or subcutaneous, and may or may not be alopecic, ulcerated, and hyperpigmented. Lesions on the legs tend to be very firm and immovable.

Histology may vary from sheets of mast cells with few eosinophils (presumably early lesions) to sections showing both sheets of mast cells with numerous eosinophils and collagen degranulation. Ultrastructural features are similar to those noted in mastocytomas of other species.[5]

Clinically, most mast cell tumors in horses do not recur after being excised (22 of 25 in one study).[5] In one anecdotal case of metastasis from a tumor on the muzzle to the regional lymph nodes, the tumor and the nodes were removed, and the horse was clinically sound 3 years later. There is some debate as to whether equine mastocytomas are benign neoplasias or focal dysplasias of mast cells.

Mastocytomas are uncommon in cattle but typically occur in young calves.[6,7] One report describes a cutaneous mast cell tumor in a kid goat.[8] Although equine mastocytomas are almost always benign, mastocytosis in cattle may be malignant or benign and therefore carries a more guarded prognosis.

Melanoma

Stephen D. White

Equine Melanomas

Melanomas occur in all domestic animals, but among the large domesticated species, they are most important in the horse. Excessive exposure to sunlight has not been definitively proven to predispose horses to the development of melanoma. A disturbance in melanin metabolism associated with graying has been hypothesized to stimulate formation of new melanoblasts or to stimulate their activity, resulting in focal areas of overproduction in the dermis and epidermis, with subsequent tumor formation.[1] A higher incidence is observed in the Arabian, Lipizzaner, and Percheron breeds, probably because gray coat color occurs more often in these breeds. There is no gender predilection.

Melanocytic skin tumors of horses traditionally have been described in aging gray horses in typical locations: ventral tail, perineum, external genitalia, lip, udder, and periocular and parotid gland regions. These tumors have been the subject of several classification schemes in attempts to correlate histopathologic appearance with clinical behavior (i.e., benign or malignant). One study distinguished three basic types of melanocytic skin tumors, as discussed next.[2]

Melanocytic nevi (melanocytoma) occur in the superficial dermis or at the epidermal-dermal junction and frequently have epithelial involvement, with nests of relatively large, mildly to moderately pleomorphic cells showing variable cytoplasmic pigmentation and occasional mitoses. More than 70% of these occur in horses younger than 6 years of age and may occur in horses of any color (not just gray). Most of these tumors occurred in atypical locations. Of 28 melanocytic nevi, only one became invasive; the rest exhibited benign behavior.

Dermal melanomas are found in the deep dermis and are composed of small, homogeneous, indistinct tumor cells, either round or dendritic, with no mitoses. (If there are multiple confluent dermal melanomas, this is referred to as *dermal melanomatosis*). About 80% of these tumors are in horses older than 6 years[2] or between 5 and 15 years[3] and are much more common in gray horses. Most of these tumors occurred in typical locations. Of 14 cases available for follow-up in one study,[2] eight had malignant behavior, as demonstrated by metastases.

In another study, clinicopathologic characteristics of cutaneous melanomas occurring in 83 Camargue-type gray-skinned horses showed that the tumors occurred most frequently underneath the tail (93.9%) and at high rates in the perianal region (43.0%), lips (33.0%), and eyelids (24.0%) but rarely in the vulva (3.8%).[4] Microscopic examination indicated that these tumors were composed mostly of melanocytes and numerous melanophages, and that these cells manifested a remarkable cellular atypia. Early stages of the tumors occurred in close association with apocrine sweat glands but not at the dermal-epidermal junction.

A clinical study was conducted on 296 gray horses of the Lipizzaner breed.[5] Of the 296 horses, dermal melanomas were present in 148 horses (50%), 68 of which were older than 15 years; 51 of these were melanoma bearing. In 75.6% of cases, melanotic tumors were detected underneath the tail. None of the affected individuals had any severe clinical effect or was handicapped in performance. The authors concluded that in contrast to melanomas in solid-colored horses, characterized by early metastases, melanomas in gray horses showed less malignancy. Affected individuals often had encapsulated nodules or structures similar to human blue nevi. This finding at least partially reflects confusion in terminology between true malignant melanomas and dermal melanomas.

Anaplastic malignant melanomas are composed of sheets of extremely pleomorphic epithelioid cells with poor pigmentation and many mitoses. These are usually seen in horses older than 20 years and occur in horses of any color. Metastasis usually occurs first to the regional lymph nodes, then to the lungs, spleen, and liver. Hematogenous spread may also occur. Metastatic growths may be larger than the primary lesions and softer in consistency.

In regard to treatment, one study reported good success with excising dermal melanomatosis from the perineal, perianal, perirectal, or ventral tail regions.[6] In a study of three horses, cimetidine (2.5 mg/kg PO q8h) was shown to decrease the number and size of melanoma growth.[7] However, another study of 10 horses found that cimetidine had no consistent effects on either the number of tumors or the tumor surface area over the 16 weeks of treatment at 5 mg/kg PO q12h.[8] Another article noted a cure rate of 81% for melanomas treated with intratumoral injections of cisplatin.[9] A recent article reported significant tumor regression when injecting interleukin-18– and interleukin-12–encoding plasmid DNA into the tumors of horses with metastatic melanomas.[10]

Bovine Melanomas

Melanomas represented a large proportion of the cutaneous neoplasms of cattle in an older study.[11] The majority are benign, well-differentiated tumors, subcutaneous in location, and without site predilection. Dark-haired cattle are predisposed, particularly the Aberdeen Angus breed. There is no gender predilection.[11] Melanomas usually occur in young cattle and are occasionally recognized as congenital lesions.[12]

Caprine and Ovine Melanomas

Melanomas have been observed only rarely in sheep and goats.[11-14] A survey of 800,000 slaughtered goats revealed only 5 melanomas.[12] The most common site for melanomas in the goat is the perineal region,[13] although there is a case report of a malignant melanoma occurring in the coronary band region.[14] Melanomas in Angora goats histologically resemble the corresponding tumors in humans.[15]

Cutaneous Lymphosarcoma

Stephen D. White

Equine Lymphoma

Cutaneous lymphoma has occasionally been reported in horses.[1-8] Both T-cell and B-cell forms have been reported.[9,10] Lesions present as either cutaneous or subcutaneous nodules. Diagnosis is made by biopsy and, ideally, immunohistochemistry to determine cell type.[7,8] In one horse, progesterone receptors were demonstrated on the lymphoma (B) cells, and the lesions regressed after removal of an estrogen-secreting ovarian tumor.[4] This horse also had a history of partial regression of its tumor after administration of a synthetic progestin, altrenogest (0.044 mg/kg PO once daily for 10 days). Another horse demonstrated reduction in tumor size after administration of another synthetic progestogen, megestrol acetate (0.2 mg/kg PO once daily for 8 days), as well as a local injection of 20 mg betamethasone into a mass.[5] Clearly, treatment is far from standardized, but the progesterone drugs may offer a reasonable treatment modality. Lymphosarcoma is discussed in Chapter 37.

Bovine Lymphoma

Cattle occasionally are affected by cutaneous lymphoma. The presentation is multifocal intracutaneous nodules, often accompanied by alopecia. Lymphadenopathy, leukocytosis, and lymphocytosis are often present, and internal organs may be affected.[11] The juvenile form is not necessarily associated with the bovine leukemia virus (BLV) and is of T-cell origin.[12]

Ovine Lymphoma

There are rare reports of cutaneous lymphoma in sheep.[13,14]

Cysts

Stephen D. White

Cutaneous cysts are benign lesions characterized by an epithelial wall with keratinous contents. Cutaneous cysts are subdivided into several types based on their histopathologic features.

Epidermal Cysts

Among large animals, epidermal cysts have been reported in horses,[1] cattle,[2] and sheep.[3] These cysts may be more properly called *follicular cysts* because the epithelial lining is probably most often derived from the follicular epithelium rather than the epidermis. The cysts can be found anywhere on the body, single or multiple, congenital or acquired, and generally range in size from 0.2 to 3 cm in diameter. The cysts are covered by intact epithelium and generally do not attach to the overlying epidermis. Microscopically, epidermal cysts consist of a wall of stratified squamous epithelium surrounding a keratin-filled lumen. Epidermal appendages are not associated with the cyst wall, a feature that distinguishes epidermal from dermoid cysts.

Epidermal cysts are thought to originate from occlusion of a hair follicle or by traumatic implantation of the epidermis. A tentative diagnosis may be made by performing fine-needle aspiration of a lesion and obtaining a fluid that is clear to brownish in color. Aspiration of the contents may temporarily decrease the size of the cyst, but it typically refills. Definitive diagnosis is made by excisional biopsy, which is curative. Epidermal cysts are benign lesions, although painful inflammatory responses and ulceration may result if the cyst is ruptured, with extrusion of contents into the adjacent dermis and subcutis.

Dermoid Cysts

Dermoid cysts are very similar clinically to epidermal cysts but are much less common. Among large animals, they have been identified in horses,[1] goats,[4] and cattle.[5] In cattle, dermoid cysts may be congenital, have been reported to be as large as 10 cm (4 inches) in diameter, and are said to develop most frequently over the cranial area of the thorax[5] and in the pharyngeal region. In horses, dermoid cysts may be single or multiple and are observed most frequently along the dorsal midline between the withers and the croup. Dermoid cysts are believed to result from displacement of embryonic cells into the subcutaneous tissue. They can be distinguished histologically from epidermal cysts by the presence of epidermal appendages within the wall of the cyst and by a lumen that often contains hair and secretions from sebaceous and sweat glands in addition to keratin. As with epidermal cysts, surgical excision is diagnostic and curative.

Dentigerous Cysts

Dentigerous cysts are a congenital defect recognized in horses and are believed to be the result of an abnormality of the first branchial cleft.[6] Clinically, a unilateral saclike swelling that contains embryonic teeth is seen at the base of the ear. The lesion may be firmly attached to the concheal cartilage or temporal bone. Dentigerous cysts tend to fistulate. Treatment consists of surgical excision.[6] Dentigerous cysts have also been reported in sheep and are suspected of being related to a nutritional deficiency of copper.[7]

Wattle Cysts

Wattle cysts are found in goats and usually are present at the base of the wattle. Nubians and Nubian crossbreeds may be predisposed to developing these cysts. The cysts are congenital, but they may not be apparent until the animal is several months old. Tentative diagnosis is based on aspiration of clear fluid, which will temporarily decrease the size of the cyst. Surgical excision is diagnostic and curative. Histologic examination reveals a cyst wall composed of one or two layers of cuboidal to columnar epithelial cells. The cyst cavity contains homogeneous, amorphous basophilic substances.[7]

Environmental Diseases

Stephen D. White

Frostbite

Frostbite is an uncommon injury among healthy, well-nourished animals, with all species being susceptible. It is caused by prolonged exposure to subfreezing temperatures. The length of time needed to cause frostbite depends on the ambient temperature, area of the body exposed, and health status of the animal. The areas most often affected by cold injury include the ears, tail, teats, scrotum, and distal legs.

Frozen tissue must be handled gently and thawed rapidly in warm water 38° to 44°C (100.2° to 111.1°F) as soon as possible after it is known that refreezing can be prevented. Tissue damage is greatly increased if thawing and subsequent refreezing occur (freeze/thaw–freeze/thaw syndrome). Tissue thawing is painful, and analgesics should be administered. Slow thawing is less painful than rapid thawing but results in much greater tissue damage. Frozen tissue should not be massaged during warming. Damaged areas are best left exposed during the healing process rather than covered with occlusive dressings, and premature débridement should be avoided because more tissue may be viable than first apparent. The animal should be given good supportive care and may have to be restrained to prevent self-mutilation. Management practices should be changed to prevent recurrence. Tissues previously damaged by freezing are more susceptible to cold injury when reexposed to subnormal temperatures.[1,2]

VetBooks.ir

Photosensitization

Photosensitivity is an abnormal reaction of the skin when exposed to light. For photosensitization to occur, there must be (1) a photodynamic agent, (2) white or lightly pigmented skin, and (3) ultraviolet A (UVA) range (320 to 400 nm). Melanin in the skin screens UV light, thereby limiting photosensitivity reactions to the white and light-colored areas of the body.[3]

There are three generally recognized categories of causes of photosensitivity:

Type I—ingestion of a photodynamic agent

Type II—congenital abnormalities in porphyrin or liver metabolism

Type III—liver disease due to a plant or toxin, which leads to accumulation of phylloerythrin and a breakdown product of chlorophyll.

Type I

Numerous plants contain various photodynamic agents[3-7]:

Common Name	Scientific Name	Agent
St. John's wort	*Hypericum perforatum*	Hypericin
Buckwheat	*Polygonum fagopyrum*	Fagopyrin
Perennial ryegrass	*Lolium perenne*	Perloline
Whiteheads	*Sphenosciadium capitellatum*	Unknown
Roadside leafbract	*Malachra fasciata*	Unknown
Cegadera	*Heterophyllaea* spp.	Anthraquinones
Texas snake cotton	*Froelichia humboldtiana*	Unknown
Biserrula	*Biserrula pelecinus*	Unknown

Additional reports describe photosensitivities apparently induced by the ingestion of gluten in horses and of cocoa shells in calves.[8,9]

Type II

There are two bovine diseases and one ovine disease in this category:

Congenital erythropoetic porphyria: seen in Holstein, Shorthorn, and Jamaican breeds. Commonly called "pink tooth" because of the coloration of the dentition, which will glow under a Wood's lamp, as will the urine. The cow may also have anemia. The cause is a deficiency of uroporphyrinogen III cosynthetase, which leads to a defect in the heme synthesis and an accumulation of uroporphyrin and coproporphyrin, which are photodynamic agents.

Bovine protoporphyria: seen in Limousin and Blond d'Aquitaine and Charolais breeds. Neither tooth discoloration nor anemia is present. This disease is caused by another defect in heme synthesis, as a defect in ferrochelatase, which leads to an accumulation of protoporphyrin, another photodynamic agent.

In Corriedale sheep, a congenital defect in liver function leads to an accumulation of phylloerythrin (see below under Type III).

Type III

As mammals ingest plants containing chlorophyll, this molecule is degraded by bacteria in the intestine into the porphyrin phylloerythrin. Some phylloerythrin is normally absorbed into the portal circulation, removed by the liver, and excreted by the bile. In liver disease the hepatic excretion of phylloerythrin is decreased, leading to excessive levels in the peripheral circulation and eventually in the skin, causing photosensitivity in about 25% of horses with liver dysfunction.[10-12] One of the more common reasons for liver disease in horses in the United States is ingestion of the following plants containing pyrrolizidine alkaloids:

Common Name	Scientific Name
Common groundsel	*Senecio vulgaris*
Ragwort, stinking Willie	*Senecio jacobaea*
Tarweed	*Amsinckia intermedia*
Rattleweed	*Crotalaria* spp.
Salvation Jane	*Echium lycopsis*

The following plants cause hepatic dysfunction (especially in ruminants), as they contain photosensitizing saponins, whose metabolites crystalize in the bile causing biliary blockage and cholangitis:

Common Name	Scientific Name
Puncture vine	*Tribulus terrestris*
Agave	*Agave* spp.
Signal grass	*Brachiaria decumbens*
Sacahuista, Bunchgrass	*Nolina texana*
Narthecium	*Narthecium ossifragum*

Consumption of alsike clover *(Trifolium hybridum)* may induce hepatic dysfunction (with histologic lesions distinct from those caused by pyrrolizidine alkaloids), leading to photosensitization signs (alsike clover poisoning, dew poisoning). Cases seem to be correlated to years with heavy rainfall and ingestion of the plant blossoms.[13] Finally, the saprophytic fungus *Pithomyces chartarum*, which grows on perennial ryegrass, contains the heptotoxin sporidesmin.

Ingested plants and feed should be noted and collected for future analysis. Environmental considerations include the type of pasture (or other material) with which the animal is in contact, the amount of time the animal is exposed to sunlight, any seasonality of the condition, and any other horses involved. A seasonal incidence would tend to negate liver disease; multihorse involvement should arouse suspicion of an ingested or contact photosensitizer. A thorough history of recent drug therapy should be obtained.

Physical examination usually reveals lesions limited to the hairless, white, or lightly pigmented areas of the skin. The involved skin is erythematous, swollen, and painful. The lesions may progress to serum exudation, thickening, fissuring, and in severe cases, necrosis and sloughing (Fig. 40.15).

Therapy is related to etiology. Chronic liver disease carries a guarded prognosis. Removal of foodstuffs containing photodynamic agents, or removal of the animal from a pasture with plants containing these agents, will often result in full recovery if the animal is also kept out of the sun for 1 to 2 weeks. Corticosteroids are helpful in controlling inflammation and pruritus. Oral prednisolone at 1 mg/kg daily for 1 week, then halving the daily dosage for a second week, is an effective regimen in this regard.

Skin Disorders of Unknown or Genetic Origin

Stephen D. White

Equine Seborrhea

Several possibly related equine skin diseases characterized by scaling and crust formation are referred to as *seborrhea*. Contrary to claims in the older literature, there is little evidence that seborrhea is related to excess sebum production by the sebaceous glands. Most types of seborrhea are probably diseases of abnormal cornification (development of the stratum corneum). Further, most cases reported as "generalized seborrhea" in the horse were probably pemphigus foliaceus, equine sarcoidosis (chronic granulomatous disease), or some

FIG. 40.15 Photosensitization. **A,** White blaze of a horse is selectively affected. **B,** White stocking of a horse is selectively affected. **C,** Area around eye where hair is less dense is most severely affected.

other immune-mediated or autoimmune disease. Mane and tail seborrhea is typified by moderate to heavy scaling, with minimal or no pruritus. Some horses have considerable alopecia of the tail.

Cannon keratosis is a common equine skin condition. It involves the cranial surface of the rear cannon bone region and rarely the forelimbs. The lesions consist of areas of scaling and crusting with varying degrees of alopecia. There is no pruritus or other signs of inflammation. Cannon keratosis occurs in both males and mares, so there is no basis for the theory that the condition is caused by urine splatter ("stud crud").[1] In one recent report, the response to treatment with four topical preparations was evaluated in an 11-year-old Morgan horse mare with histologically confirmed quadrilateral cannon hyperkeratosis. Each limb was treated for 30 days, and response to treatment was evaluated both histologically and visually. A water-based emollient and 0.1% tacrolimus ointment produced encouraging clinical responses.[2]

Linear Keratosis and Linear Alopecia

Linear keratosis and linear alopecia are rare equine dermatoses of unknown cause. There is one report in a cow.[3] Lesions do not follow blood or lymphatic vessels, nerves, or dermatomes. Because these conditions coexist in some horses, it has been suggested that they are variations of the same abnormality, and we have seen one case where both histologic presentations were simultaneously present in the same clinical lesion. Both conditions have been seen in a wide variety of breeds, but Quarter Horses appear to be predisposed. Most horses develop lesions between 6 months and 5 years of age.

Linear alopecia is characterized by gradual development of annular areas of alopecia, usually in a linear, vertically oriented configuration. One or more linear areas may be present. The lesions are usually 2 to 10 mm wide by a few centimeters to more than 1 m in length and occur on the neck, shoulder, and lateral thorax. Mild surface scale and crust may be present. Lesions are neither painful nor pruritic. Affected horses are typically otherwise healthy.

Linear keratosis is characterized by the gradual asymptomatic occurrence of one or more unilateral, linear, vertically oriented bands of hyperkeratotic papules that progress to marked hyperkeratosis and alopecia. We have seen one case where the lesions were confined unilaterally to the jugular furrow (Color Plate 40.10). Lesions vary from 0.25 to 3.5 cm in width by 5 to 70 cm in length and occur most often over the neck, shoulder, and lateral thorax. Lesions have also been reported to involve the legs, hip, and pectoral region. Again, affected horses are typically otherwise healthy.

These disorders are visually distinctive. Histopathologic findings in linear alopecia include early lymphocytic, infiltrative mural folliculitis and later granulomatous, infiltrative mural folliculitis. The mural infiltrate is often directed at the middle area (isthmus) of the follicle. Sebaceous glands may be involved in some cases, and complete follicular destruction and permanent alopecia are seen in severe chronic lesions. Histopathologic findings in linear keratosis include irregular to papillated epidermal hyperplasia and marked compact orthokeratotic hyperkeratosis.[4] We have seen one horse with lesions grossly diagnosed as linear keratosis, whereas the histopathology had features of both conditions.

Neither condition is known to undergo spontaneous resolution. Owners should be advised of the potential hereditary nature of these disorders. Linear alopecia has been anecdotally reported to respond to topical or systemic glucocorticoids, but recurrence is likely. Response to therapy is more likely to be seen in early lesions, when complete destruction of hair follicles has not occurred. Linear keratosis responds poorly to treatment. Topical keratolytic and keratoplastic agents, such as sulfur/

VetBooks.ir

salicylic acid–containing shampoos or 50% propylene glycol, can reduce the hyperkeratosis but must be continued for life. There has been some success using tacrolimus (Protopic 0.1% ointment [Astellas Pharma US, Northbrook, Ill.]), a drug similar to cyclosporine but better absorbed through the skin, once or twice daily. Because neither condition is symptomatic, observation without treatment may be an acceptable approach. Interestingly, a report exists of a familial incidence of linear epidermal nevi in Belgian horses.[5]

Albinism

Complete and partial albinism occurs in cattle, sheep, and horses. It is a genetic defect (probably autosomal recessive) in melanin synthesis, resulting in white skin, white hair, pink eyes, and photophobia. In horses, albinism must be distinguished from *lethal white syndrome*, which is primarily a problem in Paint horses (especially, but not exclusively, in overo breedings). The defective gene has also been found in American Miniature horses, half-Arabians, Thoroughbreds, and cropout Quarter Horses (foals born to registered Quarter Horses that have too much white to register with the American Quarter Horse Association [AQHA]).[6] The Veterinary Genetics Laboratory at UCD offers a diagnostic test to determine carrier status (https://www.vgl.ucdavis.edu/services/horse.php).

The lethality of albinism in horses comes from the association with intestinal aganglionosis. The foals die shortly after birth. Because some white foals are not affected, euthanasia should be performed only after signs of intestinal malfunction occur. This disease is similar to Hirschsprung's disease in humans and is linked to a mutation in the endothelin-B receptor gene.[7]

Juvenile Arabian Leukoderma (Arabian Fading Syndrome, Pinky Syndrome, Hereditary Vitiligo)

Loss of melanin in the skin (depigmentation) occurs in young Arabian horses 6 months to 2 years of age (Fig. 40.16, A). The areas most frequently affected are periocular tissues, muzzle, genitalia, anus, perineum, inguinal region, and undersurface of the base of the tail. Depigmentation may persist, repigment, or wax and wane. The condition is probably hereditary.[1]

Vitiligo

This condition is best defined as "idiopathic depigmentation." Typically no trauma has occurred to produce the loss of pigment, and other skin structures are not affected (i.e., no scarring or alopecia) (Fig. 40.16, B; Color Plate 40.11). There is no known treatment for vitiligo. The condition may be seen in any species but is perhaps best recognized in the horse.

Reticulated and Hyperesthetic Leukotrichia

Reticulated leukotrichia occurs mainly in Quarter Horses, usually as yearlings, and occasionally in other breeds. The lesions occur on the dorsal midline and consist initially of linear crusts arranged in a characteristic crosshatch pattern (Fig. 40.17). The crusts shed, alopecia occurs, and white hair grows in permanently. There is leukotrichia without leukoderma (depigmented skin). Histologically, these lesions may resemble an epidermal form of erythema multiforme, resulting in individual keratinocyte necrosis. *Hyperesthetic leukotrichia* is a similar disease clinically, except that the crusts are extremely painful to the touch. Within a few weeks, white hairs appear in the affected areas. The crusts resolve, and the pain subsides in 1 to 3 months, but the leukotrichia persists. While anectodal cases have been linked to recent rhinopneumonitis vaccination, a recent report of a case series failed to find evidence of a link to any vaccine or medication and determined that the histology differed somewhat from erythema multiforme.[8] These diseases may recur (sometimes on a seasonal basis), and there is no known effective treatment.

Hereditary Equine Regional Dermal Asthenia (Hyperelastosis Cutis)

Hereditary equine regional dermal asthenia (HERDA) occurs early in life in horses. Most affected horses are Quarter Horses, but registered Paint horses and Appaloosas with Quarter Horse lineage have developed this disease.[9,10] Many of the Quarter Horses are from high-quality cutting lines. Reported cases have been in North America, but the disease and its associated genetic defect have been reported in Europe and South America.[11-14] The disease (or similar condition) has also been reported in a crossbred Arabian mare, a Thoroughbred gelding, a Hanoverian foal, and a Hafflinger horse.[15-18] Rarely, a similar disease has been noted in cattle, termed *dermatosporaxis;* this is caused by mutations in the procollagen I N-proteinase gene.[17,19-21]

The working hypothesis for HERDA in horses is a defect in the structure or healing process of the collagen fibers in the middle to deep dermis. Affected horses have less cutaneous tensile strength than healthy horses.[22] Typically these areas are over the back and sides of the neck (Fig. 40.18). The skin in these areas may be easily torn or stretched and often develops seromas and hematomas ("blisters" filled with either serum or blood). Healing is usually adequate but often leaves unsightly

scars. Despite the regional pattern of the cutaneous signs, skin with decreased thickness was not regionally distributed in the HERDA-affected horses in one report.[23] Diagnosis is often based on the clinical signs alone; histologic findings are sometimes subtle, but "clumped" or poorly organized collagen fibers below the level of the hair follicles may be seen. A zone of middermal to deep dermal separation has been reported in two horses and is present in some biopsy samples.[10,24] Poorly oriented collagen fibers are sometimes seen on electron microscopy. Interestingly, affected horses may have decreased corneal thickness, increased tear production, and increased incidence of corneal ulcers, as well as loss of heart valve tensile strength.[25,26]

This condition is almost certainly present at birth, but HERDA is often not noticed until about 2 years of age, when horses start being trained with tack and saddle, and the resulting friction and trauma induce the typical lesions.[27] As with many genetic diseases, no effective treatment or cure exists; some of these horses have been maintained as "pasture pets."

This disease follows an autosomal recessive mode of inheritance, so for the foal to be affected, both the sire and the dam must carry the gene, and if they were bred again, there would be about a 25% chance that the next foal would also be affected.[28] Although histopathologic evaluation is informative, it is not conclusive for establishing the diagnosis. Samples of skin from the neck, croup, or back are useful for diagnosis of HERDA.[23] However, the final diagnosis must be confirmed using molecular testing.[23,29]

Recently a genetic marker was determined for this disease.[29] The marker relates to a missense mutation in equine cyclophilin B (PPIB), which in recent work has been shown to cause a functional defect in this protein, resulting in less effective catalysis of the rate-limiting step in collagen folding.[30] The Veterinary Genetics Laboratory at UCD offers a diagnostic test to determine carrier or affected status (http://www.vgl.ucdavis.edu/services/horse.php). Both carriers and clinically affected horses with HERDA should be removed from breeding programs. There is no known treatment.

Epidermolysis Bullosa

Epidermolysis bullosa (EB) includes a number of diseases typified in humans and animals by the common finding of blister formation after minor trauma. Most forms are congenital and apparent soon after birth. In animals and humans, subsets of EB are classified by the histologic location of the blister or cleft. These subtypes (and respective cleft location) are termed *EB simplex* (basal cell layer of epidermis), *junctional EB* (intralamina lucida or basal cell layer), and *dystrophic EB* (sublamina densa).

VetBooks.ir

Junctional EB has been reported in Belgian foals of both genders; in other breeds; and in a donkey, sheep, and cattle.[31-38] Lesions are usually noted within 3 days of birth and include multiple asymmetric skin erosions and ulcers, often encrusted. Lesions may be especially prominent around the coronary bands (causing the hoof to crack and slough) and on the oral, anal, and genital mucosa. Histology and ultrastructural findings indicate a cleft in the intralamina lucida of the basement membrane zone. This is presumably caused by a defect in the anchoring filaments that connect the basement membrane to filaments in the superficial dermis.[32] A laminin-5 (laminin 3A32) defect has been demonstrated in Belgians and in two French draft breeds, Trait Breton and Trait Comtois; the mutation is a cytosine insertion in exon 10 of the *LAMC2* gene.[39-41] Because of this knowledge, the Veterinary Genetics Laboratory at UCD offers a diagnostic test to determine carrier status in Belgian draft horses and related breeds (http://www.vgl.ucdavis.edu/services/horse.php). The defect in some ruminants has also been noted to be associated with the *LAM* gene.

Clinical presentation and the age of the foal are highly suggestive of EB diagnosis. Histology and, ideally, electron microscopy are required to confirm the diagnosis. There is no known treatment, and affected horses as well as the sires and dams of affected horses should not be bred; the mode of inheritance is autosomal recessive.

The disease previously known as *epitheliogenesis imperfecta* in Saddlebreds is now recognized as *junctional epidermolysis bullosa*. Lesions are most common on the limbs, head, and tongue. Hooves may slough in severe cases. Clinical presentation is usually diagnostic.[42-45] In moderately to severely affected animals, the disease is fatal within a few days; the foals die of septicemia or other developmental abnormalities. Mildly affected areas may heal by scar formation.

Ruminants

Epidermolysis bullosa has been reported in cattle and sheep. The simplex form has been reported in Angus and Friesian-Jersey crossbred cattle (in the latter, a keratin 5 defect was noted), junctional EB in a Charolais calf (deficient expression of an epidermal integrin), and dystrophic EB in Brangus calves.[46-49] In sheep, dystrophic EB in the white Alpine, Assaf, Suffolk, South Dorsett Down, and black face Scottish breeds has been shown or theorized to involve mutations in the gene encoding for collagen VII.[50-53] Junctional EB has been described in German black-headed mutton sheep and churra sheep, with the defect in the former traced to the formation of laminin 332, similar to the defect in the Belgian horses.[54,55] Junctional EB has also been described in Charolais, Belgian Blue, and Danish Hereford cattle; the defect in the latter two is also tied to the laminin gene.[56-58] Clinical signs of EB in ruminants are similar to those seen in horses, with ulcers, especially around the coronary band and in the oral cavity.

Eosinophilic Granuloma (Nodular Necrobiosis, Collagenolytic Granuloma)

Eosinophilic granuloma is the most common equine nontumor nodular disease in our practice. In most cases the etiology is unknown, although a hypersensitivity reaction to insect bites has been suggested. There is no apparent age, breed, or gender predilection. The disease often begins in warmer months. Lesions up to 5 cm (2 inches) in diameter may be single or multiple and most often affect the neck, withers, and back (Fig. 40.19). Skin biopsy reveals multifocal areas of abnormal-staining collagen surrounded by granulomatous inflammation containing eosinophils, lymphocytes, and histiocytes.[1] This is not thought to be caused by degeneration, but rather by degranulation of eosinophils and the coating of normal collagen fibers with the degranulated material.[59]

FIG. 40.19 Eosinophilic granuloma (nodular necrobiosis) with dermal nodules on a horse's withers. *(Courtesy Dr. Anthony Stannard.)*

Development of equine eosinophilic granuloma has been noted in areas of previous injections using standard silicone-coated, stainless steel hypodermic needles.[60] The reaction may occur at sites of IV and IM injections. Lesions consist of nonpainful cool, raised papules or nodules 0.25 to 1 cm in diameter at sites of previous injection. The nodule appears 24 to 48 hours after the injection, and the subsequent eosinophilic granuloma can persist for months to years. Affected horses do not develop a lesion at the site of injection if nondisposable, noncoated needles are used. The use of the noncoated needles is recommended for any horse that develops injection-site collagenolytic granulomas.

Horses with solitary or a few lesions may be treated by surgical excision (not in the saddle area) or glucocorticoid injections under the lesions. Triamcinolone acetonide (3 to 5 mg per lesion) is effective. It has been recommended that no more than 20 mg triamcinolone acetonide be administered at once to any horse because any more of this drug may cause laminitis.[1] Horses with multiple lesions may be treated with oral prednisolone at 1 mg/kg once daily for 2 to 3 weeks. Multiple small (<1 cm) lesions may be indicative of insect bite hypersensitivity.

Cutaneous Amyloidosis

Cutaneous amyloidosis is an uncommon nodular dermatosis of unknown etiology. There is no age, breed, or gender predilection. The condition appears to be a primary form of amyloidosis, in that concurrent inflammatory processes are not present, and amyloid (a fibrillar protein substance derived from immunoglobulins) deposition is usually restricted to the skin and occasionally the regional lymphatics, regional lymph nodes, and upper respiratory mucosa.[1,18] One case was documented as being caused by lambda light-chain deposition from an extramedullary plasmacytoma.[61] Another horse showed amyloidosis concurrent with lymphoma.[62]

Papules, nodules, and plaques on the head, neck, shoulders, thorax, or inguinal areas are firm, 0.5 to 10 cm in diameter, nonpainful, and nonpruritic. The overlying skin is normal, although it may scale or crust in severe cases (Fig. 40.20). The course of cutaneous amyloidosis is progressive and prolonged. Megestrol acetate may be an effective treatment (0.2 mg/kg PO q24h until lesions resolve). Because certain forms of primary amyloidosis in humans have a genetic basis, it may not be advisable to use affected horses for breeding until more is learned about the genetics of the equine disorder.

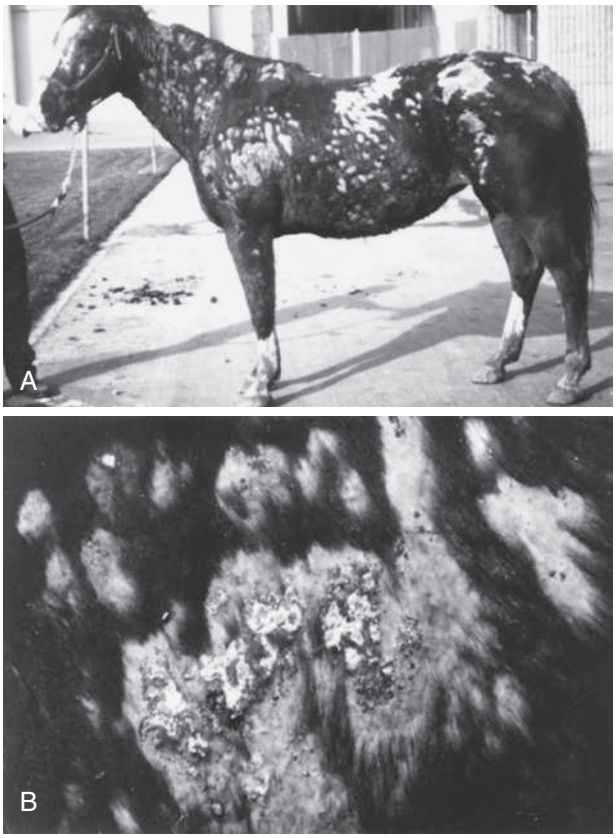

FIG. 40.20 **A,** Cutaneous amyloidosis in a horse. **B,** Close-up of skin of A. *(Courtesy Dr. Anthony Stannard.)*

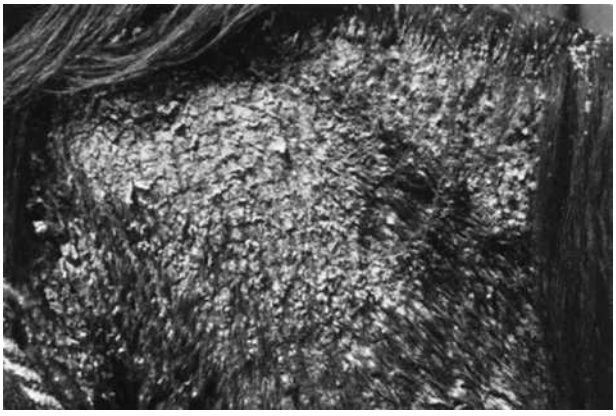

FIG. 40.21 Equine sarcoidosis (generalized granulomatous disease) in a horse. In addition to scaling and crusting skin lesions, the horse had systemic involvement. *(Courtesy Dr. Anthony Stannard.)*

Equine Sarcoidosis (Generalized Granulomatous Disease)

Equine sarcoidosis is characterized by skin lesions and usually concurrent systemic involvement. It is *not* a neoplastic disease and should *not* be confused with equine sarcoids.

The disease is encountered infrequently, and there is no known breed predilection. Geldings may be at increased risk.[63] The skin lesions typically are generalized scaling and crusting associated with varying degrees of alopecia (Fig. 40.21). Occasionally the disease is focal or multifocal in distribution. Rarely, the skin lesions consist of nodules or large tumor-like masses. The different types of skin lesions may coexist. In addition to skin lesions, the most frequent presenting complaints are weight loss, decreased appetite, and a persistent low-grade fever. Lung involvement is manifested by exercise intolerance, increased resting respiratory rate, and mild dyspnea.[64-66] One report showed positive titers to *Borrelia burgdorferi* in three of four horses with equine sarcoidosis,[67] another found evidence of equine herpesvirus 2,[68] and a recent report described *Mycobacterium* DNA in the liver and skin of a horse with sarcoidosis.[69] However, other investigations, using PCR, immunohistochemistry, and histologic stains, were unable to demonstrate the presence of any causative organism.[62,70]

Diagnosis is by histopathology and ruling out infectious etiologies. The major histologic change is the presence of noncaseating granulomas consisting of aggregates of epithelioid cells and multinucleated giant cells. Neutrophils, lymphocytes, and plasma cells are present in small numbers. In the skin the granulomas tend to be located in the superficial portion of the dermis. Because of the small number of horses studied and the variability of clinical signs, response to therapy has not been well documented. An abstract reported that 5 of 6 horses did well and lived longer than 1 year with prednisolone treatment.[71] Another extensive review showed that some horses did well on corticosteroid therapy (usually at doses approximating those used to treat pemphigus and other autoimmune skin diseases); GI involvement was a sign of poorer prognosis.[63] Recently reported cases suggest that some horses with sarcoidosis may have localized rather than generalized skin disease and confirm that spontaneous resolution (seemingly when the stress of working is reduced or eliminated) may occur.[72,73]

Chronic Progressive Lymphedema

Chronic progressive lymphedema (CPL) is the term for a condition seen in Shires, Clydesdales, Belgians, and probably other draft breeds (Color Plate 40.12). It is characterized by progressive swelling, hyperkeratosis (thickening), and fibrosis (hardening) of the skin on the lower legs. This chronic progressive disease starts at an early age, progresses throughout the life of the horse, and often ends in disfigurement and disability of the limbs. Inevitably, it leads to the horse's premature death. In the Belgian draft horse, it has reduced the average life expectancy of a stallion from 20 to only 6 years.

The pathologic changes and clinical signs closely resemble a condition known in humans as *chronic lymphedema* or *elephantiasis nostras verrucosa*. The lower leg swelling is caused by abnormal functioning of the lymphatic system in the skin, which results in chronic lymphedema (swelling), fibrosis, a compromised immune system, and subsequent secondary infections of the skin. Based on preliminary research, it appears that a similar pathogenic mechanism is involved in the disease that affects these specific draft horse breeds.

The clinical signs of this disease are highly variable. The earliest lesions are characterized by skin thickening and crusting; both are often visible only after clipping the long feathering. Secondary infections develop very easily in these horses' legs and usually consist of either chorioptic mange or bacterial infections. Both dark skin and white skin on the lower legs are equally affected. These lesions are consistent with pastern dermatitis, certainly seen in other breeds. In horses with CPL, however, these lesions do not respond well to therapy.

As the disease progresses, one or two thick skin folds and sometimes multiple small, well-demarcated ulcerations develop, predominantly in the rear of the pastern region. The ulcerations are covered with adherent crusts. Manual removal of the crusts or even movement during exercise results in bleeding. These small sores may seem to respond initially to various topical medications but often reverse course, only to progress in severity and multiply in number. Small lesions tend to coalesce into

VetBooks.ir

larger and more intractable (resistant to treatment) areas of skin ulceration. Over time, the lesions extend up the leg, often affecting the skin as high as the knees or hocks. These lesions are, at the very least, irritating to the horses and at times can be quite painful. Severely affected individuals often exhibit generalized swelling in all four legs.

This condition is therefore primarily a lymph system disease, and the pastern dermatitis in these draft horses is secondary to the body's inability to supply fluids properly and oxygenate the skin of the lower leg. The lymphatics break down over time, and the protein-rich fluid leaks into the tissues of the lower leg, which results in fibrosis of the tissues under the skin and thickening of the skin itself. The tissue fibrosis leads to even more blockage of fluid within the legs, inhibiting circulatory flow. This results in neovascularization, a process by which the body develops new blood vessels in a futile attempt to provide oxygen to its tissues.

Researchers suspect that a deficiency or abnormality in the connective tissue component known as *elastin* is the underlying factor and perhaps the cause of the lymphatic degeneration in these horses.[74,75] In affected animals, the lymph vessels and deep tissues of the skin do not have sufficient amounts or the proper configuration of elastin. The lack of this critical tissue element apparently instigates the progression of disease and the chronic progression of clinical signs. One report documents high levels of antielastin antibodies in affected horses.[76] A more recent report found that affected horses had increased amounts of dermal elastin in both the distal limb and the neck, whereas unaffected horses of a susceptible breed had decreased amounts. These findings support an earlier hypothesis that CPL of horses is a generalized disease. Reduced efficiency of the elastic network in supporting the dermal lymphatics may explain the development of CPL.[77]

As the condition becomes more chronic, the lower leg enlargement becomes permanent, and the swelling is firm on palpation. More of the thick skin folds and large, poorly defined, firm nodules develop. The nodules may become quite large and often are described as golf ball or even baseball sized. Both skin folds and nodules first develop in the back of the pastern area. With progression, they may extend and encircle the entire lower leg. The nodules become a mechanical problem because they interfere with free movement and are frequently injured during exercise. This disease often progresses to include massive secondary infections that produce copious amounts of foul-smelling exudates, generalized illness, debilitation, and even death.[75,76]

In one report of possibly the same condition in several draft breeds, the authors found a perivascular dermatitis dominated by T lymphocytes with an increase in major histocompatibility complex (MHC) class II–positive, dendritic-like cells. Immunohistochemical labeling for cytokeratins CK5/6(4), CK10, and CK14 indicated a change in their expression pattern. This correlated with the degree of epidermal hyperplasia, indicating abnormal differentiation of keratinocytes. There was a statistically significant correlation between the severity of skin lesions and several other factors, including increasing age, increasing cannon circumference, prominence of anatomic structures (e.g., fetlock tufts of hairs, ergots, chestnuts), and bulges in the fetlock region.[78] Another more recent report, again looking at various draft breeds (Rhenish German, Schleswig, Saxon-Thuringian, and South German), identified a quantitative trait loci for CPL.[79]

Zinc Responsive Dermatitis

In Holstein-Friesian cattle, zinc responsive dermatitis is a hereditary autosomal recessive defect in GI zinc absorption, also known as lethal trait A 46, and is characterized by diarrhea, skin lesions, poliosis (gray hairs), and a decreased suckle reflex. Skin lesions involve inflammation and crusts around the eyes, base of ears, coronary bands, and muzzle; these may become generalized. Plasma zinc concentrations of calves are normal at birth. The histology of skin lesions shows parakeratosis.[80]

Oral administration of zinc reverses signs in 1 to 3 weeks.

Recently a similar disease, albeit one associated with a different mutation, was described in Fleckvieh cattle. Treatment is uncertain, as the mutation does not appear to involve a problem with intestinal transport of the zinc.[81]

In goats and sheep this may be caused by ingestion of alfalfa (which is high in calcium and therefore blocks zinc uptake) or overliming the soil with calcium salts, creating a zinc-deficient soil. Crusts, bilateral symmetrical alopecia, rough hair coat, abnormal claw growth with weight loss, stunted growth, abnormal (kyphotic) gait, and anorexia may all be seen.[82] Histopathology of skin shows parakeratosis and hyperkeratosis; this may be hereditary in some dairy goats.[83]

Equine Endocrine and Metabolic Diseases

Kelsey A. Hart

Pituitary and Hypothalamus

Dianne McFarlane

Physiology of Equine Hypothalamic-Pituitary Axis

The pituitary gland is composed of two embryologically distinct portions: an adenohypophysis, derived from invagination of the pharyngeal epithelium known as *Rathke's pouch*, and the neurohypophysis, derived from neural tissue of the hypothalamus. The adenohypophysis can be further divided into the pars distalis, pars tuberalis, and pars intermedia. The pars distalis contains five different endocrine cell types, each of which is responsible for the release of a unique hormone or set of hormones in response to hypothalamic-releasing factors delivered from the median eminence via the hypothalamic-hypophyseal portal system. The pars tuberalis is a highly vascular band of cells surrounding the pituitary stalk. The pars tuberalis is rich in melatonin receptors and is believed to be involved in regulating the seasonal rhythm of reproductive hormone production.[1] The neurohypophysis or pars nervosa is a collection of nerve axons and terminals that originate in the paraventricular and supraoptic nuclei of the hypothalamus. Oxytocin and arginine vasopressin (antidiuretic hormone) produced in the cell bodies of these nuclei are transported into the pars nervosa for storage and eventual release into the systemic circulation.

The pars intermedia of the horse incorporates tissue derived from both the adenohypophysis and neurohypophysis.[2] It is composed of a single endocrine cell type, the melanotrope. Melanotropes are directly innervated by nerve terminals of the hypothalamic periventricular dopaminergic neurons. These originate in the periventricular nucleus of the hypothalamus adjacent to the third ventricle, project through the infundibulum, and terminate in the pars intermedia (Fig. 41.1).[3] These neurons release the neurotransmitter dopamine, which acts to tonically inhibit the release of hormones from adjacent melanotropes. Dopamine released from the nerve terminals interacts at dopamine (D2) receptors on the melanotropes to inhibit cell proliferation, transcription of proopiomelanocortin (POMC), and release of POMC-derived peptides.[4] Additional regulatory signals to the pars intermedia may be delivered by direct systemic arterial supply and from the hypothalamic-hypophyseal portal veins.[5] In addition to being under tonic inhibition, melanotropes are also positively regulated by thyrotropin-releasing hormone (TRH), which stimulates hormone release from melanotropes.[6] Additional regulatory molecules likely exist but are poorly defined in the horse.

The primary product of the melanotrope is the hormone precursor protein POMC, which is also expressed by the corticotropes of the pars distalis. However, due to differential post-translational processing by proteases called *prohormone convertases*, each cell type secretes a different complement of POMC-derived peptides (Fig. 41.2). Due to the action of prohormone convertase I, POMC in corticotropes is primarily processed into adrenocorticotropic hormone (ACTH). ACTH circulates to the adrenal cortex, where it stimulates secretion of cortisol. Melanotropes contain active prohormone convertase I and II, and therefore POMC in the pars intermedia (PI) is cleaved into the secretory peptides, α-melanocyte stimulating hormone (α-MSH), β-endorphin (β-end), and corticotropin-like intermediate lobe peptide (CLIP). A small amount of ACTH may also be produced. Further processing of the peptides, including cleavage of C-terminal amino acids and *N*-acetylation, serves to control the activity of the final peptide product. For example, the most abundant form of β-end produced in the normal horse's pars intermedia is Ac-β-end (1-27), which lacks opioid activity. The most abundant β-end in horses with pituitary pars intermedia dysfunction (PPID) is β-end (1-31), which is an opioid agonist.[7]

The physiologic role of the pars intermedia POMC-derived peptides, α-MSH, β-end, and CLIP, has not been extensively studied in the horse. In other species, α-MSH has several diverse actions, which are mediated through interaction with one of five distinct G-protein–coupled melanocortin receptors. α-Melanocyte stimulating hormone is named such due to its ability to induce skin pigmentation in amphibians. Its role in pigmentation is through interaction with melanocortin receptor 1 (MC1R), which is predominantly expressed in skin. In horses, mutation of the *MC1R* gene is associated with the chestnut

VetBooks.ir

coat color.[8] In white Camarque horses the degree of coat pigmentation is directly correlated to the plasma concentration of α-MSH.[9] α-MSH is also an integral mediator in control of energy homeostasis. MC3R and MC4R are both expressed in the central nervous system (CNS), particularly in the hypothalamus, where they function in the leptin-melanocortin pathway, regulating appetite-satiety balance and fat metabolism.[10] Animals and humans lacking functional MC3R or MC4R are obese, and melanocortin receptor defects are a common monogenetic cause of obesity in humans.[11] Plasma α-MSH concentration in obese men has been reported to be higher than in lean men.[12] It has been suggested high plasma concentration in obese individuals may be an attempt to maintain homeostasis in individuals with a defect in MC4R. Plasma α-MSH concentration was also found to be positively correlated to obesity in horses.[13] Another function of α-MSH is as a potent anti-inflammatory agent.[14] α-MSH has been demonstrated to have multiple immune-modulating effects. Its most profound effect is in regulation of cytokine response. α-MSH inhibits activation of NF-κB by lipopolysaccharide (LPS) and interferon-γ (IFN-γ). Data in mice have suggested that α-MSH may suppress LPS-mediated inflammation by facilitating the interaction of IRAK and IRAK-M.[15] IRAK is a kinase that functions in activation of NF-κB following TLR-4 (the receptor for bacterial LPS) stimulation.[15] IRAK-M is a negative regulator of IRAK. As a result, NF-κB activation and proinflammatory cytokine release of tumor necrosis factor (TNF)-α, interleukin (IL)-1β, and IL-6 are all decreased following α-MSH administration. Fever and other clinical evidence of inflammation are also reduced. In addition, α-MSH has been shown to inhibit human and rodent neutrophil function, including adhesion, chemotaxis, and oxidative burst.[16-17] High α-MSH plasma concentration in horses was also associated with decreased oxidative burst and adhesion.[18] β-End is a known endogenous opioid. Secretion of β-end provides analgesia and behavioral modification. It also suppresses immune responsiveness and has effects on vascular tone.[19-20] Corticotropin-like intermediate lobe peptide (CLIP, ACTH 18-34) has not been extensively studied in any species. In pancreatic islet cells in culture, CLIP was shown to be a pancreatic β-cell secretagogue, stimulating the release of insulin.[21] However, when administered to rats by either intraperitoneal or intraventricular injection, ACTH but not CLIP resulted in release of insulin and decrease in blood glucose.[22]

A distinct seasonal effect on the activity of the pars intermedia of horses and ponies has been demonstrated in horses residing in tropical and temperate environments.[23-30] Plasma α-MSH concentration is considerably higher in horses and ponies in the northern hemisphere in August through October, compared with samples collected in the winter, spring, and early summer.[23-28] Similarly, horses in the southern hemisphere experience higher plasma α-MSH concentrations during shortening day length, from February to April.[29-30] An effect of season on α-MSH concentration has been described for humans, hamsters, and sheep.[31-33] The functional importance of the seasonal cycle is unknown, but several physiologic events occur in parallel with the α-MSH cycle. In sheep, body weight, voluntary food intake, and condition all peak simultaneously with α-MSH, with seasonal maximums occurring in September. Soay sheep with a surgically created hypothalamic-pituitary disconnection have an increase in circulating concentration of α-MSH and chronic increase in body weight.[32] These findings suggest that α-MSH or other POMC-derived peptides may play a role in metabolic preparation for winter in sheep. It is possible that horses and ponies have a seasonal increase in POMC-derived peptides to metabolically prepare them for a decrease in accessible food observed in the wild in winter. If so, dysregulation of this pathway might be associated with abnormalities in body weight and fat storage. Weight loss and abnormal fat distribution are two clinical signs associated with equine PPID. Development of a winter coat also begins as length of day decreases in the fall. The development of hypertrichosis in horses with PPID leads one to speculate that the naturally occurring seasonal increase in POMC-derived peptides contributes to development of winter coat growth. This has not been critically assessed in equids.

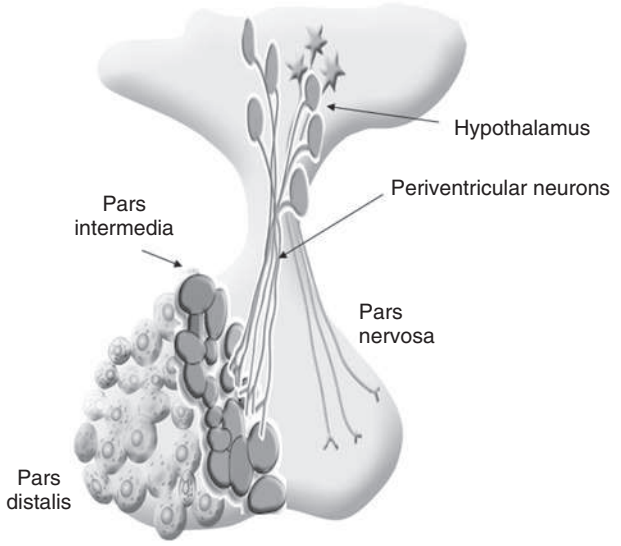

FIG. 41.1 Physiology of the equine pituitary pars intermedia. The melanotropes of the pars intermedia produce the hormone precursor protein, proopiomelanocortin (POMC), which in the pars intermedia is cleaved into the hormones, α-melanocyte stimulating hormone (α-MSH), β-endorphin (β-end), and corticotropin-like intermediate lobe peptide. Production of POMC in the pars intermedia is under inhibitory control by dopamine released from the nerve terminals of the periventricular neurons. The cell bodies of the periventricular neurons are in the hypothalamus, adjacent to the third ventricle.

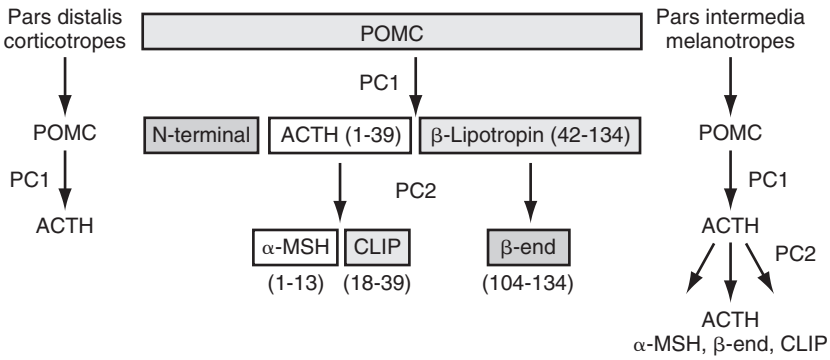

FIG. 41.2 Proopiomelanocortin (POMC) processing. POMC is cleaved by prohormone convertase I into adrenocorticotropic hormone (ACTH) in the pars distalis and into α-melanocyte stimulating hormone, β-endorphin, and corticotropin-like intermediate lobe peptide by prohormone convertase I and II in the pars intermedia. Only a small amount of ACTH is produced by the normal pars intermedia.

VetBooks.ir

Equine Pituitary Pars Intermedia Dysfunction

Equine PPID is one of the most common diseases of horses and ponies 15 years and older.[34-36] PPID was originally termed *equine Cushing disease* because of features similar to human Cushing disease. However, in contrast to human Cushing disease, PPID affects the pituitary pars intermedia rather than the pars distalis, is typically not a neoplastic condition, and the adrenocortical contribution to the clinical syndrome is of much less importance. To avoid confusion, equine Cushing disease is now more correctly referred to as PPID.

In the past 2 decades the population of aged horses has increased dramatically. This, in conjunction with the vast amount of information now available online to the horse-owning public, has led to a heightened client awareness of age-associated equine health issues and a desire to promote healthy aging in their horses. As a result, diagnostic testing and treatment of horses for PPID has increased. Yet despite increased clinical recognition of this disease, much about PPID remains poorly understood.

Pathophysiology

The pathologic hallmark of PPID is hypertrophy, hyperplasia, and microadenoma or macroadenoma formation in the pituitary pars intermedia with increased secretion of POMC peptides. Horses with PPID develop enlarged pituitaries that may exceed five times normal weight. As the pars intermedia expands, it compresses the adjacent pituitary lobes and hypothalamus, often resulting in a loss of function of these tissues. In contrast, the pars intermedia remains active in horses with PPID, secreting relatively large quantities of POMC-derived peptides into the peripheral circulation. Horses with disease may have as much as a 40-fold increase in plasma concentration of pars intermedia POMC-derived peptides.[37] Clinical signs of disease likely result from a combination of increased circulating POMC peptides and loss of neuroendocrine function of adjacent tissues.

Evidence indicates loss of dopamine inhibition is critical in the pathology of PPID. Dopamine and dopamine metabolite concentrations in the pars intermedia of PPID horses are decreased eightfold compared with age-matched controls.[7] Systemic supplementation of dopamine or a dopamine agonist to horses with PPID results in a decrease in plasma concentration of POMC peptides.[37] Horses treated with the dopamine agonist pergolide show improvement in both clinical signs and biochemical abnormalities associated with disease.[38-41] Immunohistochemistry of formalin-fixed tissue showed a fivefold decrease in pituitary dopaminergic nerve terminals and a 50% reduction in the number of dopaminergic periventricular cell bodies in the hypothalamus of PPID animals.[42] Considered together, this evidence suggests a loss of functional periventricular dopaminergic neurons—"dopaminergic neurodegeneration"—occurs in horses with PPID (Fig. 41.3). Loss of periventricular dopaminergic inhibition of the pars intermedia in other species results in pathologic changes similar to those of PPID. Surgical disruption of the periventricular hypophyseal dopaminergic tracts in rats results in increased expression of pars intermedia melanotropes.[43] In addition, D2 dopamine receptor knockout mice develop pars intermedia lesions similar to PPID.[4] These data suggest PPID is primarily a disease of hypothalamic origin, rather than the consequence of a spontaneously forming pituitary adenoma.

One potential cause for dopaminergic neurodegeneration is oxidative stress. Oxidative stress causes modification of cellular components including proteins, DNA, and cell membrane lipids due to excessive exposure to reactive oxygen species leading ultimately to cell death or, in the case of neurons, neurodegeneration. Dopaminergic neurons are particularly vulnerable to oxidative damage because dopamine metabolism itself produces free radicals. Horses with PPID have evidence of oxidative damage, including accumulation of pars intermedia 3-nitrotyrosine[42] and decreased plasma thiol.[44] The oxidative damage in PPID does not appear to be the result of impaired antioxidant capacity because systemic and pituitary antioxidant capacity of affected horses appears unchanged.[45]

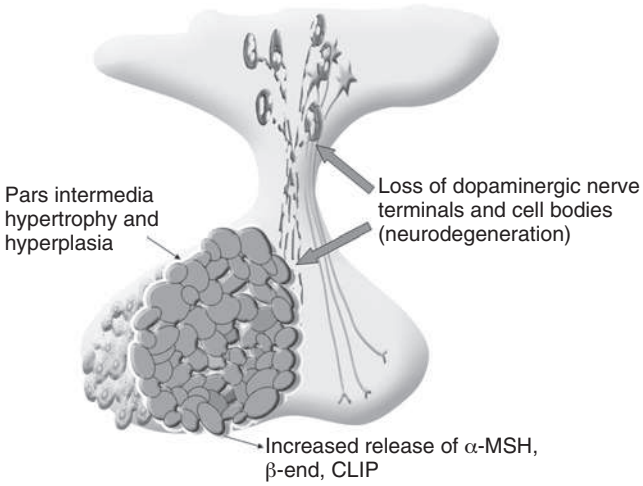

FIG. 41.3 Pathophysiology of equine pituitary pars intermedia dysfunction. Loss of functional dopaminergic periventricular neurons leads to a decrease in dopamine at the pars intermedia. This in turns results in dysinhibition of the melanotropes of the pars intermedia. The outcome is hypertrophy and hyperplasia of the pars intermedia and increased systemic release of the pars intermedia proopiomelanocortin (POMC)-derived peptides, α-melanocyte stimulating hormone (α-MSH), β-endorphin (β-end), and corticotropin-like intermediate lobe peptide.

FIG. 41.4 Typical horse with pituitary pars intermedia dysfunction (PPID). This 22-year-old Morgan mare shows obvious hypertrichosis. Other clinical signs of PPID in this horse included laminitis and weight loss despite an excellent appetite.

Clinical Signs

Equine PPID affects many aged equids, resulting in a variety of clinical signs including hypertrichosis (hirsutism), muscle atrophy, regional fat accumulation, polydipsia, polyuria, secondary infections, lethargy, infertility, persistent lactation, exercise intolerance, and sweating dysregulation (Fig. 41.4).[46-51] Laminitis and metabolic abnormalities including hyperglycemia and hyperinsulinemia also occur in approximately 30% of horses with PPID.[48] It is now thought that endocrinopathic laminitis occurs in horses with PPID due to concurrent insulin

dysregulation or equine metabolic syndrome (EMS), rather than as a direct result of PPID itself.

The most unique clinical manifestation of PPID is an abnormally long, curly hair coat that fails to shed (previously referred to as *equine hirsutism*, although more correctly called *hypertrichosis*). Often, horse owners may report the horse sheds its winter coat slowly or incompletely in the year(s) before development of a full failure to shed. Hair may be initially retained along the legs or under the mandible (Fig. 41.5). The mechanism responsible for development of hypertrichosis in horses with PPID has not been reported. The onset of hypertrichosis in an aged horse or pony is considered essentially pathognomonic for PPID, although the author has observed similar hair coats in severely debilitated aged animals with confirmed normal pituitary pars intermedia function.

In the author's experience, weight loss due to muscle mass atrophy is the most common and often the earliest clinical sign of PPID (Fig. 41.6). Despite weight loss, PPID horses often have a potbellied appearance and, as a consequence, owners may fail to notice the lost weight. Weight loss and muscle atrophy may result from several factors, including poor dentition, poor nutrition, heavy parasite burden, minimal exercise, and protein catabolism induced by increased cortisol activity. Histologic evidence of type 2 myofiber atrophy has been documented in muscle biopsies from horses with PPID, consistent with corticosteroid-associated muscle atrophy in other species.[52] Significant improvement in muscle mass was observed in a large group of horses with PPID after 6 months of treatment with pergolide mesylate, suggesting overexpression of POMC peptides contributes directly or indirectly to the mechanism of muscle atrophy.[41]

FIG. 41.5 Coat changes vary among horses with pituitary pars intermedia dysfunction (PPID). Retained hair along the lower limbs **(A),** under mandible **(B),** and as guard hairs and tufts along trunk **(C).**

FIG. 41.6 Horse with pituitary pars intermedia dysfunction (PPID). The major clinical sign of disease in this horse with PPID was weight loss. Muscle mass atrophy along the dorsum, with a potbelly appearance, is characteristic of PPID.

Despite weight loss and muscle mass atrophy, horses with PPID often have abnormal accumulations of fat, most notably in the crest of the neck, tailbase, sheath, and superorbital fossa. This fat accumulation typically predates the weight loss and has a similar pattern as that observed in horses with equine metabolic syndrome (EMS). The similarity of the clinical signs and at-risk breeds of these two diseases has resulted in a misdiagnosis of PPID in animals that have EMS. Unlike what was previously postulated, these two conditions, PPID and EMS, are no longer considered mutually exclusive conditions. There has also been speculation that animals with EMS or sustained obesity with hyperinsulinemia may be at greater risk for developing PPID as they age. Although epidemiologic data are currently lacking to support this association, client-provided anecdotal data suggest this may warrant more critical assessment.

Polydipsia and polyuria (PU/PD) occurs in some horses with PPID and is typically mild in severity.[46-47,49-51] The mechanism responsible for PU/PD may include (1) compression of the pars nervosa resulting in decreased arginine vasopressin (antidiuretic hormone) production, (2) osmotic diuresis secondary to hyperglycemia and glucosuria, or (3) cortisol induced. Cortisol is thought to cause PU/PD in other species by interfering with the secretion and/or action of arginine vasopressin.[53] Evidence suggests ACTH and cortisol may inhibit the renin-angiotensin-aldosterone axis as well. The mechanism of PU/PD in horses with PPID has not been extensively examined. Glucosuria is not a common finding in horses with PPID. In one study, two PPID horses with marked hyperglycemia were found to have similar water consumption to normal horses, suggesting that osmotic diuresis is unlikely a major mechanism of PU/PD in the PPID horse.[51]

Horses with PPID have been reported to be more susceptible to infection, including endoparasitism, bacterial sinusitis, skin infections, abscesses, and respiratory infections.[46-47,54-56] The morbidity and mortality of secondary infection in equine PPID have been reported to range from 27% to 48%.[49-50,54-55] In the absence of parasite control, a heavy parasite burden is common.[56] Routine, quantitative fecal egg counts are recommended to ensure an adequate anthelmintic program. Vigilance on the part of the owner and veterinarian is important in both prevention and early recognition of infections because they may be clinically insidious. Bronchopneumonia was found at necropsy in 7 of 19 horses with PPID.[57] Bronchopneumonia should be considered in the PPID horse with fever or tachypnea.

Laminitis secondary to PPID is reported to occur in approximately 30% to 40% of diagnosed cases and can necessitate euthanasia in affected animals.[41,49-51] When adult horses with laminitis of unknown origin were examined, 30% had evidence of PPID based on the presence of clinical signs (abnormal hair coat) and diagnostic test results.[58] Although an earlier study suggested 70% of undiagnosed laminitis cases might be due to PPID, this study relied on plasma ACTH concentration measured irrespective of season and in the absence of clinical signs for the diagnosis.[59] The reliability of plasma ACTH concentration for diagnosis of presymptomatic PPID, particularly in thrifty horses in the fall, is likely poor. The pathogenesis of laminitis in PPID is not currently well understood, but endocrinopathic laminitis is the subject of ongoing

investigation. Multiple lines of study support a primary role for hyperinsulinemia and insulin dysregulation in the induction of endocrinopathic laminitis.[60-65] Current data suggest that PPID is a comorbidity or risk factor rather than a primary inciting factor in the development of endocrinopathic laminitis.[48] Therefore, clients should be advised to assess all horses with insulin dysregulation (ID, equine metabolic syndrome) for PPID and all animals with PPID for ID. In horses with concurrent PPID and ID, the utmost care should be taken to manage risk factors for laminitis and minimize dietary nonstructural carbohydrates that could perpetuate ID.

Diagnosis of Pituitary Pars Intermedia Dysfunction

Equine PPID is both common and life threatening; therefore early and accurate diagnosis with appropriate intervention is considered critical. Antemortem diagnosis of PPID currently relies on testing hypothalamic-pituitary-adrenal axis responsiveness or measurement of endogenous plasma concentrations of POMC-derived peptides such as ACTH. These tests have been the subject of recent evaluation, and the search for improved testing strategies is considered an ongoing research priority.[66] Accepted best practices for the diagnosis of PPID have evolved significantly over the past 5 years, and further changes are likely to follow.

Currently, three antemortem diagnostic tests are most commonly used in practice settings: (1) the overnight dexamethasone suppression test (DST), (2) measurement of endogenous plasma ACTH concentration, and (3) ACTH release following thyrotropin-releasing hormone stimulation. The overnight DST was long considered the "gold standard" method of antemortem PPID diagnosis.[67] In the unaffected horse, intramuscular (IM) administration of dexamethasone decreases release of ACTH from the pars distalis, resulting in a serum cortisol concentration of less than 1 µg/dL (27.59 nmol/L) 19 hours after dexamethasone (Fig. 41.7).[67] Horses with PPID fail to suppress serum cortisol concentration due to ACTH production from the pars intermedia. Although originally this test was reported to have a sensitivity and specificity of 100%, horses included in that study were selected for having end-stage PPID, resulting in a favorable bias when assessing test performance.[67] Although highly specific for PPID, the DST has shown poor performance in identifying horses with earlier PPID. In fact, the DST was only useful in identifying horses with end-stage disease (defined as those with hypertrichosis and grossly enlarged pituitary adenomas) when a random population was assessed using necropsy as the gold standard.[68]

Measurement of endogenous concentrations of POMC-derived peptides is also useful in the diagnosis of PPID.[69] Measurement of plasma ACTH concentration is the most commonly used method for diagnosis of PPID in ambulatory practice because it requires collection of only a single plasma sample and poses no risk to the patient. Difficulty in sample handling was long cited as a limitation of this test; however, more critical evaluation has found equine ACTH to be more stable in plasma than originally assumed, and as long as a plasma sample remains cooled, separation of plasma can be delayed as long as 12 hours without affecting results and without the need for special preservatives (e.g., aprotinin).[39,50,70] Measurement of plasma concentrations of ACTH was originally reported to have a sensitivity and specificity of approximately 80% to 90%.[50,69] However, evaluation of a larger, randomized equine population has found the test to have a sensitivity and specificity of approximately 70% and 80%, respectively.[68] α-MSH concentration measurement, although used in research to similarly assess pars intermedia function, is not significantly better than ACTH concentration in identification of PPID and is not commercially available.[27,68-69,71]

Seasonal variation in both static and dynamic testing of pars intermedia function has been well documented.[23-30,72-73]

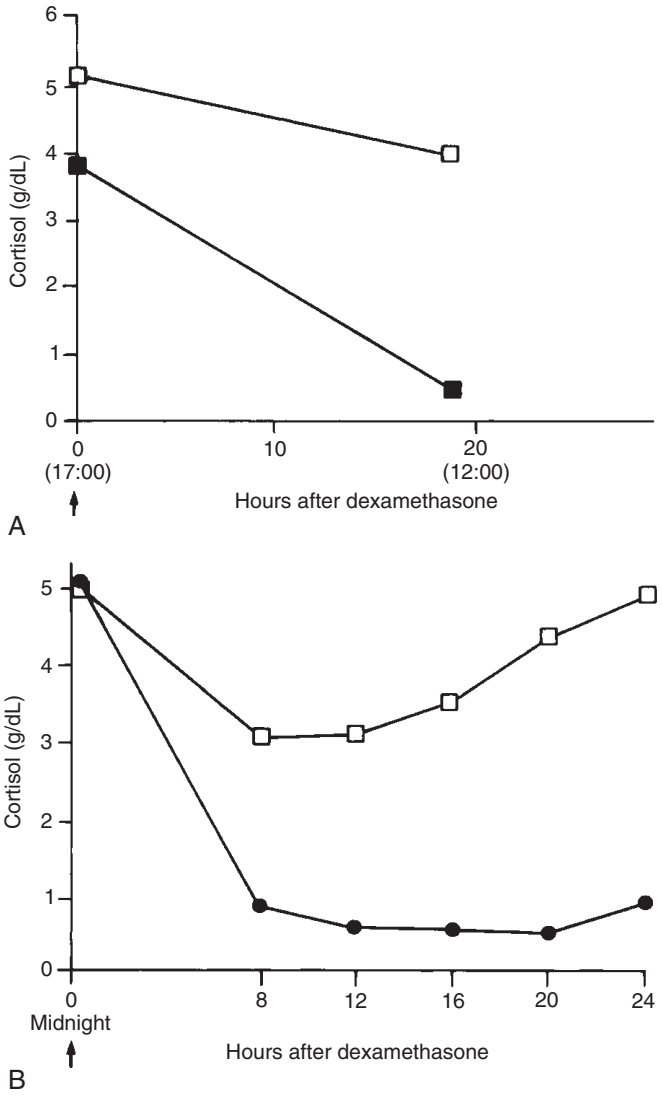

FIG. 41.7 Dexamethasone suppression test. □, Cushing; ■, control; ↑, 40 µg/kg dexamethasone intramuscularly; **A,** overnight; **B,** standard.

Testing performed in autumn, between August and October in the northern hemisphere or February and April in the southern hemisphere, yields a significantly greater hormone concentration than testing performed between November and July.[23-30,72-73] Initially, these findings led to the recommendation to avoid endocrine testing in autumn. However, further work has demonstrated that the difference in ACTH concentration between normal horses and those with PPID is much greater during autumn.[26] As a consequence, provided seasonally specific reference intervals are available, ACTH testing in autumn is more discriminating and therefore preferable to testing during other times of the year.

A positive test result in an animal with clinical signs of PPID is considered strong diagnostic evidence. However, due to the poor performance of the DST and ACTH concentration at identifying early disease, it is not uncommon for a clinician to have a suspicion of PPID in a patient that has a negative diagnostic test result. When this occurs, repeating testing at a later date or further testing using a provocative test is indicated. The dynamic test that has been shown to most accurately identify PPID is the thyrotropin-releasing hormone (TRH) stimulation test with measurement of plasma

VetBooks.ir

ACTH concentration.[74-76] TRH is known to be a physiologic releasing factor of the equine pars intermedia.[6] Although this test was initially performed by documenting an increase in serum cortisol concentration after TRH administration, measurement of plasma ACTH rather than serum cortisol has proven more reliable.[6,77] Plasma ACTH response is a more direct assessment of pars intermedia activity and eliminates the influence of adrenal gland response or ACTH bioactivity. It has been demonstrated that in PPID, immunoreactive plasma ACTH is not as bioactive as plasma ACTH from the healthy horse.[78-79] Therefore, in horses with PPID the TRH response may be attenuated at the level of cortisol release. The initial recommended protocol for the TRH stimulation test was to measure plasma ACTH concentration at time 0, 10, and 30 minutes after intravenous administration of TRH (1 mg/horse or 0.5 mg/pony).[76] However, to reduce cost and improve efficiency, most practitioners choose to collect only the 0- and 10-minute samples, as data are lacking for improved test performance with inclusion of the additional 30-minute sample. Current recommendations suggest limiting use of the TRH stimulation test to nonfall seasons.[66] Although several investigators have collected TRH stimulation data during the fall, TRH response is highly variable and may depend on such factors as breed and geographic location.[80-81] Although unlikely to be practical in most cases, advanced imaging of the pituitary using computed tomography (CT) or magnetic resonance (MR) has also been examined in a limited number of cases as a method for documenting pituitary or pars intermedia enlargement.[82-85] Accuracy of CT at estimating width, height, length, and volume of the equine pituitary gland in disarticulated heads from 25 normal horses was determined to be 81% to 93%, 58% to 71%, 88% to 99%, and 43% to 53%, respectively.[83] In a more recent study in which CT measurements were performed in a small number of live horses, accuracy was between 92% and 105%, likely due to the larger dose of contrast agent administered.[84] Despite the ability to characterize overall size of the pituitary, CT does not provide information on the internal structure of the gland, including the relative size of the pituitary lobes and presence of microadenomas. Magnetic resonance imaging is the preferred diagnostic imaging modality for pituitary masses in humans, and its usefulness in characterizing the pituitaries of horses is currently being evaluated.[85]

Necropsy Findings

Postmortem examination of the horse with PPID reveals a grossly enlarged pituitary due to hypertrophy and hyperplasia of the pars intermedia.[86-89] The normal horse's pituitary typically weighs between 1 and 3 g; the affected horse's pituitary may be two to five times this size. Enlargement may be due to an adenoma (>1 cm), which often contains areas of hemorrhage and necrosis. Alternatively, microadenomatous (≤1 cm) hyperplasia may be present. Melanotropes in the affected gland are pleiomorphic (polyhedral or spindle shaped) with eosinophilic, granular cytoplasm.[86-89] Cells are organized into nodules, rosettes, bundles, or follicular structures separated by fine septal tissue. Pigment deposition (lipofuscin) is common in the pars nervosa, and hemosiderin may be observed when hemorrhage is present.[57] Other lesions include compression of the pars distalis, pars nervosa, or in the case of large tumors that outgrow the sella turcica, compression of the optic chiasm or hypothalamus. Associated lesions of other organs are also common, including those related to immunosuppression such as intestinal parasitism, pneumonia, abscesses, or sinusitis.[57] Laminitis may be observed in horses with PPID and insulin dysregulation; however, PPID alone is not typically associated with laminar pathology.[48] Mild enlargement of the pars intermedia is also observed in the healthy aged horse,[89] and moderate enlargement with microadenomas has been observed in clinically normal horses during the autumn.[88]

Treatment and Prognosis

Treatment of PPID is aimed at improving general health and reducing the risk of disease complications such as laminitis and infections. Management practices should be optimized for care of an aged horse. Diet and feeding practices, dental and hoof care, and deworming schedule should be assessed. Feeding of a pelleted diet designed for senior horses along with strategic deworming and correction of dental abnormalities are useful in maintaining the animal's weight and improving overall general health. Body clipping the horse that fails to shed during warm weather is critical to limit excessive sweating and avoid hyperthermia. Careful observation for evidence of infection followed by early intervention is important to avoid protracted illnesses. Due to the strong anti-inflammatory effects of POMC peptides, clinical signs of infections are often mild and don't reflect the severity of disease. Assessment of insulin regulation and vigilant attention to diet and hoof care are essential to avoid laminitis in those horses with concurrent PPID and insulin dysregulation.

Pharmaceutical interventions for PPID function by decreasing the concentration of circulating POMC peptides and/or cortisol, which theoretically should reduce the risk of disease complications beyond what can be achieved by management alone. Ideally, treatment should also reverse or retard the hyperplastic growth of the pars intermedia, thereby limiting compression of adjacent tissues.

The preferred drug for the treatment of PPID is pergolide, a dopamine agonist, which has been shown to improve clinical signs and diagnostic test results in treated animals.[38-40] An initial dose of 0.002 mg/kg orally every 24 hours has been recommended.[46,66] Response to the drug should be assessed by both clinical improvement and normalization of diagnostic test results. If no response is observed in 4 weeks, the dose is increased by 0.001 to 0.002 mg/kg increments monthly until clinical signs and biochemical abnormalities normalize.[46] In some horses, splitting the daily dose into two 12-hour treatments also may improve response. Complications associated with pergolide use in the horse include anorexia, colic, and diarrhea. These are typically dose dependent and often resolve spontaneously following a reduction in dose. Once an effective dose is established, endocrine testing should be repeated every 6 to 12 months to ensure hormonal control is maintained because horses may require periodic increases in dose over time. Although other dopaminergic agonists, such as bromocriptine and cabergoline, have been shown to be effective in suppressing pars intermedia activity, the only approved and well-studied dopaminergic agonist for the treatment of PPID at this time is pergolide (Prascend).[90]

Cyproheptidine, a drug with antiserotoninergic, antihistaminergic, and anticholinergic activity, was one of the original drugs used to treat horses with PPID. However, several studies using objectively measurable outcomes failed to show consistent efficacy of the drug.[38-39] In addition, although historically inexpensive, the cost of cyproheptidine has increased significantly, making pergolide the more rational current treatment choice. Cyproheptidine may be useful as an adjunct therapy in horses resistant to pergolide monotherapy. Cyproheptidine may be added at 0.3 to 0.5 mg/kg orally once daily to horses that show minimal response to a 0.006 mg/kg or higher dose of pergolide.[46] Cyproheptidine has been associated with induction of seizures in rodents and therefore may be contraindicated in horses with a history of previous seizure activity.[91]

The prognosis of horses with PPID is not well documented. Many horses live for years following diagnosis, particularly if receiving optimized management. Reports of PPID horses that have responded to pergolide for more than 5 years suggest long-term effective treatment is achievable.[92] As with all diseases, early recognition, appropriate intervention, and avoidance of complications are the keys to a positive outcome.

Adrenal Glands

Kelsey A. Hart

Physiology of the Adrenal Gland and Hypothalamic-Pituitary-Adrenal Axis

As in other species, in the horse the paired adrenal glands lay immediately craniomedial to the kidneys. Equine adrenal glands weigh approximately 15 g each and are approximately 8 to 10 cm in length, 3 to 4 cm wide, and 1.5 cm thick, though there is much variation in adrenal size and shape among individual horses. Each gland is divided into an outer cortex that secretes corticosteroids and an inner medulla that secretes catecholamines.

The adrenal medulla functions as a neuroendocrine organ and is essentially a modified sympathetic ganglion. Preganglionic sympathetic neurons extend from the central nervous system and synapse directly on adrenal medullary chromaffin cells; when stimulated, these cells release catecholamines directly in the systemic circulation to produce a global sympathetic response. In the horse, the primary adrenal medullary catecholamine appears to be epinephrine, though norepinephrine and dopamine are also produced.[1] Diseases affecting the adrenal medulla are rare in horses—as in all species—though adrenal medullary neoplasms are reported.

The adrenal cortices are divided into three cellular zones: (1) the outer zona glomerulosa; (2) the middle zona fasiculata, which is the largest zone and comprises approximately 75% of the weight of the gland; and (3) the narrow inner zona reticularis. Cells in the zona glomerulosa are primarily responsible for the secretion of mineralocorticoids (e.g., aldosterone) in response to hypotension and electrolyte derangements (hyperkalemia, hyponatremia). Zona fasiculata cells synthesize and secrete glucocorticoids (e.g., cortisol, corticosterone, 11-deoxycortisol) in response to stimulation by adrenocorticotropic hormone (ACTH) after activation of the hypothalamic-pituitary-adrenal (HPA) axis (Fig. 41.8) by physiologic or pathophysiologic stressors. The predominant circulating glucocorticoid in the horse is cortisol.[2] Cells in the zona reticularis also secrete small amounts of glucocorticoids but primarily produce adrenal androgens such as dehydroepiandrosterone (DHEA) and androstenedione. All corticosteroid hormones are structurally similar with a common sterol backbone and one 5-carbon and three 6-carbon rings, and they share a common synthetic pathway originating from cholesterol (Fig. 41.9). The specific corticosteroids produced by a particular adrenocortical cell depend on which specific biosynthetic enzymes are expressed in that cell (see Fig. 41.9), which varies between the three functional zones.

All steroid hormones are lipophilic and thus are transported in the plasma predominantly bound to plasma proteins, including albumin and steroid-binding globulins such as cortisol-binding globulin (CBG). However, as steroid hormone receptors are located in the cytoplasm of steroid-responsive cells, it is only the free, unbound portion of circulating steroid hormones that is available to enter cells via diffusion across the plasma membrane to bind these intracellular receptors. Binding of the steroid hormone to the receptor causes conformational changes that allow dissociation of regulatory heat shock proteins, permitting the hormone-receptor complex to localize to the nucleus, bind DNA at hormone-response-elements (HREs), and upregulate or downregulate transcription of steroid hormone-responsive genes.

Glucocorticoids are the most abundant circulating adrenal corticosteroid hormone and play an integral role in the endocrine response to stress. The HPA axis (see Fig. 41.8) is activated when physiologic, pathophysiologic, or environmental stressors activate peripheral and central nervous system components, whose signals are then interpreted and integrated in the hypothalamus. This stimulates hypothalamic paraventricular nuclei, resulting in the release of corticotropin-releasing hormone (CRH) into the hypothalamic-hypophyseal portal vessels. CRH then acts locally in the adjacent anterior pituitary gland to stimulate CRH receptors on the cell surface of pituitary corticotroph cells, resulting in the release of adrenocorticotropic hormone (ACTH, corticotrophin) into the systemic circulation.

ACTH binds cell surface receptors (melanocortin 2 receptor, MC2R) on adrenocortical cells and stimulates the adrenal glands to synthesize and secrete cortisol. MC2R is a G protein–coupled transmembrane receptor that acts via adenylate cyclase to increase cyclic AMP levels, which then activate biosynthetic enzymes necessary for cortisol synthesis, including 3-β-hydroxysteroid dehydrogenase (3-β-HSD), 17-α-hydroxylase, 21-α-hydroxylase, and 11-β-hydroxylase (Fig. 41.9). This latter enzyme catalyzes the final step in cortisol synthesis from 11-deoxycortisol and is present only in glucocorticoid-producing cells.[3]

Cortisol is not stored in adrenocortical cells but rather is secreted into the systemic circulation immediately following ACTH-induced synthesis. In most adult mammals, including

horses, approximately 90% to 95% of circulating cortisol is bound to CBG and albumin.[4-8] Many cell types are sensitive to glucocorticoids, permitting cortisol to exert diverse effects necessary for maintenance of homeostasis and stress responses in both health and disease. Essential glucocorticoid-mediated physiologic responses include maintenance of blood pressure, provision of energy to tissues, and control of an appropriate inflammatory response. The sum of cortisol's systemic effects serves to reduce the physiologic stress that initially activated the HPA axis, to ultimately restore basal HPA axis tone. In addition, cortisol itself acts via negative feedback mechanisms at hypothalamic, pituitary, and adrenal levels to further downregulate HPA axis activity. Thus, with an intact HPA axis, plasma cortisol concentrations are maintained at a level appropriate for the existing degree of physiologic stress (see Fig. 41.8).

Cortisol secretion patterns in adult horses exhibit both ultradian (pulsatile) and circadian rhythms with peak secretion in the morning and the nadir in the evening, similar to many other species.[9-12] These ultradian and circadian rhythms are easily disrupted in horses by simple routine changes and illness.[9,12] Cortisol responses to ACTH stimulation testing in adult horses are described and suggest adult horses show a comparable dose-dependent effect of exogenous ACTH on cortisol concentrations as is described in other species.[11,13-15] In general, an approximately twofold to fivefold increase in cortisol concentration is observed within 30 to 90 minutes after IV administration of a 0.1 to 10 μg/kg dose of exogenous ACTH (cosyntropin) in healthy adult horses[13,15]; the magnitude of cortisol increase varies with the ACTH dose administered.

HPA axis function in the foal differs from both adult horses and other species in several key ways. Compelling evidence shows that maturation of the HPA axis occurs in the days just before parturition and continues during the first several weeks of life, much later than is described in other species.[16-19] Premature foals have lower serum cortisol and higher ACTH concentrations than full-term foals immediately postpartum.[19] These low baseline cortisol and concurrent high ACTH concentrations in premature foals imply that foals may have impaired adrenocortical sensitivity to ACTH, limited cortisol synthetic capacity, or both, as compared with adult horses.

Data from ACTH stimulation test responses in foals support this theory, as premature foals show a blunted cortisol response to exogenous ACTH, with only a 28% increase in plasma cortisol 30 to 60 minutes following stimulation, as compared with a 208% increase in normal-term foals.[16] Some evidence suggests that the fetal foal's adrenal gland may be incapable of synthesizing cortisol and some other steroid hormones until late in gestation. In contrast to most other species, fetal foals do not express substantial levels of the key steroidogenic enzymes cholesterol side chain cleavage enzyme, 17α-hydroxylase, and 3-β-HSD (see Fig. 41.9) until just before parturition in the foal,[20,21] much later than is described in other species.[22]

Furthermore, adrenocortical function may not be fully mature at birth even in full-term foals. Though increased at birth due to the stress of parturition, by 12 to 24 hours of age, mean basal cortisol concentrations are onefold to twofold lower in healthy neonatal foals than reported mean concentrations in healthy adult horses despite comparable or higher concurrent

VetBooks.ir

ACTH concentrations in foals.[23-27] This apparent decreased cortisol response to endogenous ACTH in the full-term neonatal foal is supported by further evidence of limited cortisol responses to exogenous ACTH. Insulin-induced cortisol responses in foals within 12 hours of birth are less than half of the responses achieved in 7- to 14-day-old foals,[28] and healthy-term neonatal foals aged 1 to 7 days are reported to have approximately half the magnitude of cortisol response to ACTH stimulation testing than adult horses.[13,24] This decreased adrenocortical responsiveness appears to persist during the first few months of life, as 12-week-old foals show significantly greater cortisol responses to a low-dose (0.1 µg/kg) ACTH stimulation test than younger foals.[29]

Finally, foals differ from adult horses in their plasma cortisol binding capacity and cortisol secretion and metabolism patterns. In foals younger than 1 week of age, 30% to 60% of circulating cortisol is free, in contrast to 5% to 10% in adult horses.[30] This is likely due to decreased CBG concentrations in foals, as has been shown in infants.[31,32] Free cortisol is preferentially excreted and metabolized over bound cortisol,[33] so it is not surprising that increased cortisol clearance rates in foals as compared with adult horses have recently been described.[12] Healthy full-term foals appear to be able to increase their daily cortisol production rate to compensate for this increased clearance, though as serum total cortisol concentration at 1 week of age remains significantly lower in foals than adult horses,[12] foals' capacity to further and appropriately increase cortisol production in severe stress may be limited. It is likely that impaired cortisol responses in neonatal foals result from multiple factors, including decreased cortisol synthetic capacity and increased cortisol clearance and possibly other as yet undefined difference in ACTH sensitivity or activity. Regardless of the cause, this evidence of fetal and neonatal HPA axis immaturity is certain to substantially impact foals' stress responses during the neonatal period.

Mineralocorticoids (e.g., aldosterone) are produced in small quantities relative to glucocorticoids but have equally important physiologic roles. Angiotensin II—via activation of the renin-angiotensin-aldosterone system by hypovolemia/hypotension or increases in plasma osmolality—and increased plasma potassium concentration are the primary stimulants of aldosterone synthesis and secretion. ACTH is also necessary for aldosterone synthesis, but ACTH administration to healthy adult horses resulted in a decrease in plasma aldosterone concentration in contrast to increases seen in other species.[34,35]

Like glucocorticoids, aldosterone circulates in the plasma bound to albumin or steroid-binding globulins and primarily acts by binding cytosolic mineralocorticoid receptors to alter transcription of genes necessary for sodium and potassium transport. Mineralocorticoid receptors are predominantly expressed in sodium-transporting epithelia in the distal renal tubules and colon, with lesser expression in the rest of the intestinal tract and heart. Aldosterone induces transcription of an aldosterone-regulated kinase that increases activity of apical membrane sodium channels.[36] The net effect of this is increased sodium flux across epithelial cells, resulting in increased renal and intestinal sodium and water resorption and concurrent stimulation of potassium excretion via the basolateral Na^+/K^+ ATP-ase.[36] Mineralocorticoids are vital for appropriate fluid and electrolyte balance, and mineralocorticoid deficiency rapidly results in hyponatremia, hyperkalemia, and hypovolemia.

Reported resting and exercising plasma concentrations of aldosterone in horses have been described.[37,38] In contrast to their limited cortisol responses to appropriate stimuli, newborn foals appear to be able to mount a substantial aldosterone response to hypovolemia/hyponatremia.[19,39] In fact, one study suggested that the aldosterone response in foals appears to be exaggerated in comparison with that in adult horses and may reflect differences in tubular sensitivity to aldosterone between neonates and adults.[39] However, well-established reference ranges for plasma aldosterone concentrations in foals are not currently available.

In adult males, circulating androgens are primarily of testicular origin, but in females more than half of plasma androgens may originate from the adrenal cortices. ACTH is necessary for the synthesis and secretion of adrenal androgens, but another factor (or factors) that is as yet unidentified is also required for adrenal androgen synthesis.[11] Adrenal androgens are also transported in the plasma bound to albumin and CBG and act via cytosolic steroid hormone receptors to modulate gene transcription. DHEA and androstenedione can be extra-glandularly metabolized to active testosterone and estrogens and play a particular important role in early pubertal sexual development in most species. Androstenedione concentrations in adult horses are reported, and sex and age variations in adrenal androgen concentrations may be relevant but at present are poorly understood in horses and foals.[26,40] Increased adrenal androgen production is postulated to play a role in mares with estrus-related behavior problems, though this has not been definitively proven.[26]

Adrenal Gland Disorders

Critical Illness-Related Corticosteroid Insufficiency

Critical illness–related corticosteroid insufficiency (CIRCI) (also known as *relative adrenal insufficiency*) has been described in septic foals and adult horses with colic. The condition is best understood in people and is defined as an insufficient cortisol response or inadequate cortisol activity for the existing degree of critical illness.[41-45] CIRCI is discussed in detail in the later section on endocrine dysfunction in critical illness.

Non-CIRCI Adrenocortical Insufficiency in Adult Horses

Classic adrenocortical insufficiency characterized by glucocorticoid and mineralocorticoid insufficiency and unrelated to critical illness is not well defined in horses or foals, and Addison's disease—permanent adrenocortical insufficiency secondary to immune-mediated adrenocortical destruction—has not been reported. Transient adrenal insufficiency characterized by low basal ACTH and cortisol concentrations and impaired cortisol responses to ACTH stimulation testing has been described in one horse following abrupt cessation of long-term anabolic steroid supplementation.[46] A syndrome of "adrenal exhaustion" resulting in lethargy, anorexia, and poor performance is also anecdotally described in racehorses and has been attributed to adrenal insufficiency associated with long-term anabolic steroid administration or chronic stress. Horses with presumptive adrenal exhaustion are often treated with exogenous ACTH for presumed adrenocortical stimulation, though measurement of basal cortisol concentrations and ACTH stimulation testing in race and endurance horses has not provided convincing evidence for adrenal insufficiency in these equine athletes.[47,48] The potential for iatrogenic adrenal insufficiency associated with HPA axis suppression by exogenous steroid administration, though, should be considered in horses on chronic glucocorticoid or anabolic steroid supplementation, and care should be taken to avoid abrupt cessation of such therapy. Decreased cortisol responses to ACTH are also described in mares with abnormal estrus-related behavior,[26] but the clinical significance of this behavior is not known.

In addition, the adrenal glands appear to be a shock organ in the horse and can also undergo hypoxic or ischemic damage during bouts of endotoxemia, sepsis, and systemic inflammatory response syndrome (SIRS).[15,49] Thus, there is the theoretical potential for protracted or permanent adrenocortical dysfunction

VetBooks.ir

in animals who survive critical illness, though this specific manifestation is not reported in horses or foals to date. Adrenocortical insufficiency should be considered in horses with persistent lethargy, weight loss, hyponatremia, hypochloremia, hyperkalemia, or hypoglycemia, especially if they have recently received exogenous corticosteroids or recovered from critical illness. Failure to increase serum cortisol concentration greater than or equal to 1.5- to 2-fold baseline values by 30 minutes after a low-dose ACTH stimulation test (≤0.5 µg/kg IV) or greater than or equal to 3- to 4-fold baseline values by 90 to 120 minutes after high-dose ACTH stimulation test (≥1 µg/kg IV) is consistent with a diagnosis of adrenocortical insufficiency.[13,15]

Adrenal Medullary Neoplasia

Although nonfunctional adrenal medullary nodules may be an incidental finding at necropsy in the horse, functional adrenal medullary tumors (pheochromocytoma) are also rarely reported. One recent report described finding them in 0.95% of equine necropsies across two North American university teaching hospitals between 2007 and 2014.[50-54] Pheochromocytoma can be an incidental finding at necropsy, but clinical signs resulting from increased circulating catecholamines may also be seen. Such signs include excessive sweating, agitation, colic, tachycardia, mydriasis, hyperlactatemia, hyperglycemia, and hypertension.[50] Pheochromocytomas are predisposed to hemorrhage, and hemoperitoneum secondary to ruptured pheochromocytoma is described in horses.[50,51,55] Although most cases are diagnosed at necropsy, determination of urinary catecholamine levels can be used for antemortem diagnosis if an abdominal mass and appropriate clinical signs are detected.[53] Pheochromocytomas appear to occur frequently along with other endocrine abnormalities such as thyroid adenoma, PPID, or adrenal hyperplasia, or in a multiple endocrine neoplasia syndrome described in people, small animals, and horses.[50,54,55]

Hypoaldosteronism

In people, primary hypoaldosteronism is uncommon and most frequently occurs as a result of congenital defects in some component of the aldosterone biosynthetic pathway.[11] Hypoaldosteronism is also reported in renal diseases that damage the juxtaglomerular apparatus integral to function of the RAAS, and peripheral resistance to aldosterone is also reported in people.[11] Such syndromes have not been described in horses, but idiopathic hypoaldosteronism is described in an alpaca.[56] In addition, hypoaldosteronism is a documented cause of renal tubular acidosis (RTA) in people[57] and should not be overlooked as a possible contributor to RTA in horses.

Anhidrosis

Babetta Breuhaus

Description of Disease

Anhidrosis is characterized as an inability to sweat in response to appropriate stimuli. It occurs in geographic areas that experience hot, humid weather for prolonged periods of time. Clinical signs are especially likely to occur when nighttime temperatures do not fall below 70° F (21° C). Classically, anhidrosis affects horses that are not accustomed to these environmental conditions and are moved to a hot, humid area. However, partial or complete anhidrosis is also diagnosed in horses that have grown up in these same areas. It appears that horses that are worked or exercised in hot, humid conditions are more likely to develop the condition than horses that are not worked. Stress may also contribute to onset of the problem. One large epidemiologic study conducted in Florida concluded that Thoroughbreds and warmbloods, especially those with a family history of having developed anhidrosis, were more likely to develop the condition.[1] The study also supported earlier beliefs that horses that performed more strenuous work and horses that were not born in Florida were at increased risk for becoming anhidrotic. The prevalence of anhidrosis was increased, both in terms of percent of farms that housed at least one anhidrotic animal and of overall percent of affected horses, in horses residing farther south within the state.[1]

Etiology and Pathophysiology

The cause of anhidrosis is unknown. Presumably, there is an abnormality in stimulation or production of sweat. Equine sweat glands produce sweat as an ultrafiltrate from plasma; water and electrolytes are secreted into sweat gland ducts, and this fluid is transported to the skin surface as sweat. Physiologic stimulation of sweating in horses is achieved by activation of α_2-adrenergic receptors, by direct neural stimulation and from circulating catecholamines.[2-4] It is unclear whether nerve fibers act directly on the sweat glands themselves or on local capillaries, thereby altering delivery of circulating agonists.[5] Purinoceptors of the P2Y family may also be involved in stimulation of sweat production. Sweat glands from anhidrotic horses do not respond normally to direct stimulation, and there is histologic evidence of sweat gland atrophy.[6,7] However, it is unknown whether the observed sweat gland atrophy is the primary cause of anhidrosis or merely secondary to disuse. Histologic examination of skin from anhidrotic horses showed no evidence of neural disruption to the sweat glands,[7] and circulating concentrations of epinephrine are actually higher in anhidrotic horses than in horses that sweat normally.[8] This suggests that the problem is more likely caused by decreased ability of sweat glands to respond to stimulation, rather than failure of the thermoregulatory system to perceive the need to sweat or failure of stimulation to sweat. Cultured epithelial cells from sweat glands of anhidrotic horses had lower transepithelial resistance compared with cells derived from sweat glands of horses that were able to sweat freely.[9] In addition, cells from anhidrotic horses failed to show a change in short circuit current (indicative of chloride secretion) in response to purinoceptor or β-adrenoceptor agonists. Most theories of anhidrosis pathogenesis suggest that chronic stimulation to sweat in a hot, humid environment might lead to downregulation and/or desensitization of α_2-adrenoreceptors. The observation that only some horses living in a given environment develop anhidrosis, as well as the recent evidence of a breed and familial predisposition to the problem, suggest a possible genetic predisposition as well. It seems likely that β-adrenoceptor polymorphisms exist in horses and that certain polymorphs are more susceptible to downregulation, though scientific evidence for this theory is currently lacking.

In addition to a neural mechanism, there may also be an endocrine component to this disease. Pregnant mares were found to be somewhat less at risk of developing anhidosis than nonpregnant mares.[10] An association of anhidrosis with hypothyroidism most likely stems from the observation that thyroid supplementation helped anhidrotic horses racing in Hong Kong in the 1950s.[11] However, the author has not observed any improvement in anhidrotic pleasure horses supplemented with thyroid hormones, and measurement of thyroid hormones at rest and in response to TRH showed no difference between normal horses and horses with anhidrosis.[12]

There is evidence in some humans that acquired idiopathic anhidrosis may have an immunologic pathogenesis. Serum IgE concentration was increased in one reported case.[13] Sweat gland atrophy with infiltration by lymphocytes and mast cells and IgG and C3 deposition in the basement membrane has been described.[13,14] Steroid therapy improved the ability of one of

VetBooks.ir

FIG. 41.10 Horses that cannot cool by sweat production will often show dilated peripheral skin vessels.

these patients to sweat. An immune-mediated basis for anhidrosis has not been studied in the horse. Basement membrane was noted to be thickened in skin biopsies from 10 anhidrotic horses.[7] However, inflammation (leukocyte infiltration) was noted in only one of six anhidrotic horses housed at ambient conditions.[7]

Expression of the water channel aquaporin-5 was decreased in sweat glands from anhidrotic horses compared with sweat glands from horses that sweated normally.[15] While these results may help explain why hypohidrotic or anhidrotic horses cannot produce as much sweat as normal horses, it is not clear whether loss of these water channels is a cause or a consequence of decreased sweat gland secretory capacity. A recent review provides additional detail on the physiology and pathophysiology of equine sweat gland function and dysfunction.[16]

Clinical Signs and Differential Diagnoses

Early clinical signs of hypohidrosis include exercise intolerance, particularly in warm humid weather, and tachypnea, initially during or after exercise, and then at rest as the severity of disease increases. Owners may initially suspect that their horse has a respiratory problem. As hypohidrosis worsens or the horse becomes anhidrotic, owners realize the horse is not sweating as much as would be expected for the level of work it is performing, or it is taking longer than normal to cool out after exercise. Areas of residual sweat production often include under the mane, in the axilla or inguinal areas, and under the saddle. Dilated vessels under the skin may be noted (Fig. 41.10). A few horses exhibit extrusion of salt crystals without accompanying water (Fig. 41.11). Body temperature can increase to dangerous levels if signs are not recognized and affected horses continue to work in hot weather. The hair coat often becomes dry and thin in chronically affected horses, particularly over the face (Fig. 41.12) and cannon bones.

Clinical Pathology and Diagnostic Tests

Hypohidrosis or anhidrosis can be included in a differential diagnosis of exercise intolerance on the basis of history and clinical signs. The diagnosis can be confirmed by performing an intradermal sweat test.[6,17-20] Six serial 10-fold dilutions of an α_2-adrenergic agonist such as terbutaline (10^{-3} w/v to 10^{-8} w/v) are prepared. Each dilution (0.1 mL) is injected intradermally along the neck or pectoral region. In normal horses, a localized area of sweat will appear at the site of injection at all concentrations, except perhaps the most dilute concentration (10^{-8}). The amount of sweat produced at each site is proportional to the concentration of terbutaline injected (Fig. 41.13). Sweating will first be noted in normal horses within 5 minutes of injection at the higher concentrations. Onset of sweat production may be delayed and amount of sweat produced reduced in hypohidrotic horses, or hypohidrotic horses may only sweat at the higher concentrations of terbutaline. Anhidrotic horses do not sweat, even at the highest concentration.

FIG. 41.11 Salt crystals secreted in response to exercise (lunge test) in an anhidrotic horse. Following a lunge test, this horse excreted the salt crystals shown here, without a fluid component to the sweat. The author has observed this in two horses diagnosed with anhidrosis.

While failure to sweat in response to intradermal terbutaline injection confirms a diagnosis of anhidrosis, horses that are hypohidrotic may continue to produce sweat, even at the lower concentrations. For these horses, a lunge test will help confirm the diagnosis. Body temperature, heart rate, and respiratory rate are recorded. The horse is then lunged at a trot for 30 minutes on a hot day. During this time, the horse is observed for evidence of sweat production. Body temperature, heart rate, and respiratory rate measurements are made immediately at the end of lunging and every 10 minutes thereafter for the

VetBooks.ir

FIG. 41.12 Chronic anhidrosis often causes facial hair loss or thinning.

FIG. 41.13 Terbutaline intradermal sweat test. Six serial 10-fold dilutions of terbutaline are injected intradermally along the neck. Normal horses, such as the one shown here, will sweat at the injection site of all concentrations, except perhaps the most dilute (10^{-8} w/v). In the normal horse, sweating will typically begin within 5 minutes of injection. Reduction in the amount or delay in onset of sweating is diagnostic for hypohidrosis. A complete failure to sweat in response to all terbutaline concentrations is diagnostic for anhidrosis.

next 30 minutes. While the heart rate response reflects the degree of fitness, the body temperature and respiratory rate responses correlate better to the horse's ability to cool itself. If the horse's respiratory rate is not back to what it was before the onset of lunging by 30 minutes after the end of the exercise, it is highly likely that the horse is having a problem cooling.

The most likely differential diagnoses for hypohidrosis include various respiratory diseases. In the author's experience, some hypohidrotic or anhidrotic horses also have mild airway inflammation, documented most often by increased mast cells or eosinophils in bronchoalveolar lavage fluid. It is unknown whether the two problems coexist coincidentally or if there is a mechanistic link. Either way, it is likely that airway inflammation would decrease the ability of a horse to use its respiratory system to help cool itself, and this is likely to be more critical in a horse that cannot sweat.

Treatment, Prevention, and Prognosis

The only consistently successful treatment is movement of the horse to a cooler environment, although this is not always practical or feasible. Other environmental or dietary alterations may or may not be helpful. For hypohidrotic horses or horses that are having their first episode of anhidrosis, it is important to stop any workload and decrease the stress level. Concurrent disease conditions, such as airway inflammation, should be appropriately treated. Shade, fans, misting fans, and window air conditioners can be used to try to decrease the temperature in the horse's local environment. Applying water by hose or sponging the horse with water during the hot part of the day can take the place of sweat. Electrolyte supplementation (especially KCl) has been advocated,[18,19] and various products are available commercially that appear to help some, but not all, horses. One such supplement (One AC, MCPO, Phoenix, Ariz.) contains L-tyrosine, ascorbic acid, niacin, and cobalt and claims to improve sweat production by supplying precursors to dopamine synthesis. The theory is that dopamine improves skin vasodilation, resulting in increased blood flow to sweat glands during exercise. To the author's knowledge, there are no studies at present to support or deny this claim. Other treatments that have been used with mixed success include vitamin E administration,[21,22] acupuncture, and Chinese herbs.[18,19]

Medical therapy of anhidrosis has primarily been unrewarding. Anecdotally, the α_2-adrenergic agonist clenbuterol increases sweat production in hypohidrotic horses and may be useful if used sparingly, only when weather conditions are particularly bad (i.e., extremely high heat and humidity). However, traditional recommendations are to avoid use of α_2-adrenergic agonists in hypohidrotic horses because their use theoretically might precipitate complete anhidrosis.[23] In a recent study, oral clenbuterol administration was shown to lose its beneficial effect on airway reactivity after 21 days of administration, but prolonged clenbuterol administration had no effect on results of intradermal terbutaline sweat tests.[24] However, the horses used in that study were neither hypohydrotic nor anhidrotic. The effect of prolonged α_2-adrenergic agonist administration on sweating or response to intradermal sweat tests in anhidrotic horses has not been reported. There is increasing evidence in human medicine that combination treatment of chronic airway disease with both α_2-adrenergic agonists and corticosteroids results in a synergistic effect, with corticosteroids helping to prevent desensitization and tolerance to α_2-adrenergic agonists and α_2-adrenergic agonists potentiating the anti-inflammatory effects of the corticosteroids.[25,26] Thus, combination therapy may be useful in hypohidrotic horses, but to date no controlled studies have been performed. Corticosteroid therapy may also be useful if there is an immune component to the pathogenesis of anhidrosis.

Once a horse has had an episode of anhidrosis, certain measures can be taken to try to prevent recurrence of the problem in subsequent years. Before the hot part of the year begins, start the horse on any supplements that have been helpful previously and make certain the horse is cardiovascularly fit. Also, make sure that any respiratory problems are under control before the onset of hot weather. As the hot season approaches, try to avoid procedures that might require administration of heavy doses of α_2-adrenergic agonists (e.g., xylazine, detomidine) that stimulate the horse to sweat. Plan to do these procedures during the cooler parts of the year. During hot periods, work the horse only during the cool parts of the day. Use external water sources to cool the horse to decrease the need for the horse to sweat.

VetBooks.ir

The prognosis for hypohidrotic horses is guarded for future athletic performance in a hot environment. It is the author's opinion that the longer an anhidrotic horse has been left untreated or unmanaged, the less likely the horse will be to sweat again despite any of the treatments described earlier. However, if an underlying disease or problem can be identified and treated successfully in a horse that is just becoming hypohidrotic, the likelihood that the horse will sweat better the following season is improved.

Thyroid Gland

Babetta Breuhaus

Thyroid Gland Physiology

Thyroid gland physiology and control of thyroid hormone secretion in horses is similar to other species. Thyroid hormones are important for growth, maturation of organ systems, and regulation of metabolism. They stimulate protein synthesis and catabolism, increase body heat production, and stimulate basal metabolic rate. The thyroid gland concentrates iodides from the blood and synthesizes and secretes both thyroxine (T_4) and tri-iodothyronine (T_3). Once secreted, thyroid hormones circulate both bound to proteins and unbound ("free"), with the free fractions being the active fractions. T_3 is more metabolically active than T_4, and although some T_3 is secreted by the thyroid gland along with T_4, the main source of T_3 in the body is from conversion of T_4 to T_3 in peripheral tissues.

Thyroid hormone secretion is regulated by the hypothalamus and pituitary. Thyrotropin releasing hormone (TRH), made in the paraventricular nucleus and released from the median eminence of the hypothalamus, stimulates release of thyroid stimulating hormone (TSH) from the anterior pituitary, which circulates to the thyroid gland to stimulate release of thyroid hormones. Plasma thyroid hormones exert negative feedback on the hypothalamus and pituitary to limit further release of TRH and TSH. Neurotransmitters that play a role in thyroid hormone regulation include α-adrenergic agonists (stimulatory) and somatostatin and dopamine (inhibitory). Glucocorticoids and the cytokines TNF and IL-1β also inhibit TSH secretion.

As most recently reviewed,[1] alterations in thyroid hormone status that have been described in horses include thyroid gland neoplasia, hyperthyroidism, and hypothyroidism. Certain drugs, diets, and physiologic or pathophysiologic states can also influence circulating thyroid hormone concentrations.

Thyroid Gland Neoplasia

Thyroid gland neoplasias are not uncommon, and it is not unusual to find them as incidental findings during necropsy of older horses.[2,3] Thyroid adenomas are most common, but other reported thyroid neoplasias include carcinomas, adenocarcinomas, and C-cell tumors. Although there are also scattered case reports of hypothyroid or hyperthyroid horses due to a thyroid tumor, most thyroid gland tumors are benign and nonfunctional. The glands enlarge physically, but there is no metastasis and circulating thyroid hormone concentrations remain within normal limits. As such, treatment of most thyroid gland neoplasias is unnecessary, until or unless the glands become big enough to start to interfere with swallowing or breathing. Once a thyroid gland tumor becomes enlarged enough for the owner to notice it, a reasonable approach is to measure circulating thyroid hormones (both total and free concentrations of T_4 and T_3). Provided that circulating thyroid hormone concentrations are normal, and provided that the horse is comfortable and the tumor is not big enough to interfere with alimentary or respiratory function, surgical removal is not recommended. The size of the gland should be monitored. If the gland starts to enlarge rapidly or if circulating thyroid hormone concentrations increase, then expedient surgical excision is recommended. After thyroidectomy, the horse will need to be treated with thyroid hormone supplementation to maintain circulating concentrations of thyroid hormones within the normal range.

Hyperthyroidism in Adult Horses

Hyperthyroidism is extremely rare in horses. There are three documented case reports in the literature, and all of these have been associated with thyroid gland neoplasias.[4-6] Circulating thyroid hormone concentrations are also sometimes temporarily increased in horses exposed to excess iodine, such as in a topical blister. Clinical signs of hyperthyroidism in horses include weight loss, tachycardia, tachypnea, hyperactive behavior, ravenous appetite, and cachexia. Diagnosis is confirmed by measurement of increased circulating concentrations of thyroid hormones. A T_3 suppression test can also be performed. Treatment of a hyperactive thyroid tumor has generally been thyroidectomy. It is recommended that biopsy and nuclear scintigraphy be performed before thyroidectomy to determine if both right and left sides of the thyroid gland are hyperplastic or neoplastic. If so, removal of only one side may obviate the need for postoperative thyroid hormone supplementation. It is also possible for one side of the gland to be hyperactive while the other side is normal or suppressed. In this situation, nuclear scintigraphy is important to identify which side of the gland needs to be removed. In one case report, a hyperthyroid horse was treated successfully with oral propylthiouracil.[6] The horse responded rapidly to treatment that was initiated at 8 mg/kg once daily and then maintained at the same dose every other day.

Hypothyroidism in Adult Horses

Hypothyroidism in the horse has been poorly understood in the past, but most now agree that primary hypothyroidism is rare. Although autoimmune thyroid disease is somewhat common in people and dogs, it has only been described in one report of histologic changes found at necropsy in a group of horses in Eastern Europe.[7] The prevalence of true hypothyroidism in adult horses is unknown but is almost certainly overestimated. Hypothyroidism has been thought to contribute to a variety of problems in the horse, including obesity, laminitis, anhidrosis, recurrent rhabdomyolysis, and poor fertility. However, documentation of hypothyroidism in such cases for the most part does not exist. Anecdotal reports of beneficial effects of thyroid hormone supplementation in these horses are also largely unsubstantiated. Despite this, many horses with these conditions receive thyroid hormone medication over extended periods of time, and many—if not all—of them do not need it. Besides the obvious waste of money, potential health risks associated with unnecessary thyroid hormone supplementation have only been minimally explored in horses.[8] In humans, thyrotoxicosis or oversupplementation with levothyroxine can result in decreased bone density, increased risk of atrial fibrillation, and possible increased risk of myocardial infarction or precipitation of congestive heart failure.[9]

Clinical signs of hypothyroidism in adult horses appear to be subtle. Traditionally, horses that gained weight easily, had cresty necks, and tended to suffer from recurrent bouts of laminitis were thought to be hypothyroid. However, in the author's experience, thyroid function tests in horses that fit this description are typically normal and it is more likely that these horses either have PPID or equine metabolic syndrome. In the few published case reports of horses that were documented to be hypothyroid based on abnormal thyroid function testing, clinical signs were primarily lethargy, exercise intolerance, and poor

hair coat quality.[10-12] In experiments in which horses were made hypothyroid, either by surgical removal of the thyroid glands or by administration of antithyroid drugs,[13-25] obesity and laminitis were not reported. Although resting heart rate, cardiac output, respiratory rate, and rectal temperature decreased in horses after thyroidectomy,[17] and serum concentrations of triglycerides, cholesterol, and very low-density lipoproteins increased,[16] the changes were mild and absolute values remained within the normal reference interval for adult horses. For this reason, measurement of these parameters would not help identify a hypothyroid horse in the general population.

Other Alterations of Thyroid Function

Certain physiologic states, drugs, diets, and pathologic states can alter thyroid hormone synthesis, metabolism, or binding, resulting in altered serum concentrations of thyroid hormones. For example, fasting lowers circulating concentrations of thyroid hormones in many species studied, including the horse.[26] Phenylbutazone or dexamethasone administration, strenuous exercise, and diets high in energy, protein, zinc, and copper have also been shown to alter circulating concentrations of thyroid hormones in horses.[27-35]

Nonthyroidal Illness Syndrome

Nonthyroidal illness syndrome is well described in humans, dogs, and cats suffering from systemic illnesses. In humans, milder forms of illness result in decreases in serum concentrations of T_3, with T_4 remaining within the normal range or only slightly decreased. As nonthyroidal illness becomes more severe, total T_4 decreases and eventually free T_4 also begins to decrease. The magnitude of thyroid hormone suppression has been correlated to severity of disease and mortality.[36-38] Mechanisms by which thyroid hormones decrease during illness include decreased peripheral conversion of T_4 to T_3 by 5'-deiodinase, altered binding to serum carrier proteins, and hypothalamic-pituitary dysregulation or suppression.[38-42] Recent reports in adult horses and foals suggest that nonthyroidal illness syndrome is similar in horses compared with other species.[43-48] In adult horses, thyroid hormone concentrations are negatively correlated with severity of disease and TSH is not appropriately increased.[47] Total and free T3 decrease with mild disease, with total and free T4 remaining in the normal range. However, as severity of disease increases, T3 is further suppressed and T4 also begins to decrease, with some severely ill horses having virtually no measurable circulating thyroid hormones. Thus, true thyroid gland status cannot be accurately determined in ill horses. It appears that free T4 by dialysis is least affected by illness and therefore would be the best choice if evaluation of thyroid function could not wait until an ill animal was healthy again.

Thyroid hormone concentrations, particularly T3, have also been found to be lower in sick and septic foals compared with healthy foals.[44-46,48] Thyroid hormone concentrations were inversely correlated to sepsis score,[44] and nonsurviving foals had lower concentrations of thyroid hormones compared with surviving foals.[44,48]

Fescue Ingestion

Tall fescue *(Festuca arundinaceae)* is a perennial grass that is grown commonly in the southeast because it is relatively easy to establish, has a long growing season, and has good disease and drought resistance that allow it to survive hot, humid summers. A variety of reproductive problems have been described in mares consuming fescue, and these have been shown to be caused by alkaloids produced by an endophytic fungus *(Neotyphodium coenophialum)* that lives symbiotically on the fescue plant and acts as a dopamine agonist.[49] Since TSH release from the pituitary is inhibited by dopamine,[50] it has been suggested that fescue consumption could lead to secondary hypothyroidism. Fescue ingestion was proposed as the cause of lower serum TSH concentrations in mares and foals consuming endophyte-infected fescue on a farm in central Kentucky, compared with mares and foals on a nearby farm grazing pastures that were mainly free of endophyte-infected fescue.[51] However, the author found no differences in baseline concentrations of thyroid hormones or TSH or in their responses to administration of TRH, in adult, nonpregnant horses fed endophyte-infected fescue seed for 2 months.[52] It appears that dopamine acts more as an acute modulator of TSH secretion, rather than as the primary control. In humans, while acute dopamine blockade results in increased TSH secretion and increased circulating thyroid hormones, chronic administration does not cause long-term alterations in thyroid hormone status.[50] Thus, it is likely that compensatory mechanisms override any dopaminergic effect of chronic fescue ingestion on the thyroid axis in the horse.

Syndromes Purportedly Associated With Hypothyroidism

Obesity

As mentioned earlier, horses that gain weight easily and have a tendency to deposit fat in the crest of the neck, over the rump and tailhead, or in the sheath have long been regarded as hypothyroid. It is now known that these horses most likely have insulin dysregulation and EMS and have normal thyroid function. Anecdotally, thyroid hormone administration to these horses usually has not resulted in substantial weight loss, especially if feed consumption is not restricted and the amount of thyroid hormone supplementation is titrated to maintain serum thyroid hormone concentrations in the normal range. However, administration of levothyroxine at a dose of approximately 0.1 mg/kg/day (48 mg) long term was associated with weight loss and increased insulin sensitivity in six healthy, euthyroid mares, despite the fact that they had access to pasture and a round bale of hay during the day and were given hay at night when they were stalled.[8,53] Although serum total T_4 concentrations increased four to five times their presupplementation concentrations, no adverse health effects were observed. Thus, when used to help obese horses lose weight, the amount of thyroid hormone given needs to be enough to make the horse mildly hyperthyroid. It is preferable for feed intake to be controlled at 1.5% to 2% of the desired body weight per day, consisting of grass hay or other feed that is low in soluble carbohydrates. It is important to understand that when thyroid hormones are administered in this manner, they are being used as a pharmacologic tool and should only be given for a short period of time; lifelong administration is not indicated.

Laminitis

A role for decreased thyroid function in the pathogenesis of laminitis was proposed but is poorly documented and remains a controversial topic. While decreased serum thyroid hormones have been associated with some horses that experience acute laminitis, it is extremely unlikely that hypothyroidism alone causes laminitis. In 13 studies in which hypothyroidism was induced by either surgical removal of the thyroid glands or administration of propylthiouracil, laminitis did not occur.[13-25] Thus, any alterations in serum thyroid hormone concentrations in horses experiencing laminitis are likely caused by factors associated with the episode of laminitis, rather than the underlying cause of laminitis. Such factors could include drugs used to treat laminitis (e.g., phenylbutazone), development of nonthyroidal illness syndrome, or a direct effect of factors such as endotoxin or one of the inflammatory cytokines that

VetBooks.ir

contribute to the onset of laminitis in some cases. In the author's experience, TRH stimulation tests performed in horses that have suffered an episode of laminitis or that have had bouts of recurrent laminitis show normal thyroid hormone responses when these tests are performed once the horse is stabilized and has been off all medications for 4 weeks.

Despite evidence of normal thyroid function in horses with laminitis, some veterinary clinicians still believe that treatment of horses with iodinated casein during an acute episode of laminitis results in improvement. These horses often are treated without prior measurement of thyroid hormones. Some are treated even when measurement shows serum thyroid hormone concentrations to be within the normal range. These horses are then often kept on thyroid hormone supplementation indefinitely. To date, no controlled studies have been performed to determine whether or not administration of thyroid hormones during acute episodes of laminitis is beneficial. However, since the action of α-adrenergic agonists on vasculature is usually vasodilatory, it is possible that thyroid hormone administration increases circulation to the foot by its ability to potentiate α-adrenergic receptor numbers and sensitivity.[54-56] Or it is also possible that thyroid hormone supplementation alters carbohydrate and fat metabolism in a way that increases insulin sensitivity.[57] Thus, any potential beneficial effect of thyroid hormone administration in horses suffering from laminitis may be pharmacologic rather than physiologic.

Anhidrosis

Anhidrosis is a condition of adult horses characterized by a decreased ability or inability to sweat in response to appropriate stimuli. The cause is unknown. Hypothyroidism has long been associated with anhidrosis, perhaps because treatment with iodinated casein was reported to help increase sweat production in anhidrotic horses in the 1950s.[58] However, the author found that baseline concentrations of thyroid hormones and TSH were normal in horses with anhidrosis.[59] Thyroid hormone responses to TRH were also normal, but TSH responses to TRH were significantly greater in anhidrotic horses than they were in horses with normal sweat production. The clinical significance of this greater TSH response to TRH in anhidrotic horses is unknown. Because equine sweat glands are stimulated to secrete by activation of α_2-adrenergic receptors and thyroid hormones modulate adrenergic receptor function, perhaps making horses mildly hyperthyroid restores α-adrenergic receptor numbers or sensitivity or potentiates sweat responses to whatever neural stimulation remains.

Rhabdomyolysis

A link between hypothyroidism and rhabdomyolysis was suggested by a report of muscle stiffness, poor performance, and rhabdomyolysis in 4 Thoroughbred and 2 Standardbred racehorses that had low baseline T_4 concentrations.[60] The horses improved after administration of iodinated casein. However, T_4 response to TSH was normal in these horses. A subsequent study showed normal resting concentrations of T_4 but decreased T_4 response to TRH in five horses that had suffered previous episodes of rhabdomyolysis.[61] In a study of 18 Quarter Horses with polysaccharide storage myopathy and 18 Thoroughbreds with recurrent exertional rhabdomyolysis, circulating concentrations of T_4 and T_3 were within normal range. Stimulation tests were not performed.[62] Thus, a role for hypothyroidism in the pathophysiology of equine rhabdomyolysis is unclear. Because it is now known that the clinical syndrome of rhabdomyolysis is caused by more than one underlying pathophysiologic etiology, it is possible that hypothyroidism might contribute to some, but not all, cases of equine rhabdomyolysis. If hypothyroidism is suspected, thyroid function should be assessed, ideally by measuring both resting concentrations of free thyroid hormones, as well as by response to TRH or TSH. If resting concentrations of free thyroid hormones are found to be low, nonthyroidal illness syndrome due to other factors should be ruled out before thyroid hormone supplementation is prescribed.

Infertility in Mares

Thyroid hormone administration to broodmares to theoretically improve fertility has been a fairly common practice. This occurs despite a lack of evidence that the mares were actually hypothyroid in the first place or that thyroid hormone supplementation improves equine fertility. This practice presumably is an extrapolation from human medicine, where hypothyroidism in women adversely affects fertility. However, two of three fillies that had undergone thyroidectomy became pregnant without thyroid hormone supplementation,[13] and two additional studies including hundreds of horses failed to show an association between thyroid hormone status and conception rates in mares.[63,64] The first study[63] was performed in 329 clinically normal broodmares.[63] Resting serum T_4 concentrations were below the reference interval in 12% of the mares, within the reference interval in 86%, and increased in 6% of the mares. There was no association between serum T_4 concentration and whether or not the mare was pregnant 15 to 16 days after ovulation. There also was no association between whether or not the mare was receiving thyroid hormone supplementation (60 were, 269 were not) and pregnancy status. In the second study,[64] resting serum concentrations of total T_4 and T_3, as well as their responses to TRH, were measured in 79 Thoroughbred and Standardbred broodmares. Resting and stimulated thyroid hormone concentrations were not different between mares that did and did not become pregnant.

Although the studies referenced earlier suggest there is no association between thyroid status and fertility or infertility in the mare, hypothyroidism might contribute to infertility in a small subset of mares as in women. However, given that true hypothyroidism appears to be rare in the horse, this would have to be a small number of mares, certainly not the number of mares that are currently being routinely supplemented with thyroid hormone. Is there any basis then to the clinical impression held by some that thyroid hormone supplementation helps some mares get pregnant? Perhaps if there is, it is more related to obesity, insulin resistance, and equine metabolic syndrome than to hypothyroidism. Women with insulin resistance and metabolic syndrome are subfertile, and there is evidence that thyroid hormone administration to normal weight mares increases insulin sensitivity.[53,57] Thus, it is possible that some insulin-resistant, overweight mares are subfertile, and thyroid hormone supplementation is beneficial in those cases, not because they were hypothyroid in the first place but because it improves their insulin sensitivity. At the time of this writing, no studies have been performed to examine this hypothesis.

Assessment of Thyroid Function in Adult Horses

Thyroid glands of the horse can be assessed by measuring circulating concentrations of thyroid hormones, measuring response to stimulants such as TRH or TSH, testing the ability of administration of exogenous thyroid hormone to suppress endogenous hormone, imaging (including ultrasound, computed tomography, magnetic resonance imaging, and nuclear scintigraphy), and biopsy.

Reference ranges for thyroid hormone concentrations in healthy adult horses and neonatal foals have been published.[1] Donkeys appear to have higher circulating thyroid hormone concentrations than do horses.[65] Because certain drugs and pathophysiologic states can lower serum concentrations of thyroid hormones in otherwise euthyroid horses, it is important that thyroid hormone measurement or function tests not be

VetBooks.ir

performed while horses are ill, are receiving other drugs, or are on thyroid hormone supplementation. The author recommends that thyroid hormone testing be performed in horses that have not received any medications for at least 2, and preferably 4, weeks before testing. If a horse has been receiving thyroid hormone supplementation without prior documentation of hypothyroidism, the author recommends weaning the horse off supplementation and then testing thyroid function once the horse has not received any supplementation for at least 4 weeks.

Tests that are currently available for assessment of thyroid function in the horse include measurement of total and free fractions of T_4 and T_3 and response of these hormones to administration of either TRH or TSH.[27-29,61,66-69] Although results of TRH or TSH stimulation tests are thought to provide a better indication of thyroid status than single point-in-time measurements of thyroid hormone concentrations, they can be more difficult to perform in a field setting.

To perform a stimulation test, a control blood sample is obtained, TRH (1 mg to the average 450- to 500-kg horse) or TSH (5 IU) is given intravenously, and subsequent blood samples are obtained. Most references say that T_3 should double at 2 hours, and T_4 should double at 4 hours. The author routinely performs TRH stimulation tests and prefers to measure both T_3 and T_4 before and 1, 2, and 4 hours post TRH administration in order to make sure the peaks are not missed. In 36 normal horses that participated in various studies conducted by the author, the mean increase in total T_4 was 2.2 times baseline at 4 hours. However, the range was 1.3 to 3.8 times baseline. Increases in free T_4 and free T_4 by dialysis (mean and range) were 1.7 (1.1 to 2.1) times and 1.8 (1.1 to 2.8) times at 4 hours, respectively. Increases in total and free T_3 (mean and range) were 3 (1.1 to 10.3) times and 4.2 (1 to 53) times at 2 hours, respectively. These seemingly lower thyroid hormone responses to TRH injection are in agreement with findings in a recent report of levothyroxine administration to normal horses.[70] Closer examination of data from the author's horses revealed that, in general, the few individuals with small increases in T_4 or T_3 either started with higher resting values or had peaks that occurred later (T_4) or earlier (T_3) than 4 or 2 hours. Individuals with lower T_4 responses in general were not the same individuals with lower T_3 responses. Thus, one must be careful when interpreting results of a TRH stimulation test. Failure of T_3 to double by 2 hours or T_4 to double by 4 hours after TRH injection does not necessarily mean that the horse is hypothyroid. Animals with high responses tended to be animals with very low resting thyroid hormone concentrations.

If single point-in-time measurement of thyroid hormones is the only option available for evaluation of thyroid status, measurement of free fractions of thyroid hormones (alone or in conjunction with measurement of total amounts of hormone) provides more useful information than measurement of total amounts of thyroid hormones alone. Measurement of serum TSH concentrations in single samples also likely will aid diagnosis of thyroid status, though a well-validated methodology for this test in horses is not commercially available.

During illness in humans, measurement of serum free T_4 by direct methods often underestimates values, when compared with measurements of free T_4 after dialysis or ultrafiltration.[71-75] This also appears to be the case in dogs[76] and horses.[43] Thus, serum concentrations of free T_4 measured by equilibrium dialysis are more likely to reflect true thyroid status in ill horses, compared with other methods of free T_4 measurement. Measurement of fT_4D instead of fT_4 may help prevent equine clinicians from misdiagnosing ill horses as being hypothyroid.

A T_3 suppression test has been described[5,6] and may be useful to confirm hyperthyroidism. A blood sample is obtained before intramuscular administration of 2.5 mg 3,5,3′-triiodothyro-L-thyronine (T_3) diluted in 5 mL sterile saline, given twice daily for 7 doses (4 days). Additional blood samples are drawn 5 minutes before each dose of T_3 and then twice daily on days 5 and 7 and in the morning of day 10. In normal horses, T_4 and T_3 measurements will be within reference range in the control blood sample. Administration of exogenous T_3 should result in a 10- to 20-fold increase in T_3 concentration, while T_4 gradually decreases, remaining suppressed for at least 5 days after the last dose of T_3. In hyperthyroid horses, control blood samples will have increased concentrations of T_4 and T_3. The increase in serum T_3 after T_3 administration is not as pronounced as in normal horses, but T_3 does remain increased throughout the administration period. T_4 does not suppress.

Ultrasound imaging is most helpful when thyroid glands are enlarged. Ultrasound imaging can differentiate enlargement due to solid tissue versus cystic fluid. It is also useful as an aid in getting a representative biopsy sample if thyroid neoplasia is suspected. Nuclear scintigraphy is useful to demonstrate gland activity, which may or may not be equal in the right and left lobes.

Treatment of Hypothyroidism in Adult Horses

Management of horses that have been properly diagnosed as being hypothyroid or horses that have undergone thyroidectomy theoretically should be fairly straightforward. Serum thyroid hormone concentrations should be monitored, and dosages of thyroid hormone supplementation adjusted to maintain serum thyroid hormones in the normal range. This is not necessarily as simple as it sounds. T_4 is the most common form of thyroid hormone supplementation, and while T_4 administration increases serum concentrations of T_4, serum concentrations of T_3 may not change or may actually decrease if T_3 is not also given or if the horse is not truly hypothyroid. In addition, T_4 dosage recommendations have been made on the basis of thyroid hormone concentrations obtained after thyroid administration to normal horses with intact thyroid glands[77] (Chen 1984). Thyroid hormone pharmacokinetics may be different in truly hypothyroid horses; pharmacokinetic studies in horses made hypothyroid by thyroidectomy or by administration of antithyroid drugs would be useful. Until such studies are performed, the following recommendations can be made. T_4 is available in several forms. Iodinated casein contains approximately 1% T_4 and is given at 5 to 15 g/horse/day PO[13] (Lowe 1974). The recommended starting dose of levothyroxine was 20 µg/kg horse/day PO,[77,78] but a more recent study suggested that doses as high as 50 to 100 µg/kg/day are well tolerated and may be necessary.[70] If a sensitive TSH assay becomes commercially available, dosages should be adjusted to normalize TSH.

Thyroid Function in Normal Neonatal Foals

Fetal concentrations of T_3 are low.[79] In many species, fetal serum thyroid hormones increase just before birth and probably play a role in the rapid growth and organ system development that occur in late gestation. Normal neonatal foals have serum concentrations of thyroid hormones that are approximately 10 times adult concentrations.[48,80,81] Thyroid hormones remain high during the first week of life and then slowly decline, reaching normal adult concentrations by approximately 1 month of age. These high concentrations of thyroid hormones are thought to be important in thermoregulation, regulation of cell differentiation, and maturation of many body systems, especially the respiratory, nervous, and musculoskeletal systems. Thyroid hormones increase thermogenesis by increasing metabolic rate and, of particular relevance to the neonate, increasing heat production from brown fat.[82] Thyroid hormones also stimulate lung development and surfactant production, and these effects are potentiated by concurrent administration

of glucocorticoids.[83] Skeletal growth and maturation are stimulated synergistically by thyroid hormones and growth hormone.[84] The mechanism(s) by which thyroid hormones are increased in the peripartum period is (are) unknown. One might expect the increase to be centrally driven. However, in a study by the author,[48] serum TSH concentrations were not increased in equine neonates, compared with adults, nor did they change over the first month of life, while serum thyroid hormone concentrations were declining.

Thyroid Function in Premature Foals

Premature human infants experience transient hypothyroxinemia, with serum T_4 concentrations correlated to gestational age.[85-88] In a study by the author, serum concentrations of total and free thyroid hormones and TSH, both at rest and in response to TRH, were measured in normal, healthy neonatal foals that were full term (normal foals), in hospitalized premature neonatal foals (premature foals), and in full-term neonatal foals that were ill and hospitalized for conditions similar to premature foals (sick foals) to determine the possible contributions of an immature hypothalamic-pituitary axis and nonthyroidal illness to thyroid dysfunction in premature foals.[48] Normal foals did not receive any medications. Both sick and premature foals received medications routinely used to treat conditions including (but not limited to) failure of passive transfer, sepsis, and perinatal asphyxia syndrome. Premature foals had significantly lower serum concentrations of total and free fractions of thyroid hormones than normal foals. Baseline serum concentrations of TSH were not different, but TSH responses to TRH were exaggerated in premature foals compared with normal foals. Serum concentrations of total and free T_3 and TSH were similar in sick term foals and sick premature foals, suggesting that both of these groups of foals were experiencing nonthyroidal illness syndrome, primarily a low T_3 state. However, premature sick foals also had significantly lower total and free T4 concentrations compared with age-matched full-term sick foals, suggesting that premature foals also experience hypothyroxinemia, similar to infants. More profound alterations in thyroid function in premature foals, compared with sick term foals, may be caused by an immature hypothalamic-pituitary-thyroid axis. It remains to be seen whether early thyroid hormone supplementation in premature foals might improve short-term survivability and preserve long-term athletic function. Traditional thought has been that administration of thyroid hormones to patients with nonthyroidal illness syndrome is not beneficial and might even be detrimental. However, these beliefs have been challenged,[38,39] and the issue remains controversial. While results are variable, treatment of premature human infants with T_4 has resulted in improved IQ and neurologic development at 2 years of age[85,86] and may reduce the incidence of cerebral palsy in extremely preterm infants.[89] T_3 administration to human neonates with severe respiratory distress syndrome improved survival.[90] However, in a recent study, levothyroxine administration to premature infants was associated with development of late-onset refractory hypotension.[91] By increasing metabolism, levothyroxine therapy may lead to acute adrenal insufficiency.[92]

Congenital Hypothyroidism in Foals

Two syndromes of congenital hypothyroidism have been described in foals. Hypothyroid foals with visible goiters have been produced by mares ingesting either too much or too little iodine or by mares ingesting goitrogenic plants.[93-95] These foals are born weak, with poor sucking and righting reflexes, hypothermia, and developmental abnormalities of the musculoskeletal system, including tendon contracture or rupture and delayed bone development, particularly of the small cuboidal bones of the carpus and tarsus. Thyroid hormone supplementation to more severely affected foals may improve survivability, but dosage recommendations are scarce. Irvine recommends basing the dose on secretion rate.[84] For oral administration of T_4, this would equal $10 \times 0.22 \times$ kg bwt $\times 0.08 \times$ plasma T_4 (μg/L), or approximately 2.5 mg/day PO for a 1- to 3-day-old 50-kg foal. Because there is a time delay for T_4 to act and T_3 is more active than T_4, T_3 supplementation at one-third the calculated T_4 dose may provide more benefit initially.

A second syndrome of congenital hypothyroidism has been described in foals, primarily in the western parts of the United States and Canada.[96-100] This syndrome is characterized by thyroid gland hyperplasia, increased gestational length, and musculoskeletal abnormalities, including mandibular prognathia, flexural limb deformities of the front legs, ruptured digital extensor tendons, and incomplete ossification of the carpal and tarsal bones. Despite the prolonged gestation, other indicators of prematurity may be present, such as a silky hair coat. At the time of birth, baseline serum concentrations of T_4 and T_3 are usually within the normal neonatal ranges, but the response to TSH administration is decreased.[101] The cause is unknown but suspected to be a dietary deficiency or toxicity of the mare during gestation. Likely candidates include nitrate toxicity, iodine and/or selenium deficiency, or goitrogenic plant ingestion by the mare.[99,101] Because thyroid hormone concentrations are normal at the time of birth, thyroid hormone supplementation is usually not administered. Supportive care to try to prevent collapse of the carpal and tarsal bones is recommended.

Equine Metabolic Syndrome

Nicholas Frank

Definitions

Equine metabolic syndrome (EMS) is a collection of risk factors for endocrinopathic laminitis, and the term *syndrome* is used because multiple factors contribute to the risk of laminitis developing in an individual horse, pony, or donkey.[1] Risk factors include ID, which is the central endocrine disorder of EMS, as well as increased adiposity, hypertriglyceridemia, altered adipokine production, and cardiovascular abnormalities. The term *insulin dysregulation* encompasses the different glucose and insulin alterations observed in affected horses, including fasting hyperinsulinemia, postprandial/postsugar hyperinsulinemia, and tissue insulin resistance (IR).[2] It is likely that EMS has a genetic basis because the syndrome has a higher prevalence in certain breeds of horse or bloodlines. For example, Andalusians, Arabians, Morgan horses, Paso Finos, ponies, and warmbloods are more likely to be affected by EMS than Standardbreds and Thoroughbreds.

If EMS susceptibility is determined by genetics, then it is essential that we identify and manage modifying factors that exacerbate the condition. Although most horses with EMS are overweight, a lean phenotype is also identified and these patients may present with the primary complaint of laminitis. It is conceivable that we will identify multiple forms of EMS in the future in the same way that researchers have recently defined different types of diabetes mellitus in humans.[3] The EMS phenotype typically develops when genetically predisposed animals encounter environmental factors that promote obesity and exacerbate ID.

It is important to distinguish EMS from pituitary pars intermedia dysfunction (PPID) yet recognize that both disorders can occur concurrently and influence one another. These disorders are compared in Table 41.1.

Etiology

Genetics play a role in EMS development, and research studies provide evidence of breed differences in ID susceptibility.

VetBooks.ir

TABLE 41.1

Comparison of Equine Metabolic Syndrome and Pituitary Pars Intermedia Dysfunction

Equine Metabolic Syndrome (EMS) Clinical Presentation	Pituitary Pars Intermedia Dysfunction (PPID) Clinical Presentation
Any mature horse Obesity and regional adiposity; prominent fat pads along the crest of the neck, above the tailhead, or in the prepuce/mammary gland; animals often described by owners as *easy keepers* A lean EMS phenotype is also recognized with regional adiposity Some affected horses appear normal but have excessive insulin responses to oral sugars Infertility or abnormal cyclicity in mares Subclinical or clinical laminitis; acute episodes occurring after exposure to pasture or feed with high sugar content Excessive insulin responses to oral sugars Commonly accompanied by insulin resistance	Begin evaluating horses at 10 years of age **Early PPID:** Subtle regional hypertrichosis and/or delayed shedding for a few weeks; duller, coarser hair coat Reduced muscle mass, shift in metabolism, poor performance **Advanced PPID:** Generalized hypertrichosis (hirsutism) Weight loss and skeletal muscle atrophy; rounded abdomen More pronounced fat deposits along the neck crest and in front of the tailhead in some cases Recurrent or chronic infections such as sinusitis, skin infection, dental disease, or hoof abscesses Reproductive abnormalities including infertility and persistent lactation Chronic laminitis in some cases
Pathophysiology	**Pathophysiology**
Not fully established Current theories focus on a genetic predisposition to insulin dysregulation; affected horses have excessive insulin responses to oral sugars Hyperinsulinemia might promote increased adiposity Obesity, lack of exercise, and PPID are modifying factors and lower insulin sensitivity, with insulin resistance exacerbating hyperinsulinemia Laminitis results from persistent hyperinsulinemia	Loss of dopaminergic inhibition leads to hyperplasia and hypertrophy within pituitary pars intermedia Excessive proopiomelanocortin (POMC) production with resulting increased α-melanocyte-stimulating hormone, adrenocorticotropin hormone, corticotropin-like intermediate peptide, and β-endorphin production
Management Goals	**Management Goals**
To reduce glucose and insulin responses to oral sugars by limiting the sugar content of the diet Limit access to pasture To induce weight loss if obese by restricting caloric intake To improve insulin sensitivity through weight loss and exercise Appropriate farrier care	Improvement in clinical signs and hormone concentrations through pergolide treatment Provision of supportive care including body clipping, appropriate farrier care, dentistry, and nutrition

Jeffcott and colleagues[4] detected differences in glucose tolerance and insulin sensitivity between ponies and Standardbred horses, with fat and laminitic ponies having lower responses to exogenous insulin (and therefore lower insulin sensitivity) than Standardbreds. Standardbred horses, mixed-breed ponies, and Andalusian cross horses also show differences in postprandial insulin responses to meals, providing further evidence of breed-related variability in glucose and insulin dynamics.[5] A more detailed examination of genetics was performed in Arabian horses using genome-wide association, and an EMS locus was identified.[6] Evidence has also been presented to suggest that EMS susceptibility follows familial lines in ponies associated with dominant expression of one or more genes with incomplete penetrance because of environmental or epigenetic factors.[7]

Environmental factors, including diet and exercise, play important roles in the development of obesity and the EMS phenotype. Feeding grain to a susceptible animal is enough to induce obesity, and the grass consumed on pasture represents a significant source of calories that contributes to weight gain. Carbohydrate intake on pasture is influenced by grazing time, the area available for grazing, and the nonstructural carbohydrate (NSC) content of pasture grasses. NSC content varies by geographic location, climate, soil quality, and season. EMS affects adult horses, and there is no reported sex predilection. Age impacts insulin metabolism in horses, as it does in other species.[8,9]

Clinical Signs and Differential Diagnoses

The medical history may provide clues that the horse is affected by EMS because genetically predisposed animals readily gain body mass and are sometimes referred to as "easy keepers" or "good doers" by their owners. Most horses, ponies, and donkeys with EMS are obese, and a thicker than normal neck crest is noted on physical examination. This form of regional adiposity is associated with ID in affected horses, and the cresty neck score can be applied to more objectively measure the amount of fat in this region.[10] Over time, regional adiposity develops in other locations such as the tail head, prepuce, or mammary glands. Many horses with EMS suffer from generalized obesity and have body condition scores of 7 or greater on a 1 (poor) to 9 (extremely fat) scale.[11] A mare suffering from EMS is shown in Fig. 41.14. Laminitis may have started to develop without the owner noticing. Horses should be turned in tight circles to detect lameness. Divergent growth rings ("founder lines") or widening of the white line may be detected when the hooves are examined closely, and these signs provide evidence of subclinical laminitis.[12,13] Radiographs are recommended as part

FIG. 41.14 Photograph of a 7-year-old Morgan horse crossbred mare that suffers from equine metabolic syndrome.

of the initial examination, and radiographic evidence of third phalanx displacement may be detected, even when lameness has not been reported.

Clinical Pathology

Hypertriglyceridemia and mildly increased plasma gamma glutamyl transferase (GGT) activities are detected in some horses, ponies, and donkeys with EMS, but complete blood count and other plasma biochemical analysis results are normal. Hyperglycemia is occasionally detected in affected horses and it is appropriate to use the term *diabetes mellitus* when this problem persists and becomes a chronic condition. Hyperglycemia and hypertriglyceridemia are more likely to occur when horses with ID are challenged by systemic disease and hospitalization, and this is sometimes referred to as *metabolic decompensation*. Older horses with concurrent ID and PPID are susceptible to this problem, and insulin therapy may be required to control hyperglycemia and glucosuria.[14]

Low resting total triiodothyronine (tT_3) or total thyroxine (tT_4) concentrations are detected in some horses with EMS, but the significance of this finding has been overstated in the past. It is a common misconception that obese horses suffer from hypothyroidism because obesity is associated with hypothyroidism in dogs and humans. However, most animals have normal TRH stimulation test results, and low tT_3 and tT_4 concentrations, if present, should be attributed to extrathyroidal changes in thyroid hormone metabolism or low thyroid-stimulating hormone (TSH) concentrations. Phenylbutazone is an extrathyroidal factor that significantly lowers serum tT_4 concentrations in horses because of protein binding, and this drug is commonly used to treat laminitis.[15]

Thyroid-stimulating hormone concentrations vary as the body adapts to different metabolic states, and this might also explain why low thyroid hormone concentrations are sometimes detected in horses with EMS. This is referred to as *secondary hypothyroidism* and can be confirmed by documenting low TSH concentrations. Unfortunately, diagnostic laboratories do not measure equine TSH at present, so it is difficult to confirm the diagnosis of secondary hypothyroidism. Levothyroxine supplementation is controversial in these cases, and in the author's opinion, levothyroxine supplementation should be reserved for horses with persistently low free thyroxine concentrations and abnormal TRH stimulation test results. Levothyroxine can also be administered at higher dosages for 3 to 6 months to accelerate weight loss, and that protocol is described later.

Diagnostic Testing

Measures of adiposity should be performed, including body condition score, cresty neck score, and ultrasound measurements of abdominal or subcutaneous fat depth.[16] Diagnostic testing for ID is required for all patients in high-risk breed groups, and the Equine Endocrinology Group provides current recommendations for diagnosing and managing EMS on their website (https://sites.tufts.edu/equineendogroup/). Horses are screened for ID by measuring basal (or resting) insulin concentrations under fed conditions or by performing an oral sugar test (OST).[17] The assay used to measure plasma or serum insulin concentrations should be considered before either test is performed, and a diagnostic laboratory with experience handling equine samples should be selected. Insulin concentrations have been measured by radioimmunoassay for the majority of publications on EMS, including the 2010 American College of Veterinary Internal Medicine consensus statement,[1] but some diagnostic laboratories are now using chemiluminescent or enzyme-linked immunosorbent assays to measure insulin. The reference intervals provided as follows are for insulin concentrations measured by radioimmunoassay, and adjustments must be made if other insulin assays are used.

Some clinicians prefer to screen horses by measuring basal insulin concentrations before performing an OST because of owner concerns (not supported by evidence) about inducing laminitis with a stimulation test. If this approach is followed, detection of high insulin concentrations confirms the diagnosis of ID, but horses with normal results must undergo dynamic testing before normal insulin status can be assumed. Insulin concentrations were previously measured under fasting conditions because this is the approach taken in human medicine,[1] but this recommendation has changed and blood samples should be collected when horses are consuming hay or grazing on pasture. Grain should be withheld for 6 hours before blood collection. When measuring basal (fed) insulin concentrations, an insulin concentration greater than 50 μIU/mL provides strong evidence of ID, concentrations in the 20 to 50 μIU/mL range provide weak evidence, and there is no evidence of ID if the insulin concentration is less than 20 μIU/mL. Note that some laboratories provide insulin concentrations in pmol/L, and an approximate conversion factor of 7 is used to convert units from μIU/mL to pmol/L.

The OST is performed by fasting the horse for a minimum of 4 hours and preferably 6 hours in order to minimize the impact of gastric emptying on test results.[18] When the OST is to be performed in the morning (8:00 and 9:00 a.m.), the horse should receive one flake of hay between 10:00 p.m. and 12:00 a.m. the night before, and then all feed should be withheld until after the test is completed. Water should also be withheld during the test. Corn syrup (Karo Light, Cordova, Tenn.) is administered by mouth using 60-mL catheter-tip syringes at a dosage of 0.15 mL/kg, and blood samples are collected 60 and 90 minutes afterwards. Plasma glucose and insulin concentrations are measured, and an insulin concentration greater than 60 μIU/mL at 60 or 90 minutes provides strong evidence of ID, concentrations in the 45 to 60 μIU/mL range provide weak evidence, and there is no evidence of ID if insulin concentrations are less than 45 μIU/mL at both time points.[5,10] Detection of plasma glucose concentrations greater than 125 mg/dL (6.9 mmol/L) at 60 or 90 minutes raises concerns about uncompensated insulin resistance or diabetes mellitus.[19]

The OST can be further simplified for use in the field by instructing the owner to administer the corn syrup themselves and then the veterinarian arrives in time to collect blood samples at 60 and 90 minutes. When the OST is repeated to monitor the progress of an individual patient with ID, only dichotomous results (ID or normal insulin status) should be considered

VetBooks.ir

significant because repeatability is low for absolute values.[20,21] A recent study provides evidence that a higher dose of corn syrup (0.45 mL mg/kg) improves test repeatability in ponies, and a cutoff value of 40 μIU/mL at 60 or 90 minutes is applied when this dose is selected and insulin concentrations are measured by Immulite chemiluminescent assay.[22]

An in-feed oral glucose test (OGT) can be selected instead of the OST, and this test is performed by fasting the horse overnight and feeding a small meal containing dextrose powder (0.75 or 1.0 g/kg body weight) mixed with water and a small quantity of chaff or low-sugar chopped forage the next morning. A blood sample is collected 120 minutes later, and an insulin concentration greater than 80 μIU/mL is consistent with ID when the 0.75 g/kg dose of dextrose is used.[23] Dextrose (1 g/kg mixed in 2 L water) can also be administered via nasogastric tube to eliminate the variability in consumption time associated with horses consuming a meal, and an insulin cutoff value of 110 μIU/mL at 120 minutes has been proposed for diagnosing ID.[24] When oral glucose test results were compared with OST results in the same group of horses and ponies, 85% agreement was detected.[25]

Basal glucose, insulin, leptin, and triglyceride concentrations can be measured to screen horses for ID, and referral laboratories may soon offer measurement of serum high-molecular-weight (HMW) adiponectin concentrations. Plasma leptin concentrations are positively correlated with body condition in equids, and the Cornell Animal Health Diagnostic Center uses a cutoff value of 10 mg/mL to define hyperleptinemia in horses. A reference interval has been reported for leptin concentrations in donkeys.[26] Serum adiponectin concentrations are negatively correlated with insulin concentrations, and low values are therefore detected in horses with ID.[21,27] Basal glucose concentrations should always be measured at the same time as insulin concentrations in case uncompensated insulin resistance or diabetes mellitus is developing.[28,29]

The combined glucose-insulin test (CGIT) can be used to measure tissue insulin sensitivity in horses. This test involves withholding feed overnight, collection of a baseline blood sample, and IV infusion of 150 mg/kg BW 50% dextrose solution, immediately followed by 0.10 IU/kg BW regular insulin.[30] Blood samples are collected at 1, 5, 15, 25, 35, 45, 60, 75, 90, 105, 120, 135, and 150 minutes post infusion. Both glucose and insulin responses must be assessed, and insulin resistance is defined by blood glucose concentrations remaining above baseline for 45 minutes or longer. The insulin response is assessed by measuring insulin concentrations at 0 (preinjection) and 45 minutes. Insulin concentrations greater than 20 μIU/mL at baseline or greater than 100 μIU/mL at 45 minutes are considered abnormal. These values reflect the amount of insulin secreted by pancreatic beta cells in response to dextrose, as well as clearance of exogenous and endogenous insulin. This test does not, however, allow assessment of the insulin response to oral sugars, which involves secretion of the incretin hormones, glucagon-like peptide-1 (GLP-1) and gastric inhibitory peptide (GIP; also known as glucose-dependent insulinotropic polypeptide). There is a small risk of inducing hypoglycemia when the CGIT is performed, so 60 to 120 mL of 50% dextrose solution should be administered intravenously if muscle fasciculations or profound weakness develops. Note that stress is an important cause of transient IR, and horses should remain calm before and during the procedure to avoid false-positive results.

Pathophysiology

Individual horses that are genetically predisposed to EMS readily gain weight and have high blood insulin concentrations. The specific genetic modification(s) present in equids with EMS have not been identified, but several hypotheses are being tested at present. One hypothesis is that affected horses have altered regulation of the incretin hormones, GLP-1 and GIP, which are secreted from the small intestine in response to ingested sugars and other nutrients, and stimulate the insulin secretion from pancreatic beta cells.[31] Incretin hormones raise insulin concentrations and slow gastric emptying as glucose concentrations increase after feeding, and both incretin hormones are degraded by the enzyme dipeptidyl transferase 4. It is therefore hypothesized that postprandial hyperinsulinemia is more pronounced in horses with EMS because of increased secretion or slowed degradation of incretin hormones. Hyperinsulinemia might then promote lipogenesis and contribute to the development of obesity in affected animals. Active GLP-1 concentrations have been measured in horses and ponies, and research is ongoing in this area.[5,21,31,32]

A second potential mechanism for hyperinsulinemia is increased secretion of insulin to compensate for rising glucose concentrations. This is the concept of compensatory hyperinsulinemia, and it fits well with our understanding of diabetes mellitus in humans. Beta cells secrete more insulin to maintain euglycemia if glucose load increases, and the animal compensates for reduced insulin sensitivity using this mechanism. Detection of higher than normal basal or OST blood glucose concentrations indicates that this compensatory mechanism is failing, and the horse has entered an uncompensated state that may progress to diabetes mellitus. Horses with EMS typically maintain blood glucose concentrations within the reference interval, but decompensation can occur when stress or systemic disease is encountered, and hyperglycemia develops at these times. Evidence for compensated IR comes from research studies involving the administration of somatostatin analog octreotide to horses. Somatostatin inhibits insulin secretion from pancreatic beta cells, and horses with ID develop more pronounced hyperglycemia in response to octreotide injection, when compared with normal horses.[33,34] Hyperinsulinemia therefore reflects altered glucose metabolism and ID, and it is difficult to separate the effects of these disturbances on the health of the horse. Glucose load increases with increased consumption of sugars and glucogenic amino acids in the diet, as well as with tissue insulin resistance, which occurs with obesity, pregnancy, stress, systemic inflammation, PPID, and glucocorticoid administration.[2] Internal fat depots may also play a role in the pathophysiology of EMS, and the concept of internal pathologic fat must be considered. Adipose tissues secrete inflammatory cytokines as obesity progresses,[35-37] and adipokine production shifts, with increased leptin secretion and decreased adiponectin production in obese animals.[27] High-molecular-weight adiponectin concentrations are negatively correlated with insulin concentrations in horses with ID, and this may contribute to the development of insulin resistance in affected animals.[27] Adipose tissue deposits in different regions of the body might also respond differently to obesity. Higher concentrations of mRNA coding for IL-1 beta and IL-6 have been detected in nuchal ligament adipose tissue, when compared with adipose tissues from other regions of the body in horses.[35]

Insulin secreted by pancreatic beta cells enters the portal circulation, and approximately 70% of insulin is cleared from the blood as it passes through the liver in horses.[34] Decreased insulin clearance might therefore contribute to hyperinsulinemia, a hypothesis supported by the finding of low C-peptide/insulin ratios in horses with EMS.[34] Potential causes of decreased insulin clearance include a decreased number of functional insulin receptors within the liver or altered hepatocyte or endothelial cell function. Lipid accumulation within the liver is a potential mechanism linking obesity with hyperinsulinemia in horses, and mildly increased plasma GGT activities are detected in some patients. Intestinal disease, endotoxemia, and systemic inflammation also compromise liver function, potentially explaining why systemic inflammation exacerbates hyperinsulinemia.[38]

VetBooks.ir

Management

If ID is confirmed, an immediate adjustment in diet is required to lower the amount of sugar ingested. It is assumed that the risk of laminitis increases when blood insulin concentrations rise and remain increased for extended periods, so affected horses must be placed on a diet with low sugar content. Obesity, PPID, pregnancy, inadequate exercise, corticosteroid administration, and diseases inducing systemic inflammation are all modifying factors that exacerbate ID and increase the risk of laminitis. If obesity is present, the initial focus of management should be weight loss and pergolide must be prescribed if concurrent PPID is diagnosed. A thorough diet history is required, and if obesity is a factor, the diet of the horse must be adjusted to decrease energy intake. As long as hoof structures are sound, horses should be exercised to increase energy consumption and accelerate weight loss, and an exercise program consisting of daily or every other day trotting, cantering, or hillside work for 30 to 60 minutes is recommended. A more strenuous exercise regimen is required because lower intensity exercise has not been shown to improve insulin sensitivity in overweight and obese Arabian horses.[39] Body fat mass decreased in ponies that were placed on a low-intensity exercise regimen, but insulin sensitivity did not improve in all animals.[40] Swimming may be an effective method of exercising equids with EMS, and a recent study showed that plasma insulin concentrations decreased in healthy Thoroughbred horses subjected to this form of exercise.[41]

Many horses with EMS are being overfed, and removal of grain from the diet is sufficient to induce weight loss. Pasture access should be restricted in obese animals because horses with EMS often maintain the same body condition unless grass intake is limited. Recommended strategies for limiting grass consumption include (1) housing the obese horse with EMS with a companion in a small grass paddock that is one third to one half of an acre (a square with 120- to 150-ft dimensions), (2) application of a grazing muzzle during turnout, or (3) strip grazing with an electric fence. Affected horses can also be housed in a dirt paddock, but this recommendation is reserved for horses with severe hyperinsulinemia, such as those with OST insulin concentrations greater than 60 μIU/mL.

Each patient should be individually assessed before formulating a management plan. A mildly affected horse with EMS that is obese as a result of overfeeding generally responds well to energy restriction and may eventually return to pasture, as long as a grazing muzzle is used. Grazing at night or in the early morning is safer for horses with EMS, except after a hard frost when grasses rapidly accumulate sugars. In contrast, a severely hyperinsulinemic horse with recurrent laminitis should be held off pasture initially and then housing conditions can be adjusted, depending on subsequent test results.

If removing grain from the diet and limiting pasture access does not result in weight loss, the amount of hay fed should be progressively decreased. Hay should be fed in an amount equivalent to 1.5% to 2% of current body weight (e.g., 18 to 24 lb grass hay/day for a 1200-lb horse). If the horse is not losing weight after 4 weeks, the amount fed should be lowered to 1.5% of ideal body weight (15 lb hay/day for an ideal weight of 1000 lb). An obese horse or pony that is not losing weight after an additional 4 weeks can then be lowered to 1.0% of ideal body weight in hay (10 lb/day), but this is the minimum amount recommended. Trace minerals, protein, and vitamin E (1000 IU per day) should be provided to horses on a hay-only diet in order to maintain adequate micronutrient and protein intake.

Attention must also be paid to the sugar content of the diet if basal insulin concentrations are high or OST results confirm severe ID. In these cases, care should be taken to only feed hay with low NSC content because simple sugars and hydrolyzable starches raise insulin concentrations in affected horses. Mild and severe insulin dysregulation have not been defined through objective research, but the author has greater concern when OST insulin concentrations exceed 60 μIU/mL at 60 or 90 minutes. Many commercial laboratories analyze hay samples and report water-soluble carbohydrate (WSC) and starch percentages, which are equal to the NSC content when added together. WSCs include simple sugars and fructans, whereas cellulose and lignin are structural carbohydrates. A cutoff value of 10% has been selected for defining low NSC content, but it should be noted that this value was not derived from definitive research studies. Nevertheless, hay with less than 10% NSC on a dry matter (DM) basis is recommended for horses with ID and feeds with even lower values may be required for severely affected animals. Soaking hay in cold water for 30 to 60 minutes before feeding lowers the soluble sugar content of the feed, although results vary considerably depending on the type of hay.[42] A number of commercial products are also available as bagged hay or forage alternatives if low-NSC hay cannot be purchased. Most horse owners ask to feed a small amount of concentrate to encourage horses to enter their stalls and consume supplements. Half a measuring cup of low-NSC commercial pelleted feed can be fed to EMS horses twice daily when needed.

Some horses with EMS have a lean phenotype, and these patients are challenging to manage because they require sufficient energy to maintain body condition, which must be accomplished with low-NSC feeds. Many of these animals have lower body condition scores, but regional adiposity is still observed and increased internal adipose tissue depots may be detected by ultrasound examination. Measuring plasma or serum leptin concentrations provides insights into the biological activity of adipose deposits because hyperleptinemia (>10 ng/mL) is detected in affected horses, and these results can be shared with horse owners to encourage compliance with management recommendations.[43] An important question to address is whether the animal is concurrently affected by PPID because this catabolic disease induces weight loss. All EMS horses older than 10 years of age should therefore undergo diagnostic testing for PPID. Other EMS horses with a lean phenotype may have been obese in the past and are lean now because of successful diet and exercise plans. Diets that provide energy in the form of fat and fiber should be selected to maintain or increase body mass in lean EMS horses, and basic feeds such as soaked molasses-free beet pulp and vegetable oil are acceptable. Commercial low-NSC pelleted feeds are also available for purchase, and vegetable oil (0.5 to 1 cup twice daily), rice bran, or a high-fat concentrate can be added to the diet if additional calories are required.

Treatment

There are two indications for pharmacotherapy to manage EMS in horses. The first is for managing obesity when other approaches have failed, and the other is for the management of hyperinsulinemia in refractory cases. Levothyroxine sodium can be prescribed for the management of obesity when this problem persists despite diet and exercise changes. Some obese horses readily lose body fat mass when placed on an energy-restricted diet, whereas others remain overweight, even when energy intake is significantly reduced. The term *weight loss resistance* is applied in these cases, and these are the same horses, ponies, and donkeys that are described as easy keepers.[44] Ponies, miniature horses, and donkeys are particularly challenging to manage and may remain obese, even after they have spent months on an energy-restricted diet. Levothyroxine sodium (Thyro-L, Lloyd, Inc., Shenandoah, Iowa) can be administered to reduce body fat mass and improve insulin sensitivity in these horses and is administered by mouth or in the feed at a dose of 0.1 mg/kg body weight once daily.[45,46] One teaspoon of Thyro-L powder

VetBooks.ir

contains 12 mg levothyroxine sodium, so a horse with body mass of 500 kg receives 48 mg (4 tsp) per day. A higher dosage, 0.15 mg/kg body weight, which is equivalent to 72 mg (6 tsp) per day, may be selected if there is no change in body condition after 3 months. Treatment is continued until the horse reaches ideal body condition score or until the end of the 6-month period. When treatment is discontinued, the dosage is lowered to 0.05 mg/kg (24 mg for a 500-kg horse)/day for 2 weeks and then 0.025 mg/kg (12 mg)/day for 2 weeks. Gradual discontinuation of the drug is necessary because endogenous thyroid axis activity is suppressed while it is being administered. Medical problems have not been associated with the administration of levothyroxine to healthy horses for 12 months,[47] although some horses exhibit increased activity and mild hyperexcitability when treated. Pasture access must be restricted when horses are treated with levothyroxine; otherwise, effects on body mass are compensated for by increased feed intake.

Long-term administration of levothyroxine at lower dosages is controversial. Although obese horses often have low or fluctuating resting thyroid hormone concentrations, low thyroid hormone concentrations accompany many systemic conditions and are not associated with adverse health effects. There is little medical justification for thyroid hormone supplementation at lower dosages in horses with EMS, but it remains common practice.

The second indication for drug therapy is persistent hyperinsulinemia. Metformin and canagliflozin are used for the management of diabetes mellitus in humans, and they have also been administered to horses. Of the choices available, metformin is the least expensive and this drug can be used for the long-term management of postprandial hyperinsulinemia. Dosages selected for horses range from 15 to 30 mg/kg metformin hydrochloride given 2 to 3 times daily PO, and the drug should ideally be administered 30 to 60 minutes before feeding. Oral bioavailability of metformin is low in equids (7.1 ± 1.5% in unfed horses and 3.9 ± 1.0% in fed horses),[48] and this may explain why responses to treatment vary among individual horses. The strength of scientific evidence supporting the use of metformin in equids is weak because only three research studies have been performed to date and just two of them included affected animals.[49-51] In 2008, Durham and colleagues[49] administered metformin (15 mg/kg PO q12h) to ponies and horses with ID and reported improvement in insulin concentrations and proxies for insulin sensitivity. In contrast, Tinworth and colleagues[50] failed to demonstrate beneficial effects of metformin treatment (15 mg/kg PO q12h for 21 days) on insulin sensitivity in insulin-resistant ponies. Short-term effects of metformin on glucose and insulin dynamics were examined by Rendle and colleagues[51] by administering a single dose of metformin (30 mg/kg) before an oral glucose challenge test. Metformin blunted increases in plasma glucose and insulin concentrations induced by administering dextrose (0.5 g/kg body weight) with a meal. Responses to metformin appear to vary among individual horses, so one approach is to assess the effect of metformin treatment on postprandial hyperinsulinemia in the individual horse by measuring insulin concentrations measured 2 hours post feeding, before and after treatment is initiated.

Canagliflozin is another option for managing hyperinsulinemia in equids, but this drug is expensive at present and this limits its use. At the time of writing, the safety and efficacy of canagliflozin has only been evaluated in one study,[53] so this drug is only recommended for severely affected patients whose health is threatened by laminitis. Canagliflozin is available as Invokana (Janssen Pharmaceuticals, Inc., Titusville, N.J.; 100 mg tablets) for use in humans. The high cost of canagliflozin limits its use in average-sized or large-sized horses, but it can be used for short-term management of acute hyperinsulinemia if, for example, a horse with ID breaks out of its enclosure and grazes on pasture or inadvertently consumes grain. In these situations, canagliflozin may be administered for 3 to 7 days with the goal of limiting the anticipated increase in insulin concentrations after acute exacerbation of ID. Long-term treatment with canagliflozin can be considered for miniature horses and small ponies, and the author prescribes canagliflozin at a dosage of 0.4 mg/kg q24h PO. Care should be taken to assess liver function and plasma triglyceride concentrations before prescribing canagliflozin. The drug should not be administered to patients with liver disease and care should be taken to monitor plasma triglyceride concentrations after treatment is initiated because canagliflozin may exacerbate hyperlipidemia in equids. Hypoglycemia, ketosis, and urinary tract infections are complications observed in humans receiving canagliflozin,[54] but these problems were not encountered in the preliminary study.[53] It should be noted, however, that canagliflozin has only been administered to a small number of horses to date, so it is possible that additional complications will be discovered if the drug gains wider use. For this reason, it is important to explain to clients that Invokana is designed for use in humans and is being used off-label in horses. Potential complications must be explained, and a good client-veterinarian relationship should exist before this new medical treatment is selected. Canagliflozin is a sodium-glucose co-transporter-2 (SGLT2) inhibitor, and inhibition of this transporter within the proximal tubule of the kidney increases glucose loss in the urine.[54] Blood glucose concentrations decrease in response to treatment, and the amount of insulin secreted to maintain euglycemia decreases as a result.

PPID may develop in middle-aged or older horses with EMS, and this endocrine disorder exacerbates ID. Pergolide is a dopamine receptor agonist used for the treatment of PPID in horses. It is available as Prascend (Boehringer Ingelheim Vetmedica, Inc., Ingelheim, Germany). The starting dosage is 0.002 mg/kg PO daily, and higher doses are selected for horses with more advanced PPID. Several studies provide evidence of an association between PPID and ID, but it is important to note that PPID horses can have normal insulin status, so diagnostic tests for ID must be performed to evaluate the individual animal.[55-57] Three groups are identified: equids with ID alone, those with PPID and ID, and equids with PPID alone. Medical management of PPID with pergolide typically improves insulin status in horses affected by both endocrine disorders, and this suggests that PPID exacerbates ID by increasing insulin secretion, decreasing insulin clearance, or lowering insulin sensitivity. It has been proposed that pergolide exerts an independent effect on insulin dynamics in horses, but only one study has been performed to test this hypothesis. Horses with clinical signs of EMS were placed on 1 mg pergolide/day and OST insulin concentrations decreased over time (McFarlane D.; personal communication).

Wellness Evaluations

Horses belonging to breed groups with a high risk of EMS should undergo wellness evaluations every 6 to 12 months. The minimum database for each visit includes an updated diet and exercise history; physical examination and body condition scoring; visual inspection of the hooves for signs of laminitis; basal glucose, insulin, leptin, and adiponectin concentrations; and/or OST results.

Endocrinopathic Laminitis

Melody Anne de Laat and Cathy McGowan

Endocrinopathic laminitis is a common debilitating cause of lameness in horses and ponies associated with endocrine disorders, most notably equine pituitary pars intermedia dysfunction

VetBooks.ir

(PPID) and equine metabolic syndrome (EMS). Common to these disorders appears to be disturbed glucose and insulin regulation, now termed *insulin dysregulation* (ID).[1] Field studies have demonstrated the link between laminitis and insulin resistance and hyperinsulinemia since the 1980s.[2-4] In 2004, the term *endocrinopathic laminitis* was introduced "to differentiate laminitis occurring in association with proinflammatory and intestinal conditions from laminitis developing from putative hormonal influences."[5] However, it was not until experimental research unequivocally showed a direct link between hyperinsulinemia and laminitis[6,7] that the concept of laminitis being a clinical syndrome resulting from different causes really solidified.[8] The research involved development of a hyperinsulinemic model of laminitis and resulted in laminitis occurring in 100% of normal ponies or horses exposed to hyperinsulinemia (>1000 μIU/mL) while maintaining euglycemia (5 mmol/L) using a modified euglycemic-hyperinsulinemic clamp technique.[6,7] All treated ponies or horses were healthy, young, lean, and without any history of laminitis. There was no evidence of endocrine or systemic illness on blood tests before, during, or after the experiments, and no animals showed evidence of gastrointestinal involvement throughout the experiments.[6,7]

This important shift in our understanding of laminitis has allowed a wealth of new research into endocrinopathic laminitis and improved our understanding of the pathophysiology, diagnosis, treatment, and prevention of this highly prevalent form of laminitis.

Epidemiology

Endocrinopathic laminitis occurs worldwide, and it has been reported to be the most common form of laminitis[8,9]; however, a full epidemiologic understanding has been hampered by poor case definitions of laminitis, especially in distinguishing endocrinopathic causes.[10] The true frequency of endocrinopathic laminitis across the whole population is unknown, but it can be as high as 34% in EMS-susceptible breed groups[11] and 82% in retrospective case series of PPID.[12] A more robust cohort study from the United Kingdom reported 9.9% ponies and cobs 7 years of age or older, excluding PPID and without a history of laminitis developing laminitis during a 3-year period.[13] Endocrinopathic laminitis does appear to recur with reasonable frequency, with the recurrence rate reported to range between 33% and 70% depending on the timeframe studied.[14,15] The data indicate a seasonal influence on disease occurrence, with a tendency for more new cases to occur in spring and summer when consumption of pasture high in nonstructural carbohydrates is more likely.[15,16] Even though not studied specifically for endocrinopathic laminitis, increasing age and breed have been proposed as risk factors for laminitis, while it is unclear whether a sex predisposition exists.[17-19] There are no direct data to support a genetic origin for the disease beyond the proposed genetic predisposition to underlying endocrinopathies, such as EMS/ID.[20] More simply, some studies have investigated an association between height and laminitis incidence, with the hypothesis that ponies are at greater risk of disease than horses, but the data are inconclusive.[16]

More recently, a focus on metabolic and endocrine parameters has resulted in the identification of some clear risk factors for endocrinopathic laminitis. Increased basal and dynamic serum insulin concentrations have been correlated with an increased risk of laminitis occurrence.[13,21-23] In addition, hyperleptinemia and hypoadiponectinemia increase the risk of laminitis.[13,22] Morphometric data are also supportive in some breeds, with increased BCS (≥7/9) and CNS (≥4/5) in combination with basal insulin (> 32 μIU/mL) or leptin (>7.3 ng/mL) being associated with an increased risk of pasture-associated laminitis.[22] Horses and ponies with PPID have an increased risk of both ID and laminitis. [24] Horses with PPID have 4.65 times the odds of developing laminitis and are 2.7 times more likely to have hyperinsulinemia than age-matched controls.[24]

Clinical Signs

Endocrinopathic laminitis typically results in lameness in all four limbs, which can vary from mild or even subclinical to severe debilitating pain. The degree of lameness was graded by Obel in 1948[25] using a simple but effective scale of 1 to 4. Although this grade was developed using laminitis associated with systemic inflammatory conditions (starch overload and retained placenta; SIRS-associated), it is still relevant 60 years later for endocrinopathic laminitis.[25] Supportive findings such as typical gait, weight shifting, increased or bounding digital pulses, and pain on hoof testers may be found.[26] The hyperinsulinemic model confirmed clinical suspicion that endocrinopathic laminitis is slower in onset than SIRS-associated laminitis. Ponies and horses subjected to hyperinsulinemia developed laminitis slowly in all four limbs, with the onset of lameness associated with laminitis (Obel grade 2) by approximately 48 hours.[6,7]

It is also important to recognize that endocrinopathic laminitis can occur in the absence of pain. Experimentally, evidence of histologic lesions of laminitis was detected as early as 6 hours post exposure to hyperinsulinemia, [27] and in response to much lower circulating concentrations of endogenous insulin than in the hyperinsulinemic model,[28] which supports the contention of lamellar lesions and laminitis occurring before or without lameness. In a study of naturally occurring laminitis it was noted that hoof capsular changes such as divergent rings occurred in all histologically confirmed laminitis cases, but gross pathological changes did not correspond to the duration of lameness.[29] Divergent rings could extend the full length of the hoof wall in horses with a short history of lameness, which based on the growth rate of the hoof wall confirmed the occurrence of a preclinical stage in some horses.[29]

Histology

The hyperinsulinemic model has also facilitated more in-depth study of the pathologic lesions associated with laminitis. As early as 6 hours post exposure to hyperinsulinemia or after 48 hours of hyperglycaemia, marked elongation of the secondary epidermal lamellae is observed.[27,28] It is this lesion of epithelial cell stretching associated with a loss of cytoskeletal integrity that is the crucial early lesion in laminitis.[8] Epithelial cellular changes are observed alongside the stretching including altered orientation and shape, apoptosis, and mitosis.[30] Histopathology was less severe, and fewer inflammatory cells infiltrate than laminitis caused by systemic inflammatory diseases or carbohydrate overload models.[31]

The histology of naturally occurring endocrinopathic laminitis is similar to the hyperinsulinemic model and shows a range of lesions with overall stretching and lengthening of primary and secondary lamellae. Abaxially (underneath the hoof wall) there is apoptosis, lamellar fusion and hyperplasia, and keratinization that may lead to tearing and separation. Axially (adjacent to P3) there is tapering of the primary and secondary lamellae in variable amounts.[29] In both experimental hyperinsulinemia and in naturally occurring endocrinopathic laminitis, the lesion is not basement membrane driven as has been proposed from research in SIRS-associated models. Early cellular changes are associated with limited and localized basement membrane damage likely to be associated with the cytoskeletal disruption within the epithelial cells.[8]

Pathophysiology

Considerable research effort has been invested in exploring the pathogenesis of endocrinopathic laminitis. While significant

progress has been made, certain elements of the pathophysiology remain elusive, with uncertainty surrounding exactly which pathways engender the demise of the lamellar structure during laminitis onset. What is clear is that in cases of ID, whether from PPID or EMS, hyperinsulinemia is a catalytic factor for lamellar failure.[6,7,29,32] However, precisely how insulin drives the lamellar lesions to induce clinical laminitis remains unclear. The lamellar epithelial cells appear to be devoid of insulin receptors,[33] which suggests that an indirect action of insulin on the structure is most likely.

Early studies focused on impaired lamellar metabolism and potential interference with glucose supply during the initiation of lamellar separation.[34,35] Current consensus is that the lamellae are an insulin-independent tissue, with a profusion of the glucose transporter 1 (GLUT1).[36,37] Further, the lamellae do not appear to be rich in GLUT4, which is the principal insulin-dependent transporter and predominates in insulin-sensitive tissues such as striated muscle and adipose tissue.[36,37] GLUT1 does not rely on insulin to drive glucose uptake and predominates in highly metabolic tissues such as the brain and epithelium, where interruptions to glucose supply would be problematic.[38] As such, the lamellae appear well equipped to meet their metabolic demands.

Once it was shown that failure of glucose uptake was an unlikely catalyst for lamellar failure, investigations into the potential involvement of glucose toxicity, oxidative stress, and lamellar glycation were undertaken.[39] Despite these processes being evident in the pathophysiology of type 2 diabetes mellitus sequelae,[40] data demonstrated that glycoxidative processes were only upregulated after the onset of lamellar pathology[39] and therefore this hypothesis was not supported.

Despite obesity, which is often associated with EMS, being a proinflammatory state, there is little evidence to support a major role for inflammation in endocrinopathic laminitis pathophysiology. Histologic studies of both naturally occurring and experimentally induced laminitis have demonstrated minimal leukocyte infiltration, unlike the marked inflammation in SIRS-associated laminitis.[31] Further, gene and protein studies of the lamellae have not reached a consensus that proinflammatory cytokines are key instigators of endocrinopathic laminitis pathophysiology.[41,42] Lastly, an active role for matrix metalloproteinases (enzymes secreted by leukocytes that degrade the extracellular matrix) in the onset of endocrinopathic laminitis has not been supported,[43] unlike in other forms of the disease.[44]

Similarly, the role of blood flow in the inception of endocrinopathic lamellar pathology is unclear. Insulin receptors are present on lamellar endothelial cells,[33] which is supportive of the potential for the vasculature to be involved in disease pathogenesis. By differential intracellular signaling through one of two different pathways, insulin is capable of stimulating the release of a key vasodilator, nitric oxide, or the potent vasoconstrictor, endothelin-1. The normal effect of insulin is vasodilation through the so-called metabolic pathway.[45] Bounding digital pulses are a common and familiar clinical sign associated with acute laminitis,[26] and their presence would seem to indicate an increase in blood flow to the hoof early in laminitis development. In agreement with this was a study that demonstrated a persistent increase in the hoof wall temperature, suggestive of vasodilation, in horses during the early stages of insulin-induced laminitis.[7] It has been suggested that an increase in blood flow to the hoof may assist in the delivery of catalytic factors, such as growth factors, inflammatory cytokines, or metalloproteinases.[46] The fact that the use of a vasodilatory agent alone was unable to induce laminitis[47] suggests that additional factors are essential for increased blood flow to potentially be causative of laminitis.

An ischemic or hypoxic pathogenesis for laminitis also makes physiologic sense and is supported by the knowledge that persistent weight bearing on one limb, which may reduce blood flow to the foot, can induce the disease.[48] While investigations in vivo of lamellar ischemia have not been attempted, data from isolated, perfused vessel studies suggest that experimental preincubation with insulin may drive intracellular signaling away from the metabolic pathway, with aberrant vessel contraction observed in response to insulin in the lamellae.[49-50] The same effect was seen where vessels had been collected from horses with naturally occurring endocrinopathic laminitis.[51] However, ischemic lesions have not been observed histologically[27,29,30] and how ischemia may contribute to the pathogenesis of endocrinopathic laminitis remains unclear.

Perhaps the most promising line of research for uncovering the exact pathophysiology lies in understanding how aberrant intracellular signaling in the epithelial cells, especially the shift away from the metabolic pathway as has been shown in the vasculature, may be driving their demise. Insulin is a growth factor and may still exert its effect directly on the tissue, such as by signaling through, or upregulating, other receptors. Insulin can bind to insulin-like growth factor 1 (IGF-1) and hybrid insulin/IGF-1 receptors,[52] and these are both possible targets, especially considering that IGF-1 receptors have been identified on lamellar epithelial cells, and that they are differentially expressed during experimental laminitis.[33,53] Insulin may also regulate the expression of other growth factor receptors in the lamellae, such as the epidermal growth factor receptor,[54] with signaling achieved by a variety of local or circulating ligands. Activation of all of these receptors can trigger common intracellular signaling pathways that cause cellular damage via cytoskeletal disruption, leading to the well-defined initial lesion of lamellar and cellular stretching.[8,55]

Management, Prognosis, and Prevention

Endocrinopathic laminitis remains difficult to manage. However, better understanding of the cause, and in particular the relationship with ID, has allowed a focus on monitoring and management of the underlying problem to reduce recurrence in the future.[56] Further, pathologic understanding of the lesion and the potential for a subclinical phase leading to divergent hoof rings or other hoof capsular changes as an early warning[29] has meant that prevention before lameness is more achievable in some cases.

Laminitis management strategies focus on pain relief and remediation of gross hoof defects[15] (also see Laminitis section in Chapter 38). Pain relief can often be achieved with nonsteroidal antiinflammatory drugs (NSAIDs), although in severe cases opioids or multimodal analgesia may be necessary. More recently, there has been increased interest in targeting neuropathic pain with gabapentin, although the potentially low oral bioavailability of this drug may limit its efficacy.[57,58] Restriction of movement in severe cases is important, and provision of deep bedding is recommended.[59] Additional pain relief can be achieved with hoof supports, such as moldable pads that are designed to cushion the palmar hoof surface and ease the breakover. Farriery is also recommended to reform hoof biomechanics, and specialist ongoing hoof care is often required.[59]

Treatment of the underlying endocrinopathy is also central to management, as a reduction in hyperinsulinemia is crucial for reducing the risk of recurrence. The prognosis for endocrinopathic laminitis is variable. Severe, intractable cases carry a poor prognosis, and euthanasia is often the only humane option in these animals. Milder cases with a clear underlying endocrinopathy that can be addressed and the absence of marked displacement of the distal phalanx carry a fair prognosis if appropriately and promptly managed.

Prevention of endocrinopathic laminitis should be the key focus, and identification of hoof capsular changes indicative of laminitis on clinical examination[26] should prompt appropriate endocrinologic testing. The goal should be to identify animals

VetBooks.ir

at particular risk of this form of laminitis in the preclinical phase and instigate strategies to reduce the likelihood of disease onset. Studies have indicated that hyperinsulinemia indicative of ID is the strongest predictor of disease.[3,4,9,11,13,29] The predictive power of insulin concentration is also apparent in animals with PPID[21,32] and has been supported more recently by the finding that an abnormal oral glucose test result was predictive of laminitis risk.[23] Combining tests for insulin, leptin, adiponectin, and morphometry may support a diagnosis of ID, but further research in this area is required.

In conclusion, the paradigm shift in our recognition and understanding of endocrinopathic laminitis has greatly improved our ability to appropriately focus management and prevention on the underlying endocrinopathy. More research will help pinpoint risk factors, improve diagnostic tests, and improve treatments for the underlying endocrinopathies, and as these are developed, so too the toolkit for preventing laminitis will grow.

Parathyroid Gland, Calcium, and Phosphorus Regulation in Horses

Ramiro E. Toribio

Calcium

Calcium is the fifth most abundant element in the body, representing ≈1.5% of the body weight. Physiologic functions such as signal transduction, muscle contraction, hormone secretion, enzyme activation, gene transcription, cell division, cell membrane stability, cell migration, neuromuscular excitability, and blood coagulation are calcium dependent.[1-3] Processes that result in cell injury and death, such as free radical production, cytokine release, protease activation, excitotoxicity, vasoconstriction, and apoptosis, also require calcium.[2,3]

Calcium has structural and nonstructural functions, and it is found in three main compartments: the skeleton, soft tissues, and the extracellular fluid. Approximately 99% of the total body calcium (and 85% of phosphorus) is in the skeleton as hydroxyapatite ($Ca_{10}[PO_4]_6[OH]_2$) in a calcium–to–phosphorus ratio of 2 : 1. As part of the skeleton, calcium provides support against gravity, protects vital internal organs, and houses blood-forming elements. The skeleton is also a reservoir for calcium. Nonstructural functions are related to calcium as a regulatory ion. The remaining calcium is present in the cell membrane, mitochondria, endoplasmic reticulum, and extracellular fluid.[1-3] In blood, most calcium is in plasma as a free or ionized form (≈55%), bound to proteins (≈40%), and complexed to anions such as citrate, bicarbonate, phosphate, and lactate (≈5%) (Fig. 41.15).[1-4] In adult horses, serum ionized calcium represents 50% to 55% of the total serum calcium, while in foals ionized calcium is 43% to 56% of the total serum calcium.[2-8] Free, unbound, or ionized calcium (Ca^{2+}) is the biologically active form of calcium. Of the protein-bound calcium, approximately 80% is associated with albumin and 20% with globulins. Calcium binds to negatively charged or anionic proteins, and this affinity is pH dependent. During acidosis, increased H^+ concentrations decrease Ca^{2+} binding to anions, resulting in increased plasma Ca^{2+} concentrations. Alkalosis lowers Ca^{2+} concentrations. Hypoalbuminemia results in total hypocalcemia (pseudohypocalcemia), with Ca^{2+} concentrations remaining within the normal range.

Calcium and phosphorus requirements in horses depend on age, physiologic status, and amount of work or exercise performed (Table 41.2). Serum Ca^{2+} concentrations are not a reliable indicator of dietary calcium intake. A balanced diet for horses must have 0.15% to 1.5% of calcium and 0.15% to 0.6% of phosphorus in feed DM (Box 41.1). A

calcium–to–phosphorus ratio less than 1:1 can have negative effects on calcium absorption and skeletal development; however, a calcium–to–phosphorus ratio as high as 6:1 for growing horses may not be detrimental if phosphorus intake is adequate.[9] Adult horses should receive approximately 40 mg of calcium/kg/day (Table 41.2). Average horses must absorb 20 to 25 mg of calcium and 10 to 12 mg of phosphorus/kg/day to meet their needs and balance losses. Calcium and phosphate content in some mineral supplements and equine feeds are presented in Tables 41.3 and 41.4.

Horses have distinctive features with regard to calcium metabolism. These include high serum total and ionized calcium concentrations,[8] a poorly regulated intestinal calcium absorption (high absorption),[10] high urinary fractional excretion of calcium,[8] low serum concentrations of vitamin D metabolites,[11-14] and decreased parathyroid gland sensitivity to Ca^{2+}.[15,16]

Most calcium absorption occurs in the small intestine.[10,17,18] Compared with other species, horses absorb a larger proportion of the dietary calcium. Horses can absorb 50% to 75% of the calcium and less than half the phosphorus in their diet, with little effect of age.[10] Calcium absorption is inversely related to dietary calcium content. High content of phosphate (or phytate, oxalate) inhibits calcium absorption; however, high dietary calcium content has minimal effect on phosphorus absorption. Oxalates reduce calcium absorption. Some plants containing harmful amounts of oxalate are listed in Table 41.5. The dietary cation-anion balance (DCAB) affects Ca^{2+} absorption in horses; a low DCAB increases intestinal Ca^{2+} absorption, while a high DCAB has the opposite effect.[19] Glucocorticoids decrease intestinal absorption of calcium, decrease bone resorption, and increase urinary excretion of Ca^{2+} in horses.[20,21]

Calcium is eliminated through feces, urine, milk, sweat, and the fetus. In the kidney, approximately 60% calcium is reabsorbed in the proximal tubules by passive mechanisms and 35% is reabsorbed in the thick ascending loop of Henle and

Sugar beet	*Beta vulgaris*

[a]These plants have an oxalate content higher than 0.5% of dry matter or a calcium-to-oxalate ratio of less than 0.5.

distal tubules by active mechanisms.[22] The rest (≈5%) represents the urinary fractional excretion of calcium. Endogenous losses of calcium in horses have been estimated around 20 to 25 mg/kg/body weight/day. Assuming a 50% calcium digestibility, a 500-kg horse would require 20 g of calcium to replace losses, or 40 mg/kg/day; growing and lactating horses can double these requirements. Interpretation of the urinary excretion of calcium could be difficult because horses eliminate large amounts of calcium (primarily calcium carbonate) in urine.[2,3,23]

Phosphorus

Phosphorus represents ≈1% of body weight, with most (85%) located in the skeleton as hydroxyapatite crystals, 15% in blood and soft tissues, and less than 0.1% in the extracellular fluid. In blood, phosphorus exists as organic (intracellular) and inorganic (extracellular) phosphates. Organic phosphate consists of phosphate esters (phospholipids) bound to proteins and blood cells and represents most of the phosphorus in circulation; however, only inorganic phosphate (PO_4) is measured. PO_4 is found as ionized phosphate (≈50%), complexed with cations (Na^+, Ca^{2+}, Mg^{2+}; ≈35%), and bound to proteins (≈15%). At pH 7.4, PO_4 exists as divalent (HPO_4^{2-}) and monovalent ($H_2PO_4^-$) anions in a 4:1 ratio. In acidosis this ratio is 1:1 and can be as high as 9:1 during alkalosis.[24] In soft tissues, most of the phosphate is organic and intracellular. It is incorporated into nucleic acids, phospholipids, and energy compounds such as ATP and creatine phosphate. Thus, phosphate is important for muscle contraction; neurologic functions; enzyme activity; electrolyte transport; oxygen transport (2,3 DPG); intermediary metabolism of proteins, carbohydrates, and fats; gene transcription; and cell proliferation and differentiation. PO_4 regulation is closely associated to Ca^{2+} homeostasis.

Phosphorus requirements depend on age, physiologic status, and amount of work or exercise performed (Table 41.2). In horses, phosphorus absorption ranges from 20% to 55% and occurs in the small and large intestines.[17,25] Excess dietary aluminum may reduce PO_4 absorption[26-28]; however, magnesium does not seem to interfere with PO_4 absorption in horses.[29] In the kidneys, most of the PO_4 is reabsorbed in the proximal tubules by a Na^+-dependent mechanism and the urinary fractional excretion of PO_4 in horses is low (<0.5%).

Chronic excess of phosphorus results in clinical signs consistent with calcium deficiency including lameness, abnormal cartilage and bone development, fractures, and osteodystrophia fibrosa (nutritional secondary hyperparathyroidism). Acute renal failure and hypoparathyroidism are associated with hyperphosphatemia. Conditions that result in cell membrane fragility and lysis such as hemolysis, rhabdomyolysis, and tumor necrosis may cause hyperphosphatemia. Critical illness and metabolic acidosis can also increase extracellular PO_4 concentrations in horses and foals.[30]

Hypophosphatemia occurs from inadequate intake, decreased intestinal absorption, renal waste, hyperparathyroidism, sepsis, intracellular shift, and some malignancies. Intracellular PO_4 shift is a common cause of hypophosphatemia in critically ill humans and small animals and occasionally occurs in horses with starvation, refeeding syndrome, and parenteral nutrition (hyperglycemia, hyperinsulinemia).

Chronic phosphate deficiency can be manifested as weight loss, weakness, pica (depraved appetite), lameness, and developmental orthopedic disease (DOD). Rickets, as described in other species with PO_4 or vitamin D deficiency, is not a recognized condition in foals. Serum PO_4 concentration is more indicative of dietary phosphorus intake and status than serum Ca^{2+} because PO_4 homeostasis is not as precise as that of Ca^{2+}.

Normal calcium, magnesium, phosphorus, and regulatory hormone concentrations are presented in Table 41.6. Ionized calcium concentrations are lower in foals and pregnant mares than adult horses.[5,6,23] Of interest, serum total and ionized magnesium concentrations tend to be higher in foals than adult horses.[5,6,23] Serum PO_4 concentrations and alkaline phosphatase activity are greater in foals compared with adult horses due to growth, increased intestinal absorption, bone osteoblastic activity, and bone formation.[2,6]

TABLE 41.6

Normal Calcium, Magnesium, Phosphorous, and Regulatory Hormone Concentrations in Horses

Total calcium in horses (mg/dL)	11.1-13 (2.8-3.25 mmol/L)
Total calcium in foals (mg/dL)	11-14 (2.75-3.5 mmol/L)
Ionized calcium in horses (mg/dL)	6-7 (1.5-1.75 mmol/L)
Ionized calcium in foals (mg/dL)	5.8-6.6 (1.45-1.65 mmol/L)
Phosphorus in horses (mg/dL)	2-4.8 (0.64-1.54 mmol/L)
Phosphorus in foals (mg/dL)	4.4-8.4 (1.4-2.7 mmol/L)
Total magnesium in horses (mmol/L)	0.53-0.91 (1.27-2.2 mg/dL)
Total magnesium in foals (mmol/L)	0.56-1.11 (1.34-2.66 mg/dL)
Ionized magnesium in horses (mmol/L)	0.46-0.66 (1.10-1.58 mg/dL)
Ionized magnesium in foals (mmol/L)	0.43-0.67 (1.03-1.61 mg/dL)
PTH (pmol/L)	<4 (<40 pg/mL)
Calcitonin (pg/mL)	<40 (12 pmol/L)
PTHrP (pmol/L)[a]	<3 (<30 pg/mL)
FE_{Ca} (%)	2-8
FE_P (%)	0-0.5
$25(OH)D_3$	1.90 ± 0.23 ng/mL—winter[12] 2.43 ± 0.09 ng/mL—summer[12] 4.2 ± 0.34 ng/mL—winter[14] 6.2 ± 0.36 ng/mL—summer[14]
$1,25(OH)_2D_3$	18.6 ± 7.3 pg/mL—winter[14] 18.7 ± 8.0 pg/mL—summer[14] 55.0 ± 24.0 pmol/L[11]

[a]Measured in ethylenediaminetetraacetic acid (EDTA) plasma.

FE_{Ca}, Urinary fractional excretion of calcium; *FE_P*, urinary fraction excretion of phosphorus; *PTH*, parathyroid hormone; *PTHrP*, parathyroid hormone–related protein.

Conversion units: Calcium (mmol/L = mg/dL × 0.25; mg/dL = mmol/L × 4); magnesium (mmol/L = mg/dL × 0.4; mg/dL = mmol/L × 2.43); phosphorus (mmol/L = mg/dL × 0.323; mg/dL = mmol/L × 3.1)

Data from the College of Veterinary Medicine, Ohio State University, unless otherwise noted. Foal calcium and magnesium data from recent publications.[5,6]

Calcium and Phosphorus Homeostasis

Extracellular ionized calcium (Ca^{2+}) concentrations are regulated by a homeostatic system that includes three hormones: parathyroid hormone (PTH), calcitonin, and 1,25-dihydroxyvitamin D_3 ($1,25[OH]_2D_3$, calcitriol); three body systems (kidney, intestine, and bone); and a calcium-sensing receptor (CaR).[2,3,23] PTH increases during hypocalcemia and hyperphosphatemia while calcitonin increases during hypercalcemia (Fig. 41.16). Under physiologic conditions parathyroid hormone-related protein (PTHrP), which also activates the PTH-1 receptor, has little effect on Ca^{2+} homeostasis.[31] PO_4 regulation is closely associated with Ca^{2+} homeostasis. Extracellular ionized magnesium (Mg^{2+}) has permissive effects on calcium homeostasis by facilitating PTH secretion and action.

VetBooks.ir

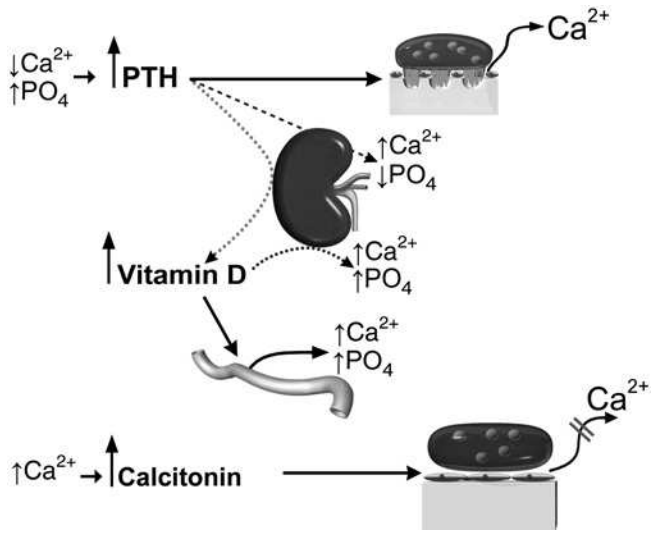

FIG. 41.16 Calcium and phosphate homeostasis. A decrease in serum Ca^{2+} or increase in serum PO_4 concentrations increases PTH secretion. PTH increases renal Ca^{2+} reabsorption and vitamin D synthesis, decreases renal PO_4 reabsorption, and increases osteoclastic bone resorption. In turn, vitamin D increases intestinal absorption and renal reabsorption of Ca^{2+} and PO_4 and facilitates bone resorption. On the contrary, hypercalcemia decreases PTH secretion and stimulates calcitonin secretion to inhibit osteoclastic bone resorption.

Organs involved in PO_4 homeostasis include the intestine (absorption), kidneys (excretion), and bone (storage). Extracellular PO_4 concentrations are under the control of various endocrine factors including PTH, $1,25(OH)_2D_3$, calcitonin, insulin, and the fibroblast growth factor-23 (FGF-23)/klotho axis.[3] In healthy animals, endocrine control of intestinal absorption of PO_4 is minimal, but hormones such as $1,25(OH)_2D_3$ can increase absorption in PO_4-deficient states. PTH and the FGF-23/klotho axis are considered the main regulators of PO_4 concentrations.[32-34] Information on phosphatonins (FGF-23), which inhibit renal PO_4 reabsorption and $1,25(OH)_2D_3$ synthesis in a number of species,[32-35] is limited in the horse.[30]

PTH is secreted by the chief cells of the parathyroid gland in response to hypocalcemia and hyperphosphatemia. Parathyroid chief cells detect changes in Ca^{2+} concentrations by a calcium-sensing receptor (CaR).[16,36] Through the PTH receptor, PTH increases renal Ca^{2+} reabsorption (distal nephron), decreases renal PO_4 reabsorption (proximal tubules), stimulates renal calcitriol synthesis (proximal tubules), and stimulates osteoclastic bone resorption (see Fig. 41.16). Calcitriol ($1,25[OH]_2D_3$) increases intestinal absorption and renal reabsorption of Ca^{2+} and PO_4 and inhibits PTH synthesis and secretion.[2,3] PTH secretion is under the influence of Ca^{2+}, PO_4, and vitamin D. Biologically active intact PTH is measured with immunometric assays.

Vitamin D plays an important role in Ca^{2+} and PO_4 homeostasis and, to a lesser extent, in magnesium metabolism. Vitamin D_2 (ergocalciferol) and vitamin D_3 (cholecalciferol) are secosterols derived from photolytic cleavage of the B rings of ergosterol (plants and yeasts) and 7-dehydrocholesterol (animals), respectively. Vitamin D_3 is transported to the liver by a vitamin D–binding protein (GC-globulin), where it is hydroxylated (25-hydroxylase) to 25-hydroxyvitamin D_3 ($25[OH]D_3$, calcidiol), which is then transported to the kidney to produce the active metabolite, $1,25(OH)_2D_3$ (calcitriol), by 1α-hydroxylase. In mammalians, $25(OH)D_3$ is considered the main circulating form of vitamin D. However, recent studies found that $25(OH)D_2$ was the main vitamin D metabolite in equine blood.[37,38] Hypocalcemia, hypophosphatemia, and PTH stimulate $1,25(OH)_2D_3$ synthesis by inducing renal 1α-hydroxylase activity, whereas hypercalcemia, hyperphosphatemia, FGF-23, and $1,25(OH)_2D_3$ inhibit 1α-hydroxylase.

Vitamin D stimulates intestinal absorption and renal reabsorption of Ca^{2+} and PO_4 and, to a lesser extent, of Mg^{2+}. $1,25(OH)_2D_3$ increases the expression and activity of proteins important for transcellular Ca^{2+} transport, including epithelial Ca^{2+} channels, Ca^{2+} binding proteins (calbindin D_{9k}, calbindin D_{28k}), Na^+/Ca^{2+} exchangers, and Ca^{2+}-ATPases.[2,3,39] The effects of $1,25(OH)_2D_3$ on intestinal absorption and renal reabsorption of PO_4 are mediated by Na^+/PO_4 cotransporters.[3] In addition, $1,25(OH)_2D_3$ increases Mg^{2+} renal reabsorption.[40] In bone, $1,25(OH)_2D_3$ increases bone matrix synthesis and mineralization and stimulates osteoclastic activity and bone resorption. In the parathyroid gland, $1,25(OH)_2D_3$ inhibits chief cell proliferation, PTH synthesis, and secretion.[41] Vitamin D deficiency results in rickets in young animals and osteomalacia in adults; however, the existence of rickets in the horse is not well documented.

Calcitonin is a 32–amino acid peptide secreted by the parafollicular cells (C cells) of the thyroid gland in response to hypercalcemia in a number of species, including the horse.[39,42] Calcitonin inhibits osteoclast function and bone resorption, and it decreases renal reabsorption of Ca^{2+} and PO_4 in most species.[2,3]

Parathyroid hormone-related protein (PTHrP) is produced by almost every tissue in the body and has a broad range of functions that have little to do with Ca^{2+} homeostasis.[31] Under physiologic conditions, PTHrP functions (morphogenesis, cell differentiation) are considered to be paracrine, autocrine, and intracrine. For the most part, the endocrine functions of PTHrP are considered pathologic (humoral hypercalcemia of malignancy; HHM). HHM is a paraneoplastic syndrome that results from excessive secretion of PTHrP by some tumors. By interacting with PTH receptors, PTHrP promotes bone resorption and inhibits renal Ca^{2+} excretion, causing hypercalcemia in humans and domestic animals, including the horse.[43-48]

The *FGF-23/klotho axis* plays central functions in calcium, phosphorus, and vitamin D regulation. FGF-23 is considered the main PO_4-regulating hormone and is secreted by osteocytes in response to $1,25(OH)_2D$ and PTH.[49-51] It promotes renal PO_4 excretion by decreasing renal Na^+/PO_4 cotransporter numbers and suppressing 1α-hydroxylase activity, therefore reducing $1,25(OH)_2D_3$ synthesis.[49,51-54] FGF-23 also inhibits PTH synthesis and secretion.[49,51-54] Klotho is a protein that functions as a coreceptor for FGF-23 in the kidney and parathyroid gland.[50,51,55] Abnormalities in the FGF-23/klotho axis were recently documented in critically ill foals.[30] Foals with high FGF-23 and low klotho serum concentrations had more severe disease and were more likely to die.[30]

Organs involved in Ca^{2+} homeostasis (parathyroid gland, thyroid gland, and kidney), known as the *calcium-sensing system*, express a calcium-sensing receptor (CaR) that is activated by extracellular Ca^{2+} and to lesser affinity by Mg^{2+}.[36] CaR activation inhibits PTH secretion and stimulates CT secretion in various species, including the horse.[15,16,39] In the kidney, CaR regulates Ca^{2+} and Mg^{2+} reabsorption independently of PTH. Renal CaR activation inhibits the furosemide-sensitive $Na^+/K^+/2Cl^-$ cotransporter in the distal nephron, resulting in diuresis and urinary waste of Ca^{2+} and Mg^{2+}, in humans and horses.[36,56]

Calcium Disorders in the Horse

Calcium dysregulation in the horse is associated with hypocalcemic and hypercalcemic disorders. Equine pathologic conditions characterized by abnormal calcium homeostasis include hypoparathyroidism,[57-59] primary hyperparathyroidism,[60-62] nutritional secondary hyperparathyroidism,[63] renal failure,[64] humoral hypercalcemia of malignancy,[43-47] vitamin D toxicity,[65,66] exercise-induced hypocalcemia,[67,68] idiopathic hypocalcemia of foals,[69] cantharidiasis,[70]

gastrointestinal disease,[23,70-74] and sepsis.[6,8,23,71,73,74] Low Mg^{2+} concentrations can contribute to calcium dysregulation. Other conditions that may have abnormal calcium and phosphorus regulation include calcinosis,[75] idiopathic systemic granulomatous disease (sarcoidosis),[3] and equine bone fragility syndrome.[76]

Hypocalcemic Disorders

Conditions associated with hypocalcemia in the horse are presented in Box 41.2. Calcium deficiency can be acute or chronic. Horses with acute calcium deficiency develop clinical signs associated with neuromuscular excitability and decreased smooth muscle cell contractility (Box 41.3). A decrease in extracellular Ca^{2+} concentrations increases cell membrane Na^{+} permeability, decreasing the resting membrane potential, thus making muscle cells and nerve fibers more excitable. This results in spontaneous and continuous discharges, muscle fasciculations, tremors, tetany, and seizures. Tachycardia and cardiac arrhythmias may be present, although bradycardia may develop during severe hypocalcemia. Low serum Mg^{2+} concentrations are a frequent finding in horses with hypocalcemia and can further aggravate neuromuscular excitability. Chronic calcium deficiency in general is manifested as abnormal cartilage and bone development (DOD) and lameness. When calcium deficiency is suspected, feed analysis is recommended to determine if dietary calcium and phosphorus content is adequate.

Synchronous diaphragmatic flutter (SDF) or "thumps" may occur in horses with hypocalcemia associated with gastrointestinal disease,[23,70] endurance exercise,[77] hypoparathyroidism,[59,78] idiopathic hypocalcemia,[69] tetany (lactation, transport),[79] sepsis,[23] blister beetle toxicosis,[70,80] retained placenta,[23,81,82] and alkalosis.[2,3] SDF develops when depolarization of the right atrium stimulates action potentials in the phrenic nerve as it crosses over the heart. Clinically, these animals have a rhythmic movement on the flank from diaphragmatic contractions that are synchronous with the heartbeat.

During alkalosis there is increased Ca^{2+} binding to albumin resulting in ionized hypocalcemia. Alkalosis also increases Mg^{2+} binding to proteins. Exercising horses may develop alkalosis from hyperventilation (respiratory alkalosis) and chloride losses in the sweat (metabolic hypochloremic alkalosis). Hypochloremic metabolic alkalosis may develop in horses with proximal gastrointestinal disease due to luminal chloride retention or losses in nasogastric reflux. Hypomagnesemia is common in horses with SDF and hypocalcemia.

Hypocalcemic tetany is the development of sustained skeletal muscular contractions in horses with hypocalcemia. Although hypocalcemic tetany can occur in any horse with hypocalcemia, lactating mares and horses transported for long distances are at greatest risk. Lactation tetany in mares may occur anytime immediately before foaling up to the end of the lactation period. In particular, mares producing large amounts of milk and eating diets low in calcium, grazing lush pastures, or performing physical work (draft mares) are at risk. Clinical signs may include anxiety, depression, ataxia, muscle fasciculations and tremors, stiff gait, tachypnea, dyspnea, dysphagia, hypersalivation, and hyperhidrosis (Box 41.3).[2,3]

Hypocalcemic seizures, seen in foals and adult horses, are caused by decreased CNS extracellular Ca^{2+} concentrations leading to increased neuronal excitability. Clinical signs usually improve with calcium treatment, although some animals may require repeated treatments. In general, horses and foals with refractory hypocalcemic seizures have a poor prognosis for recovery.

Ileus and *retained placenta in mares* are both believed to result in part from decreased smooth muscle tone and contractility secondary to hypocalcemia.[2,3] While in skeletal muscle most of the Ca^{2+} required for contraction comes from the sarcoplasmic reticulum, in smooth muscle Ca^{2+} comes from the extracellular space.[2] For this reason, any condition that results in hypocalcemia can decrease smooth muscle contractility. Retained placenta in mares occurs in up to 10% of foalings,[81] and it has been associated with hypocalcemia.[81]

Hypoparathyroidism in horses is characterized by hypocalcemia, hyperphosphatemia, hypomagnesemia, and decreased serum PTH concentrations. Primary hypoparathyroidism results from decreased secretion of PTH, while secondary hypoparathyroidism results from magnesium depletion and sepsis. There are few documented cases of primary hypothyroidism in horses.[58,78] Hypoparathyroidism should be suspected in any horse or foal with refractory hypocalcemia. Clinical signs include ataxia, seizures, hyperexcitability, SDF, tachycardia, tachypnea, muscle fasciculations, bruxism, stiff gait, recumbency, ileus, and colic.[2,3,58,83] Laboratory findings include hypocalcemia, hyperphosphatemia, and low or normal serum intact PTH

BOX 41.2

Equine Clinical Conditions in Which Hypocalcemia Has Been Reported

Acute renal failure
Bicarbonate administration
Cantharidin toxicosis (blister beetles)
Chronic renal failure
Colic
During lactation (lactation tetany)
During transport (transit tetany)
Dystocia
Endotoxemia
Endurance exercise
Enterocolitis
Furosemide administration
Heat stroke
Hypomagnesemia
Late pregnancy
Liver disease
Magnesium toxicosis
Malignant hyperthermia
Oxalate ingestion
Pancreatitis
Pleuropneumonia
Postoperative myopathy
Primary hypoparathyroidism
Retained placenta
Rhabdomyolysis
Sepsis

BOX 41.3

Clinical Signs Reported in Horses With Hypocalcemia

Anxiety
Asphyxia
Ataxia
Bruxism
Cardiac arrhythmias
Colic
Convulsions
Death
Depression
Dysphagia
Dyspnea
Excitation
Hyperhidrosis
Hypersalivation
Hyperthermia
Ileus
Laryngeal spasm
Muscle fasciculation
Seizures
Stiff gait
Synchronous diaphragmatic flutter
Tachycardia
Tachypnea
Tetany
Tremors
Trismus

concentrations. Hypomagnesemia may be present in some horses and foals.[6,23] Secondary (functional or acquired) hypoparathyroidism is poorly documented in the horse; however, some critically ill foals and horses with hypocalcemia have impaired parathyroid gland function,[6,8,23] which could be a form of hypoparathyroidism secondary to inflammatory cytokines and/or hypomagnesemia.

A syndrome consistent with hypoparathyroidism, characterized by abnormally low PTH concentrations, hypocalcemia, SDF, and muscle fasciculations, has been recognized in young Standardbred and Thoroughbred horses by the author. The condition develops progressively, initially associated with poor performance and SDF. In some animals it has been reported after a surgical procedure (e.g., castration), while in others it has been linked to excessive calcium supplementation. The underlying cause of this disorder remains unknown. Suppression of mechanisms responsible for calcium homeostasis from excessive calcium administration, immune-mediated parathyroiditis, cytokines, and mutations in the calcium-regulatory system are potential explanations.

A number of critically ill foals develop a form of hypocalcemia that is refractory to calcium treatment.[69] These foals have low or normal PTH concentrations despite hypocalcemia, suggesting hypoparathyroidism. This condition has been called *neonatal idiopathic hypocalcemia*.[69] It is believed that abnormal parathyroid gland function may result from increased inflammatory cytokines.[6,69] Prognosis for survival in foals with refractory hypocalcemia is poor.

Sepsis and *endotoxemia* are the most common causes of hypocalcemia in equine patients admitted to veterinary hospitals.[6,8,23] Clinical observations also indicate that hypocalcemia is common in horses with severe gastrointestinal disease.[23,71,73] Hypocalcemia in septic patients often results from parathyroid gland dysfunction (insufficient PTH secretion), as well as intracellular calcium sequestration.[2,3,23] Inflammatory mediators known to be increased in horses and foals with sepsis and endotoxemia such as TNF-, IL-1, and IL-6 have been shown to increase CaR activation and decrease PTH secretion by equine parathyroid cells.[16]

Horses under intense *exercise* develop electrolyte and acid-base abnormalities. *Exercise-induced hypocalcemia* may result from Ca^{2+} losses in the sweat; intracellular movement of Ca^{2+}; increased Ca^{2+} binding to albumin, lactate, phosphate, and bicarbonate during alkalosis; and parathyroid gland dysfunction.[2,3,67,68]

Oxalate toxicity causes hypocalcemia by interfering with calcium absorption; a diet consisting of 1% of oxalate or higher can reduce most intestinal calcium absorption.[84] It is important that the equine diet contains less than 0.5% of oxalate or a calcium–to–oxalate ratio over 1:0. Clinical signs associated with oxalate excess are those of phosphate excess, calcium deficiency, and nutritional hyperparathyroidism. Signs of acute hypocalcemia may develop.[85] Neurologic signs from excessive bone loss and vertebral fractures have been documented.[85] Oxalates are present in several grasses and toxic plants (Table 41.5).

Equine cantharidiasis (blister beetle toxicosis) is a condition reported in the southwestern and midwestern United States and results from the ingestion of alfalfa contaminated with beetles (*Epicauta* spp.) that produce cantharidin (cantharidic acid).[70,80] Clinical signs develop from the irritant effects of cantharidin on mucosal surfaces (gastrointestinal and urinary tracts). Cantharidin often causes acute hypocalcemia and hypomagnesemia. Thus, clinical signs of severe hypocalcemia (muscle fasciculations, SDF, ataxia, dyspnea, laryngeal spasm, and cardiac arrhythmias) may be present.[70,80] It is unclear why these horses develop hypocalcemia; however, it may be a combination of severe gastrointestinal disease associated with acute renal tubular necrosis and parathyroid gland dysfunction.

Hypocalcemia and hypomagnesemia are common findings in horses with *acute renal failure*.[2,3] Reabsorption of Ca^{2+} and Mg^{2+} in the kidney is highly dependent on functional tubular cells,[2] and these cells are susceptible to various insults (hypoxia, ischemia, toxins).[22]

The pathogenesis of hypocalcemia in *exertional rhabdomyolysis* is unknown.[86] It is speculated that damage to muscle fibers during intense exercise results in Ca^{2+} influx and sequestration in the sarcoplasmic reticulum.

Treatment of Hypocalcemia

Calcium deficit, maintenance, losses, and sequestration should be considered when treating hypocalcemia. If parathyroid gland function is normal, minimal to no calcium supplementation may be required. Most horses with hypocalcemia do not show overt signs of hypocalcemia. Lack of therapy, however, can result in development of additional complications, in particular ileus. Horses with functional kidneys can rapidly eliminate large amounts of calcium, and hypercalcemia from excessive calcium administration is rare, particularly if the horse is receiving fluid therapy. When possible, calculate the calcium deficit on the basis of Ca^{2+} concentrations (mg/dL = mmol/L × 4). From a practical standpoint, the use of standard formulas for electrolyte deficit can be used (multiplied by 10 as calcium is expressed as mg/dL). Total calcium can be used to estimate calcium deficit, keeping in mind that total calcium has more variability than Ca^{2+} concentration as it is dependent on plasma protein concentration. A horse can have total hypocalcemia, but serum Ca^{2+} concentrations may be within the normal range (pseudohypocalcemia), and calcium administration may not be necessary. It is also important to remember that 9.3% of calcium gluconate is elemental calcium, which means that a 23% solution of calcium gluconate contains 2.14% of elemental calcium or 21.4 mg/mL. Avoid the use of injectable calcium chloride as it can cause subcutaneous irritation.

Frequent monitoring of Ca^{2+} concentration and adjustment of dosage is important. Rapid administration of calcium may result in cardiovascular complications, especially in septic horses, which may be more vulnerable to the toxic effects of calcium. In our experience, horses can handle high calcium dosages. For an average-size horse with mild ionized hypocalcemia (5.0 mg/dL), we administer 50 mL of 23% calcium gluconate per 5 L of crystalloid fluids, at a fluid rate twice maintenance. Oral treatment with calcium salts is feasible in some horses with non–life-threatening, refractory hypocalcemia. Dicalcium phosphate and calcium carbonate (limestone, 200 to 300 g/day) can be used safely (Table 41.3). In horses with refractory hypocalcemia, measuring Mg^{2+} concentrations is highly recommended.

Hypercalcemic Disorders

Hypercalcemic disorders in horses are divided into two groups: (1) parathyroid gland-dependent hypercalcemia (develops due to parathyroid gland hyperfunction) and (2) parathyroid gland-independent hypercalcemia (develops despite parathyroid gland suppression). This distinction is clinically relevant in the differential diagnosis and interpretation of specific diagnostic tests, including intact PTH, PTHrP, Ca^{2+}, PO_4, and vitamin D concentrations. Parathyroid gland-dependent hypercalcemia in the horse is limited to primary hyperparathyroidism, while parathyroid-independent hypercalcemia results from various conditions (secondary hyperparathyroidism, chronic renal failure, hypercalcemia of malignancy, hypervitaminosis D, calcinosis, and idiopathic systemic granulomatous disease).

Primary hyperparathyroidism results from an excessive and autonomous synthesis and secretion of PTH by the parathyroid gland that is not responsive to the negative feedback of Ca^{2+}. Primary hyperparathyroidism has been reported in ponies and horses,[58,60-62,87,88] and results from parathyroid adenomas or

VetBooks.ir

parathyroid hyperplasia. The elevated PTH concentrations increase renal Ca^{2+} reabsorption, decrease PO_4 reabsorption, increase $1,25(OH)_2D_3$ synthesis, and increase bone resorption (osteodystrophia fibrosa). Laboratory findings include hypercalcemia, hypophosphatemia, hypocalciuria, and hyperphosphaturia. PTHrP concentrations are within normal limits (low or undetectable). Clinical findings include facial bone enlargement, lameness, and a poor body condition. Radiographic findings include decreased long and facial bone density, fibrous proliferation of the maxilla and mandible, and loss of the lamina dura surrounding the molars.[60] Endoscopic examination may reveal narrowing of the nasal passages.

Nuclear scintigraphy and ultrasonography were successfully used to detect and remove a functional parathyroid adenoma in a pony.[87] Ultrasonography was useful to identify parathyroid tissue within the thyroid gland of a horse with signs and laboratory findings consistent with primary hyperparathyroidism.[88]

Postmortem findings include enlargement of the maxilla and mandible, stenosis of the nasal passages, and loosening of premolars and molars. Histologic evaluation of the parathyroid gland is important to confirm the diagnosis of primary hyperparathyroidism; however, finding the parathyroid glands in the horse is a challenge due to their small size and variable location.[2,16]

Secondary hyperparathyroidism is characterized by excessive secretion of PTH in response to hyperphosphatemia and hypovitaminosis D from chronic renal failure (renal secondary hyperparathyroidism) or hyperphosphatemia and/or hypocalcemia from nutritional imbalances (nutritional secondary hyperparathyroidism). *Renal secondary hyperparathyroidism* is not a well-recognized disease in the horse. Unlike humans and small animals in which chronic renal failure results in hyperphosphatemia, horses with chronic renal failure (CRF) often have hypophosphatemia. Moreover, the hypercalcemia in horses with CRF is the result of renal Ca^{2+} retention rather than increased PTH concentrations.[2,3,89] The increased Ca^{2+} concentrations in turn decrease PTH secretion; thus, PTH concentrations in horses with CRF frequently are below or within the normal range.[3,57] In contrast, *nutritional secondary hyperparathyroidism* is a well-documented pathologic condition of the horse[2] and is described in more detail as follows.

Nutritional Secondary Hyperparathyroidism

Definition and Etiology

Horses fed diets low in calcium, high in phosphorus, high in oxalates, or with a phosphorus–to–calcium ratio of greater than or equal to 3:1 may develop nutritional secondary hyperparathyroidism, also known as bran disease, miller's disease, big head, osteodystrophia fibrosa, osteitis fibrosa, and equine osteoporosis.[2,3,63,90-94] Pastures and toxic plants with high content of oxalates (Table 41.6) predispose to secondary hyperparathyroidism. The condition remains endemic in some areas in Latin America, North America, Africa, Asia, Australia, and Europe.[63,85,90,92,95-99]

Pathogenesis

Excessive dietary PO_4 reduces intestinal calcium absorption and results in hyperphosphatemia. With advances in animal nutrition, this condition is rarely associated with excessive grain feeding, but more commonly linked to the ingestion of oxalate-rich plants. Large amounts of oxalate (oxalic acid) bind dietary calcium to form insoluble calcium oxalate (CaC_2O_4), reducing calcium absorption. Oxalate also binds magnesium, but the complex (MgC_2O_4) is more soluble than CaC_2O_4 and more likely to be absorbed. Both high-phosphorus and low-calcium diets induce parathyroid cell hyperplasia and stimulate PTH secretion in the horse.[3,100] Hyperphosphatemia directly stimulates PTH secretion and inhibits renal $1,25(OH)_2D_3$ synthesis. Because $1,25(OH)_2D_3$ inhibits parathyroid cell proliferation, low $1,25(OH)_2D_3$ concentrations contribute to parathyroid cell hyperplasia and PTH secretion. Hyperphosphatemia also results in the formation of calcium phosphate precipitates, further reducing blood Ca^{2+} and inducing additional PTH secretion. PTH increases osteoclastic activity, bone resorption, and bone loss (Fig. 41.17).[101] There is facial bone loss

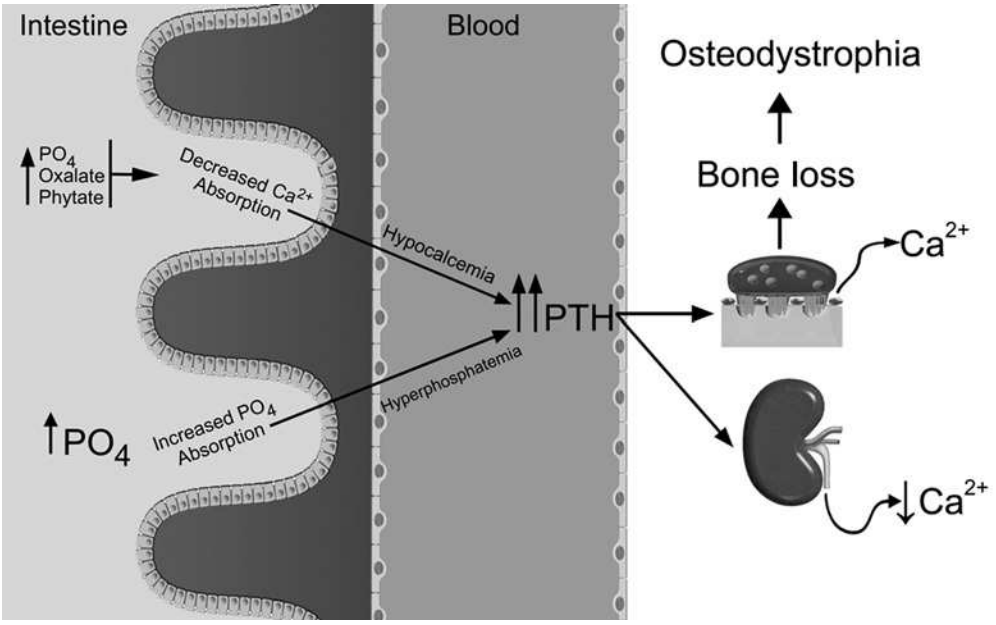

FIG. 41.17 Pathogenesis of nutritional secondary hyperparathyroidism in horses. Excessive dietary phosphorus reduces intestinal absorption of calcium and induces hyperphosphatemia. In addition, phosphate, oxalate, and phytate bind dietary calcium to reduce absorption. Both high-phosphorus and low-calcium diets induce parathyroid cell hyperplasia and stimulate PTH secretion. PTH increases osteoclastic activity and bone resorption, resulting in bone loss (osteodystrophia fibrosa).

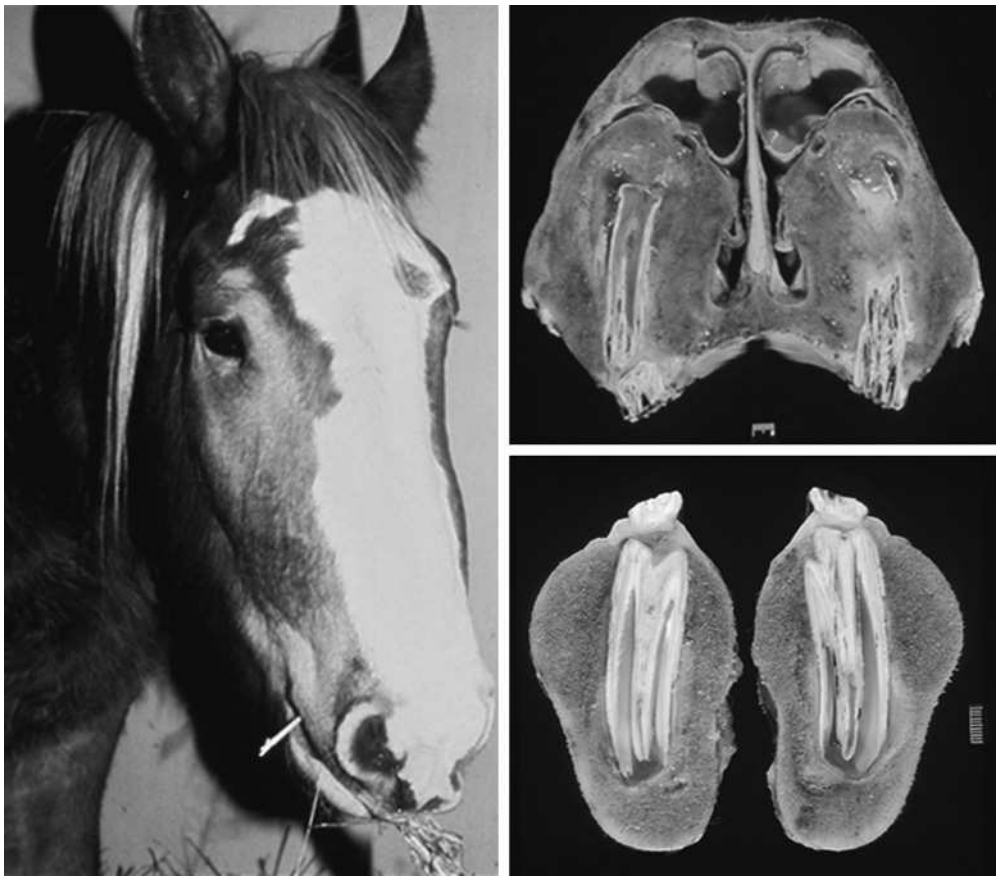

FIG. 41.18 Big head. Two-year-old Belgium horse presented to The Ohio State University Veterinary Medical Center with clinical signs consistent with nutritional secondary hyperparathyroidism, including facial bone enlargement and upper respiratory noise. The horse was fed excessive amounts of grain. There was narrowing of the nasal passages, loss of bone mass, and excessive accumulation of unmineralized bone matrix (osteodystrophia fibrosa) in maxillary and mandibular bones.

with excessive accumulation of subperiosteal unmineralized connective tissue (osteodystrophia fibrosa) resulting in facial enlargement (big head) (Fig. 41.18). Because this is a condition of slow progression, the homeostatic mechanisms that regulate extracellular Ca^{2+} concentrations (PTH, vitamin D, calcitonin) in general are effective in maintaining Ca^{2+} within the normal range. These horses preserve normocalcemia at the expense of the skeletal reserves and rarely develop clinical signs of acute hypocalcemia.

Clinical Signs

Clinical signs result from increased bone resorption and include unthriftiness; intermittent, shifting lameness; and a stiff gait. Younger animals may develop physitis and limb deformities. There is a typical and symmetric swelling of the facial bones; however, facial bone enlargement may not be evident in old horses (see Fig. 41.18). The facial changes and increased bone resorption around molars and premolars may result in masticatory problems. These horses are physically weak and may be in poor body condition from the pain associated with lameness and mastication. In severe cases, teeth may become loosened and spontaneous fractures of long bones may occur. Upper airways obstruction, dyspnea, and epiphora may be present.[3,63,90-92] Vertebral demineralization and compressive neurologic signs may occur.[85]

Acute hypocalcemia may develop from high dietary oxalate content combined with a low-calcium diet.[85] In addition, absorption of soluble oxalate can chelate calcium in circulation to worsen signs of hypocalcemia. Soft tissue mineralization was described in a foal suspected of having nutritional secondary hyperparathyroidism.[102]

Laboratory Findings

Typical laboratory changes in horses with nutritional secondary hyperparathyroidism include hyperphosphatemia, hypocalcemia or normocalcemia (hypercalcemia is unusual), and increased intact PTH concentrations, especially if the animal is eating a low-calcium or high-phosphorus or high-oxalate diet at the time of evaluation. The urinary fractional excretion of calcium is low (hypocalciuria) while the excretion of phosphorus is increased (hyperphosphaturia). Urinary excretion of phosphorus greater than 2% is common in horses ingesting oxalate-rich plants.[95] Serum alkaline phosphatase activity and collagen degradation products may be increased. Laboratory findings may be within normal limits if the animal is eating a balanced diet.

Radiologic Findings

Decreased bone density is frequent; however, bone mass must be decreased by 30% before it can be detected radiographically.[3] Decreased facial bone density along with fibrous proliferation is a consistent finding. Resorption of alveolar sockets and loss of the dental lamina dura may be present before other radiographic changes are present, and long bones are affected only in advanced cases. Radiolucency and osteopenia may be evident in long bones, vertebrae, and ribs early on; however, a patchy osteoporotic pattern may be present, in particular with chronic oxalate toxicity.[85]

VetBooks.ir

Necropsy

There is increased bone resorption, bone fragility, accumulation of fibrous tissue around facial bones, obstruction of nasal passages, and parathyroid gland hyperplasia (see Fig. 41.18).

Treatment

Diet evaluation is indicated. Eliminate or reduce any grain-based diet and avoid high-containing oxalate feeds. The addition of alfalfa to the diet may be helpful. Supplementation with calcium carbonate (limestone; $CaCO_3$) or dicalcium phosphate may result in improvement.[63] Ground limestone, which contains no phosphorus, is recommended as a good source of calcium (35%). An affected animal may require a total of 100 to 300 g/day. The diet should have a Ca:P ratio of 3 to 4:1. Limestone may decrease feed palatability, and adding molasses should be considered. Supplementation with vitamin D has been proposed. Horses may require 9 to 12 months for complete recovery, although some bone changes may not regress. Confinement of severely affected horses is advised. The use of NSAIDs may be indicated in some animals. Bisphosphonates have not been evaluated with this condition.

Hypervitaminosis D

Definition and Etiology

The ingestion or administration of ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3) results in disturbances of the calcium and phosphorus metabolism in horses.[65,66,103-105] Ingestion of plants containing 1,25$(OH)_2$D-like compounds results in typical clinical signs of vitamin intoxication.[103-109] The ingestion of *Solanum glaucophyllum (S. malacoxylon)* results in a condition known as "enteque seco" in Argentina and "espichamento" in Brazil.[105,106,108,109] In Hawaii, *Solanum sodomaeum*, and the southern United States, jessamine *(Cestrum diurnum)* may cause hypervitaminosis D.[103,104,107,109] In Europe, the ingestion of golden oat *(Trisetum flavescens)* results in enzootic calcinosis.[110-112]

Pathogenesis

Hypervitaminosis D increases the intestinal absorption and renal reabsorption of calcium and phosphorus. Hyperphosphatemia is the most consistent and early laboratory finding in horses with vitamin D intoxication.[65,66,102] Serum calcium concentrations may be increased or within the normal range.[65,66,102,103,106] Hypervitaminosis D results in parathyroid cell atrophy and decreased PTH secretion. In addition, hypercalcemia contributes to decrease PTH secretion, lowering bone turnover. Azotemia and hyposthenuria may be present.[65,66]

Clinical Signs

Most clinical findings in horses with hypervitaminosis D are the result of hyperphosphatemia. These horses often have weight loss, poor appetite, lameness, and painful stiffness, and they are reluctant to move. Acute death from severe cardiovascular mineralization has been reported.[65,66] Polyuria and polydipsia are frequent findings. In cases with hypercalcemia, mineral deposition in the kidneys may precede mineralization elsewhere, resulting in renal failure. Lameness is probably due to calcification of ligaments and tendons.

Radiologic Findings

These horses often have increased bone density, decreased size of the medullary cavity, and increased calcification of soft tissues.

Treatment

Reducing dietary calcium intake and the use of calcium-binding agents such as sodium phytate has been proposed.[105] Glucocorticoids are used in humans with hypervitaminosis D because they may inhibit the vitamin D–mediated intestinal calcium absorption. In equids, glucocorticoids decrease intestinal absorption of calcium, increase urinary excretion of calcium, and decrease bone resorption.[20,21] Dexamethasone has been administered to horses with hypervitaminosis D with variable results. Drugs that suppress osteoclastic bone resorption (bisphosphonates) have not been evaluated in horses with hypervitaminosis D. The prognosis for horses with hypervitaminosis D is poor.

Necropsy Findings

Postmortem examination may reveal mineralization of soft tissues. Mineralization of the endothelium of the aorta and pulmonary vessels, as well as of the endocardium, is frequent. Mineralization may be found in the kidney, liver, lymph nodes, lungs, ligaments, and tendons. Osteopetrosis of epiphyses and metaphyses may be present. Atrophy of the parathyroid gland can be severe.[107]

Hypercalcemia of Malignancy

Humoral hypercalcemia of malignancy (HHM, pseudohyperparathyroidism) is a paraneoplastic condition in which humans and animals develop hypercalcemia associated with various types of tumors. These malignancies secrete parathyroid hormone–related protein (PTHrP), which interacts with PTH receptors to increase renal reabsorption of Ca^{2+} and bone resorption.[113] In horses, HHM has been associated with squamous cell carcinoma, adrenocortical carcinoma, lymphosarcoma, multiple myeloma, and ameloblastoma.[2,3] Laboratory findings include hypercalcemia, hypocalciuria, hypophosphatemia, hyperphosphaturia, normal or low PTH concentrations, and increased PTHrP concentrations. HHM should be suspected in any horse with hypercalcemia, no evidence of renal disease, and normal PTH concentrations.

Neonatal Hypercalcemia and Asphyxia

Clinical observations indicate that a number of critically ill newborn foals develop hypercalcemia associated with peripartum asphyxia (neonatal encephalopathy). The mechanisms underlying this problem remain unknown, although it is speculated to be associated with placental insufficiency.

Idiopathic Systemic Granulomatous Disease

This is an immune disorder documented in horses and ponies (equivalent to human sarcoidosis), in which crusty skin lesions develop along the coronary bands and mucocutaneous junctions. Granuloma formation in multiple organs is the hallmark.[114-116] Some animals may develop hypercalcemia.[114] Lesion distribution may resemble those of multisystemic eosinophilic epitheliotropic disease of horses. It has been proposed that excessive production of vitamin D or PTHrP by granulomatous cells leads to hypercalcemia in these animals.[3,114] Similar lesions have been documented in horses and cattle grazing hairy vetch *(Vicia villosa)*.[117,118]

Calcinosis

Soft tissue calcification (liver, heart, kidney, lungs, vessels, muscle), hyperphosphatemia, and elevation of the calcium × phosphorus product were documented in horses with a number of pathologic conditions.[75] This disorder is different than enzootic calcinosis from the ingestion of plants with vitamin D–like activity. The mechanism by which these animals develop calcinosis is unclear, although it is likely that hyperphosphatemia plays a role.

Equine Bone Fragility Syndrome

The equine bone fragility syndrome (BFS) or silica-associated osteoporosis (SAO) is a chronic and progressive disorder of horses characterized by increased respiratory efforts, exercise intolerance, skeletal deformation, lameness, stiffness, and fractures.[119,120] (Also see the Equine Bone Fragility section in Chapter 38.) Horses of any age are affected.[119,121] Bowing of appendicular bones (scapula in particular), lordosis, and neurologic signs from vertebral deformation and spinal cord compression have been documented.[119,120] The pathogenesis remains unclear, but it has been associated with pulmonary silicosis. Radiographically, there is osteopenia and a respiratory pattern consistent with silicosis. Intracellular silica crystals (silica dioxide) in bronchoalveolar cells and pulmonary macrophages, as well as evidence of dystrophic calcification, are consistent with SAO. A high concentration of cristobalite, a fibrogenic form of silicate, is found in regions of California where the condition is more common (Monterey shale soil).[76,119,120,122] Histologically, there is excessive osteoclastic activation and bone resorption. In the respiratory tract there is pulmonary granuloma formation, fibrosis, and lymphadenitis.[76] The diagnosis of BFS is based on clinical history, clinical findings, geography, and imaging (ultrasonography, radiography, and scintigraphy). Nuclear scintigraphy is the best diagnostic modality, but scapular ultrasonography can be diagnostic in some animals.[121] Management of these horses depends on clinical signs and prevention. Nonsteroidal antiinflammatory drugs should be considered in animals with orthopedic pain considering that their use can increase the risk of fractures. Glucocorticoids may be necessary in severe pulmonary disease, but they also enhance bone loss. This is one of the few equine conditions in which bisphosphonates may be indicated.[123] Zoledronate has reduced the severity of clinical signs and scintigraphic findings in horses with BFS.[123] Decreased physical activity and dietary manipulation are recommended.

Treatment of Hypercalcemia

Hypercalcemia as an equine emergency is rarely presented; however, the differential diagnosis of hypercalcemia is important for its treatment. Few disorders in the horse are associated with hypercalcemia (hyperparathyroidism, CRF, HHM, hypervitaminosis D). Mild to moderate hypercalcemia in general is not life-threatening, and treatment should be directed to the primary cause. Parathyroidectomy will be treatment of choice for primary hyperparathyroidism.[87] Bisphosphonates and calcimimetics (cinacalcet) are also recommended in people with hyperparathyroidism[124,125]; however, information on their use for this condition in horses is lacking. Bisphosphonates can cause renal injury in people and, anecdotally, in horses as well. In theory, calcitonin could reduce serum calcium concentrations, but this effect is transient. Surgical removal of epithelial tumors can be a successful treatment for HHM. Some horses with lymphosarcoma may show improvement with chemotherapy. Bisphosphonates and gallium nitrate have shown benefits in reducing serum calcium and bone resorption in people with HHM.[126] Bisphosphonates improved signs in horses with BFS.[123] In severe cases of hypercalcemia that may require medical treatment, initial therapy should include the administration of 0.9% saline solution and loop diuretics. Furosemide is the diuretic of choice because it inhibits the $Na^+/K^+/2Cl^-$ cotransporter in the distal tubules, increasing the urinary excretion of calcium. Thiazide diuretics are contraindicated because they stimulate calcium reabsorption. Glucocorticoid administration should be considered, in particular for horses with hypervitaminosis D.

Phosphorus Disorders in the Horse

Disorders of phosphorus homeostasis can be acute or chronic, resulting in hypophosphatemia or hyperphosphatemia. In critically ill horses hypophosphatemia is more frequent, while in foals hyperphosphatemia is more common.[6,127]

Hypophosphatemic Disorders

Hypophosphatemia develops from reduced intestinal PO_4 absorption, increased urinary PO_4 excretion, and intracellular shift of PO_4 (redistribution). Acute hypophosphatemia often reflects PO_4 redistribution from the extracellular to intracellular compartment and not necessarily imply total body PO_4 depletion. However, PO_4 depletion may occur in animals that have been sick for many days. From personal experience, hypophosphatemia seems to be more common in small equids, usually associated with hyperlipemia and parenteral nutrition. Intestinal PO_4 absorption is reduced by gastrointestinal disorders, hypovitaminosis D, PO_4-deficient diets, and interfering substances. Urinary excretion of PO_4 is increased with hyperparathyroidism, hypovitaminosis D, malignancies that secrete phosphatonins or PTHrP, chronic renal failure, and drugs. Sepsis, carbohydrate-rich diets, hyperglycemia, insulin administration, starvation, refeeding syndrome, hyperlipemia, and parenteral nutrition (hyperglycemia, hyperinsulinemia) decrease serum PO_4 mainly through insulin-mediated intracellular shift of PO_4 and enhanced glycolysis. Catecholamines act by a mechanism similar to insulin shifting PO_4 into the cell. Alkalosis induces hypophosphatemia by stimulating phosphofructokinase activity (glycolysis) and the need for PO_4 to synthesize ATP. In horses with a history of malnutrition, close monitoring of serum PO_4 concentrations is indicated once caloric intake resumes because they may develop refeeding syndrome. Clinical signs of acute hypophosphatemia in horses often go unnoticed. Signs are consequence of PO_4 regulatory functions on energy metabolism, cell membrane stability, and ion transport.[3] These include muscle weakness, fasciculations, dysrhythmias, neuromuscular excitability, ileus, and cell membrane fragility and lysis (hemolysis, rhabdomyolysis). Signs from mild hypophosphatemia are difficult to document. Severe hypophosphatemia can result in tissue hypoxia from reduced erythrocyte content of 2,3-bisphosphoglycerate. Chronic hypophosphatemia is rare in horses and manifests as weight loss, weakness, depraved appetite (pica), reduced bone density, DOD, lameness, and hemolysis. Ideally, therapy for hypophosphatemia would be based on the extracellular deficit, which should be overestimated because PO_4 is a major intracellular anion and cellular depletion is likely to occur in animals with prolonged hypophosphatemia. Preferred parenteral solutions include potassium phosphate and sodium phosphate. Critically ill horses can be supplemented with oral potassium phosphate or sodium phosphate (chemical grade or with phosphate-based enema solutions). Oral supplementation with dicalcium phosphate is a good option in animals with chronic phosphate deficiency.

Hyperphosphatemic Disorders

Hyperphosphatemia develops from increased PO_4 absorption; acute renal injury; hypoparathyroidism; vitamin D toxicity; metabolic acidosis; cell lysis (hemolysis, rhabdomyolysis, tumor necrosis); or iatrogenic causes.[3] Lactic acidosis may cause hyperphosphatemia by shifting PO_4 to the extracellular compartment. Metabolic acidosis and high intracellular ATP concentrations inhibit phosphofructokinase, a key enzyme in glycolysis that uses PO_4 for carbohydrate phosphorylation. Overuse of phosphate-based enemas can cause hyperphosphatemia in foals. Unlike other species, chronic renal failure is an uncommon cause of hyperphosphatemia in horses. Inappropriate blood sample handling can result in spurious hyperphosphatemia. Hemolysis, hyperbilirubinemia, hypertriglyceridemia

VetBooks.ir

(hyperlipidemia), and hyperproteinemia can falsely elevate PO_4 values (pseudohyperphosphatemia). Multiple myeloma can cause pseudohyperphosphatemia from high circulating immunoglobulin concentrations. Acute hyperphosphatemia may cause hypocalcemia from interactions between PO_4 and Ca^{2+} and reduced renal synthesis of $1,25(OH)_2D$. Hyperphosphatemia is common in critically ill foals.[6,127] The pathogenesis of chronic hyperphosphatemia is described in the Nutritional Secondary Hyperparathyroidism section. Clinical signs of acute hyperphosphatemia are similar to those of acute hypocalcemia and include tetany, hyperexcitability, muscle fasciculations, colic, and dysrhythmias. Signs of chronic hyperphosphatemia are those of calcium deficiency, including lameness, orthopedic pathologies, fractures, and osteodystrophia fibrosa. Treatment of hyperphosphatemia is based on primary pathology and duration, which in some instances may not be necessary. In acute hyperphosphatemia, fluid therapy and diuretics are indicated. Dietary PO_4 restriction must be implemented in chronic hyperphosphatemia. Dialysis and phosphate binders are impractical and expensive. Calcium carbonate is a cheap phosphate binder that also provides calcium supplementation. Phosphate-binding polymers (e.g., sevelamer) are the most effective way to treat chronic hyperphosphatemia in other species, but their use is not described in horses.

Endocrine Dysfunction in Critical Illness

Kelsey A. Hart • Ramiro E. Toribio

The endocrine response to illness is vital for ensuring organ, tissue, and cellular health during disease and includes simultaneous increases and decreases in the activity of multiple endocrine axes. Pathophysiologic stressors alter the activity of these pathways at multiple levels and through different mechanisms, with the ultimate aim of supporting the patient through the stress of illness and subsequent restoration of homeostasis. In general, the endocrine response in critical illness results in stimulation of a variety of cardiovascular, metabolic, and immune responses that help support perfusion and organ function, heal damaged tissues, and eliminate pathogens. In addition, some aspects of growth and metabolism are suppressed to free up resources to assist with meeting these goals. The endocrine response ensures that a patient responds predictably and appropriately to therapeutic interventions. Thus, clinicians depend on their patients' having intact endocrine function to aid in their recovery from a variety of diseases. This section will discuss general aspects of endocrine assessment in the critically ill patient and current perspectives on the function of specific endocrine systems in critical illness, including the hypothalamic-pituitary-adrenal (HPA) axis, renin-angiotensin-aldosterone system (RAAS) and blood volume/blood pressure regulation, endocrine pancreas and energy metabolism, thyroid axis, parathyroid gland, and growth hormone (GH) axis.

Assessment of Endocrine Function in the Critically Ill Patient

Endocrine dysfunction during critical illness can be due to a primary underlying and previously unrecognized endocrine disorder (such as undiagnosed PPID in a geriatric horse undergoing colic surgery to correct a strangulating small intestinal lesion), or secondary endocrine dysfunction can develop as a result of factors related the underlying severe illness (such as development of insulin resistance in an endotoxemic horse with colitis). The latter situation is more common, as a large number of studies have provided evidence that transient secondary dysfunction in one or more of the aforementioned endocrine systems is common in critical illness and can be associated with substantial increases in disease morbidity and mortality in both people and animals.[1-6] This sort of endocrine dysfunction in the critically ill patient exemplifies the "two-hit" model, with the first hit being the primary critical illness and resultant physiologic stress and suppression of endocrine function and the second hit being the inability to respond appropriately to the physiologic stress of the primary illness due to the endocrine dysfunction. It is important to note that because there is a great deal of redundancy and "cross-talk" between individual endocrine systems, dysfunction in one system can impact the function of multiple endocrine pathways. Further, a number of studies have demonstrated that endocrine intervention can improve outcomes in some critically ill patients with evidence of disturbed endocrine function.[1,4,6] Thus, accurate assessment of endocrine function is vitally important in the critical care setting.

In health, mechanisms for assessment of endocrine function include measurement of basal circulating hormone concentrations and dynamic tests, including suppression tests if overactivity of an endocrine access is suspected and stimulation tests if insufficient endocrine activity is suspected. Tests that induce physiologic stress such as the insulin tolerance test can also be used to globally assess endocrine axis function. These same assessment options are available in a clinical setting but are often too dangerous to be used in critically ill patients. Cutoff values for plasma hormone concentrations and dynamic test responses that suggest appropriate function in the unstressed patient are not applicable to the critically ill patient undergoing severe pathophysiologic stress. The critically ill patient is also in a dynamic state, with a constantly changing and evolving endocrine response,[7] so one-time responses do not always accurately represent endocrine function. Negative feedback mechanisms that govern endocrine axis function during health may not operate normally during critical illness. Availability of biologically active hormones to target tissues may be altered in illness, due to alterations in levels of hormone binding proteins, post-translational modifications, and variations in hormone metabolism. Hormone activity at the target organ might be altered by changes in receptor number, affinity, or signaling due to factors associated with the primary disease. Finally, while commercial assays are available for measurement of most of the hormones of interest in critically ill people, availability of these assays for veterinary species can be limited and turnaround time for receipt of test results may be unacceptably long for critically ill patients requiring immediate diagnosis and treatment.

Thus, endocrine assessment in the critically ill patient often requires assessment of function via multiple methodologies. Basal hormone concentrations from multiple levels of an endocrine axis can be assessed simultaneously, and dynamic testing can be assessed in conjunction with basal hormone concentrations to provide a more comprehensive picture of the function of the entire axis. Free, biologically active hormone concentrations can be measured if alterations in binding proteins are anticipated. Methodology for detection of hormone activity at the level of the target tissue would be ideal but is not commercially available for most hormones; thus, clinical evaluation of the patient with a high index of suspicion for evidence of endocrine dysfunction can be an important additional "test" to assess tissue hormone activity in the critical care setting. For example, as detailed later, critical illness–related corticosteroid insufficiency (CIRCI) appears to be fairly common in people with septic shock and can be treated with cortisol replacement in the form of low doses of hydrocortisone. Frequently used methodology for CIRCI diagnosis includes documentation of a low basal cortisol concentration, a decreased cortisol response

VetBooks.ir

to ACTH stimulation testing with a variety of protocols, or decreased free cortisol concentration. However, none of these methods are perfect and can result in false negatives and false positives, so in some intensive care units (ICUs) the decision for hydrocortisone treatment is based simply on clinical evidence of CIRCI (persistent hypotension in the face of fluid and vasopressor therapy) rather than specific endocrine test results.

In sum, because endocrine responses are necessarily, dramatically, and variably altered in critical illness, it can be difficult to define what degree of alteration is expected and appropriate and what degree is inappropriate in the critically ill patient. Currently available methodology can be used to assess endocrine function during critical illness in most patients, but expectations for universally applicable guidelines for test interpretation and diagnostic cutoff values are likely unrealistic. Rather, the astute clinician must be aware of common endocrine disturbances seen in critical illness and consider testing and/or endocrine intervention in a timely fashion to prevent development of more severe and potentially fatal complications.

HPA Axis

The HPA axis is the master regulator of various endocrine systems. It modulates cardiovascular, metabolic, and immune activity in response to physiologic needs and stressful events, with the ultimate goal of maintaining organ function. It regulates circulating concentrations of corticosteroid hormones, which are vital for appropriate stress responses in both health and disease. Upon stressful stimulation, the hypothalamus releases corticotropin-releasing hormone (CRH, CRF) and arginine vasopressin (AVP) into the pituitary portal system to stimulate pituitary corticotrophs to secrete adrenocorticotropic hormone (ACTH). In horses, AVP is an important releasing factor for ACTH. ACTH acts on the *zona fasciculata* of the adrenal cortices to induce the synthesis and secretion of the glucocorticoid hormones. To a lesser extent, ACTH also induces aldosterone secretion by the adrenocortical *zona glomerulosa*.

The predominant circulating glucocorticoid hormone in animals, including horses, is cortisol, though corticosterone is also present at moderate concentrations in cattle and goats. [Note: because HPA axis dysfunction in critically ill animals is best characterized in horses and the individual glucocorticoid hormones have similar effects, cortisol will be used to refer to all glucocorticoid hormones for the purpose of this review.]

Cortisol has diverse systemic effects on a variety of target tissues; during critical illness, the sum of these effects helps to maintain blood pressure, coordinate energy metabolism, and regulate the immune and inflammatory response. However, a number of studies suggest that up to 40% to 60% of people, dogs, and horses with sepsis and septic shock suffer from transient HPA axis dysfunction (CIRCI).[2,4,8,9] In these patients, the cortisol response to illness is inadequate for the existing degree of physiologic stress and ACTH concentrations. Circulating cortisol concentrations may be increased from basal levels found in healthy unstressed individuals but are still not adequate to meet demands to support and regulate cardiovascular, metabolic, and inflammatory responses.[4,10] In some patients with CIRCI, cortisol concentrations may be appropriately increased, but peripheral glucocorticoid resistance results in impaired cortisol activity in target tissues.[4,10]

The pathogenesis of CIRCI is poorly understood and is likely multifactorial. Pathophysiologic manifestations of cortisol deficiency can result from dysfunction at one or more levels of the HPA axis, including: (1) inadequate regulatory hormone (CRH, AVP, ACTH) secretion; (2) impaired adrenal sensitivity to ACTH due to receptor antagonism or downregulation; (3) impaired adrenal cortisol synthetic capacity due to loss of substrate or enzymatic failure ("adrenal exhaustion" or "loss of adrenal reserve"); or (4) impaired cortisol activity in the target tissues due to decreased glucocorticoid receptor (GR) expression or activity or intracellular conversion of cortisol to cortisone, which cannot bind the GR.[4,10] This HPA axis dysfunction may be a result of direct injury to one or several components of the HPA axis caused by hemorrhage, ischemia, or necrosis associated with the primary illness.[4,10] In addition, the HPA axis can be suppressed by specific drugs (e.g., etomidate),[11] bacterial components such as endotoxin,[12] or the patient's own immune response.[10,13]

One key aspect of CIRCI is that the HPA axis dysfunction is transient, in contrast to absolute adrenal insufficiency (Addison's disease), which is characterized by permanent glucocorticoid and mineralocorticoid insufficiency.[4] Thus, patients with CIRCI that recover from their primary disease regain normal HPA axis function and do not require lifelong steroid supplementation. However, due to the vital role the HPA axis plays in the physiologic response to the stress of illness, the occurrence of CIRCI during critical illness substantially worsens the morbidity and mortality of the primary disease. For instance, septic people with CIRCI have significantly higher incidence of multiple organ failure and decreased survival rates as compared with septic patients with appropriate HPA axis function.[4,9,10,14-16] Thus, appropriate management of CIRCI in conjunction with treatment of the primary illness is critical.

Current understanding of HPA axis function in critically ill horses and foals is limited; to date, CIRCI is best characterized in septic neonatal foals.[17-23] Although basal ACTH and cortisol concentrations are higher in septic foals than healthy age-matched control foals and in nonsurviving foals (as one would expect with the stress of illness), several studies have reported significantly increased ACTH-to-cortisol ratios in nonsurviving septic foals.[17,19,21,23] Such high ACTH-to-cortisol ratios, with high ACTH concentrations and low corresponding cortisol concentrations, suggest cortisol synthetic failure at the level of the adrenal gland may occur in the septic full-term foal.

Findings from ACTH stimulation tests in hospitalized foals also provide evidence for adrenocortical dysfunction in this population. Peak and delta cortisol (peak–basal cortisol concentration) responses to ACTH stimulation tests do not consistently differ between healthy and ill foals, but increased disease severity and poorer prognoses were associated with decreased cortisol responses to ACTH stimulation in hospitalized foals.[20,22] Specifically, nonsurviving foals had significantly lower delta cortisol responses to low-dose ACTH stimulation as compared with survivors,[22] and foals that met criteria for CIRCI (as characterized by an inadequate delta cortisol response to a high-dose ACTH stimulation test) had a significantly greater incidence of shock, multiple organ dysfunction syndrome, and nonsurvival than foals with an adequate cortisol response to ACTH.[20] When human diagnostic criteria for CIRCI[24] based on inadequate delta cortisol responses to high-dose ACTH stimulation were adapted and applied to hospitalized foals 1 week of age or younger, approximately 50% of all hospitalized foals and a subgroup of septic foals met these criteria.[20]

The incidence of CIRCI in critically ill horses has only been examined in one study to date, but findings suggest it may also occur in this population.[25] Twenty-four percent of severely ill horses had inappropriately low basal cortisol concentrations at hospital admission, and 85% of these horses had inadequate delta cortisol responses to ACTH stimulation.[25] Marked adrenal hemorrhage at necropsy was also seen in nonsurviving horses in this study.[25]

In concert, this evidence suggests that CIRCI occurs in critically ill and septic neonatal foals and in critically ill horses with comparable frequency and impact as in people with similar illnesses.

VetBooks.ir

The clinical presentation of CIRCI is typically vague and insidious, as signs related to the primary illness usually predominate. Indeed, it is the primary illness that should prompt the clinician to consider CIRCI as a possible complicating factor because data in people, dogs, horses, and foals suggest it is more likely in certain diseases than others.[4,5,10,20,25] Recent studies in horses suggest that CIRCI should be considered as a possible complication in any critically ill horse or foal, but particularly in septic foals and horses with evidence of SIRS.[19-22,25] Clinicians should also have a high index of suspicion for cortisol insufficiency in premature foals due to the late maturation of the HPA axis and adrenal gland in foals. Human studies suggest that CIRCI also occurs in conjunction with acute respiratory distress syndrome (ARDS), massive trauma, and major surgery,[4,10] so it should also not be overlooked in horses with similar diseases.

Specific manifestations of CIRCI are directly related to inadequate cortisol support for maintenance of blood pressure, nutrient metabolism, and regulation of the immune/inflammatory response, and they can include one or more of the following: (1) persistent hypotension despite appropriate volume resuscitation and vasopressor support; (2) persistent hypoglycemia or hyperlactatemia despite glucose support and adequate perfusion; or (3) persistent signs of SIRS. Diagnostic criteria for SIRS in some groups of ill horses and foals have been investigated and include tachycardia, fever or hypothermia, leukocytosis (neutrophilia), leukopenia (neutropenia), and increased band neutrophils.[26-30] Specific signs of mineralocorticoid deficiency (such as persistent hyponatremia, hypochloremia, or hyperkalemia) are not a consistent feature of CIRCI but do occasionally occur.

Specific diagnostic criteria for CIRCI in horses or foals are not well defined. Indeed, determination of the ideal diagnostic criteria for CIRCI in any species is inherently difficult as quantifying a universally appropriate cortisol response to variable and constantly changing disease severity in individual patients is next to impossible. Thus, standard diagnostic criteria for CIRCI in people and infants are not widely accepted, but current recommendations include documentation of either (1) an inappropriately low basal cortisol concentration during critical illness or (2) an inadequate delta cortisol response to high-dose (supraphysiologic) ACTH stimulation testing.[24] Testing for CIRCI in people is typically done at ICU admission for patients with diseases likely complicated by CIRCI (e.g., sepsis, ARDS) or when clinical signs consistent with CIRCI, such as persistent hypotension after fluid and vasopressor support, are identified. Cutoff values for adequate basal and delta cortisol concentrations in illness are based on responses to environmental stress in healthy individuals.

In general, measurement of basal plasma hormone concentrations offers a rapid and safe means of assessing adrenocortical function in the critically ill horse or foal. There are commercial radio- and chemiluminescent immunoassays validated for measurement of plasma or serum equine cortisol concentrations.[31,32] In foals, age-related variation in HPA axis function needs to be considered when determining cutoff values for CIRCI diagnosis.[20,22,33] Specific basal cortisol cutoff values for diagnosis in CIRCI in ill foals or horses have not been critically evaluated, but basal cortisol less than 9.9 µg/dL in foals 4 hours old and younger, less than 7 µg/dL in foals 12 to 24 hours old, less than 4.4 µg/dL in foals 36 to 48 hours old, less than 2.5 µg/dL in foals hours to 7 days old, and less than 9.7 µg/dL in horses that have been used to diagnose CIRCI in recent reports.[20,25] However, due to the pulsatile nature of cortisol secretion, plasma concentrations can vary widely during a 24-hour period in both healthy and sick horses and foals with time of day, season, emotional state, and moment-to-moment changes in physiologic stressors.[34,35] Thus, correct interpretation of a single random cortisol concentration in an individual animal as appropriate or not can be difficult. Further, diagnosis of CIRCI based on a low basal cortisol concentration was not correlated with increased disease severity of decreased survival in septic foals, as was diagnosis based on ACTH stimulation testing.[20]

Assessment of cortisol concentrations in conjunction with regulatory hormone (ACTH, CRH) concentrations can provide a more comprehensive picture of HPA axis function. Plasma CRH and ACTH concentrations are easily assessed in most species via commercially available immunoassays, but as the majority of CRH is secreted into the hypothalamic-hypophyseal portal vessels rather than into the systemic circulation, accurate measurement of CRH requires sophisticated sampling methodology. In addition, while in healthy individuals ACTH and cortisol concentrations are fairly closely correlated, ACTH-cortisol dissociation is not uncommon during illness in horses and foals.[23,35] Documentation of an increased ACTH–to–cortisol ratio might be helpful for CIRCI diagnosis, especially in foals, but due to wide variation in these parameters in individual animals,[17,19-21] specific cutoff values for appropriate ACTH–to–cortisol ratios are not currently proposed for diagnosis of CIRCI in horses or foals. Even though cortisol and its ratio with ACTH concentrations are used as indicators of HPA axis function in sick foals, progesterone and dehydroepiandrosterone (DHEA) sulfate were found to be good predictors of HPA axis dysfunction and outcome in hospitalized foals.[23]

Dynamic tests like the ACTH stimulation test circumvent some of these limitations with diagnosis of CIRCI based on basal hormone concentrations. Typically, in the classic "high-dose" ACTH stimulation test, serum cortisol concentration is measured just before and 30 to 90 minutes after intravenous or intramuscular administration of a supraphysiologic quantity of ACTH (Cosyntropin, 1 to 2 µg/kg or higher).[20,40,41] This high-dose ACTH stimulation test produces a maximal adrenal response, so an inadequate increase in cortisol concentration in this test is used to diagnose both absolute, irreversible adrenal insufficiency (e.g., Addison's disease) and transient CIRCI.[4,24,36,37]

However, the high-dose ACTH stimulation test may be less sensitive for diagnosis of the transient, reversible HPA axis suppression that occurs in CIRCI. In some patients with CIRCI, the adrenal gland fails to produce an appropriate cortisol response to physiologic concentrations of ACTH but may still respond adequately to supraphysiologic ACTH concentrations.[38,39] A measurable cortisol response can be produced by administration of lower ACTH doses (0.01 to 0.2 µg/kg IM) in horses and foals,[20,22,25,40,41] and such "low-dose" stimulation tests could also be used to diagnose CIRCI in equine patients. Delta cortisol responses vary more with foal age and dose of ACTH administered, but in general an increase from basal cortisol less than onefold to twofold 30 minutes after low-dose ACTH stimulation testing[20,22,25,40,41] and less than threefold to fourfold 90 to 120 minutes after high-dose ACTH stimulation testing[20,40,41] may be suggestive of CIRCI in horses and foals. However, one study that examined a paired low-dose/high-dose ACTH stimulation test in hospitalized foals found significant associations between increased disease severity and nonsurvival and inadequate cortisol responses to the high dose but not the low dose of ACTH.[20]

It is important to note, however, that ACTH stimulation tests only evaluate the adrenal component of the HPA axis. Therefore, patients with cortisol insufficiency due to impaired HPA axis function at the hypothalamic and/or pituitary levels may produce an appropriate cortisol response to exogenous ACTH that could be falsely interpreted as intact HPA axis function. Insulin tolerance, CRH stimulation, and metyrapone tests are preferred for global assessment of the HPA axis and diagnosis of HPA axis hypofunction and have been described in foals and horses.[42-45] However, risks associated with severe hypoglycemia and the potential for preexisting glucose/insulin

VetBooks.ir

derangements in critically ill horses and foals limit the utility of insulin tolerance testing in patients with potential CIRCI, and the CRH stimulation and metyrapone tests are currently limited by expense and reagent availability, so these tests are not currently recommended for diagnosis of CIRCI in horses and foals.

Finally, some of the physiologic consequences of CIRCI may be associated with cortisol resistance in peripheral tissues rather than circulating cortisol insufficiency; in fact, some patients may have impaired cortisol metabolism and ACTH-cortisol dissociation.[10,46-48] Decreased glucocorticoid receptor binding affinity is described in horses with SIRS and is associated with nonsurvival.[49] In such cases, all of the previously mentioned tests may suggest intact HPA axis function, with appropriate endogenous cortisol concentrations and normal responses to dynamic testing, despite clinical evidence of cortisol insufficiency such as persistent hypotension, metabolic derangements, or inflammatory dysregulation.

Specific therapeutic protocols for management of CIRCI in horses or foals have not been critically evaluated. It is important to remember that the goal of CIRCI treatment is *physiologic* cortisol replacement, as a number of studies in septic patients have demonstrated deleterious effects of high-dose (supraphysiologic) corticosteroid regimens in sepsis.[24] Thus, it may be ideal to avoid more potent and longer-acting corticosteroids such as dexamethasone and prednisolone in favor of hydrocortisone (which is identical to endogenous cortisol), though these drugs are sometimes used in people with CIRCI.

In one case report, a septic foal with adrenocortical insufficiency—as evidenced by a low basal cortisol and impaired cortisol response to ACTH stimulation—demonstrated clinical improvement and eventual normalization of cortisol responses following a course of corticosteroid supplementation in addition to standard therapy for sepsis.[18] Recent evidence also suggests that in healthy 2- to 6-day-old foals, a short tapering course of hydrocortisone (1.3 mg/kg/day divided q4h IV) has potentially beneficial anti-inflammatory effects without significantly impairing innate immune function.[50] Adjustment of daily cortisol production rates in foals based on a "illness factor," as has been done in people to determine steroid supplementation regimens in CIRCI, suggests that a hydrocortisone dose of 1 to 4 mg/kg/day divided q4-6h may be appropriate for foals with CIRCI.[35] However, this or other corticosteroid regimens have not been critically evaluated in septic foals or horses with CIRCI.

Healthy newborn foals have high pregnane concentrations at birth that decrease gradually over the first 48 hours post foaling.[23,51] In the brain, progesterone, DHEA, and pregnenolone can be converted into neuroactive steroids (e.g., allopregnanolone) that promote neurogenesis, neuronal plasticity, and neuroprotection, modulate CRH and AVP synthesis, and influence the HPA axis. Neurosteroid actions in neurons and glial cell are mediated by the $GABA_A$ receptor. Increased progestogen and neuroactive steroid concentrations have been associated with disease severity, neurologic abnormalities (neonatal maladjustment syndrome [NMS]), prematurity, and mortality in hospitalized foals.[23,52] The mechanisms leading to high neurosteroid concentrations in critically ill foals remain unclear, but it has been speculated to be a consequence of altered intrauterine to extrauterine transition, as well as adrenocortical enzymatic shifts during illness.[23,52] Progesterone, 17α-hydroxyprogesterone, and allopregnanolone concentrations are often elevated in septic compared with healthy and sick nonseptic foals.[23,52] If progesterone derivatives are involved in the pathogenesis of NMS, reducing their concentrations could be beneficial. Finasteride and dutasteride are 5α-reductase inhibitors used in men for alopecia and prostatic hypertrophy to block the conversion of testosterone to 5α-dihydrotestosterone. These drugs also block the conversion of progesterone to 5α-dihydroprogesterone, a key precursor for allopregnanolone, and have been proposed as potential treatments for specific cases of NMS.

RAAS, Blood Volume, and Blood Pressure Regulation

Hypovolemia and hypotension are common in critically ill people and animals, and regulation of blood pressure and blood volume is quite complex. The RAAS, HPA axis, and arginine vasopressin (AVP, also known as antidiuretic hormone or ADH) work independently and in concert to control these responses during both health and illness. The RAAS is activated when macula densa cells in the renal juxtaglomerular apparatus sense decreases in blood volume or blood sodium concentration or increases in plasma potassium concentration, resulting in renin release. Renin cleaves plasma angiotensinogen to angiotensin I, which is then further processed to the potent vasoconstrictor angiotensin II by pulmonary angiotensin-converting enzyme (ACE). In addition to vasoconstriction, angiotensin II induces aldosterone release from the adrenal cortices. Aldosterone increases blood volume and pressure by activating the renal tubular sodium potassium ATPase and epithelial sodium channels to enhance renal sodium and water reabsorption, as well as potassium excretion. Increases in plasma osmolality and decreases in arterial pressure are also detected by hypothalamic osmoreceptors and arterial stretch receptors, respectively, stimulating hypothalamic AVP synthesis and release from the posterior pituitary. The primary effect of AVP is the insertion of aquaporin channels in the renal medullary collecting ducts to increase water reabsorption, thus increasing blood volume and blood pressure. AVP also can directly induce arteriolar vasoconstriction and activates the HPA axis by inducing pituitary ACTH release. HPA axis activation and resultant increases in plasma cortisol further aid blood pressure regulation via direct cardiac inotropic effects and downregulation of the vasodilator nitric oxide.

In critical illness, RAAS activation is important for blood pressure and electrolyte regulation, but excessive activation can have detrimental effects. Angiotensin II has recently been demonstrated to have proinflammatory effects, and associations between angiotensin II and increased organ failure and mortality have been described.[53] Transient hyperreninemic hypoaldosteronism is observed frequently in people with septic shock and is associated with the development of acute renal failure in these patients.[54] This hypoaldosteronism could be a reflection of adrenocortical suppression in CIRCI and could play a role in persistent hypotension in affected patients, but as described earlier, specific signs of mineralocorticoid deficiency like electrolyte derangements are uncommon in CIRCI. Information regarding specific RAAS responses in critically ill horses is limited. Hypotensive adult horses demonstrated increased aldosterone concentrations before fluid resuscitation, but aldosterone responses to hypotension appear to be exaggerated in neonatal foals.[55] RAAS activation in critically ill foals is mainly characterized by an increase in angiotensin II and aldosterone concentrations.[56] Renin activity and aldosterone concentrations were also increased in horses with experimentally induced laminitis but might represent appropriate responses to concurrent hyponatremia rather than pathologic RAAS activation.[57] Effects of RAAS on activation on inflammatory status and mortality are not described in horses or foals.

AVP concentrations are initially increased in most acutely critically ill patients, stimulated by the development of hypotension and systemic inflammation (proinflammatory cytokines are potent AVP secretagogues).[3,58] In many patients with septic shock, AVP concentrations tend to fall dramatically despite persistent hypotension, consistent with relative AVP deficiency due to both depletion of stored AVP and inhibition of AVP

VetBooks.ir

synthesis.[58] Tissue AVP activity may also be impaired by inflammatory responses in critical illness.[3] However, there are conflicting reports regarding associations between increases or decreases in AVP concentration and mortality in critically ill patients.[58] Increased AVP concentrations were observed in adult horses with naturally occurring hypovolemia, but not in a small group of hypotensive foals, suggesting AVP responses in foals might be immature.[55] Larger studies documented higher AVP concentrations in septic foals and an association among high AVP concentrations, hypoperfusion, and decreased survival.[59] Vasopressin infusions are sometimes used as vasopressors in hypotensive people, but variable efficacy and concerns regarding potential side effects associated with decreased skin and splanchnic blood flow limit its clinical application.[21,58] Studies investigating the safety and efficacy of vasopressin infusions in horses and foals are lacking, though vasopressin is used anecdotally as a vasopressor in some critically ill neonatal foals with reported success.

Adrenomedullin also plays a role in hemodynamics. Adrenomedullin is a vasodilator peptide of the calcitonin gene family produced by chromaffin cells of the adrenal medulla, cardiac myocytes, and cells in other tissues. It has antiapoptotic and antiinflammatory properties, attenuates ischemia and reperfusion injury, modulates vascular tone, enhances microcirculatory function, promotes angiogenesis, reduces intestinal mucosa permeability, counteracts the RAAS, inhibits aldosterone secretion, increases natriuresis, and supports cardiovascular function during SIRS and sepsis.[60,61] Adrenomedullin concentrations are increased in people with sepsis and endotoxemia, hypertension, heart failure, and myocardial infarction.[61-63] Its production by cardiac myocytes is stimulated by TNF-α, IL-1β, angiotensin II, endothelin-1, and hypoxia. Adrenomedullin concentrations were valuable to individualize human patients who require hemodynamic support.[64] Adrenomedullin analogs have been proposed as therapeutic agents and there are ongoing clinical studies using monoclonal antibodies to the N-terminus of adrenomedullin to prolong its half-life in septic human patients.[60] A recent study found high plasma adrenomedullin concentrations in critically ill compared with healthy foals; however, concentrations were not different between septic and nonseptic foals and were not associated with survival.[65]

Thyroid Axis

In critical illness, activity of the hypothalamic-pituitary-thyroid axis is suppressed, resulting in decreased plasma triiodothyronine (T3) and thyroxine (T4) and increased reverse T3 (rT3) concentrations, a syndrome called nonthyroidal illness syndrome (NTIS) or euthyroid sick syndrome. This syndrome is well described in humans, dogs, and cats suffering from systemic illnesses, and recent reports suggest that NTIS is common in sick horses and foals.[66-69] The syndrome is described in detail earlier in the Thyroid Gland section.

Parathyroid Gland and Calcium Regulation

Calcium dysregulation is common in critically ill people and animals and is presumed to be associated with parathyroid gland dysfunction, vitamin D deficiency, or both.[70-72] Ionized hypocalcemia has been documented in septic foals and horses with intestinal disease, as well as in horses with experimental endotoxemia.[71,73] High parathyroid hormone (PTH) concentrations were found in most horses and foals with hypocalcemia and are consistent with an appropriate endocrine response to low calcium, but some hypocalcemic horses had low PTH concentrations that could be indicative of parathyroid gland dysfunction in this population.[71,73,74] In both people and foals, increased PTH concentrations were associated with decreased survival, but factors other than hypocalcemia likely contributed to this finding as no difference in calcium concentration was found in nonsurviving foals.[71] Proinflammatory cytokines can impact PTH secretion and activity and might play a role in these calcium disturbances in critically ill horses and foals.[71] Calcitonin and PTH-related protein (PTHrP) concentrations were not different between healthy and sick foals,[71] and renal calcium excretion was not different in horses with enterocolitis,[74] suggesting these factors are not responsible for hypocalcemia in critically ill horses and foals. Procalcitonin (PCT), the precursor of calcitonin, is used in human critical care medicine as a highly specific marker of sepsis. Increased PCT concentration was documented in horses with clinical evidence of SIRS, and endotoxin administration to horses induces a rapid PCT response.[75,76]

Information on vitamin D metabolites in critically ill horses and foals is lacking. It was recently shown that hypovitaminosis D is common in critically ill foals.[77,78] Hospitalized foals had lower serum concentrations of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D (active vitamin D, calcitriol) that were associated with hypocalcemia, disease severity, and mortality.[77,78] The mechanisms by which critically ill foals develop hypovitaminosis D remain unclear but could be a consequence of renal and intestinal losses, decreased concentrations vitamin D binding protein, and renal PTH resistance.

Another system of relevance in calcium and phosphorus homeostasis is the fibroblast growth factor-23 (FGF-23)/klotho axis. FGF-23 inhibits renal 1α-hydroxylase activity (vitamin D activation) and sodium/phosphorus cotransporter expression (promotes phosphaturia) and suppresses PTH secretion. Klotho is the coreceptor for FGF-23 and has multiple properties, including antisenescence, antioxidation, antiapoptosis, and cytoprotection. Disturbances in the FGF-23/klotho axis were recently documented in critically ill foals, and hospitalized foals with high FGF-23 or low klotho concentrations were more likely to die.[77]

Energy Axes (Endocrine Pancreas and Orexigenic System)

Insulin, glucagon, cortisol, and epinephrine are considered the main endocrine components of the energy axis; however, it is clear that this is a complex system in which many other hormones (growth hormone, ghrelin, leptin, adiponectin, somatostatin, and incretins) are also important.

Glucose derangements are common in critically ill people and animals. In people, hyperglycemia due to previously undiagnosed diabetes mellitus or "stress hyperglycemia" is most common and is associated with increased morbidity and mortality.[1] Hyperglycemia is also common in horses with GI disease, and persistent hyperglycemia is associated with decreased survival in this population as well.[79,80] In critically ill neonatal foals, both hypoglycemia and hyperglycemia are reported and are associated with a poorer prognosis.[81] Hypoglycemia in septic neonatal foals is most likely related to decreased nursing due to illness and lack of substantial glycogen stores, but mechanisms resulting in hyperglycemia in critically ill people and animals appear to be more complication. Stresses of critical illness activate the HPA axis, sympathoadrenomedullary responses, and the GH axis, resulting in increased concentrations of the counter-regulatory hormones cortisol, catecholamines, GH, and glucagon. These hormones act directly and indirectly to increase blood glucose by increasing hepatic gluconeogenesis, inhibiting insulin release, and impairing glucose utilization in the periphery.[1] Proinflammatory cytokines like TNF-α and IL-1 are also frequently increased in critically ill patients and can induce peripheral insulin resistance in people and laboratory animals by interfering with insulin signaling.[1] Experimental endotoxemia in healthy horses has been shown to decrease insulin sensitivity.[82,83] Insulin sensitivity has not been thoroughly investigated in

VetBooks.ir

critically ill horses and foals to date, but one study documented higher insulin concentrations in nonsurviving septic foals[84] and a recent report found evidence of insulin dysregulation and endocrine pancreatic dysfunction in nonsurviving horses with the systemic inflammatory response syndrome.[85]

Glucose derangements have important clinical consequences in critical illness, as evidenced by the increases in morbidity and mortality discussed earlier. The consequences of hypoglycemia are obvious, as CNS function depends on glucose availability. Clinical sequelae related to hyperglycemia can be equally important, as hyperglycemia results in volume depletion through osmotic diuresis and subsequent electrolyte and acid-base derangements and perfusion impairment.[1] Hyperglycemia can also result in tissue damage via increased production of reactive oxygen species and related lipid peroxidation, damaging tissues like cardiac muscle, vascular beds, and worsening ischemia-reperfusion injury in various tissues such as ischemic intestine.[1] Hyperglycemia also alters blood flow to certain tissues by inhibiting formation of the vasodilator nitric oxide and can cause hemostatic abnormalities through a variety of mechanisms.[1] Finally, immune function is impaired in hyperglycemia by inhibiting phagocytic and chemotactic function in macrophages and neutrophils, respectively.[1]

Because of the negative consequences associated with hyperglycemia, the effects of tight glycemic control with exogenous insulin therapy have been investigated in a number of human studies. Initial studies found a substantial reduction in mortality in patients subject to tight glycemic control protocols that aimed to keep blood glucose concentrations between 80 and 110 mg/dL in comparison with less stringent control (<180 mg/dL).[1,6,86] However, additional studies did not document such a benefit, and some studies actually found an increase in mortality and adverse hypoglycemic events with intensive insulin therapy for tight glycemic control.[1] At present, a blood glucose target of 110 to 180 mg/dL is recommended in critically ill people.[87]

To the authors' knowledge, similar studies investigating insulin therapy and blood glucose goals in animals are not described in the literature, so although the use of insulin (±glucose) infusions in critically ill horses may be indicated to combat persistent hyperglycemia in these patients, specific recommendations for blood glucose control in critically ill horses and foals are not available. There is also a unique consideration for such therapy in horses because insulin infusions at high rates have been associated with laminitis development in normal horses and ponies[88,89] and hyperinsulinemia is associated with endocrinopathic laminitis.[90] Thus, while this has only been described anecdotally, glucose and/or insulin infusions could possibly potentiate the development of laminitis in susceptible animals. The use of insulin-sensitizing drugs like metformin or pioglitazone could be useful for managing sepsis-mediated insulin resistance in horses to avoid a potential risk of insulin-mediated laminitis, but to date these drugs have not been examined in clinical equine sepsis and recent evidence suggests that their effects on insulin sensitivity in horses may be variable at best.[73,91,92]

The role of other hormonal regulators of energy metabolism—including leptin, ghrelin, GH, adiponectin, glucagon, somatostatin, and incretins—in critically ill people or animals is not well understood. These hormones are altered in many patients with critical illness, but alterations vary across studies and populations.[84,91] Glucagon concentrations are consistently elevated in septic foals, likely as a compensatory mechanism to a negative energy balance characterized by hypoglycemia and hypertriglyceridemia.[84]

Leptin and adiponectin are hormones produced by adipose tissue (adipokines), exemplifying the important role of adipose tissue in energy endocrine homeostasis via the so-called gut-brain axis.[73,93] Leptin regulates satiety by decreasing hunger (anorexigenic) and enhances energy expenditure by increasing insulin sensitivity. Ghrelin is a GH-releasing factor secreted by P/D1 cells of the stomach and neurons in the arcuate nucleus of the hypothalamus in response to hypoglycemia and fasting to enhance hunger (orexigenic). Ghrelin also regulates food-seeking behavior to maintain energy homeostasis. Thus, ghrelin and leptin work in opposite ways at the hypothalamic level. Adiponectin participates in energy regulation by increasing insulin sensitivity and fatty acid oxidation, but it also has anti-inflammatory properties. Leptin and adiponectin blood concentrations are proportional to body condition in humans and horses.[94,95] Similar to insulin and GH during disease, resistance to leptin and adiponectin may occur in critical illness.[96]

GH Axis

The GH axis plays an important role in supporting metabolism, gut mucosal function, wound healing, and immune function during critical illness.[97] Loss of the GH pulsatile pattern is common in critically ill humans, where high plasma GH concentrations are not followed by increases in IGF-I, indicating GH resistance. However, GH deficiency may occur in some patients; either mechanism can result in relative GH insufficiency, which can increase catabolism and impair wound healing.[73,97] In critically ill people, recombinant GH supplementation has been used to decrease protein catabolism and initially appeared beneficial, though more recent studies have demonstrated associations with increased mortality, resulting in recommended cessation of the use of the compound in human ICUs.[97] GH actions are predominantly mediated via IGF-1, which is often decreased in critical illness.[73,97] GH has not been extensively studied in critically ill horses or foals, but a recent study found higher GH and lower IGF-1 concentrations in septic foals, suggesting that GH resistance may occur in this population of foals, as well as in people.[98]

Recent work in people has also demonstrated interactions between ghrelin and the GH axis—ghrelin activates the GH receptor, and in addition to hunger, it also stimulates GH secretion.[73,97] One study demonstrated higher ghrelin concentrations in septic compared with healthy foals; however, no association with survival was found.[98] High ghrelin and low IGF-1 (negative regulator for GH secretion) likely enhances GH secretion in critically ill foals. Ghrelin has been evaluated as a potential therapeutic agent to reduce inflammation, increase muscle mass, and treat cachexia and anorexia (anorexia nervosa) in other species. Ghrelin or related compounds may provide a means for provision of anabolic support to critically ill patients.

Ruminant Metabolic Diseases and Metabolic Modifiers

Macromineral and Bone Problems of Ruminants

Jesse Paul Goff

Introduction

Seven macrominerals, Na, K, Cl, Ca, Mg, P, and S, are considered essential for life. Inappropriate amounts of any of the macrominerals needed by ruminants can cause insufficiency and clinical disease including the "downer cow." Ca disorders, such as milk fever, are not associated with insufficient diet Ca but rather an inability of the cow to use dietary Ca and bone mineral stores of Ca at the onset of lactation. Na, K, Mg, and Cl are the major electrolytes of blood, extracellular, and intracellular fluids and influence blood volume, resting cell membrane potentials, and acid-base status. Many factors can contribute to the "downer cow syndrome" in addition to mineral challenges as outlined in Table 41.7. This chapter highlights the most common problems associated with each micromineral, focusing on identification of the problem, cause and prevention of the problem, and treatment options.

Calcium

The Ca concentration in adult cow blood is normally 9 to 10 mg/dL (2.25 to 2.5 mM). Blood Ca concentration in calves younger than 4 months old will generally be a little higher, 9.8 to 11 mg/dL (2.2 to 2.75 mM), which may reflect the need for more Ca to promote calcification of new bone. About half of blood Ca is bound to proteins such as albumin and globulins, and a small portion (4% to 7%) is complexed to compounds such as citrate. The remaining Ca is in the blood in an ionized form at a concentration of 1 to 1.13 mM. This is the biologically active portion of Ca in the blood. It is the predominant form of Ca in the extracellular fluids bathing the tissues. The percentage of blood Ca that is ionized is affected by blood acidity; it varies from 42% to 43% of total Ca during compensated alkalosis and reaches 47% to 48% of total Ca during compensated acidosis. The 600-kg cow's blood normally contains approximately 3.25 g Ca, and the extracellular fluids of the cow contain a total of 10.5 to 11 g Ca (Fig. 41.19).

Periparturient Dairy Cow Ca Metabolism

The onset of lactation imposes a large homeostatic challenge to the dairy cow. The day before calving, the 600-kg cow uses 7 to 8 g Ca for maintenance needs plus another 10 g Ca to allow fetal skeleton development, for a total of about 18 g Ca. To maintain Ca balance, 18 g Ca must be absorbed from the diet. Ca in dietary forages and concentrates are generally only about 30% available. If the forage and grains of the diet supply the Ca (no limestone or other more bioavailable Ca mineral is added to the diet) and the cow is consuming about 13 kg DM/day, the diet can be as low as 0.46% Ca and will meet the Ca demands of the cow.

At calving, the 10 g Ca needed for fetal skeletal development is replaced by a much larger Ca demand for colostrum and milk production. Holsteins produce an average of 7.5 kg first milk colostrum containing about 2.3 g Ca/kg. Harvesting that colostrum removes 17 g Ca from the blood. Within an hour of removal of the colostrum, the mammary gland will take up from the blood about three quarters of the Ca needed to form the transition milk (to be removed 12 hours later at the next milking).[1] This is estimated to be another 13 g Ca. This brings the Ca lost from the blood to about 30 g Ca within a few hours of harvesting colostrum. The total Ca lost in the first day of lactation (milk Ca from first two milkings plus Ca sequestered in mammary for the next days milk) will approach 40 g Ca. Adding in the 8 g Ca maintenance requirement and the total amount of Ca leaving the blood on the day of calving approaches 46 to 48 g. This represents a 28- to 30-g Ca increase in net Ca that must enter the blood the day of calving compared with the day before calving. This represents removal of every g of Ca from the blood an additional eight to nine times during that first day compared with the day before calving. Amazingly, most cows successfully meet this challenge.

TABLE 41.7

Primary Causes of Recumbency Initiating the "Downer Cow Syndrome"

A. Mineral imbalances
   1. Hypocalcemia—plasma Ca <5 mg/dL
   2. Hypomagnesemia—plasma Mg <1.2 mg/dL
   3. Hypophosphatemia—plasma P <1.0 mg/dL
B. Severe endotoxemia—moderate reduction in plasma Ca (5.5-7.5 mg/dL), Mg, and P
C. Dystocia—damage to obturator and L6 branch of the sciatic nerve
D. Pregnancy toxemia syndrome—low plasma Ca, Mg, P, and glucose
E. Fractures
F. Coxofemoral luxation
G. Rupture of gastrocnemius muscle
H. Lymphosarcoma of spinal cord

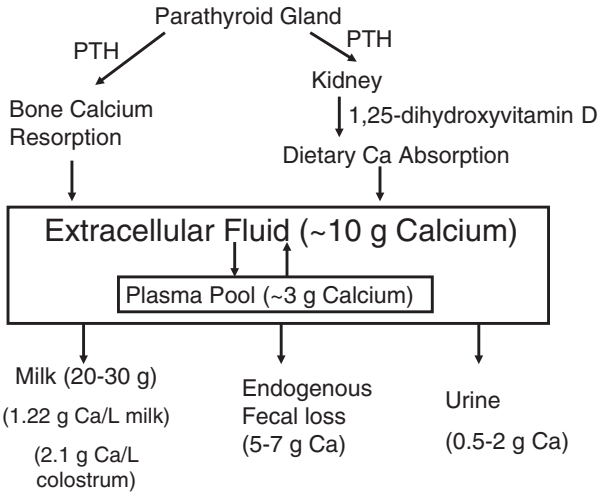

FIG. 41.19 Calcium homeostatic response of the 600-kg cow in early lactation to a decline in blood Ca concentration at the onset of lactation. *PTH*, Parathyroid hormone.

VetBooks.ir

Many cows, including nearly all first-calf heifers, will suffer only a small, temporary decline in blood Ca around the time of calving as Ca homeostasis mechanisms succeed in raising the blood Ca concentration back to normal. This is initiated by the parathyroid glands, which sense any decrease in ionized blood Ca concentration and secrete parathyroid hormone (PTH). G protein–coupled PTH receptors on bone osteoblast and osteocyte and kidney cells bind the PTH, resulting in an increase in intracellular cyclic AMP concentrations to initiate various actions within the target bone and kidney cells. PTH rapidly (within minutes) reduces urinary Ca loss, which can correct small Ca imbalances. However, because urinary Ca losses are typically below 0.5 g/day, it has a limited capacity to impact Ca balance at the onset of lactation. Continued secretion of PTH will stimulate osteocytic osteolysis, which involves moving Ca from the fluid surrounding each osteocyte sitting in its lacunae through the canalicular system and into the blood of the Haversian canal system in bone. This response is quite fast and moves about 9 g Ca into the blood of the typical cow within several hours. PTH will also stimulate renal conversion of vitamin D into the hormone, 1,25-dihydroxyvitamin D. This hormone acts on intestinal epithelial cells to stimulate active transepithelial movement of dietary Ca into the blood. This can bring large amounts of Ca into the blood, but it takes 24 to 36 hours to become fully active. Continued PTH secretion can also stimulate osteoblasts to secrete receptor activator of nuclear factor kappa-β ligand (RANKL). RANKL stimulates bone osteoclast recruitment and activation within trabecular and cortical bone. This has the potential to remove large amounts of Ca from the skeleton (over 1 kg Ca in the first 5 weeks of lactation) to help achieve Ca balance, but this process may take 48 to 72 hours to become fully active in older cows. When operating properly, the cow experiences only a small decline in blood Ca concentration (<8 mg/dL in nearly half the older cows), which lasts less than 18 hours before being restored to normal.[2]

Periparturient Hypocalcemia and Milk Fever in Dairy Cows and Goats

In some cows the Ca homeostatic mechanisms are slow to respond, resulting in moderate (blood Ca <8 mg/dL) to severe hypocalcemia (blood Ca <5.5 mg/dL) that may extend into the first 3 to 5 days of lactation. Cows with severe hypocalcemia can develop milk fever. This occurs in roughly 3% to 4% of dairy cows in the United States each year, usually within 24 hours of calving. Cows can occasionally develop milk fever before calving as a result of Ca sequestration by the mammary gland in preparation for production of colostrum. Milk fever cows exhibit muscle paresis and muscle twitching. Hypocalcemia causes neuron cell membranes to be more permeable to Na, lowering the resting membrane closer to threshold potential. The neurons are hyperexcitable, which can activate muscle twitching and tetany in the animal.

Normally, action potentials move down the axon of nerves depolarizing the terminus of the nerve axon. This opens voltage-gated Ca channels in the nerve terminus. Extracellular fluid Ca^{++} enters the neuron, causing the neuron to release acetylcholine into the synaptic cleft, resulting in muscle contraction. Hypocalcemia reduces the amount of Ca^{++} available to enter the axon terminus following an action potential, inhibiting acetylcholine release into the synaptic cleft. The result is muscle paresis. In most species, the effect of hypocalcemia on nerve excitability predominates and tetany is observed. However, in ruminants the effect of hypocalcemia on acetylcholine release at the myoneural junction predominates and muscle paresis is the main clinical sign.

Note that this is not always the case. In the ruminant that is severely hypomagnesemic (Mg <1.25 mg/dL) and hypocalcemic (Ca <5 mg/dL), the predominant clinical sign is tetany rather than the paresis observed in the milk fever cow fed adequate Mg. Ordinarily, Mg in the synaptic cleft of the myoneural junction competes with Ca for entry into the nerve axon following depolarization. If Ca alone is low, the entry of Ca into the axon is inhibited, causing paresis. However, in the case of the cow with grass tetany (described later), Mg in the extracellular fluids at the myoneural junction synaptic cleft is so low that even the low level of Ca in the extracellular fluids can successfully enter the axon and stimulate ACH release and muscle contraction. Because the hypomagnesemia increases excitability of nervous tissue and the myoneural junction can respond, the clinical presentation is tetany.

Early in the course of the milk fever syndrome, the cow is ataxic and muscle twitching can be observed. Eventually the cow may be unable to stand. The neck of the recumbent cow is typically tucked back into the flank. The cow is lethargic and depressed. Rumen motility will be slow to absent. The heart rate is generally increased to 80 to 100 beats per minute (bpm), but the sounds are muffled, reflecting poor cardiac output. Blood flow to the periphery is reduced. Thermoregulation is impaired, and the cow's body temperature will move toward the ambient temperature. In most cases, ambient temperature is below 38° C, so the ears feel cold and body temperature is often 36.5° C to 38° C (98° F to 100.5° F). However, in hot climates the body temperature can be dangerously elevated, which threatens life more rapidly than being hypothermic. Breathing is shallow.

Cows that develop milk fever before calving may not be able to contract the uterus enough to expel the calf. Milk may leak from the teats as the teat sphincter muscle fails to maintain muscle tone. Cows also have poor swallowing reflexes, so drenches and boluses should not be administered to them if they are recumbent. If these cows are not kept up on their sternums, rumen fluids may move up the esophagus into the pharynx and come out the nasopharynx or, worse, be aspirated on inspiration.

Blood samples obtained from milk fever cows will be low in Ca, generally below 5.5 mg/dL and usually below 4 mg/dL. Blood Mg concentrations are typically elevated (>2.3 mg/dL or 0.95 mM) due to action of PTH to enhance renal tubular Mg reabsorption. However, if inadequate diet Mg is fed to cows, the Mg concentration will be below 1.9 mg/dL (0.78 mM). This signals the clinician that hypomagnesemia may be a factor contributing to hypocalcemia in the cows (see later). Cows with milk fever are often hypophosphatemic with blood inorganic phosphate (P) concentration below 4 mg/dL (1.3 mM). Often, blood P is between 2.5 and 3.5 mg/dL (0.8 to 1.1 mM) in milk fever cows. Occasionally, blood P concentration will be below 1 mg/dL (0.3 mM) (see Hypophosphatemic Downer Cow section later). Blood K concentration is generally from 2.5 to 4 mEq/L, the result of inappetence and the action of PTH to reduce renal tubule potassium reabsorption. Milk fever cows will have plasma cortisol concentrations that exceed 20 ng/mL, approximately 15-fold above normal cortisol concentrations. These levels may contribute to immune suppression of the periparturient cow. Hypocalcemia can also directly impair immune cell responses, increasing susceptibility of cows to opportunistic infection of the uterus and mammary gland.

Differential diagnosis should rule out other disorders that can cause the downer cow syndrome. This includes toxic mastitis and toxic metritis, usually caused by coliform bacteria. Milk should be expelled from each teat before treatment of milk fever to rule out mastitis. Inappropriate treatment of endotoxic cows with intravenous Ca can cause death as endotoxins increase sensitivity of cardiac muscle to Ca, causing the heart to stop in systole. Trauma from calving (damage to the obturator and more commonly the L6 branch of the sciatic nerve) and pelvic or limb fractures need to be ruled out. The presence of a second calf in the uterus must also be ruled out.

Subclinical hypocalcemia, in which blood Ca is below 8 mg/dL but above 5.5 mg/dL, may affect 25% of heifers and more than half of older cows. Although not as severe as clinical milk fever, these cows are more immune suppressed than normocalcemic cows and at greater risk of metritis, ketosis, and retained placenta. The degree of hypocalcemia and the length of time the cow is hypocalcemic greatly influence susceptibility to these secondary disorders.

Pathogenesis of Milk Fever

When Ca homeostasis is working properly, the cow experiences only a small and short-lived decline in blood Ca concentration during the periparturient period. A reduced ability of bone and kidney cells to respond to PTH stimulation is implicated as the defect in Ca homeostasis that results in prolonged or severe hypocalcemia. The primary factors affecting tissue responsiveness to PTH are metabolic alkalosis and hypomagnesemia.

Metabolic Alkalosis and Diet Cation-Anion Difference

During metabolic alkalosis the tertiary structure or shape of the PTH receptor on bone and kidney cell surfaces is changed, reducing its affinity for PTH. This reduces the amount of cyclic AMP made inside target cells inhibiting the cells from carrying out their role in Ca homeostasis (Fig. 41.20). Dietary cations, such as K^+, Na^+, Ca^{++}, and Mg^{++}, will raise the pH of the blood of the cow if they are absorbed into the blood. Dietary anions, such as chloride, sulfate, and phosphate, will acidify the blood of the cow if they are absorbed into the blood. Cations or anions in the diet that are not absorbed have no impact on blood pH. The difference in the number of mEq of cations and anions *absorbed* from the diet helps determine blood pH.[3] Cows are typically in a state of compensated metabolic alkalosis as their diet consists of forages that are typically high in K^+. Since K^+ is absorbed from the diet with nearly 100% efficiency, forage K^+ is strongly alkalinizing. Na^+ in the diet or water is also highly alkalinizing as Na^+ is also absorbed with nearly 100% efficiency. Ca^{++} and Mg^{++} cations can be present in diets in relatively high concentrations, but they are absorbed from the diet with much lower efficiency than K^+ or Na^+. Any absorbed Ca^{++} and Mg^{++} cations will also contribute to the alkalinity of the blood. Cows in a state of compensated metabolic alkalosis as a result of being fed a high K diet do not respond to PTH stimulation as well as cows placed in a state of compensated metabolic acidosis by addition of anions to their diet. Metabolic alkalosis impairs bone Ca resorption. In addition, the ability of PTH to stimulate timely production of 1,25-dihydroxyvitamin D is impaired, reducing the utilization of dietary Ca.

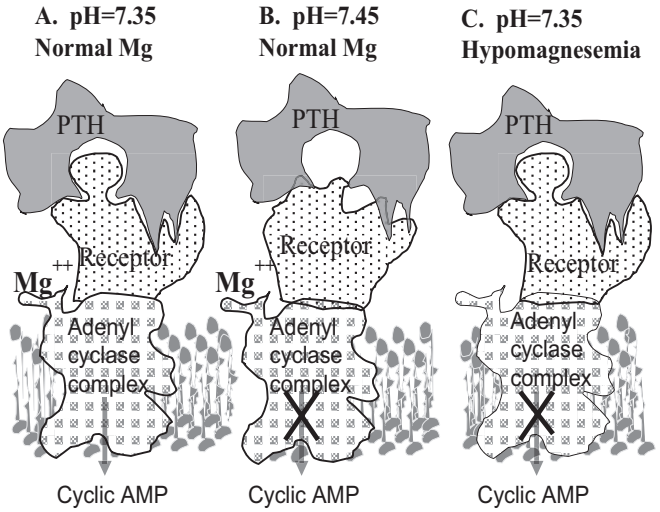

FIG. 41.20 Parathyroid hormone (PTH) affects at the surface of target bone and kidney cells. (A) Under normal conditions, PTH released in response to hypocalcemia interacts with its receptor, located on the surface of bone and kidney cells, in a lock and key fashion. This stimulates G proteins and adenylate cyclase (adenylate cyclase complex) resulting in production of cyclic AMP, which acts as a second messenger within the cytosol of target cells. This initiates mechanisms such as bone Ca resorption and renal production of 1,25-dihydroxyvitamin D to restore blood Ca concentration to normal levels. **(B)** Alkalotic conditions induced by high-potassium diets induce a change in the shape of the PTH receptor protein so that it is less able to recognize and bind PTH, resulting in failure to activate the cell by producing cyclic AMP. **(C)** Mg is required for function of the adenylate cyclase complex. Hypomagnesemia reduces ability of PTH stimulated cells to produce cylic AMP, resulting in failure to activate the cell.

Adjusting Dietary Cation-Anion Difference to Reduce Alkalosis in the Cow

Since K is the primary mineral causing the metabolic alkalosis that interferes with PTH function, reducing diet K content is an important step in dry cow diet formulation. Mature forages contain less potassium than young forages, and forages grown where manure or potash has been applied to the soil will have high potassium content. Cool-season grasses and legumes will remove much more potassium from the soil than they need for growth, while warm-season grasses (including corn) do not. Forages harvested when the soil is moist (spring growth) generally have higher K content than forages grown during the drier months. By restricting K application to the soil, it is possible to avoid luxury consumption of K by legumes and cool-season grasses. Producers should also be aware that forages take up Cl from the soil and it is possible to find hays that are low K and high (1% to 1.2%) Cl. Producers should use the lowest dietary cation-anion difference (DCAD) forage possible, not simply the lowest K forage. Forages intended for the close-up dry cow should routinely be analyzed for both K and Cl by a wet chemistry method. Near-infrared determinations of forage mineral content are not currently useful.

Anions can be added to the diet to bring the cow into a state of compensated metabolic acidosis. Diet chloride anions are absorbed with nearly 100% efficiency. Sulfate anions can also help acidify the cow, but sulfate is not absorbed as well as chloride and has approximately 60% the acidifying activity of chloride. Although phosphate anions are acidifying, they should not be added to close-up dry cow rations as they actually impair Ca homeostasis (see Phosphorus later). When sufficient anions are added to the precalving diet, they induce a compensated metabolic acidosis in the cow, improving tissue sensitivity to PTH. This restores the competency of Ca homeostatic mechanisms and facilitates a rapid return to normocalcemia after blood Ca concentration decreases at the onset of lactation.

Blood pH is difficult and expensive to measure. Urine pH generally reflects blood pH and can be determined in cows on farm to determine the degree to which an anionic diet has placed the cow in a state of compensated metabolic acidosis. Urine pH can be checked 72 or more hours after a ration change. Urine samples should be free of feces and made on midstream collections to avoid alkalinity from vaginal secretions. In cows offered feed twice daily, the timing of the urine collection does not seem critical. In cows fed limited amounts of feed so as to achieve an empty bunk, the diurnal variation in urine pH can be a full pH unit. Checking urine pH routinely allows the farm to develop confidence that the DCAD is effective and safe. Published studies where anionic salts have improved periparturient Ca status have had an anion-supplemented group of cows with urine pH below 7.0 and usually closer to 6.0.[4]

Several DCAD equations have been developed to estimate the relative effect diet macrominerals and their charges might have on the animal's blood pH. DCAD mineral concentrations are expressed as mEq of the cations and anions-per-kg diet or per-100-g diet.

1. DCAD = (Na + K) – (Cl + S)
2. DCAD = (Na + K + 0.15 Ca + 0.15 Mg) – (Cl + 0.6 S + 0.5 P)
3. DCAD = (Na + K) – (Cl + 0.6 S)

The differences in the equations reflect whether or not all macrominerals were considered and whether efficiency of absorption of the mineral from the diet was considered. One meta-analysis of published studies on periparturient hypocalcemia found the equation DCAD = (Na + K) – (Cl + 0.6 S) had the strongest ability to predict urine pH and the strongest association with milk fever incidence.[4] However, the equation DCAD = (Na + K) – (Cl + S) remains the most widely used equation.

Guidelines on the DCAD needed, expressed as (Na + K) – (Cl + S), to achieve different urine pH levels in cows are estimated below. DCAD of + 50 mEq/kg results in average urine pH of cows of approximaely 7.5. Urine pH will be around 7.0 when DCAD is approximately 0 mEq/kg and 6.3 when DCAD is approximately between –75 and –125 mEq/kg (Fig. 41.21). These are approximations, and it must be stressed that this particular DCAD equation overvalues the acidifying action of sulfate and ignores the alkalinizing action diet Ca and Mg have on blood and urine pH. Diets with anions added can be unpalatable and can depress DM intake (DMI). Commercial anion supplements that are more palatable than traditional ammonium, Ca, Mg, chloride, and sulfate salts have been developed. Even these products will depress DM intake once urine pH falls below about 5.9.[5]

As DCAD decreases, the degree of hypocalcemia experienced by the periparturient cow will also generally decrease. There are, however, caveats to this premise. If the addition of anions to the diet fails to acidify the cow enough to cause urine pH to be less than 7.5, there will be no demonstrable improvement in periparturient Ca status. And if the DCAD is too low, the cow is pushed into a state of uncompensated metabolic acidosis, which will greatly decrease DM consumption just before calving (see Fig. 41.21). As DCAD is reduced, the net amount of acid excreted into the urine increases until urine pH reaches about 6.3. When urine pH is below 6.3, the net acid excretion in urine is no longer well correlated to DCAD.[6] Below 6.3, the kidney begins to also excrete ammonium cations into the urine, slowing a further decline in urine and blood pH. The ammonium arises from the combining of H^+ with ammonia that diffuses into the tubular fluid as urine pH is reduced below 5.9. This ability of the kidney to neutralize the excess H^+ allows the cow to remain in a state of compensated metabolic acidosis until urine pH reaches approximately 5.5. Urine pH below 5.3 is indicative of uncompensated metabolic acidosis, which will cause severe reductions in DM intake leading to ketosis, displaced abomasum, and immune suppression.[2,5] There is evidence that dry cows with urine pH of 7.3 will be significantly less hypocalcemic than cows with urine pH of 8, but they will exhibit more hypocalcemia than cows with urine pH of 6.0. There is little evidence the degree of hypocalcemia experienced by cows with urine pH of 5.7 is less than in cows with urine pH of 6.3.

Another question revolves around the proper level of Ca to include in the diet of the cow fed anions. Anionic diets, ranging from 0.45% to 1.7% Ca, have been used successfully. Once the dietary Ca requirement of the cow has been met, the addition of Ca to precalving diets has little effect on periparturient Ca status if cows have been acidified to the same extent. However, diet Ca, especially when added as calcium carbonate, has a mild alkalinizing effect that will necessitate addition of more anions to achieve the same degree of urine acidification, which can increase the risk of DMI depression. The author prefers that prepartum diet Ca matches lactation diet Ca (0.8% to 1.1% Ca), with all of the Ca coming from forages and anion supplements.

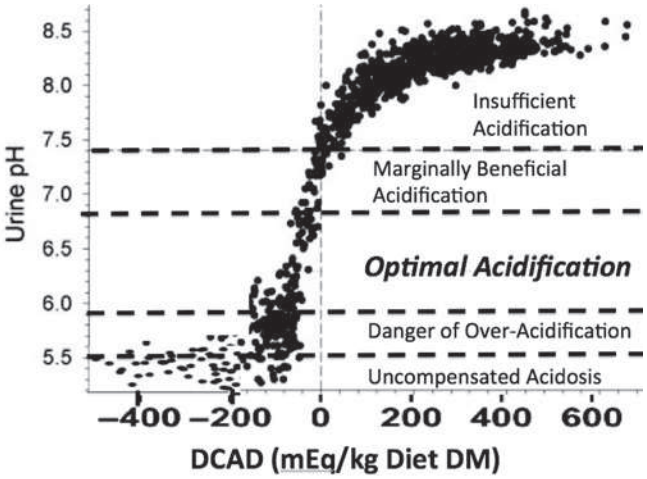

FIG. 41.21 Effect of dietary cation-anion difference (DCAD = [Na + K] – [Cl + S]) in mEq/kg on urine pH of individual cows. Zones of expected contribution to improvement of periparturient Ca status are depicted by horizontal dashed lines. The data on cows fed diets with DCAD below –250 mEq/kg are not well represented as feed intake declines precipitously in cows fed these diets. *(Adapted from Charbonneau E, Pellerin D, Oetzel GR: Impact of lowering dietary cation-anion difference in nonlactating dairy cows: a meta-analysis. J Dairy Sci 89:537–548, 2006 and Constable PD, Gelfert CC, Fürll M, Staufenbiel R, Stämpfli HR: Application of strong ion difference theory to urine and the relationship between urine pH and net acid excretion in cattle. Am J Vet Res 70:915–925, 2009.)*

Hypomagnesemia

A second common cause of hypocalcemia and milk fever in the periparturient cow is hypomagnesemia. Very low blood magnesium concentration (<1.2 mg/dL) can reduce PTH secretion from the parathyroid glands, which will cause blood Ca concentration to fall. This is the case when lactating beef or dairy cows are at pasture (see Magnesium section later). Less severe hypomagnesemia can alter the responsiveness of tissues to PTH. Mg must be present at adequate levels to allow the PTH/PTH receptor complex to fully activate the adenyl cyclase and allow cyclic AMP production (see Fig. 41.20). Levels below 1.7 mg/dL, which can be common particularly in the first days of lactation, do not support full activity of the adenyl cyclase linked to the PTH receptor. Cows fed adequate dietary magnesium in the prepartal ration will typically be slightly hypermagnesemic the day after parturition. When blood magnesium concentration within 24 hours after calving is not at least 1.9 mg Mg/dL, it suggests inadequate dietary magnesium.

Effect of Dietary Phosphorus on Hypocalcemia

Phosphorus (P) exists in diets and body fluids as phosphate (monobasic or dibasic PO_4^{-3}). Absorption of phosphate anions occurs primarily in the small intestine by a transepithelial process that is activated by the hormone 1,25-dihydroxyvitamin D. Because it is an anion, dietary P that is absorbed into the blood will acidify the blood. Though adding P to the diet can acidify the cow, the addition of P to the precalving diet increases the degree of hypocalcemia experienced by the periparturient cow. Serum P generally increases with dietary P. Unfortunately, a rising blood P concentration causes bone osteocytes to secrete

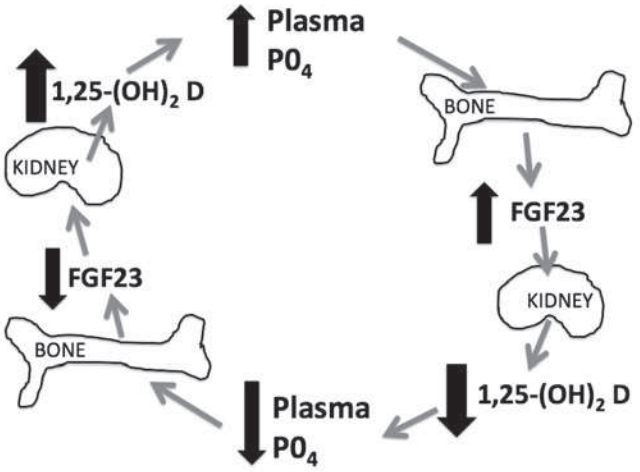

FIG. 41.22 Increasing concentrations of phosphate in plasma and extracellular fluids cause osteocytes to secrete fibroblast growth factor 23 (FGF23) into the blood. FGF23 inhibits renal synthesis of 1,25-dihydroxyvitamin D (1,25-$[OH]_2$D), which reduces dietary phosphate absorption. Conversely, low extracellular and plasma phosphate inhibits osteocyte production of FGF23 and 1,25-$(OH)_2$D synthesis increases, stimulating increased dietary phosphate absorption to raise blood phosphate concentration.

the phosphate-regulating hormone, fibroblast growth factor 23 (FGF23), to reduce blood P. FGF23 leaves the bone, circulates in the blood, and binds to its receptor on kidney cells, where it inhibits renal enzymes involved in synthesis of 1,25-dihydroxyvitamin D and increases production of enzymes that degrade 1,25-dihydroxyvitamin D. Reducing blood 1,25-dihydroxyvitamin D concentrations reduces intestinal P absorption, causing blood P to decline (Fig. 41.22). Unfortunately, reducing production of 1,25-dihydroxyvitamin D also reduces diet Ca absorption impairing Ca homeostasis.[3] Restricting P content of precalving diets can aid Ca homeostasis. Cows fed an anionic precalving diet that was 0.21% P had a lower incidence of hypocalcemia than cows fed a 0.44% P diet. They also maintained serum P concentrations that were within the normal range for cows (4 to 6 mg P/dL or 1.23 to 1.86 mmol/L) during the precalving period.

Dairy cows can develop a condition known as the hypophosphatemic downer cow. These cows exhibit low serum phosphate concentration, often below 1.5 mg/dL (0.46 mmol/L). When it is observed, it is generally a sequelae of milk fever (see Phosphorus section). It does not occur as a consequence of low dietary P, and steps taken to reduce milk fever incidence reduce the incidence of the hypophosphatemic downer cow as well.[2]

Using a Ca-Deficient Diet to Prevent Milk Fever

This strategy involves limiting diet Ca or diet Ca availability to levels that place the cow in negative Ca balance for 7 to 14 days before calving. Negative Ca balance stimulates the parathyroid gland to greatly increase secretion of PTH within 3 to 4 days of the diet Ca reduction. Prolonged exposure to high concentrations of PTH overcomes the tissue resistance to PTH that is caused by metabolic alkalosis. Ca conservation and Ca mobilization mechanisms, such as renal production of 1,25-dihydroxyvitamin D and bone Ca resorption, are activated before the onset of lactation. The cow's homeostasis mechanisms are primed by the low Ca diet and ready to respond to the Ca demands of lactation.

The studies in which milk fever was effectively prevented using the "Ca-deficient diet" strategy had total diet Ca below 20 g/day and likely supplied less than 12 g absorbable Ca each day. It is difficult to feed prepartum diets that are this deficient in Ca using typical forages when cows are fed ad libitum.

Substances that bind dietary Ca and render it unavailable for absorption can allow formulation of diets that will successfully cause prepartal Ca deficiency and reduce periparturient hypocalcemia. Zeolite A is a sodium-aluminum silicate that can bind dietary Ca in prepartum diets, rendering it unavailable for absorption. Depending on DMI, it can work when diets are as high as 0.6% to 0.7% Ca (Ca intake <75 g Ca/day) to cause "Ca deficiency" and prevent milk fever. It also binds phosphate, which may be of some aid in the prevention of hypocalcemia. Zeolite A also binds Mg and cationic trace minerals (especially Cu) in the diet, but the implications to the health of the cow are unknown. A similar approach is to use rice bran that has been treated with formaldehyde so that it is able to bypass the rumen intact. The phytic acid within the rice bran binds Ca within the lumen of the small intestine, preventing it from being absorbed, improving periparturient Ca status. It also binds dietary phosphate before calving, which may also help prevent milk fever.

Exogenous Vitamin D and Parathyroid Hormone Administration

Earlier literature often recommended feeding or injecting massive doses (up to 10 million units of vitamin D) 10 to 14 days before calving to prevent milk fever. The vitamin D was converted to 25-hydroxyvitamin D, which, at very high levels, can stimulate vitamin D receptors and increase intestinal calcium absorption to help prevent milk fever. Unfortunately, the dose of vitamin D that effectively prevents milk fever is close to the level that causes metastatic calcification of soft tissues, particularly if prepartum diet Ca is high. Lower doses are not effective and may actually induce milk fever because the high levels of 25-hydroxyvitamin D suppress PTH secretion and renal synthesis of endogenous 1,25-dihydroxyvitamin D. Recent studies using administration of the vitamin D metabolite, 25-hydroxyvitamin D, have not found that this compound can reduce the incidence of hypocalcemia, though its shorter half-life may make it less toxic than vitamin D.

Treatment with the hormone 1,25-dihydroxyvitamin D and its analogs can be an effective means of preventing hypocalcemia. Problems with cost, timing of administration and withdrawal from treatment, and lack of FDA approval have not made these treatments practical.

Synthetic PTH peptides given daily before calving can also effectively prevent milk fever, but no commercial product is currently available. Prolonged exposure of the bone and kidney cells to the high levels of PTH overcomes tissue resistance to PTH.

Other Milk Fever Risk Factors

Heifers rarely develop clinical milk fever, though 5% to 25% of them may experience subclinical hypocalcemia, with blood Ca falling below 8 mg/dL (<2.0 mM). The incidence of clinical (milk fever) and subclinical hypocalcemia increases with each subsequent lactation. Ca homeostasis in heifers is more robust than in older cows because they are still growing. Their bones will have many more mature osteoclasts present in them. PTH needs only to activate the cells. This allows them to access more bone Ca on the first day of lactation.[1] In an older cow the PTH must first induce osteoclast production from progenitor cells and then activate the cells to resorb bone Ca. Also, as cows age there is a reduction in the number of receptors for 1,25-dihydroxyvitamin D in their intestines, which may translate into slower activation of intestinal Ca transcellular absorption.

The Channel Island (Jersey, Guernsey) and, to a lesser extent, the Swedish Red and White and Norwegian Red breeds have a higher incidence of milk fever than Holstein cows. The reasons remain unclear. Jersey cow colostrum and milk have a higher

VetBooks.ir

calcium content than that produced by Holstein cows, which may place a relatively larger calcium stress on the Jersey cows. In one study, Jersey cows had significantly fewer intestinal receptors for 1,25-dihydroxyvitamin D than did Holsteins, which might slow upregulation of intestinal diet Ca absorption.

Heat stress has mixed effects on acid-base physiology and therefore Ca homeostasis. During the heat of the day the cow typically has a higher respiratory rate, using movement of air in and out of the respiratory tract to reduce body heat (similar to the panting dog). This causes blood carbon dioxide levels to decrease, which lowers blood HCO_3^- anion concentration, resulting in respiratory alkalosis. In severe heat stress the animal may drool excessively, resulting in the loss of large amounts of salivary K (and some Na) cations from the body, which can cause metabolic acidosis. Whether respiratory alkalosis or metabolic acidosis predominates determines blood pH and susceptibility to hypocalcemia at calving.

Treatment of Cows With Milk Fever

Cows that are recumbent with hypocalcemia need to be treated with intravenous Ca as soon as possible. The proper dose is 1 g Ca/100 lb body weight given at the rate of 1 g Ca/minute. Most products on the market supply between 10.5 and 12 g Ca in a 500-mL solution. Any soluble Ca salt that dissociates to provide Ca^{++} ions will be effective. Ca gluconate and borogluconate are commonly used. Calcium chloride, while effective, is rarely used today because administration outside of the vein causes tissue necrosis. Immediately after treatment the blood total Ca concentration will be at least 14 mg/dL (3.5 mM) and often reaches 20 mg Ca/dL (5 mM). When IV Ca is administered too quickly, the heart stops in systole: this occurs when blood Ca rises above 28 mg/dL (7 mM). Some practitioners will administer Ca subcutaneously to avoid cardiac toxicity. Typically the same solution used for IV treatment is used. It must be limited to about 50 mL per injection site to avoid sterile abscess due to hypertonicity of the solution. Many of these treatments also contain glucose, which further increases the risk of a sterile abscess developing at the site of subcutaneous injection. The intravenous and subcutaneous Ca treatments will support near-normal levels of blood Ca concentration for 6 to 9 hours following treatment. Giving a subcutaneous bottle of Ca immediately following the intravenous treatment does not extend the therapeutic window and prevent relapse.

Many products also provide soluble forms of Mg and K. The 1.75- to 2.25-g Mg in these products can temporarily correct hypomagnesemia, and the K helps prevent cardiac toxicity as its action on the heart can counter the inotropic action of the Ca. Phosphorus can be found in some of these products. However, the form of phosphorus found in these products tends to be phosphite or phosphinic salts, which are biologically unavailable to the cow.

If treatment is delayed, it is possible for the cow's down side hind leg to undergo the crush syndrome in which blood flow to the limb is compromised and muscle tissue starts to become necrotic. In addition, pressure that develops between the ground and greater trochanter of the femur can damage the sciatic nerve, rendering the cow unable to rise even after blood Ca has been corrected. If the cow exhibits knuckling over on the down limb when she stands following IV Ca treatment, it is likely the peroneal nerve was damaged where it crosses the lateral side of the tibia. Occasionally the forelimb radial nerve can also suffer compression damage. Cold weather speeds the damage done by recumbency. Treatment of the cow with muscle and nerve damage requires that the weight be taken off the down leg. This can entail placement of the down cow in an area with deep bedding and rolling the cow from one side to the other every 3 to 4 hours until healing occurs, which may take several days. Slings, air mattresses, and other devices have been devised to help the down cow but require great dedication to achieve recovery. The cow can also be moved into a "float tank," which uses warm water to lift the cow so she can stand in the water tank (see Chapter 35, Down Cows). Float tanks are more successful in effecting a recovery of muscle and nerve function than the other treatments described earlier. Vitamin E and selenium, B vitamins, glucocorticoids, and NSAIDs are commonly administered to down cows as adjunct therapies, but their effectiveness is not well documented.

Oral Ca risks aspiration pneumonia as the swallowing reflex is compromised. In addition, oral Ca may not raise the blood Ca fast enough to avoid the crush syndrome from developing in a recumbent cow.

Relapsing Milk Fever

About 20% of cows that have been successfully treated for milk fever with IV Ca will suffer a relapse of milk fever, often about 24 hours after initial treatment. These cows have high blood PTH concentrations but produce little 1,25-dihydroxyvitamin D at parturition, suggesting the tissues remain insensitive to PTH stimulation. Full recovery from milk fever occurs only after the cow has responded to the PTH by producing 1,25-dihydroxyvitamin D, which can be delayed for 24 to 72 hours in some cows. Some clinicians administer a second bottle of Ca subcutaneously following IV Ca treatment in the mistaken belief that this will prevent relapse. Subcutaneous or oral Ca treatment to prevent relapse will be more effective if administered 12 to 24 hours after initial IV treatment. Oral Ca treatments based on Ca chloride will also acidify the cow, improving PTH sensitivity of the tissues to help prevent relapse as well.

Oral Ca Treatments at Calving

Ca is absorbed across the intestinal mucosa by two methods. The first method is by the active transport of Ca across intestinal cells; a process mediated by the hormone 1,25-dihydroxyvitamin D. The second method is by passive diffusion across the tight junctions that hold adjacent mucosal cells together. The concept behind oral Ca supplementation is that the cow's ability to use active transport of Ca *across* intestinal cells is inadequate to help her maintain normal blood Ca concentrations. By dosing the animal with large amounts of very soluble Ca, it is possible to force Ca across the intestinal tract by means of passive diffusion *between* intestinal epithelial cells. Best results are obtained with doses of Ca between 45 and 90 g Ca/dose. For best control of hypocalcemia, a dose is given at calving and again 12 to 24 hours later. Not all of the orally administered Ca will be rapidly absorbed via the paracellular route. Administering 50 g Ca from Ca chloride as a drench in 250 mL water is roughly equivalent to administering 4 g Ca IV.[3] Unfortunately, hypocalcemic cows have poor swallowing and gag reflexes, making them vulnerable to aspiration pneumonia. Aspiration of Ca solutions leads to severe pneumonia. Ca chloride has been used in oral Ca preparations but can be caustic as a drench. Oral boluses that are coated with fat have been developed and avoid the esophageal erosions observed with many of the oral calcium chloride drenches. Ca propionate is less injurious to tissues and has the added benefit of supplying propionate, a gluconeogenic precursor. Toxic doses of Ca can be delivered orally—the LD50 is about 200 g Ca in a soluble form!

Intravenous Ca Treatment at Calving to Prevent Hypocalcemia

Some farms routinely give older cows an intravenous bottle of Ca at calving to prevent milk fever. This raises blood Ca

VetBooks.ir

quite rapidly and does reduce the risk of clinical milk fever for at least the next 12 to 24 hours. However, it may shut down Ca homeostatic mechanisms on that day, causing the cow to have lower blood Ca on days 2 and 3 after calving than cows that received no intravenous Ca treatment. Oral or subcutaneously administered Ca does not appear to shut off Ca homeostasis to the same extent and may provide more effective treatment of the cow.[7]

Magnesium

Mg is a major intracellular cation serving as a cofactor for enzymatic reactions vital to every major metabolic pathway. Extracellular Mg is vital to normal nerve conduction, muscle function, and bone mineral formation. In a 600-kg cow there is about 0.84 g Mg in the blood, 3 g Mg in all the extracellular fluids, 84 g Mg inside cells, and 210 g Mg within bone mineral. Unfortunately, bone is not a significant source of Mg that can be used in times of Mg deficit, as bone resorption occurs in response to Ca homeostasis, not Mg status. Maintenance of normal plasma Mg concentration is nearly totally dependent on continuous dietary Mg absorption.

Hypomagnesemia

Hypomagnesemia generally leads to nerve hyperexcitability, tetany, convulsion, and, too often, sudden death. Hypomagnesemia is often accompanied by and complicated by hypocalcemia. Hypomagnesemia is a common problem only in ruminants.

Cow plasma Mg concentration is normally between 1.8 and 2.4 mg/dL (0.75 and 1 mM). Normal plasma Mg concentration in sheep is between 2.2 and 2.8 mg/dL (0.90 and 1.15 mM). The kidneys play a key role in maintaining Mg homeostasis by excreting excess absorbed Mg. The renal threshold for Mg (i.e., the plasma Mg concentration at which all Mg filtered across the glomerulus is reabsorbed is 1.8 mg/dL [0.75 mM] in the cow and 2.2 mg/dL [0.90 mM]) in sheep. Plasma Mg concentrations below these levels indicate dietary Mg absorption is not sufficient. Little or no Mg will be detected in urine.

Moderate hypomagnesemia between 1.1 and 1.8 mg/dL (0.5 and 0.75 mM) is associated with reduced feed intake, nervousness, and reduced milk fat and total milk production. This can be a chronic problem in some dairy herds that often goes unnoticed. It can also predispose these animals to hypocalcemia and milk fever as described earlier.

Role of Rumen in Hypomagnesemia

Mg is well absorbed from the small intestine of young calves and lambs. As the rumen and reticulum develop, these sites become the main, and perhaps only, sites for net Mg absorption. In adult ruminants the small intestine is a site of net secretion of Mg. Mg absorption from the rumen is dependent on the concentration of Mg in solution in the rumen fluid and integrity of the Mg transport mechanisms.

The soluble concentration of Mg in rumen fluid can be low for several reasons. Chief among these are low Mg content of forages and inadequate diet supplementation. Mg solubility also declines sharply as rumen pH rises above 6.5. Grazing animals tend to have higher rumen pH because of the stimulation of salivary buffer secretion. Forages can also contain organic compounds, such as unsaturated fatty acids, that are converted to tricarballylate, which can form insoluble Mg salts in the rumen. When high grain rations are fed, rumen fluid pH is often below pH 6.5, increasing Mg solubility and thus availability.

Two mechanisms existing in rumen epithelium allow Mg to cross the apical membrane of the stratum granulosum cells in contact with the rumen fluid. One is a Na-linked transport mechanism, which relies on a high potential difference across the apical membrane to move Mg into the cell down its electrical gradient.[8] When this transporter is fully functional, the ruminant can generally meet its Mg requirements with diets that are 0.2% to 0.25% Mg. Feeding ionophores (monensin, lasalocid) can improve activity of this Na-linked Mg transport system in the rumen, increasing Mg absorption efficiency about 10%. Lush high-moisture pastures increase the rate of passage of material, including Mg, from the rumen so that Mg may leave the rumen before it can be absorbed.

Unfortunately, the Na-linked Mg transporter is disrupted by high K and high ammonia/ammonium in the rumen fluids. High K concentration in the rumen fluid depolarizes the apical membrane of the rumen epithelium, reducing the electromotive potential needed to drive Mg thru the Mg channels in the apical membrane of stratum granulosum cells.[8] Acute exposure to ammonia/ammonium similarly depolarizes the apical membrane of the stratum granulosum cells, inhibiting Mg transport by this route. Fortunately, a second Mg transport mechanism exists in the rumen epithelium that is not dependent on the potential difference across the apical membrane and therefore unaffected by diet K. However, this transporter is Mg concentration dependent (i.e., it is most effective when rumen fluid Mg ion concentration is high). Essentially, diet Mg has to be high enough to raise rumen fluid *ionized* Mg concentration above 3 to 4 mM. This may require the diet to be greater than 0.35% Mg, depending on the source of Mg and its solubility in rumen fluid. Mg content of the close-up dry cow ration and early lactation ration should be between 0.35% and 0.4% as insurance against the possibility that the active transport processes for Mg absorption are impaired.

Cows being fed a low DCAD diet to prevent milk fever and hypocalcemia are generally fed Mg as magnesium sulfate or magnesium chloride—both are highly available in the rumen and generally provide adequate amounts of Mg to use either of the rumen Mg transporters effectively. However, after calving, cows are placed on a lactation diet. Forages and magnesium oxide become the sources of Mg in these diets. Magnesium oxide (MgO) is used because it can also serve as a rumen fluid alkalinizer and help maintain rumen pH during lactation. Unfortunately, there is wide variability in availability of Mg from MgO and this often causes mild hypomagnesemia in cows during the first few days of lactation.

The reactivity of MgO with acetic acid provides a simple test of the relative availability of the MgO being considered for use in rations. Place 3 g of a MgO source in a container and slowly add 40 mL 5% acetic acid (white vinegar). Cap the container, shake well for 15 seconds, and let it sit. Shake again at the 15-minute mark and then check the pH at 30 minutes. Vinegar alone has a pH of 2.6 to 2.8. The best MgO sources will bring the pH up to 8.2 and the worst to just 3.8.[2] Because pH is a log scale, this represents more than a 10,000-fold difference in the number of hydrogen ions neutralized. In an experiment with four cows with rumen fistulas, the solubility of MgO in vitro (tested in several ways) was found to parallel their solubility in the rumen and their urinary excretion—an indication that solubility predicted absorbability.[9]

Occurrence of Hypomagnesemic Tetany

Hypomagnesemic tetany is most often associated with beef and dairy cows and ewes in early lactation grazing lush pastures high in potassium and nitrogen and low in Mg and sodium. This is the most common situation, and it is often referred to as grass tetany, spring tetany, grass staggers, rye or wheat pasture poisoning and lactation tetany. Mg deficiency occurs most often in spring or fall when pastures are growing at maximal rates and is most common in lactating ruminants as milk production removes 0.15 g Mg from the blood for each liter of milk produced. Cool weather seems to play a factor as well, probably through its effects on plant Mg uptake, though there

VetBooks.ir

is some indication that the physiologic response of the cow to cool weather affects Mg status directly.

When plasma Mg levels fall below 0.5 mmol/L or 1.1 mg/dL, twitching is sometimes seen in the muscles of the face, shoulder, and flank. As hypomagnesemia progresses, tetanic spasms of the muscles become more common, which eventually cause the cow or ewe to stagger and fall. In most cases, the clinical signs of tetany occur only when hypomagnesemia has interfered with PTH secretion and function, causing secondary acute hypocalcemia.

Hypomagnesemia will slowly cause cerebrospinal fluid (CSF) Mg concentration to decline. Clonic convulsions quickly follow, with chomping of the jaws and frothy salivation. Affected animals lay with the head arched back and legs paddling. The heart rate can approach 150 bpm, and the heartbeat is often audible without a stethoscope. Respiratory rate approaches 60/min and the rectal temperature rises and can approach 40.5° C (105° F) as a result of excessive muscular activity. The eyelids flutter, and there is usually marked nystagmus. They may get up after several minutes and repeat these convulsive episodes several times before they finally die. Hypomagnesemic tetany in calves is clinically similar to that in adults and is often accompanied by moderate hypocalcemia.

Ewes are generally hypocalcemic and hypomagnesemic. Affected ewes are usually in the second to fourth weeks of lactation and are usually suckling more than one lamb. Affected ewes are generally depressed, stand with their heads down, and are reluctant to move. As hypomagnesemia and hypocalcemia progress, they suffer tetany and clonic convulsions just as in cattle. The clinical signs in goats are similar to those observed in cattle.

CSF Mg concentrations below 1 mg/dL (0.4 mM) are responsible for the clonic convulsions seen in animals with hypomagnesemic tetany. Unfortunately, blood samples obtained during or shortly after an episode of tetany may have near-normal levels of Mg as a result of muscle damage and leakage of Mg from intracellular pools complicating diagnosis. CSF Mg concentration will remain low during tetany and also can be a reliable indicator of Mg status for up to 12 hours after death. Vitreous humor Mg concentrations below 0.4 mmol/L or 1 mg/dL are also found in animals with tetany and can be a reliable indicator for 24 to 48 hours after death provided that environmental temperatures have not exceeded 23° C. Aqueous humor has not proved a reliable sample.

Urine can be collected antemortem or postmortem. Low blood Mg concentration will not exceed the renal threshold for Mg, and as a result very little Mg will be in the urine. Urine Mg concentration below 1 mM is indicative of deficiency. Urine Mg concentration above 4.4 mM is considered normal. Urine Mg between 1 and 4.4 mM is likely insufficient Mg status.

Treatment of Hypomagnesemia

Animals exhibiting hypomagnesemic tetany need immediate treatment. This will require administering from 1.5 to 2.25 g Mg IV in the adult cow. They generally also need intravenous Ca. Most of the commercially available intravenous solutions used to treat the hypocalcemia of milk fever supply from 1.5 to 3 g Mg, usually as the chloride, borogluconate, or hypophosphite salts of Mg. Response to therapy can be disappointing, and success is related to the interval between onset of tetany and treatment. Cows should not be stimulated to rise for at least 30 minutes after treatment to avoid initiating tetany and convulsion. Cattle that will recover do so about an hour after treatment, which is the time it takes for CSF Mg concentration to return to normal. Many of these cows will relapse and require further treatment within 12 hours.

The rate of relapse can be reduced using orally administered Mg salts once the animal has regained good swallowing reflexes (to avoid aspiration pneumonia). Drenching or pumping into the rumen 100 g Mg oxide suspended in water can be effective. This provides about 52 g Mg to the animal. Adding 50 g Ca carbonate, 100 g dicalcium phosphate, and 50 g sodium chloride may enhance the effectiveness of the slurry, especially if hypocalcemia and hypophosphatemia accompany the hypomagnesemia. Alternatively, 200 to 400 mL of a 50% Mg sulfate solution can be administered by drench. Mg sulfate is more available for rumen absorption than Mg oxide. If hypomagnesemic tetany has occurred in one cow or ewe in a herd or flock, steps should be taken immediately to increase Mg intake in other members of the herd to prevent further losses. Getting an additional 10 to 15 g Mg into each pregnant cow, 20 g Mg into each lactating beef cow, and 30 g Mg into each lactating dairy cow each day, usually in a grain mix, will often prevent further hypomagnesemic tetany cases. Ewes and does can be treated with one eighth of the formulas mentioned earlier. The problem with these prevention schemes is getting the animal to actually consume the extra Mg, especially when working with animals at pasture. It can be added to a small amount of grain offered in the pasture. Mg sulfate and Mg chloride can be added to the water source, but this is only successful if the animals have no other water source to choose from.

Phosphorus

Traditionally, phosphorus in clinical medicine is abbreviated as P, although it should be understood by the reader that the biologically relevant form of phosphorus is actually inorganic phosphate, PO_4^{-3}, not elemental phosphorus. P is also a component of phospholipids, phosphoproteins, nucleic acids, and energy-transferring molecules such as ATP, but these are not detected as phosphate by the laboratory test used to measure blood inorganic phosphate. In the blood, phosphate ions are typically in the form of HPO_4^{-2} or $H_2PO_4^{-1}$. Moving phosphate between these two forms allows P to serve as an essential component of the acid-base buffer system of the body. P is second only to Ca as a major component of bone mineral, with the skeleton of a 600-kg cow containing about 3.9 kg P.

Phosphorus Homeostasis

Plasma P concentration is normally 4 to 8 mg/dL (1.3 to 2.6 mM). About 1.2 to 2.2 g P is present in the plasma inorganic P pool, and 5 to 8 g P is normally present in the extracellular P pool of a 600-kg cow. Intracellular P concentration is about 78 mg/dL (25 mM), and total body intracellular P content is about 185 g, with 5.5 to 6.5 g of P located within erythrocytes. Maintaining the extracellular P pool involves replacing extracellular P removed for bone and muscle growth, endogenous fecal loss, urinary P loss, and milk production with P absorbed from the diet or resorbed from bone. During late gestation, fetal skeletal development can withdraw up to 10 g P/day from the maternal P pools. About 0.3 g P is incorporated into each kg of body tissue (muscle) gained during growth of the animal. Production of milk removes about 0.9 g P from the extracellular pool/kg of milk produced. Salivary secretions remove between 30 and 90 g P from the extracellular P pool each day, though most of it is reabsorbed on reaching the small intestine. Factors affecting salivary phosphate secretion include the time spent ruminating (chewing activity) and the PTH status of the animal. PTH stimulates parotid salivary P secretion and can increase salivary phosphate concentrations twofold to threefold. Salivary phosphate secretions help buffer the rumen and supply rumen microbes with a readily available source of P necessary for cellulose digestion. Most of the salivary phosphate secreted is recovered by intestinal absorption. However, even on low-P diets a minimum of 5 g/day of secreted P is not recovered and is lost to feces. Urinary P loss is usually between 2 and

12 g/day. Bones of a 600-kg cow contain about 4 kg of P, some of which can be withdrawn and returned to the blood during osteoclastic resorption of bone.

Rumen microbes are able to digest phytic acid, so most of the phytate-bound P, the form of up to 70% of P in plants, is available for absorption in ruminants. P is primarily absorbed in the small intestine via an active transport process that is dependent on 1,25-dihydroxyvitamin D. This vitamin D hormone stimulates enterocytes to produce a Na^+-coupled phosphate cotransporter protein in their apical membrane, allowing efficient absorption of diet P.

Homeostasis of P

Plasma P concentrations are generally well correlated with dietary P absorption. P absorbed in excess of needs is excreted in urine and saliva. Rising serum P concentration triggers the bone osteocytes to produce the hormone fibroblast growth factor 23 (FGF23). This hormone circulates to the kidney, where it inhibits the activity of the renal enzyme that produces the hormone 1,25-dihydroxyvitmin D, and stimulates the activity of enzymes that degrade 1,25-dihydroxyvitamin D (see Fig. 41.22). The lack of 1,25-dihydroxyvitamin D reduces the active transport of P across the intestinal epithelium, lowering blood P concentration. In addition, FGF-23 also acts on renal proximal tubule cells to block Na/PO_4 cotransporters that reabsorb filtered phosphate from the tubular fluid, increasing urinary excretion of phosphate.[10]

Intestinal P absorption efficiency can be upregulated during periods of P deficiency as renal production of 1,25-dihydroxyvitamin D can be directly stimulated by very low plasma P, independent of PTH. However, the plasma P level must reach low levels (<1 or 2 mg/dL) to actually stimulate increased renal production of 1,25-dihydroxyvitamin D.

PTH, secreted during periods of Ca stress, increases renal and salivary excretion of P, which can be detrimental to maintenance of normal blood P concentrations. This is one reason that hypocalcemic animals tend to become hypophosphatemic. PTH could conceivably increase blood P concentration because it stimulates bone osteoclast mineral resorption. However, one reason the cow is hypocalcemic and secreting high levels of PTH is because the osteoclasts are not responding quickly enough to the PTH! PTH stimulates the kidney to produce 1,25-dihydroxyvitamin D, which should increase the efficiency of intestinal phosphate absorption. Complicating this further, a rise in blood P can trigger bone osteocytes to secrete FGF23 to shut off synthesis of 1,25-dihydroxyvitamin D, inhibiting intestinal absorption of Ca and P.

Acute Hypophosphatemia, Pregnancy Toxemia, and Downer Cows

Beef cows and ewes fed a diet marginal in P will have a chronic hypophosphatemia of 0.6 to 1.1 mmol/L or 2 to 3.5 mg/dL. In late gestation, plasma P can decline precipitously as the growth of the fetus accelerates and removes substantial amounts of P from the maternal circulation. These animals often become recumbent and are unable to rise, though they appear fairly alert and will often eat feed placed in front of them. Cows and ewes carrying twins are most often affected. Plasma P concentration in these recumbent animals is often less than 0.3 mmol/L or 1 mg/dL. The disease is often referred to as pregnancy toxemia and is usually complicated by concurrent hypocalcemia, hypomagnesemia, and in some cases hypoglycemia. Diets that are marginal in P are generally indicative of diets that are marginal in energy because grains are excellent sources of P.

At the onset of lactation in the dairy cow, the production of colostrum and milk draws large amounts of P out of the extracellular P pools. This alone will often cause an acute decline in plasma P levels. In addition, if the animal is also developing hypocalcemia, PTH will be secreted in large amounts, increasing urinary and salivary loss of P. In dairy cows, plasma P concentrations routinely fall below the normal range at parturition, and in cows with milk fever, plasma P concentrations are often between 0.4 and 0.75 mmol/L or 1.3 and 2.5 mg/dL. Plasma P concentrations usually increase rapidly following treatment of the hypocalcemic cow with intravenous Ca solutions. This rapid recovery is due to reduction in PTH secretion, which reduces urinary and salivary loss of P. Administration of Ca generally causes resumption of gastrointestinal motility, which allows absorption of dietary P and reabsorption of salivary P secretions that were sequestered within the rumen.

Some dairy cows developing acute hypocalcemia and hypophosphatemia do not spontaneously recover normal plasma P concentration. This is sometimes the case in cows that are classified as "downer cows." This syndrome often begins as milk fever, but unlike the typical milk fever cow, plasma P remains low, often below 1 mg/dL (0.3 mM), despite successful treatment of the hypocalcemia. Protracted hypophosphatemia in these cows appears to be an important factor in the inability of these animals to rise to their feet, but why plasma P remains low is unclear. In some cases the inability to absorb the salivary phosphate is secondary to poor rumen motility, but not in all cases. Excessive cortisol secretion might be a factor in this syndrome as glucocorticoids can force extracellular P to move inside cells.

Treatment of these "downer cows" with phosphate (PO_4^{-3})-containing solutions can effect a recovery in some animals provided they are treated before muscle and nerve damage have occurred. Unfortunately, many products suggested for intravenous use in treating this syndrome contain P as phosphite or phosphinic acid salts (PO_2^{-2}), which are biologically inactive. For proper oral treatment, the dose is 50 g P supplied in a 200-g monosodium phosphate drench. Intravenous treatment consists of 6 g P, supplied by 23 g monosodium phosphate, an amount found in many over-the-counter phosphate enema preparations sold in drugstores for human use. This author prefers to administer the phosphate dissolved in 1 L of saline. Oral treatment restores normal blood P more slowly than intravenous treatment, but the effect lasts longer. If depletion of intracellular P stores is involved in the downer syndrome, it seems likely that intravenous treatment alone will not supply enough P to replenish intracellular stores of P.

The hypophosphatemic downer cow syndrome does not appear to be caused by low P diets as affected cows are often receiving diets containing 0.4% dietary P. The best preventative measure seems to be to effective actions to avoid development of hypocalcemia. In the author's experience, hypophosphatemic downer cows are most commonly seen in the northern latitudes at the end of winter and early spring. Fluctuating temperatures caused by passing cold fronts may play a role.

Chronic P Deficiency

P deficiency is fairly common in ruminants grazing plants grown in arid climates or on tropical soils with poor soil P content or availability. While P content of the immature plant may be suitable (0.3% P-DM basis), the mature dry plants often contain less than 0.15% P. In more temperate areas, P deficiency can develop in animals grazing overly mature forages or crop residues, such as corn stalks. Sheep can, in some instances, be successfully raised on pasture that has been associated with P deficiency in cattle, suggesting that sheep are slightly more resistant to P deficiency syndromes than are cattle. This may simply reflect the higher intake/kg body weight of sheep and their habit of selecting the less mature plants, which are generally higher in P. With the exception of rickets and postparturient hemoglobinuria (discussed later), the clinical problems associated with P deficiency are general

VetBooks.ir

VetBooks.ir

and nonspecific and can include an unthrifty appearance, reduced feed intake, pica, reduced rate of gain, and reduced milk production.

Impaired reproduction has often been attributed to "P deficiency." However, in most cases cows develop P deficiency in situations that also result in concurrent energy deficiency. It is the negative energy balance that is the direct cause of reproductive failure. Unfortunately, the belief that "marginal" dietary P contributed to reproductive inefficiency has been used as justification for feeding diets that are much higher in P than is required. High-producing cows perform well in terms of milk production and fertility when fed diets containing just 0.38% P.[11]

Postparturient Hemoglobinuria

Intravascular hemolysis, anemia, and hemoglobinuria are occasionally reported during the first 6 weeks of lactation. Many, but not all, cows developing this syndrome are hypophosphatemic. Severe hypophosphatemia is postulated to depress the ability of erythrocytes to produce ATP because a key enzyme in glycolysis, glyceraldehyde-3-phosphate dehydrogenase, requires inorganic phosphate as a cofactor. Without sufficient ATP to power sodium pumps, the intracellular sodium concentration rises, the cells become more rigid and, as a result, rupture as they pass through the capillary beds.

However, hypophosphatemia alone is rarely sufficient cause for increased red blood cell fragility. Often these cows are on diets that are also deficient in selenium, copper, and energy, so attributing the cause to hypophosphatemia is likely too simplistic. Cows that have been treated for ketosis seem at greater risk of developing postparturient hemoglobinuria.

Electrolyte (Na, K, and Chloride) Issues in Ruminants

Sodium and Chloride

Sodium is the major extracellular cation of body fluids and plays a crucial role in absorption of dietary sugars, amino acids, and water. Chloride is the major anion in the body, making up more than 60% of the total anion equivalents in the extracellular fluid. Chloride helps regulate osmotic pressure of blood. Chloride is the chief anion in gastric secretions and is responsible for the low pH in the lumen of the abomasum. Chloride is actively secreted into the intestinal lumen by crypt epithelial cells and acts as the driving force for Na movement into the lumen of the gut to satisfy needs of Na/hexose and Na/amino acid symporters. Both Na and Cl always exist in a fully dissociated (ionized) state when in solution. Nerve and muscle resting membrane potentials are highly dependent on proper sodium and chloride concentrations. Most land vertebrates evolved without abundant diet Na. Therefore, they developed efficient and redundant mechanisms for Na absorption. Na and Cl transporters across the digestive tract epithelium are often coupled to maintain electroneutrality. Sodium and Cl can be absorbed from the rumen, small intestine, and large intestine. Nearly 100% of diet Na and more than 90% of diet Cl is absorbed.

Salt may be the only mineral compound that animals truly develop a craving for (perhaps phosphorus as well). Salt deficiency is often accompanied by observations of animals with pica, or abnormal appetite, with chewing or licking of wood, rocks, soil, urine, and bones being a common observation. Eventually osmotic and acid-base disturbances cause a reduction in appetite. Animals fail to grow, develop rough hair coats, and lactation comes to a halt. Long term, salt deficiency will cause death from dehydration. Nonlactating ruminants require 0.1% to 0.15% Na and 0.3% Cl. Lactation raises the requirement considerably to at least 0.4% Na and 0.5% Cl. For most species, the chloride requirement of the diet is adequately met by the combination of chloride from feedstuffs and from the salt added to meet the animal's sodium requirement.

Sodium and Chloride Toxicity

Sodium toxicity and chloride toxicity can occur separately. This is generally due to the effects these ions can have on acid-base physiology because, when fed separately, they can greatly affect the strong ion difference of the blood. However, when fed as sodium chloride the effects on acid-base physiology are negligible. Animals tolerate high levels of salt so long as they have free access to water to allow renal excretion of the salt. Salt will generally depress feed intake before the cow can ingest a toxic amount of salt. For most classes of cattle, voluntary intake of salt is up to 1.5 g salt/kg body weight per day. This amount of salt can be added to grain mixes to limit intake of grain/trace mineral/vitamin mixes fed ad libitum to animals at pasture.

Salt intoxication occurs in two phases. During the first phase, ingested Na and Cl are rapidly absorbed, causing a rapid rise in blood sodium and chloride concentrations, especially if water is restricted and prevents renal excretion of sodium. When plasma Na exceeds 160 mEq/L, water begins to move from the CSF into the plasma. If severe enough, intracellular water will be drawn from the cells in the brain causing cellular dehydration and brain shrinkage. As the brain shrinks away from the calvaria, the blood supply to brain cells can be disrupted, causing hemorrhage and thrombosis. If neuron dehydration is severe enough, convulsions and death follow. If not severe enough to kill the animal, a second phase of salt intoxication may occur over the next few days. In order to compensate for dehydration during systemic hypernatremia, brain cells try to increase the osmolarity of their intracellular spaces. This can only be partly accomplished by neuron uptake of sodium, chloride, and potassium from the CSF. However, the brain cells mostly rely on accumulation of organic osmoles such as taurine, glutamate, glutamine, and phosphocreatine within their intracellular fluids. If the hypernatremia is rapidly corrected, as might occur if water is suddenly offered to an animal that had limited access to water for a prolonged period, the osmolarity of the extracellular fluids would fall below that of the brain cell intracellular fluids. Water would tend to move across the blood-brain barrier and into the brain cells, causing them to swell. This occurs because the brain cells cannot remove the organic osmoles from the intracellular spaces as quickly as the kidneys (on ingestion of water) can correct extracellular sodium and chloride concentrations. Because the bones encasing the brain cannot expand to accommodate the edematous cells, pressure builds on the brain cells and causes necrosis of brain cells. This can cause convulsions and death. In veterinary medicine it is more common for animals to be observed in this second phase of salt intoxication. This syndrome is occasionally referred to as "water intoxication," as the rapid restoration of normal blood osmolarity by water ingestion is often the factor precipitating clinical symptoms. Correction of severe salt toxicity or water deprivation should therefore occur over a period of 2 to 3 days so that the brain's adaptive mechanisms to prevent cellular dehydration and cerebral edema are not overwhelmed.

Potassium

Extracellular K concentration is normally 3.9 to 5.8 mmol/L and plays a vital role in osmotic equilibrium, resting membrane potential, and maintenance of acid-base balance. Intracellular K concentration is 150 to 160 mmol/L. Intracellular K is a cofactor of enzymes involved in protein synthesis and carbohydrate metabolism, and K plays a major role in intracellular osmotic and acid-base equilibrium. The ratio of

VetBooks.ir

intracellular–to–extracellular fluid K concentration is the main determinant of resting cell membrane potentials. Maintenance of normal blood K concentration requires a complex balancing act between K absorption from the diet and K removal from the blood.

Hypokalemia hyperpolarizes cells, causing resting membrane potential to be even more negative (–100 mv, inside negative, rather than the normal –90 mv), making it more difficult to reach the threshold for initiation of action potentials in nerve and muscle cells, resulting in paresis. If an action potential is successfully propagated down a motor nerve, hypokalemia, because it hyperpolarizes the resting cell membrane, will reduce the amount of acetylcholine released by the nerve ending at the motor end plate. This reduces the number of muscle fibers likely to contract, causing muscle weakness.

Moderate hypokalemia (plasma K from 2.5 to 4 mM) is often due to prolonged inappetance, often secondary to other illnesses. Ketosis is commonly the factor precipitating the inappetance. Treatment of animals with steroids that have some mineralocorticoid activity has been shown to cause K concentration to fall low enough (below 2 mM) to cause muscle weakness and recumbency, causing the hypokalemic downer cow syndrome.

Hyperkalemia is most commonly encountered in ruminants secondary to the acidosis accompanying rumen lactic acidosis, ketosis, diarrhea, renal failure, and saliva loss during heat stress. Hyperkalemia initially reduces the K concentration gradient across cell membranes, making the resting membrane potential less negative (–70 rather than the normal –90 mv). Although this makes it somewhat easier to reach threshold potential, the depolarized cells have a lower ability to open Na channels at the start of the action potential. This decrease slows the inward sodium current, particularly in cardiac muscle. The slow entry of Na into the cell early in the action potential prolongs myocardial membrane depolarization and slows impulse conduction through the myocardium; as a result, an electrocardiogram reveals a prolonged QRS duration. Hyperkalemia can have drastic effects on cardiac function. Initial bradycardia due to depolarized cardiac muscle is followed by premature ventricular contractions due to failure of cardiac conduction giving rise to ectopic initiation of ventricular contraction. Finally, the heart stops in diastole.

Potassium Homeostasis

Cattle ordinarily consume diets that contain more than enough K to meet their tissue requirements. Because more than 90% of dietary K is absorbed across the intestinal tract, preventing an excessive increase in plasma K is a daily reality. The kidneys are expected to excrete any excess absorbed K. Renal K excretion is controlled by aldosterone, which enhances renal secretion of K in exchange for Na ions. High blood K concentration (hyperkalemia) can directly stimulate secretion of aldosterone by the adrenal glands. However, low plasma Na and low plasma volume are more potent triggers for aldosterone secretion. Because low plasma volume is the most potent stimulant of aldosterone secretion, it is possible to have scenarios where hypokalemia develops secondary to low plasma Na and low plasma volume. Aldosterone can also increase gastrointestinal secretion of K within saliva and pancreatic secretions, which can aid the kidneys in preventing hyperkalemia. It is important to point out that dietary K can enter the extracellular fluids rapidly following a meal, while the kidney will take several hours to excrete the excess K. Another mechanism is needed to prevent hyperkalemia following a meal. This mechanism involves shifting K from extracellular to intracellular fluids. Intracellular uptake of K is mediated primarily by insulin secreted in response to elevated plasma K concentration (and also in response to hyperglycemia or a rise in blood propionate). Insulin increases the activity of the Na-K ATPase pump, particularly in the liver and skeletal muscle, increasing uptake of K by these tissues. Ketosis can cause hypokalemia as a result of inappetance. And treatment of ketosis with intravenous glucose or oral gluconeogenic precursors, such as propylene glycol, will temporarily cause hypokalemia. These treatments cause a surge in blood insulin concentration, and the insulin will drive extracellular K into intracellular compartments.

β_2-adrenergic catecholamines (i.e., epinephrine) can also drive K intracellularly. Epinephrine probably protects the animal from hyperkalemia during and following exercise. During exercise, K is lost from muscle during excitation-contraction of muscle. Stimulation of β_2-catecholamine receptors stimulates Na-K ATPase to reduce extracellular K by driving K into muscle and liver.

Another confounding problem in understanding K metabolism is its subservient relationship with acid-base balance. Because disturbances in acid-base balance are debilitating or lethal, the maintenance of a stable pH of the extracellular fluids is of paramount importance. K can move between extracellular and intracellular fluid compartments. Movement of K from the extracellular fluids to the intracellular compartment reduces the strong ion difference of the blood, making the blood less alkaline (fewer H^+). This is a compensatory mechanism that allows the animal to cope with alkalosis. Conversely, K leaves the intracellular fluids and enters the extracellular fluids during acidosis as a means of increasing the cation content of blood to raise the pH. (Some texts refer to this as K^+-H^+ exchange to move hydrogen ions in or out of cells.)

Blood K concentrations must be interpreted cautiously. Normal blood K concentration may not indicate normal intracellular stores of K, and abnormal blood K concentration does not necessarily indicate abnormal store or concentration of K inside cells.

Because dietary K is usually more than adequate, there is not an elaborate mechanism developed to avoid hypokalemia. Under most conditions hypokalemia is corrected by simply reducing aldosterone secretion. So long as the cow is eating, hypokalemia is generally easily avoided. However, if the cow is not eating, hypokalemia could quickly ensue, as illustrated by examining K balance in the cow.

K Balance in the Cow

In a 600-kg cow there will be approximately 1150 g K within the cells of the body and about 23 g K in all the extracellular fluids, with about 7.5 g K in the plasma pool. The maintenance requirement for K is the sum of the endogenous urinary K loss (amount of K lost in urine when cows are on a K-deficient diet, which is about 0.038 g K/kg body weight) plus endogenous fecal losses (≈6.1 g K is lost/kg DM ingested). Milk contains approximately 1.5 g K/kg, and fetal development in late gestation requires about 1 g K/day.[12]

If this cow is in early lactation and ingesting 14 kg DM/day, her maintenance requirement is about 108 g K/day. If her diet is 1.5% K, she is ingesting approximately 210 g K/day and about 189 g K is absorbed. If she is producing 15 kg milk the first day of lactation, she will use 22.5 g K for milk production. Of the 189 g K entering her body, 108 g K is used for maintenance and 22.5 g K is used for milk. This leaves 58.5 g excess K to be excreted in the urine if she is to avoid hyperkalemia.

If this cow suddenly goes off feed due to some secondary illness, K balance calculations would suggest this cow would rapidly go into negative K balance. Milk production would continue to withdraw 22.5 g K/day and the obligatory urinary K loss would be about 22 g/day for a net loss of 44.5 g K. There is some lag time between the cessation of aldosterone secretion and the cessation of K secretion by the kidneys, so the urinary loss may initially be higher than the obligatory K loss in urine. Considering that there is only about 23 g K in all the extracellular fluids, the cow could develop hypokalemia.

VetBooks.ir

However, simply fasting a cow does not constitute enough of a challenge to K metabolism to cause the severe hypokalemia associated with downer cow syndrome. Holstein nonpregnant, nonlactating cows fasted for 48 hours had a decline in plasma K from 4.9 to 4.3 mmol/L. Plasma K of beef steers fasted for up to 4 days decreased from 4.1 to 3.7 mmol/L. A greater decline in blood K due to fasting is prevented by K entering the plasma pool from muscle. Hypokalemia alone can trigger a reduction in Na-K ATPase activity in muscle, leaving more K in extracellular fluids. However, reducing pump activity does not allow the muscle to replace K that chronically leaks from the muscle cell, especially during excitation of the muscle. Intracellular K concentration eventually falls, and intracellular Na concentration increases. This response is unique to muscle. Liver and other tissue intracellular K concentration does not decrease during hypokalemia.

During prolonged fasting, muscle is broken down and the muscle protein is converted to glucose. The K within the muscle cell is released during the gradual process of muscle breakdown that occurs with fasting. During the first weeks of lactation most dairy cows are in negative protein balance and, therefore, using large amounts of muscle protein to sustain milk production.

Reduced intracellular K concentration causes a loss of muscle strength. The loss of intracellular K diminishes the amount of Ca released from the sarcoplasmic reticulum during muscle activation and, as a result, the interaction between actin and myosin to cause muscle contraction is diminished. K ions must be bound to the Ca channel proteins within the sarcoplasmic reticulum if optimal Ca is to be released into the muscle cell cytosol following depolarization of the muscle cell membrane.

Hypokalemia and "Downer Cows"

K stored in muscle will generally prevent severe hypokalemia, if the animal is only off feed for a few days (before muscle is severely depleted of K). In most reports concerning clinical cases of hypokalemia and recumbency in cows, the plasma K concentration is less than 2.5 mmol/L. In many of the affected cows, plasma K concentration is less than 1.8 mmol/L. The degree of hypokalemia observed simply from inappetance of just 4 to 5 days is unlikely to be severe enough to cause flaccid paralysis in the cow. Though inappetance greatly reduces the amount of K entering extracellular pools, it seems other factors must be causing depletion of extracellular and intracellular K associated with the hypokalemic downer cow.

The possibilities causing low plasma K include exaggerated renal excretion of K and excessive uptake of K by cells. The possibilities causing intracellular K depletion include prolonged fasting and exaggerated renal excretion of K.

Factors Affecting Renal K Secretion

Excessive aldosterone secretion by the adrenal gland is relatively rare in cattle. However, drugs with glucocorticoid activity are often administered to cattle in early lactation as anti-inflammatory agents or to stimulate gluconeogenesis in cows exhibiting ketosis. If those drugs also have mineralocorticoid activity, they will stimulate urinary K secretion. In the inappetant cow the muscles are releasing K to support normal blood K concentrations. If this K is being rapidly excreted by the kidney, the muscle K pool will be quickly depleted and severe hypokalemia can ensue. Isoflupredone acetate is sometimes administered to ketotic cows for its glucocorticoid activity, but it has enough mineralocorticoid activity to enhance renal K secretion. It should only be administered one time. Most hypokalemic downer cows had a history of being repeatedly injected with isoflupredone acetate over 2 to 3 days before the onset of recumbency.

Administration of diuretics, given primarily to treat udder edema, increases K excretion in the urine. Acetazolamide and the thiazide diuretics cause a large increase in urinary K loss. Furosemide, the diuretic most commonly used in cattle, increases K loss only moderately. Penicillin, aminoglycoside antibiotics, and gossypol (from cottonseed) also increase urinary K excretion to a minor extent. Though administration of diuretics and antibiotics have not been linked to hypokalemia and the downer cow syndrome in cattle, they have been implicated as the cause of cases of severe hypokalemia in man and companion animals.

FACTORS INCREASING TRANSFER OF K FROM EXTRACELLULAR TO INTRACELLULAR POOLS. Insulin causes a rapid uptake of K by muscle and liver. Administration of exogenous insulin was considered a factor contributing to hypokalemia in several cows developing severe hypokalemia. Endogenous insulin release occurring after intravenous administration of glucose or oral administration of glucose precursors such as glycerol, propionate, and propylene glycol will also shuttle K from extracellular to intracellular pools, but the effect is unlikely to be as long lived as with exogenous insulin.

β_2-adrenergic stimulation will also drive K into muscle. Stress can elicit catecholamine release in cattle. Is stress of ketosis in early lactation a precipitating factor for hypokalemia? It does not seem likely since release of epinephrine or norepinephrine is not a major feature of ketosis in cows, as it is in humans. Fever may constitute a stressor that can elicit catecholamine release. A number of the cows described with the hypokalemic downer cow syndrome did exhibit a fever during the course of the disorder.

Systemic alkalosis will cause K to leave the extracellular fluids and could be a cause of hypokalemia. Hypochloremia, with or without alkalosis, is a common feature of the cases described by Peek and colleagues[13]. Metabolic alkalosis may have precipitated the hypokalemia, but because hypochloremia is a consistent observation in affected cows, it seems more likely that gastrointestinal ileus in the animals with severe hypokalemia caused sequestration of Cl within the abomasum. This alone will cause a metabolic alkalosis and acts to drive even more K intracellularly.

TREATMENT OF HYPOKALEMIC COW. Simply restoring plasma K is not enough. A true cure also requires restoring intracellular stores of K to optimize muscle function. Intravenous treatment is necessarily slow (to avoid hyperkalemia and heart stoppage) and should be limited to 0.5 mEq/kg/h. Oral therapy with KCl has proven a more effective therapy as enough K can be delivered to replace intracellular and extracellular K. It is also less expensive. Oral treatment consists of the administration of KCl at 100 to 150 g/dose given twice daily in several gallons of water for several days. Concomitant treatment with oral glucose precursors or intravenous dextrose to cause an insulin surge can help drive the absorbed K into the cells and will help treat the underlying ketosis present in most affected cows.[14]

If dehydration is present, plasma volume needs to be corrected first. Dehydration will cause aldosterone secretion, and much of the K absorbed across the intestine will be excreted in the urine without restoring intracellular pools. Rehydration with solutions that also provide Na will also help the cow restore normal acid-base balance.

SUBCLINICAL HYPOKALEMIA. Severe hypokalemia resulting in the down cow is a relatively rare phenomena, especially now that the role of repeated administration of steroids with mineralocorticoid activity is widely recognized and largely discontinued. Although intracellular stores of K have not been measured in affected cows, the course of the disease and poor response to intravenous K therapy alone suggest muscle depletion of K is a primary component of the disorder.

VetBooks.ir

Moderate hypokalemia does not cause the flaccid paralysis associated with the hypokalemic downer cow syndrome. Moderate hypokalemia (2.2 to 3.9 mEq/L) is common in anorexic cattle, and severe hypokalemia is prevented by the release of K from intracellular stores in muscle.

If severe depletion of muscle K causes severe loss of muscle function and down cows, does moderate loss of K from muscle cause sluggish behavior in cows? Metabolism of K in cows is poorly researched because most diets provide more than ample supplies of K to the cow. However, the fresh cow is often faced with metabolic or infectious disease challenges that cause various degrees of anorexia. Would aggressive treatment of anorexic cows with oral KCl allow better muscle function in these cows, giving them the strength to fight for space at feed bunks, and restore them to productivity sooner?

Sulfur

Ruminants require sulfur and sulfate (SO_4^{-2}) to be in the diet to allow rumen bacteria to produce the sulfur containing amino acids, cysteine and methionine, and the B vitamins, thiamine and biotin, that the bacteria need to survive. The cow can make use of these bacterial amino acids and vitamins during digestion of the microbes once they exit the rumen. As a general rule, diets that are 0.20% to 0.23% S will satisfy the requirements of rumen bacteria. Diets consisting primarily of corn silage and corn grain risk S insufficiency. Organic sulfur in the form of the essential amino acid methionine and the B-vitamins is required by all animals. Sulfur and sulfate released during metabolism of sulfur containing amino acids can be used to produce compounds such as chondroitin sulfate and glutathione.

Of greater concern is the risk of S toxicity. In ruminants, S toxicosis presents as rapidly developing central nervous system symptoms, such as ataxia, blindness, and seizures, often followed by death. Brain lesions are most commonly described as polioencephalomalacia—swelling of the cerebrum, evidenced by flattened gyri and shallow sulci. The cerebral cortex may be thinned. The distribution is symmetric. Histologic section reveals a pale layer near the junction of the gray and white matter. The affected areas of the cortex will fluoresce under ultraviolet light.

Pathophysiology of S Toxicity in Ruminants

Some rumen microbes, particularly those found in cattle consuming high-concentrate diets, convert dietary sulfur to sulfide and sulfur dioxide, which can be reduced to hydrogen sulfide gas within the rumen. The hydrogen sulfide gas does not cross the rumen wall and enter the blood and would be relatively harmless if it stayed in the rumen. However, during the eructation process ruminants normally inhale a portion of the rumen gases into the lung. Hydrogen sulfide is absorbed across the lungs during eructation and causes symptoms of central nervous system disruption in the sheep. Hydrogen sulfide is a potent inhibitor of cytochrome C oxidase vital to mitochondrial respiration, and because the brain has a high energy requirement, hydrogen sulfide toxicity is associated with symptoms of central nervous system failure and brain lesions.

There is evidence that sulfur dioxide gas generated in the rumen can cleave thiamine to cause thiamine deficiency in the ruminant, leading to cerebrocortical necrosis. However, the lesions of polioencephalomalacia commonly described during sulfur intoxication of ruminants are similar, but not identical, to the cerebrocortical necrosis associated with thiamine deficiency. Further, most cases of polioencephalomalacia attributed to sulfur intoxication are not accompanied by decreased blood thiamine concentrations and do not respond to thiamine injection.[15]

Most reports of polioencephalomalacia are made in beef cattle or lambs on high-concentrate diets (90% grain) that exceed 0.4% S. Dairy cows, typically fed diets that are at least 40% forage, are rarely reported to suffer from polioencephalomalacia, despite the fact that addition of sulfate (in the form of anionic salts) to bring diet sulfur to 0.5% is commonly practiced as a means of reducing DCAD to control milk fever. Increased use of corn distiller's grains has increased diet S intake, particularly in feedlot cattle. Sulfuric acid is commonly added to the distiller's grains during processing to control pH of the fermentation, and it is used in cleaning the fermentation system. Distiller's grains can be 0.6% to 0.8% S.

Water coming from wells can often contain high concentrations of sulfur, usually in the form of sulfate. Water quality reports typically express sulfur content of water in units of sulfate/L. Concentrations as high as 5000 mg sulfate/L are not uncommon. The maximal safe concentration of sulfate in water is 2500 mg sulfate (or 834 mg sulfur)/L (0.08% S).

Other Possible Problems Associated With S

Many sulfur-containing compounds can be injurious to animals when ingested over the short or long term. Brassica plants (kale, cabbage, turnip, swedes) are included as a major part of the ration of ruminants in some parts of the world. These plants contain isothiocyanates that interfere with thyroperoxidase action in the thyroid gland, inhibiting thyroxine production and thus leading to hypothyroidism and goiter. Diet S can also interfere with bioavailability of diet trace minerals.

Bone Disease Associated With Ca, P, or Vitamin D Insufficiencies/Excess

Bone ash content varies somewhat with the bone examined but is generally 57% to 62% of bone dry weight. The ash will be 36% to 39% Ca, 16% to 18% P, and 5% to 7% Mg in adult animals. Ca and phosphate ions come together in a ratio of 10 Ca ions to 6 phosphate ions at the point of mineralization of the bone cartilage or osteoid matrix. Failure to supply adequate Ca, P, or vitamin D will prevent bone from mineralizing properly during bone growth in young animals and during remodeling of adult bone.

Growth Plates Allow Bones to Lengthen

Bone grows in length and width in young animals. Bone lengthens at the bone growth plates or physeal plates. A growth plate is a transverse disk of hyaline cartilage between the epiphysis and diaphysis. Chondrocytes within the growth plate become arranged into columns that run parallel to the length of the bone. The columns of chondrocytes are separated by longitudinal bars of hyaline cartilage matrix. Cells within each column are directly related to each other as they are the result of mitotic division within that column. Those chondrocytes within the growth plate that are the farthest from the diaphysis make up the zone of proliferation, where cells are rapidly dividing and extending the cartilage away from the diaphysis. The next visible stage within the growth plate is the zone of maturation or zone of hypertrophy. Here the chondrocytes have stopped dividing and have become enlarged. Glycogen accumulates within the cells, and their cytoplasm becomes highly vacuolated. The lacunae surrounding these chondrocytes expands, and only thin strands of cartilage matrix separate adjacent lacunae. Next, these small strands of remaining cartilaginous matrix begin to accumulate calcium phosphate deposits. This appears to be initiated by factors, such as type X collagen, produced by the hypertrophied cartilage cells. The actual process by which bone or cartilage matrix becomes mineralized is poorly understood. Some liken it to a solution that is supersaturated with calcium and phosphorus to which addition of a foreign substance initiates crystallization. In the case of bone the

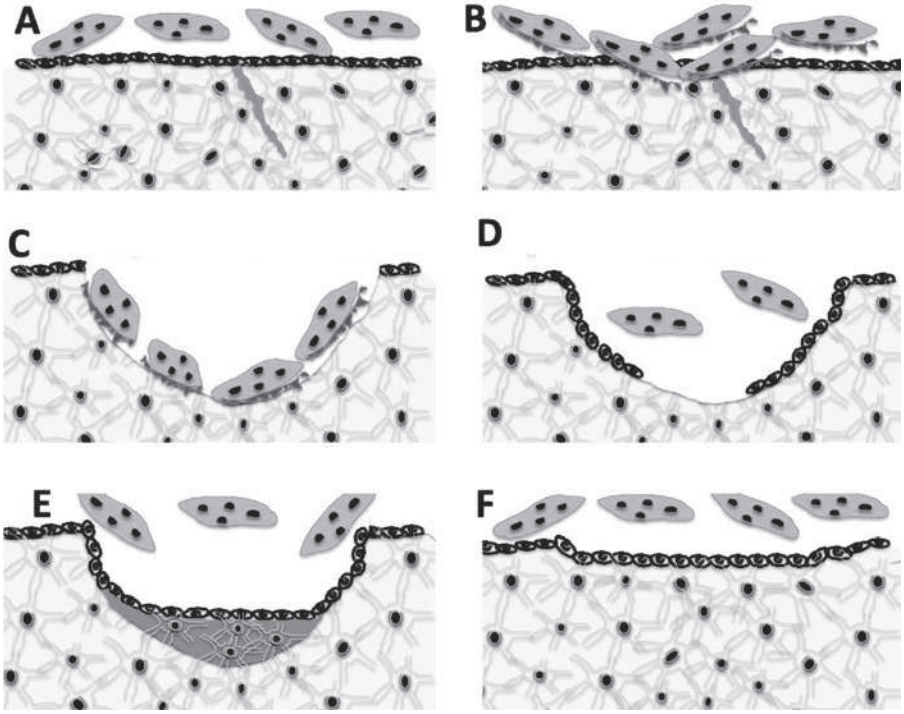

FIG. 41.23 Steps in trabecular bone remodeling. (A) Small area of bone with a microfracture destined for remodeling. Osteocytes in bone are connected to each other and to osteoblasts at endosteal surface by canaliculi. Inactive multinucleated osteoclasts rest outside the endosteum. **(B)** Activation. Osteoblasts retract from area of microfracture, and osteoclasts move into the area and develop a ruffled border. **(C)** Resorption of bone. Osteoclasts remove a shallow bowl approximately 50 μ deep into the trabecular bone. **(D)** Reversal. Osteoclasts move out of resorption lacunae, and osteoblasts move into lacunae from endosteum. **(E)** Bone matrix formation. Osteoblasts lay down unmineralized bone matrix. **(F)** Bone matrix mineralization nears completion. If blood Ca and phosphate are adequate, these minerals crystallize on γ-carboxylated glutamic acid sites of matrix proteins forming new bone to replace all the resorbed bone.

collagen fibers (or collagen in combination with glycoproteins or chondroitin sulfate) act as a nucleation catalyst, which transforms calcium and phosphate in solution in the tissue fluids into a solid mineral deposited on the collagen fibers. As the cartilage surrounding them calcifies, the hypertrophied chondrocytes undergo apoptosis or programmed cell death.

Finally, at the diaphyseal side of the growth plate, blood vessels invade the dead chondrocytes and calcified cartilage matrix and osteoprogenitor cells from the marrow spaces are brought into the calcified cartilage. As the lacunae are invaded, osteoblasts differentiate from the osteoprogenitor cells and form along the irregularly shaped bars of calcified cartilage that had once separated the columns of chondrocytes. A thin layer of bone matrix is deposited on the surface of the calcified cartilage. If conditions are favorable (adequate dietary calcium, phosphorus, and vitamin D), the new bone matrix quickly calcifies. This primary spongy bone area is often referred to as the metaphysis. As the growth process finishes, osteoclasts move into the metaphysis to reorganize and remodel the primary spongiosa to form true bone. Thus the rapidly dividing cells of the zone of proliferation continually advance the growth plate away from the diaphysis while osteoclasts and osteoblasts continually convert primary spongiosa to true bone at the diaphyseal side of the growth plate.

Bone Remodeling

Remodeling is necessary in large, long-lived animals to replace bone that is fatigued and accumulating microfractures. If bone remodeling came to a halt, the microfractures that accumulate would cause mechanical failure of the skeleton in about 2 years. Bone remodeling also serves another important function. It allows the skeleton to act as a repository of minerals by allowing transfer of calcium, phosphate, and other ions in and out of bone as needed to maintain electrolyte and acid/base balance. The hormones involved in calcium and phosphate homeostasis can greatly influence the rate and extent of bone remodeling. For example, PTH increases the number of bone sites undergoing remodeling.

Only tiny units of bone undergo remodeling at any one time. While bone remodeling in compact or cortical bone differs from that in trabecular bone, the same distinct steps—activation, resorption, reversal, and formation—occur during remodeling at both sites (Fig. 41.23).

1. **Activation.** This process converts a resting or inactive bone surface into a surface to be remodeled. How a particular section of bone is chosen for remodeling is not clear. The presence of microfractures in an area is one factor that marks an area for remodeling. This "selective" remodeling appears to be directed by a signal coming from the bone. When collagen fibrils are oriented correctly, there is a very minute electrical charge oriented along the fibrils. Microfractures upset the piezoelectric charge of that portion of bone and may initiate remodeling of that piece of bone. Deterioration of bone could also elicit secretion of autocrine or paracrine factors to initiate activation of bone remodeling. During activation, the bone lining osteoblasts retracts and shrinks in the area of bone to be remodeled, exposing the bone matrix. Multinucleated osteoclasts move onto this site, and a tight bond is formed between bone matrix and the osteoclasts. Endocrine factors such as PTH can increase the rate at which bone is remodeled, though this can sometimes lead to pathology as described later.
2. **Resorption.** The osteoclasts release acids and proteolytic enzymes from their ruffled border onto the bone surface, dissolving the organic matrix of the bone. The mineral crystals are dissolved, and the minerals along with the breakdown products of the organic matrix enter the osteoclast

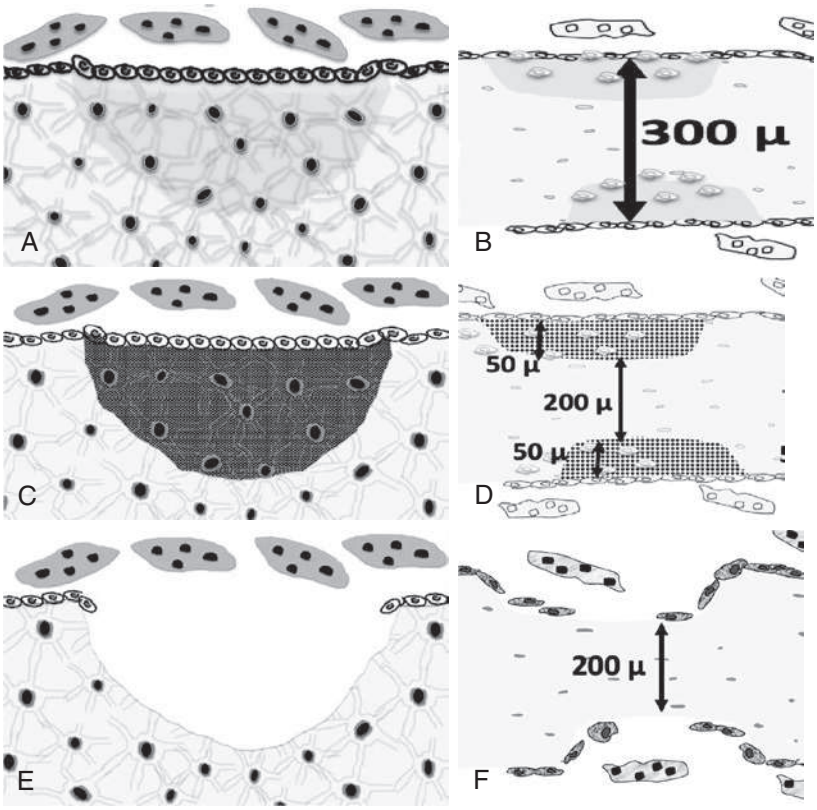

FIG. 41.24 Mineral-related problems during bone remodeling. (A) During normal bone remodeling, the bone removed from the Howship's lacunae is completely replaced by newly formed bone. **(B)** A spicule of bone with remodeling sites on either side of the bone. The normal bone width and density of a spicule of bone will be the same before and after remodeling—in this case approximately 200 µ thick. **(C)** If the cow has not received adequate dietary phosphorus or is vitamin D deficient, the matrix is produced by the osteoblasts but fails to mineralize. **(D)** The remodeled area on each side of thespicule of bone area has 50 µ of rubbery matrix in each lacunae, resulting in osteomalacia, which allows bone to bend too easily. **(E)** If the cow receives too little dietary Ca or is in early lactation, the formation of new bone is uncoupled from the resorptive phase of bone remodeling. Neither bone matrix nor mineral is replaced. **(F)** The remodeled areas on each side of thespicule of bone area have not been replaced. This leads to a net loss of 50 µ of bone from each remodeling site, causing osteoporosis.

by diffusion or specific transport processes. They are then extruded into the extracellular fluid on the opposite side of the osteoclast.

The bulk of the bone resorbed to support Ca metabolism is trabecular bone. In trabecular bone the osteoclasts resorb bone until they have formed a saucer-shaped depression in the bone that is around 50 µ in depth at its center and 200 to 300 µ in diameter. In cortical or compact bone the osteoclasts drill out a cone-shaped section of bone to create a 200 µ–diameter tunnel of varying depth (10 to 100 µ). At this point the osteoclasts quit their bone resorbing activity and leave.

3. **Reversal Phase.** This phase signals the start of the rebuilding of bone within the resorption hollow, known as a Howship's lacunae. Osteoblasts move from the bone surface down into the depths of the Howship's lacunae. Several growth factors such as insulin-like growth factor (IGF)-II and transforming growth factor–β are thought to cause osteoblasts to migrate into the Howship's lacunae to begin to replace the bone. Many other substances, including interleukin-1, platelet-derived growth factor, and IGF-I (somatomedin) are also considered candidates capable of initiating the reversal phase of remodeling.
4. **Formation.** Bone matrix formation begins with deposition of osteoid by the osteoblasts. This organic matrix consists primarily of type I collagen, proteoglycans, and smaller proteins typical of mature adult bone. In trabecular bone, the osteoid is laid down in discrete layers or lamellae about 3 mm thick with all the collagen fibrils within each lamellae oriented parallel to each other. In cortical bone the tunnel hollowed out by the osteoclasts is filled in from the outer circumference toward the center until only a small central canal containing blood vessels is left open. The collagen fibrils within different lamellae are oriented at an angle to the layer above or below, giving the bone added strength, an idea also used when lumber mills produce plywood.

Mineralization of the organic matrix is the final step in bone formation. It occurs after a time delay, which is about 20 days in man. Once triggered, the mineralization process is rather rapid. During the first few days of the process nearly three quarters of the total bone calcium will be deposited with the final 25% mineralization being completed months later. The total time for osteoblasts to complete the formation phase in a single Howship's lacunae approximates 150 days (Fig. 41.24, *A* and *B*).

RICKETS. Rickets is a disease of young, growing animals in which the cartilaginous matrix at the growth plate fails to mineralize. The bones fail to grow in length, leading to short stature. The physes themselves are wide with irregular borders making joints enlarged. Rickets is a disorder of growing animals in which the newly formed osteoid and cartilage septa within the growth plate fail to mineralize. This is most often associated with vitamin D or dietary phosphorus deficiency. Rachitic animals will be hypophosphatemic and often hypocalcemic as well. Blood phosphorus concentration in young animals is generally higher than in adult animals—a reflection of their greater requirement for phosphorus to support mineralization

VetBooks.ir

of new growing bone. When blood phosphate concentration falls below the level required to support mineralization of the cartilage and primary spongiosa, the growth plate does not mineralize. Chondrocytes within the zone of proliferation continue to elongate the cartilage model in the growth plate. Vitamin D deficiency can reduce secretion of type X collagen by the chondrocytes within the growth plate, and this may prevent the programmed cell death of chondrocytes within the zone of provisional calcification. Since the cartilage does not calcify, blood vessels cannot move into the area to begin ossification and the physis elongates. The physis is more flexible and rubbery and gives the ends of bones an enlarged look, especially evident at the growth plates within the ribs.

Osteomalacia

During bone remodeling in adult animals, vitamin D or phosphorus deficiency causes blood phosphate concentration to fall below the level needed to mineralize newly formed bone matrix during the remodeling process. Nearly all steps in bone remodeling occur except for mineralization of the newly formed matrix. When vitamin D deficiency is the cause, the animals will be hypocalcemic as well. Serum concentration of 25-hydroxyvitamin D will be below 10 ng/mL (25 nM). The lack of phosphorus prevents mineralization but does not prevent normal bone matrix secretion by the osteoblasts (see Fig. 41.24, *C* and *D*). Pathologic changes occur much more slowly than in rickets. Over a prolonged period the bones become excessively flexible, leading to extensive joint pain in these animals. Rachitic bone and osteomalacic bone will have less bone ash per unit of bone volume or bone density. The ash will have below normal % P and % Ca content.

Osteoporosis Due to Dietary Ca Insufficiency

Animals that are in a prolonged state of negative Ca balance develop osteoporosis. This bone disease can be observed whenever diet Ca is inadequate, while diet P and vitamin D are adequate. Low plasma Ca concentrations (arising from dietary Ca deficiency) can cause elevated secretion of PTH. The PTH causes increased activation of bone remodeling and increased bone resorption—there will be many more Howship's lacunae formed in the bone. However, the prolonged secretion of high amounts of PTH prevents the reversal and bone formation steps of bone remodeling. Bone resorption and bone formation are no longer coupled as they are during normal bone remodeling. The result is bone that has many sites where osteoclasts have carved-out areas in the bone, giving it a moth-eaten appearance (Fig. 41.24, *E* and *F*). Bone density and ash content are greatly reduced, but the % Ca and % P in the ash are not greatly affected. The Ca content per unit of bone volume is greatly diminished. The bone does not bend as it does in rickets or osteomalacia. Instead, it becomes more brittle and is prone to fracture. Once diet Ca becomes adequate again, younger animals can restore the bone over time through renewed remodeling. Older cows may not live long enough to remodel all the sites damaged during prolonged dietary Ca deficiency.

Lactational Osteoporosis

During lactation, in virtually all species, there is an obligatory loss of bone mass from the skeleton as a result of uncoupling of bone formation from bone resorption. In this case the osteoclasts within an area of bone being remodeled resorb bone, to the normal 50-micron depth if diet Ca is adequate, or to even greater depths if the animal is also in severe negative Ca balance. However, osteoblast movement into the resorption cavity to replace resorbed bone is temporarily put on hold and no new bone is deposited. This occurs to some extent in all female mammals shortly after parturition, even when they are in positive Ca balance. However, the degree and duration of lactational osteoporosis can be magnified greatly by negative Ca balance. Once the animal has undergone the obligatory period of lactational osteoporotic bone loss (4 to 5 weeks in the cow), and if the animal is in positive Ca balance, the osteoblasts now come back into the resorption cavity and replace the lost bone. Lactational osteoporosis can help the female meet the Ca demands of lactation by uncoupling bone formation from bone resorption. In high-producing dairy cows, dietary Ca intake is generally inadequate to meet lactational Ca demands the first 4 to 6 weeks of lactation. The cow can lose as much as 13% of her skeletal mass during this period. The bone is replaced in later lactation when diet Ca intake allows the cow to enter a period of positive Ca balance.

Nutritional Secondary Hyperparathyroidism

A deficiency of dietary Ca or diets that are excessively high in phosphate can reduce the amount of Ca that can be absorbed across the intestine into the extracellular fluids. Diets severely deficient in Ca will not supply adequate Ca to replenish Ca lost from extracellular pools. As a result, blood Ca concentration decreases and PTH secretion increases. PTH causes the kidney to reduce urinary Ca loss and increase synthesis of 1,25-dihydroxyvitamin D. But if diet Ca is too low, increasing the efficiency of intestinal Ca absorption with 1,25-dihydroxyvitamin D cannot substantially increase the amount of Ca entering the extracellular pool of Ca. In addition, a high P diet raises blood phosphate concentration, stimulating bone osteocytes to produce FGF23. The FGF23 circulates to the kidney and blocks the 1α-hydroxylase enzyme responsible for producing 1,25-dihydroxyvitamin D. This also acts to block intestinal Ca transport. The only action of PTH that can improve blood Ca concentration under these situations is to stimulate bone Ca resorption by activating more sites of bone resorption. The high PTH, high P, high FGF23, and low 1,25-dihydroxyvitamin D content of blood causes the osteoblasts that move into the Howship's lacunae to produce a more fibrous matrix than is normally produced during the bone formation phase of bone remodeling. The continued removal of bone without mineralization of the fibrous matrix results in fibrous osteodystrophy. The clinical signs of nutritional secondary hyperparathyroidism include hypertrophy of the parathyroid glands and cessation of growth in young animals. In young animals, the lack of Ca available for mineralization of bone matrix causes the growth plates to be soft, weak, and swollen. The cortices of the long bones are thin, and minor or major fractures are common. In older animals the bone of the mandible and maxilla become very malleable and teeth become loose, lending the moniker of "rubber jaw" and "bighead disease" to fibrous osteodystrophy of the bone.

Renal Secondary Hyperparathyroidism

This syndrome is due to renal failure and is occasionally observed in older cows suffering from pyelonephritis. A major function of the kidneys in most species is to remove excess phosphate from the circulation. As renal function is lost, phosphate is retained and hyperphosphatemia develops.

Hyperphosphatemia reduces the ionized Ca content of the blood. This is because Ca and phosphate ions normally exist in blood at concentrations that are slightly below the levels that would cause saturation of the fluids. The greatly elevated phosphate in blood of renal failure patients can exceed the equilibrium of Ca and phosphate in solution, causing a reduction of Ca from the blood. Lower blood Ca concentration increases

PTH secretion. As phosphate builds up in the blood, it also stimulates bone osteocytes to produce the hormone FGF23, which blocks the activation of the 1α-hydroxylase that catalyzes conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D within the kidney.[10] Therefore, even though PTH should stimulate the remaining functional renal tissue to produce 1,25-dihydroxyvitamin D, this action of PTH is blocked by hyperphosphatemia.

As renal disease progresses, the amount of renal tissue available for production of 1,25-dyhydroxyvitamin D decreases, further compounding low blood concentrations of 1,25-dyhydroxyvitamin D. This reduces dietary Ca absorption and further depresses blood Ca concentration. This in turn stimulates increased PTH secretion and, resorbing bone Ca reserves, becomes the primary means of maintaining normocalcemia. Fibrous osteodystrophy follows the prolonged secretion of PTH when accompanied by elevated blood P and FGF23 levels.

As bone Ca is resorbed, more P is also resorbed. However, the loss of renal function prevents PTH from having its usual phosphaturic effect, exacerbating the hyperphosphatemia. A vicious cycle of higher blood P leading to increased PTH secretion and increased bone resorption ensues.

In principle, calcium deficiency differs from phosphorus deficiency in that normal osteoid is formed but fails to mineralize in phosphorus deficiency, while in calcium deficiency the normal osteoid is either not formed at all (osteoporosis if blood P and FGF23 are normal or low and blood 1,25-dihydroxyvitamin D is elevated) or replaced by fibrous tissue (fibrous osteodystrophy if blood P and FGF23 is high and 1,25-dihydroxyvitamin D is low). In adult vitamin D deficiency, it is common to see mixed lesions—areas of osteomalacia, osteoporosis, and fibrous osteodystrophy all in the same bone (Table 41.8).

Hyperketonemia in Dairy Cattle (Ketosis)

Jessica A.A. McArt • Daryl Nydam

Pathophysiology

Most dairy cows visit a state of energy deficit, often termed *negative energy balance* (NEB), as they transition from late gestation to early lactation. This imbalance in energy is the result of both an increase in energy requirements—more than twice as high when compared with prepartum levels[1]—and inadequate DMI. The increase in energy demand is due to lactogenesis, which is dependent on available glucose concentrations from gluconeogenesis in the liver.[2] Ruminal fermentation provides the majority of substrates for hepatic gluconeogenesis through production of volatile fatty acids (VFA), the most abundant of which are acetic acid, propionic acid, and butyric acid. Propionic acid is absorbed by the liver via portal circulation and serves as the primary metabolite for gluconeogenesis. Acetic acid is used mainly in the liver as a major source of acetyl CoA to generate ATP, and butyric acid is absorbed directly from the rumen as the ketone β-hydroxybutyrate (BHB), which can be used by multiple tissues for energy production. Several factors (e.g., nutrition, ionophore use, DMI) determine the amount and proportion of VFA produced, and when the cow's requirement for energy exceeds her productive capacity, NEB ensues. At the individual animal level, there are several metabolic adaptations to manage NEB, which include mobilization of nonesterified fatty acids (NEFA) from body fat reserves and glucose sparing for lactogenesis. However, some animals will experience excessive NEB, and it is this excess that is associated with negative downstream outcomes such as increased risk of disease development and decreases in both milk production and reproductive performance.[3-5] As some degree of NEB postpartum is physiologically normal, it is its depth, duration, and timing that influence the cow's health and performance. The metabolites NEFA and BHB are used as markers of NEB due to the relationship among energy demands, energy reserves, and the metabolic association between NEFA and BHB. Fig. 41.25 is a graphic representation of the association between these factors, which can result in excessive concentrations of BHB and the syndrome of hyperketonemia.

To adapt to this increase in energy demands, glycerol and NEFA are released from adipose tissue in response to hormonal cues, such as glucagon, corticosteroids, adrenocorticotropic hormone (ACTH), and catecholamines. Insulin is the only hormone that will act to inhibit lipolysis and therefore decrease the amount of NEFA released from adipose tissue. Early in the postpartum period, there is both a decrease in insulin production and perhaps a transient state of insulin resistance.[1] This spares glucose for lactogenesis by decreasing glucose utilization in insulin-sensitive tissues and allowing continued lipolysis even when insulin concentrations increase, though the mechanistic pathways in postpartum dairy cows remain complicated.[6]

TABLE 41.8

Diagnosing Acute and Chronic Macromineral Insufficiency or Imbalance in Ruminants

The tissue needed to ascertain acute problems is intended to guide diagnosis of the initial cause of recumbency in downer cows. All fluid concentrations are in mg/dL. "Subclinical" indicates no readily apparent outward signs of illness. "Clinical" will generally result in a "down" cow.

Mineral	Tissues to Use	Normal	Subclinical	Clinical
Ca (Acute)	Serum	8.0-10.5	5.5-7.5	<5.0
Ca (Chronic)	Serum	8.0-10.0	8.0-10.0	6.0-10.0
	Bone ash (% Ca)	37-39	35-37	<35
	Urine	>2.0	0.5-1.5	<0.1
P (Acute)	Serum	4-6	2-4	<1.0
P (Chronic)	Serum	4-6	3-4	<3.0
	Bone ash (% P)	17-20	15-17	<12
Mg (Acute)	Serum	2.0-2.3	1.3-1.7[a]	<1.1
	Vitreous humor	1.9-2.5	1.5-1.85	<1.5
	Urine	10-25	2-5	<0.5
	Cerebrospinal fluid	2-2.5	1.5-2.0	<0.5
Mg (Chronic)	Serum	2.0-2.3	1.6-1.8	<1.5

[a]These Mg levels are low enough to cause secondary hypocalcemia.

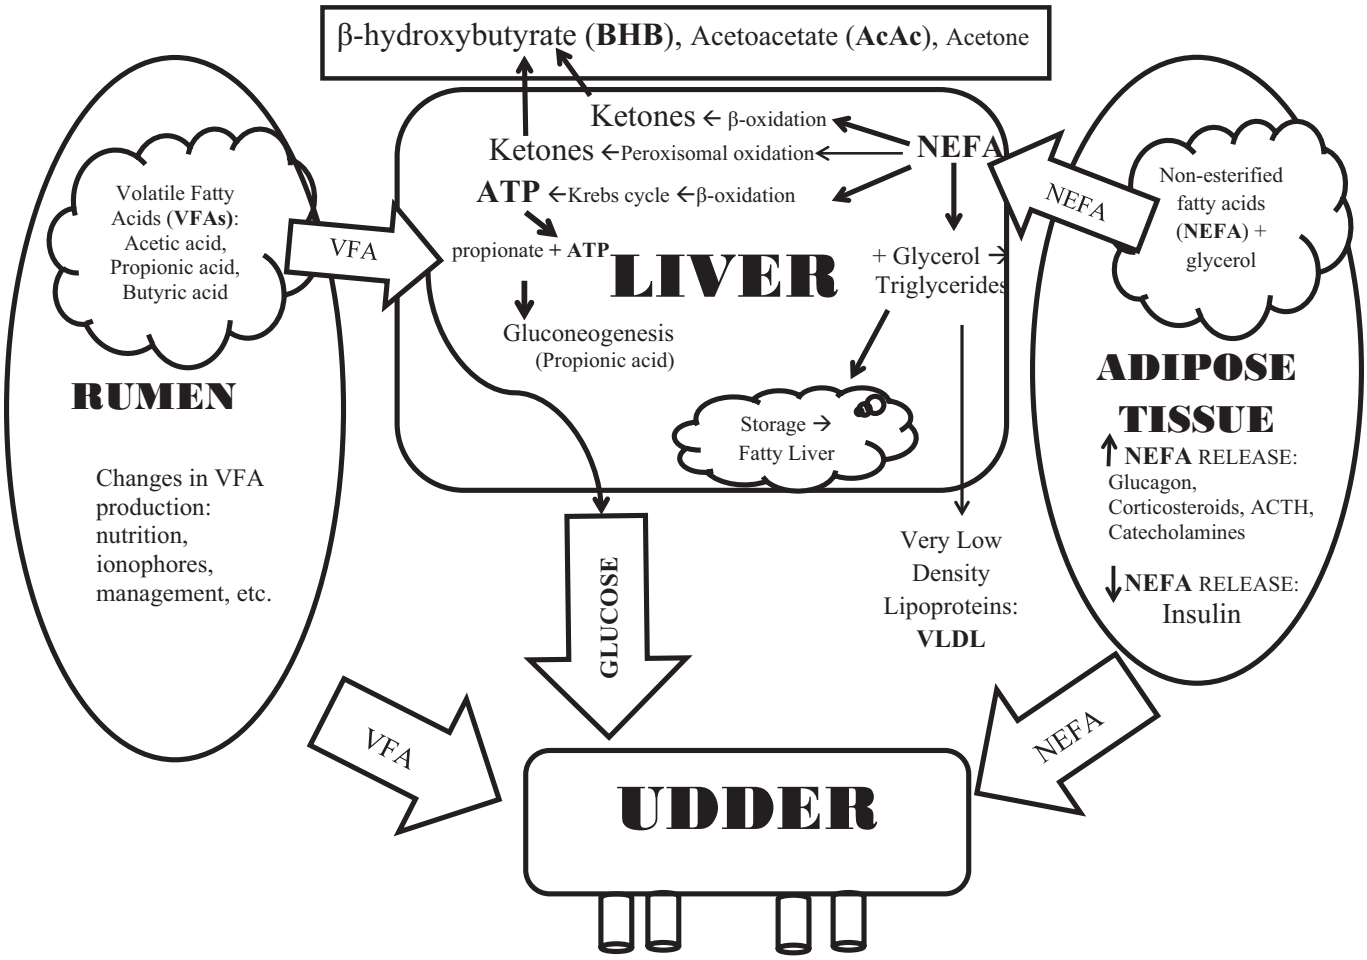

FIG. 41.25 The relationship between energy demands, energy reserves, and the metabolic association between nonesterified fatty acids (NEFA) and β-hydroxybutyrate (BHB). *ACTH*, Adrenocorticotropic hormone; *ATP*, adenosine triphosphate. *(Modified from Ospina PA, McArt JAA, Overton TR, et al: Using nonesterified fatty acids and β-hydroxybutyrate concentrations during the transition period for herd-level monitoring of increased risk of disease and decreased reproductive and milking performance, Vet Clin North Am 29:387–412, 2013.)*

The liver receives approximately one third of cardiac output and removes approximately 15% to 20% of the NEFA in circulation. Once inside the liver, NEFA can follow four pathways: complete oxidation in the tricarboxylic acid cycle (TCA) pathway to produce ATP; transport out of the liver in very-low-density lipoproteins; transformation to ketones via the β-oxidation pathway or conversion to ketones through peroxisomal oxidation; or storage in the liver as triglycerides. Thus, the continual release of NEFA into circulation is not always detrimental as NEFA is a good source of energy for several tissues in the body and can be used to synthesize milk fat. However, elevated concentrations of NEFA can result in excessive accumulation of triglycerides in the liver, resulting in hepatic lipidosis. In addition to the overtly detrimental effects of hepatic lipidosis, elevated NEFA concentrations can also adversely affect immune function,[7] and an excessive amount of circulating NEFA may promote inflammation, an important factor in common diseases such as metritis and mastitis.[8] Whether NEFA directly influences this inflammatory response or acts via mechanisms that cause immune dysfunction is currently under investigation.

As mentioned earlier, formation of ketones is a normal result of NEFA metabolism in the liver, and the three major ketones produced are acetone, acetoacetate (AcAc), and BHB. Acetoacetate can spontaneously convert to acetone and CO_2 and can also be metabolized by the enzyme β-hydroxybutyrate dehydrogenase into BHB. Acetone is excreted in urine or exhaled; it is responsible for the "fruity" breath of some ketotic cows. While BHB accounts for the majority of the total ketone pool in bovines, in lactating animals with NEB, the equilibrium between AcAc and BHB may be shifted even farther toward BHB. This shift in equilibrium may be important when selecting between the nitroprusside colorimetric spot tests, which test for acetone and AcAc, versus a test that directly measures BHB.

The mammary gland is not dependent on insulin for glucose utilization. During excessive NEB, circulating NEFAs are regularly incorporated into milk fat.[9] During NEB in the postpartum period, milk fat concentrations tend to increase and milk protein concentrations tend to decrease; thus, the ratio between fat and protein can be used as an indicator of excessive NEB and as a predictor of the risk of developing metabolic diseases.[10]

Definition

Hyperketonemia, by definition, is the elevation of ketone bodies above a physiologically normal range in blood. Although historically the terms "subclinical" and "clinical" ketosis have been used to describe this metabolic state of ketone elevation, classification into these two categories is quite subjective. It is important to remember that expression of signs consistent with ketosis has much individual-animal variation and that manifestation of these signs most likely suggests a more severe hyperketonemia compared with cows that do not show clinical signs. Recent research has provided solid and repetitive evidence of quantitative blood BHB concentration cut-points that result in increased risks of subsequent disease development and production loss.

This cut-point falls somewhere around 1.2 to 1.4 mmol/L depending on the desired sensitivity and specificity[4,5,11]; a lower cut-point results in a higher test sensitivity and lower specificity, and a higher cut-point results in a lower sensitivity and higher specificity. Thus, subclinical ketosis technically includes those cows with concentrations of BHB above 1.2 mmol/L that do not have clinical signs, and cows with clinical signs would, by definition, have clinical ketosis irrespective of what their blood concentration is (though it is often above 2.5 to 3.0 mmol/L). Hyperketonemia includes both of these categories and is the preferred term, encompassing all cows with elevated BHB regardless of expression of clinical signs. Type 1 and type 2 ketosis are terms loosely borrowed from human medicine and diabetes literature. They have limited utility in aiding our understanding of hyperketonemia in modern dairy cows or in how we prevent or treat the condition.

Clinical Signs and Differential Diagnoses

Of hyperketonemic cows, 85% to 95% have blood BHB in the 1.2 to 2.9 mmol/L range and show no aberrant clinical signs[4,12,13]; thus, we cannot detect most cases of mild or moderate hyperketonemia during a physical examination without additional diagnostic testing. Clinical signs expressed by cows with severe hyperketonemia are vague and similar to those seen with other early lactation diseases, including a loss of appetite, a decrease in milk production, and a more profound weight loss than normally seen during this period of lactation. It is important to note that the severity of hyperketonemia is not highly associated with clinical signs in that many severely hyperketonemic animals do not show clinical signs.

On physical examination, hyperketonemic animals (without concurrent disease) will have normal vital signs and may have decreased rumination frequency with more severe disease. The odor of ketones may be detected in the breath of some hyperketonemic cows, and many will have hyperketonuria. It is well established that hyperketonemia increases the risk of additional early lactation diseases such as metritis and displaced abomasum[4,12,13]; thus, a complete physical examination is necessary to identify or rule out other concurrent diseases.

In a very small percentage of severely hyperketonemic cows, an acute onset of bizarre neurologic signs will be evident, which can include excessive licking, flank-sucking, bellowing, circling, head pressing, and apparent blindness, and may progress to tremors and tetany. These cows are classified as having nervous ketosis and may be aggressive toward people or their surroundings, so care for personal safety is heightened during examination. Differential diagnoses for nervous ketosis include rabies, listeriosis, hypomagnesemia, and acute lead poisoning.

Epidemiology

Numerous studies have described the detrimental association of hyperketonemia with additional postpartum diseases, particularly metritis and displaced abomasum,[11-14] and culling in early lactation.[13,15,16] From an epidemiologic standpoint, it is important to know which disease occurs first to attribute the development of the secondary disease to the primary one. In most of the aforementioned studies, good effort has been made to record the temporal association of these diseases, and in the vast majority of cases, hyperketonemia has been diagnosed before metritis and displaced abomasum, such that 70% of metritis cases and 88% of displaced abomasum cases can be attributed to hyperketonemia.[17] This increased risk of disease, culling, and poor production rises not only as the severity of hyperketonemia increases, such that a cow with a BHB of 3.5 mmol/L is much more likely to develop a displaced abomasum as a cow with a BHB of 1.2 mmol/L, but also as the DIM at first diagnosis decreases (i.e., a cow first hyperketonemic at 3 DIM is much more likely to develop a displaced abomasum than a cow first hyperketonemic at 8 DIM).[13,14]

Peak incidence and prevalence of hyperketonemia (diagnosed in this case as a BHB concentration of 1.2 to 2.9 mmol/L) were found to occur at 5 DIM (Fig. 41.26) after intensive,

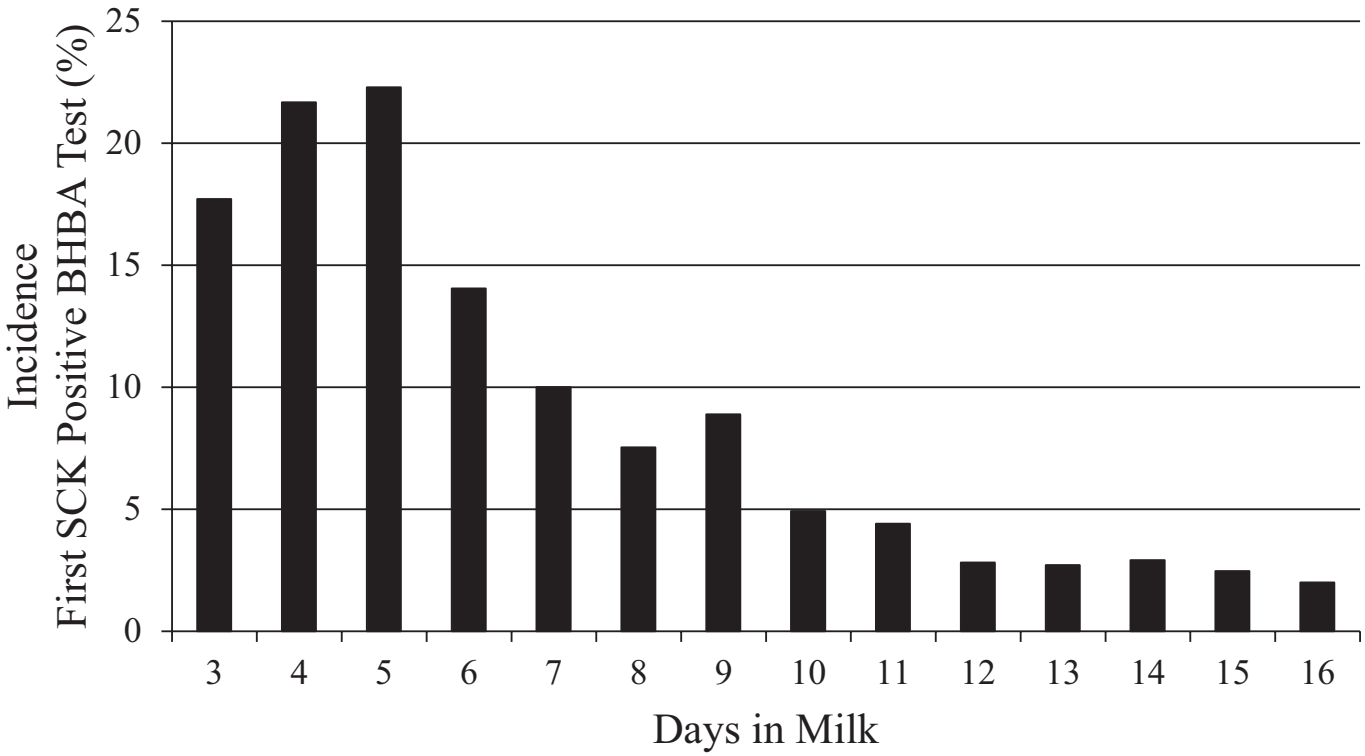

FIG. 41.26 Histogram of incidence of subclinical ketosis (SCK) in 1717 Holstein dairy cows undergoing repeated testing for SCK from 3 to 16 DIM. A positive test was defined as a blood BHBA concentration of 1.2 to 2.9 mmol/L. *(Adapted from McArt JAA, Nydam DV, Oetzel GR: Epidemiology of sub-clinical ketosis in early lactation dairy cattle. J Dairy Sci 95:5056–5066, 2012.)*

VetBooks.ir

three-times-per-week monitoring of 1717 cows on four large TMR-fed freestall dairies in New York and Wisconsin, United States.[13] A similar peak in prevalence of hyperketonemia (diagnosed as a BHB concentration of ≥1.2 mmol/L) at 1 week postpartum was reported by Duffield and colleagues[18] using data from 1010 cows on mostly component-fed tiestall dairies in southwest Ontario, Canada. As the median time to resolution of hyperketonemia was reported to be 5 days,[13] farms that test less frequently than twice per week will underestimate the true incidence.

Two important measurements that help evaluate the frequency of a disease in a farm population are incidence risk and prevalence. Incidence risk is estimated by dividing the number of cows affected with a new case by the total number of cows that have gone through this time period (i.e., the number of cows that develop a disease at any time during a given period, among those who are at risk). For determining the incidence of hyperketonemia, a cow is no longer at risk as a new case once she has been diagnosed positive. When estimating incidence, it is necessary to follow a group of cows throughout the entire time period of interest, and testing must be completed frequently enough to ensure that all cows that develop disease will be correctly identified. For example, if a disease typically lasts 5 days, all cows at risk must be tested at least two times per week. As an example, if 15 cows within a group of 50 at-risk cows that were monitored between 3 and 16 days in milk (DIM) developed hyperketonemia for the first time sometime between 3 and 16 DIM, the incidence risk of hyperketonemia during that time period would be 30% (15/50).

Prevalence is a snapshot of the amount of a disease existing in a herd at a single point in time; it is determined by one test and is thus easier to estimate than incidence. Prevalence is calculated by dividing the number of disease-positive cows by the total number of cows sampled at that point in time. For example, if 20 cows were tested on a single day and three cows were hyperketonemic, the prevalence would be 15% (3/20). At the herd level, the recommendation is to test at least 15 to 20 cows in the appropriate DIM range each time a prevalence test is conducted. The recommended number of cows to test depends on the number of cows at risk, the expected herd prevalence, and the user's acceptance of the precision of the estimate and the confidence interval around the estimate. For example, if there are 50 fresh cows at risk for hyperketonemia (i.e., between 3 and 16 DIM) and you expect the prevalence to be 15%, sampling 20 cows will allow you to be 90% confident that the prevalence you obtain is ±10% of the true herd prevalence. This is a relatively small number of animals to test, but it is only useful for determining whether a herd has a very low or very high prevalence of the disease. More cows should be tested in order to more confidently estimate the true herd prevalence. For example, sampling 40 cows in the above scenario will allow you to be 95% confident that the prevalence you obtain is ±5% of the true herd prevalence.

Knowing a herd's estimated incidence of hyperketonemia is more useful than knowing the prevalence because the best strategy for testing and treating individual cows for hyperketonemia depends on the herd incidence. However, a direct determination of the herd incidence is practically challenging because it requires repeated testing of individual cows frequently enough so that all cows that develop hyperketonemia are identified. Work by McArt and colleagues[13] showed that the average duration of hyperketonemia was 5 days; thus, cows must be sampled a minimum of twice per week in order to appropriately estimate incidence. A reasonable alternative is to conduct a simple cross-sectional sample (testing herd prevalence) and then estimate the herd incidence from the herd prevalence. Fortunately, the incidence of hyperketonemia has been consistently reported to be about twice its prevalence.[13,18] For example, if 100 early lactation cows from a herd were tested and 15 of these cows had blood BHB greater than or equal to 1.2 mmol/L, the herd prevalence would be 15% and the estimated herd incidence would be 30%.

Within-herd incidence of postpartum hyperketonemia appears to range between 25% and 60% with an average of approximately 45%; across all herds in these studies, 47% of cows tested positive at least once. The results from Duffield and colleagues,[13] however, tested cows only once weekly and thus likely underestimated the true incidence. Approximately 20% of sampled cows have elevated BHB in the first 2 weeks postpartum, with within-herd prevalence ranging from 0% to 71%.[4,14] The prevalence of herds in which more than 15% of sampled cows had increased postpartum BHB concentrations of greater than or equal to 1.2 mmol/L was 40%.[4] Chapinal and colleagues[19] reported that the prevalence of herds in which more than 25% of sampled cows had increased postpartum BHB concentrations of greater than or equal to 1.4 mmol/L was 15% in 55 herds in the United States and Canada tested within a week postpartum.

These two studies also reported on within-herd alarm thresholds and subsequent outcomes. Chapinal and colleagues[19] reported reduced milk yield based on production at first Dairy Herd Improvement test of 4.4 kg per cow per day when greater than or equal to 15% of sampled animals had prepartum BHB concentrations greater than or equal to 0.8 mmol/L. In addition, herds where greater than or equal to 25% of sampled animals had postpartum BHB concentrations greater than or equal to 1.4 mmol/L had increased odds of DA. Ospina e and colleagues[4] found that herds in which greater than 15% of sampled animals had postpartum BHB concentrations greater than or equal to 1.2 mmol/L, the risk of cows with DA and clinical ketosis was higher and the herds had an increased time to pregnancy and produced less milk compared with herds with fewer animals above the threshold. Results from these studies suggest that herds with greater than or equal to 15% to 25% of sampled animals having increased prepartum or postpartum NEFA or BHB concentrations may have more difficulty with postpartum disease, poorer reproduction, and lower milk production than herds with a lower proportion of positive animals.

Economic Impact

For cows that develop any transition cow disease, the total cost of that disease can be divided between component costs and attributable costs, where the component costs are the sum of the direct and indirect costs of that particular disease and the attributable costs include the increased risk of developing another related disease. The direct costs of a disease include labor and veterinary services associated with diagnosis and treatment, therapeutic interventions, and discarded milk required for these interventions. Indirect costs consist of future losses such as milk production, premature culling of the cow as a result of the disease, and negative impact on future reproduction. While most people readily realize the direct costs associated with a disease, interestingly, these make up a relatively small part of the total cost of a disease.

For hyperketonemia, the average component cost per case is estimated to be $117.[17] Interestingly, the direct costs associated with the disease are only approximately 6% of the total cost, with the remaining 94% of associated costs being indirect, largely future reproductive and milk production losses. When including the costs of other diseases attributable to hyperketonemia (i.e., metritis and displaced abomasum), the total cost per case is almost $290. With herd early-lactation hyperketonemia incidences averaging 40%,[13,18] annual costs due to hyperketonemia are not trivial.

Necropsy Findings

Mortality due to hyperketonemia is uncommon unless the disease is severe in nature with an associated hepatic lipidosis,

which is often the only pathologic finding during a gross necropsy examination.

CLINICAL PATHOLOGY AND DIAGNOSTIC TOOLS. The diagnostic hallmark of hyperketonemia is, as the name suggests, elevated blood ketone bodies. As BHB is the most stable ketone body in blood, its concentration is the accepted gold standard method for diagnosis of hyperketonemia. Numerous studies have assessed clinical disease incidence, culling risk, and subsequent milk production associated with various BHB cut-points to optimize use of a threshold for diagnosis of hyperketonemia, and widely used cut-points vary from 1.2 and 1.4 mmol/L.[12,14,20] As mentioned earlier, the choice of which cut-point to use depends on the user's testing purpose and desire to maximize the resulting sensitivity or specificity of the test. Recent advances in portable technology over the past decade have produced vast improvements in on-farm hyperketonemia detection with handheld point-of-care BHB meters. These can be used with whole blood, serum, or plasma and allow for an inexpensive, rapid, and accurate method for both individual cow hyperketonemia detection and herd-level disease monitoring.[21,22]

Although inexpensive, urine ketone tests, while highly specific, suffer from poor sensitivity.[23] Combined with a typical success rate of 50% when attempting to induce urination in a given cow, urine ketone tests lag behind handheld BHB meters in clinical utility for use in individual cow identification of hyperketonemia. Tests for milk ketones have a similar poor sensitivity, and given a comparable cost to blood BHB testing are an inferior test at the individual cow level. The poor sensitivity of urine and milk ketone tests precludes their use as a herd-level hyperketonemia monitoring tool.

Additional testing is usually unnecessary for diagnosis of hyperketonemia and rarely improves prognostic decision making, even in cases with accompanying hepatic lipidosis.

Treatment and Prognosis

Although hyperketonemia has been a commonly encountered disease for decades, few randomized, controlled studies have been conducting that assess the efficacy of frequently administered treatments.[24] The goal of such treatments are to increase the availability of glucose, whether directly administered or produced by the cow, to decrease adipose tissue mobilization and increase uptake of glucose by cells.

Administration of a glucose precursor, given as a drench, provides a source for gluconeogenesis and creates an insulin surge to facilitate glucose transport into cells. Food-grade propylene glycol is the most common product used for this purpose, and treatment with a multiday course has been shown to increase the speed of hyperketonemia resolution, reduce the risk of subsequent disease, and increase milk production.[25,26] Propylene glycol acts by increasing blood glucose concentrations through its conversion to propionate, both in the rumen and through hepatic metabolism of propanol, as well as by decreasing peripheral tissue glucose demand induced by circulating blood levels of propylene glycol and propanol.[27] A dose of 310 g (300 mL) once a day for 3 to 5 days is recommended; oral drenching is preferred over mixing in the feed to induce an insulin spike and for palatability reasons. Although glycerol can be administered as a glucose precursor and is highly metabolized in the rumen, no randomized field trials have been conducted to assess its effectiveness. A small study comparing propylene glycol with glycerol treatment in abomasally cannulated cows showed that glycerol had no benefit over propylene glycol treatment unless administered directly into the abomasum, which is not feasible in a clinical setting.[28] The importance of administering these glucose precursors as a drench rather than mixing with the feed is due to the desire of the resulting insulin surge, which is not seen when propylene glycol is mixed with the ration. A review of multiple studies feeding propylene glycol in the ration concluded that it had no impact on milk production when administered in this way.[29] Current trials are under way to investigate the effect of new dried propylene glycol and glycerin products fed continuously via the ration during the transition period.

Propionate has been implicated as a major player in hepatic oxidation theory, the concept that feed intake is regulated by oxidation of fuels (fatty acids, propionate, lactate, and amino acids) in the liver, with higher rate of fuel oxidation suppressing feed intake.[30] Although administration of propylene glycol and other glucose precursors increases propionate availability, no studies have shown that this treatment suppresses feed intake.[29,31] However, most field trials with the statistical power needed to appropriately answer this question cannot adequately measure DMI on an individual cow basis; thus, most studies reporting a lack of association with propionate and DMI are underpowered for this analysis.

Interestingly, the success of historical therapy with an intravenous injection of glucose (in the form of dextrose) has never been assessed in a large, randomized field trial in the treatment of hyperketonemia. A recent small study showed that intravenous administration of 500 mL of 50% glucose was effective in reducing blood BHB concentrations in hyperketonemic cows for approximately 4 hours; the transient hyperglycemia from glucose administration lasted for 2 hours. However, the most effective treatment for a prolonged decrease of blood BHB concentration was seen when intravenous glucose and oral propylene glycol were given in combination.[31] There is some debate regarding the total grams of administered glucose, with some clinicians preferring 250 mL of a 50% glucose solution over 500 mL due to the potential of a resulting insulin-induced hypophosphatemia and additional electrolyte disturbances on excretion of extra glucose by the kidney. However, no hypophosphatemia or other mineral or electrolyte disturbances were seen after 3 days of treatment with 500 mL of 50% glucose.[31] It is also debated whether a continuous intravenous infusion of 2.5% or 5% glucose over a 24-hour period is preferred over multiple 50% glucose administrations. Regardless of the inability to perform a constant infusion in a commercial herd setting, there is no evidence that one infusion method is superior over the other in the treatment of hyperketonemia.

Glucocorticoids have been used for decades to treat hyperketonemia given their action in stimulating gluconeogenesis and providing glucose precursors; however, few studies have scientifically supported the use of glucocorticoids in the treatment of hyperketonemia. Although glucocorticoids may reduce blood BHB concentrations in the short term, particularly for mild hyperketonemia cases, their use from a subsequent disease and production standpoint has rarely been assessed. Data from a recent large field trial suggest even one dose of dexamethasone (20 mg) at diagnosis of hyperketonemia may be detrimental to cows with BHB greater than 3.2 mmol/L, and that a one-dose treatment had no positive effects on health or production outcomes at any severity level.[32] Given the lack of benefits of glucocorticoids on disease incidence or milk production in mild cases and the potential detrimental effects in more severe hyperketonemia cases, the routine use of glucocorticoids is not recommended for the treatment of hyperketonemia.

Insulin has been used as an adjust therapy for hyperketonemia in conjunction with glucose administration. However, there is limited evidence supporting its use for treatment of hyperketonemia, and the high cost of most commercial products prevents their widespread use and further investigation. Insulin suppresses adipose tissue mobilization, increases uptake of glucose by tissues, and stimulates hepatic glycolysis. Its use with glucose over several days of treatment has been shown to reduce BHB, fatty acids, and liver triglycerides; however, no studies have looked at economically important outcomes from

VetBooks.ir

treatment to ascertain if insulin impacts subsequent disease incidence or milk production. Recent work suggests one dose (200 IU) of glargine insulin increases milk yield in older parity hyperketonemic cows with concurrent hypoglycemia, although it was also found to decrease milk yield in the same age group of cows that were euglycemic. Given the cost and equivocal results on health and production outcomes, the routine use of insulin for the treatment of hyperketonemia is not supported.

Vitamin B_{12} has been used in the treatment of hyperketonemia, usually in the chemically synthesized form, cyanocobalamin, and often in combination with butaphosphan (Catosal, Bayer, Shawnee, Kan.). As a vitamin B_{12}-dependent enzyme, methymalonyl-coenzyme A mutase, plays an important role in the transfer of propionate into the TCA cycle, it is thought that increasing the activity of this enzyme through administration of vitamin B_{12} may increase gluconeogenesis. The few studies that have analyzed the effect of vitamin B_{12} have found that it increases ruminations in the few days after treatment and increases the cure risk in hyperketonemic cows with concurrent hypoglycemia over that of nontreated hyperketonemic cows.[33,34] Given the low cost of vitamin B_{12}, it is often administered as an adjunctive treatment with propylene glycol at 2 to 5 mg per day, although without scientific proof of effectiveness.

The prognosis for resolution of mild hyperketonemia is excellent depending on subsequent disease development. Cows developing hyperketonemia in the first week of lactation, as well cows with more severe hyperketonemia, are at a higher risk of negative health events and poorer milk production in early lactation. Thus, both the timing of hyperketonemia development and severity can be used as prognostic indicators of subsequent disease risk.[13,32] With appropriate identification and treatment, the majority of hyperketonemic cows resolve their disease within 1 week and continue on to productive lactations. The prognoses of hyperketonemic cows that develop additional early-lactation diseases such as metritis or displaced abomasa depend on their response to treatment for the respective associated disease. Cows with accompanying severe hepatic lipidosis have a much poorer prognosis as constant and repeated nursing care is important in addition to the treatments discussed earlier, which takes considerable time and financial resources.

Herd-Level Prevention and Control

Whereas previously discussed ketone tests have great use as tools for diagnosis of hyperketonemia in individual animals, they can also be incorporated into a program for herd-level monitoring in order to assist with management decisions. It is important to note that the sensitivity and specificity of different tests can have a large impact on individual test results and, as a consequence, herd diagnosis and treatment. The probability of correctly identifying a herd as positive (i.e., having a prevalence of hyperketonemia above a certain threshold) decreases when a test with low sensitivity is used.[35] For these reasons, use of handheld blood BHB meters are suggested for herd-level monitoring.

As noted earlier, herds with a high prevalence of hyperketonemia are more likely to have a higher incidence of postpartum disease, poorer reproduction, and lower milk production. Research completed in over 150 herds in the United States and Canada suggests that this association between herd hyperketonemia prevalence and disease and production outcomes occurs when greater than or equal to 15% to 25% of animals have elevated postpartum blood BHB concentrations.[15,19] Ospina and colleagues[15] found that 40% of the 100 herds tested were above the herd alarm level. Unfortunately, hyperketonemia is an issue on many herds, and additional studies have found the incidence and prevalence of hyperketonemia to be quite high across herds in the United States, Canada, and Europe.

On a herd-level treatment basis, when the incidence of hyperketonemia rises above 25%, almost any testing and treatment strategy for hyperketonemia is economically beneficial. If herd-level incidence exceeds 50%, blanket treatment of all fresh cows with propylene glycol is recommended, beginning no earlier than 3 days in milk.[17] The delay of blanket treatment until a few days into lactation is important, as most cows are hyperglycemic in the immediate postpartum period, and administrations of propylene glycol, a glucose precursor, may exacerbate hyperglycemia and induce insulin dysregulation. If blanket treatment of all fresh cows is implemented, herd-level assessment of transition cow management, discussed later, is warranted, with repeated testing of fresh cows to monitor hyperketonemia prevalence at least monthly. The goal of herd-level hyperketonemia management strategies and monitoring programs are to keep the prevalence of hyperketonemia below 15%.[35]

Traditionally, nutritional management of dairy cows during the far-off dry period (i.e., approximately 60 to 30 days before calving) has received little attention, but it is a key area for hyperketonemia control. Indeed, many aspects of nutritional management (e.g., mineral nutrition beyond meeting basic nutrient requirements) appear to be less important during the far-off period compared with the close-up period. However, several studies[36-39] suggest that overfeeding cows beginning during this period leads to lower postpartum DMI, increased mobilization of body tissue, increased circulating concentrations of NEFA and BHB, and increased risk for metabolic disorders and poorer productive and reproductive performance. The recommended target diet formulation is to meet 110% to 120% of energy requirements during this period and metabolizable protein supply for Holsteins of over 1200 g/day. During the far-off period, macromineral considerations such as potassium are not of great concern; thus, a wider array of forages and feeds are acceptable to form the basis of diets.

As described earlier, controlling energy intake of close-up cows so that they meet, but do not dramatically exceed, their energy requirements during this period is a critical target. As has been well documented previously and supported by recent research,[4,15,35] energy intake below requirements as reflected by elevated NEFA concentrations during the close-up period is associated with increased incidence of postpartum metabolic disorders, lower milk production, and poorer reproductive performance. The recommended target energy intake of cows during the close-up period is 110% to 130% of energy requirements. For Holsteins, this is in the range of 16 to 18 Mcal/day of NEL. As a starting point, formulate the close-up diet at approximately 1.45 Mcal/kg of NEL if the group is a comingled cow/heifer group and approximately 1.38 to 1.40 Mcal/kg of NEL if the group is composed of mature animals and DMI is high. These energy densities are adjusted on the basis of actual DMI of cows on farms to achieve the overall targets for energy intake during the close-up period described earlier.

Metabolizable protein supplies of at least 1200 to 1300 g/day for cows during the close-up period should be targeted.[40] Given that lower-energy diets fed during the close-up period as described earlier typically contain limited amounts of rapidly fermentable carbohydrate (16% to 18% starch), microbial protein synthesis is limited and diets generally contain 1 to 2 kg of ruminally undegradable protein sources in order to meet the metabolizable protein recommendation outlined earlier. Furthermore, research generally supports formulation of close-up rations with methionine and lysine at levels similar to those used for lactating cows. To prevent hyperketonemia and other metabolic disorders of transition cows, it is important that neither protein nor energy are limited. This must be done while avoiding excessive energy intake.

Other management factors are certainly involved in the observed differences between farms and cows and could lead to an increased risk for hyperketonemia early in lactation.

These include inadequate cow comfort, high stocking density (e.g., >80% in the close-up and fresh group), unnecessary pen moves, inadequate heat abatement, and limited access to water. Having high-quality feed (silage high in butyric acid has been repeatedly found to cause hyperketonemia, both through a reduction in DMI and a direct conversion of butyrate to BHB in the rumen) available at least 23 hours of the day, as well as management programs in place for the prevention of infectious diseases such as mastitis and uterine infection, aid in the decrease of the risk for this metabolic derailment. Mature cows, cows that had a difficult calving, and overconditioned cows are generally at an increased risk to develop hyperketonemia at the beginning of lactation.

Bovine Somatotropin

Robert J. Collier • Dale E. Bauman

Introduction

Growth hormone (GH; somatotropin, ST) belongs to the protein family of somatolactogenic hormones produced in all mammals.[1,2] Bovine growth hormone (bGH; bovine somatotropin, bST) is the ST produced in cattle.[3,4] Although ST is named for its effects on growth, it is now known that it has a wide range of activities that are broadly classed as homeorhetic in that it coordinates metabolism to support specific physiologic states.[5,6] One of these states is lactation, and ST is also classified as a galactopoietic hormone in that it increases milk yield in established lactation.[7,8] Russian scientists were the first to extend this effect to dairy cows when they administered pituitary extract to over 2000 cows. They only gave a single injection, so the increase in milk yield lasted only a day or so, but they reported the "absolute harmlessness" of the extract and that responses were "more profitable on a well-run farm than on a farm with a poor food basis or where cattle are kept under unsatisfactory conditions."[7] In the 1940s British scientists conducted a series of studies with a goal of increasing milk supply to help alleviate chronic food shortages during World War II. They were the first to identify bST as the galactopoietic factor in pituitary extract and concluded its use "would be highly profitable to the individual farmer"; however, they also found the supply of bST was too limited to significantly impact national milk supply.[8] Additional studies with lactating cows were conducted over the decades that followed,[9,10] but these were constricted by two factors. First, supply of bST was limited to that isolated from the pituitary glands of slaughtered cows. Second, based on incorrect ideas on the mechanism of bST, scientists only worked with fat, low-producing cows (<15 lb/day).[8]

In the 1980s advances in recombinant DNA techniques made sufficient quantities of recombinant bovine growth hormone (rbST) available for the use as a milk production enhancing agent.[11,12] Approval of rbST for use in lactating dairy cows in the United States was obtained by Monsanto Company from the U.S. Food and Drug Administration (FDA) in 1993 and marketing began in 1994.The following sections will cover the chemistry, production response and mechanism of action, cow health and well-being, human safety, and sustainability implications of rbST use in the dairy industry.

Chemistry

Somatotropin is a peptide hormone composed of amino acids, and the sequence of these amino acids differs among species.[3] Bovine somatotropin is a protein hormone consisting of either 190 or 191 amino acids depending on the variant and having a molecular weight of 22 kDa (Fig. 41.27).[13] The mass variants of pituitary bST, associated with the presence or absence of alanine at position 191 of the molecule, are considered secretory process alterations and not genetic in nature. Additional variants have either valine or leucine at position 127, which represents a genetic difference (see Fig. 41.27).[13,14] Thus, there are four possible pituitary variants of somatotropin circulating in the blood of cattle with either alanine or phenylalanine at the carboxyl terminus and either leucine or valine at position 127 (Fig. 41.28). The distribution of these pituitary variants across the dairy breeds is shown in Fig. 41.29. Due to the presence of heterozygotes in some breeds, it is possible in some animals to have all four forms of the pituitary variants in circulation

at the same time.[4] Additional mass variants occur due to dimerization of bST molecules, but these forms are considered inactive.[15] Formation of somatotropin dimers also occurs in production of rbST, but these are also inactive.[16] There is no evidence that any of the types of variants of bovine somatotropin are metabolized differently. The plasma kinetics of bST were shown to be consistent with a two-compartment model with half-lives estimated at 8.2 and 29.1 minutes for the two compartments.[17] The compartment with the short half-life appears to represent free somatotropin while the compartment with the extended half-life was believed to represent the somatotropin bound to a protein complex.[17] Free and bound bST represent 100% of total somatotropin measured by radioimmunoassay of bovine blood.

Recombinant variants produced by companies seeking to use bST commercially were either the same as native bST or differed only slightly at the amino terminus.[18] The rbST currently marketed in the United States has the U.S. Adopted Name (USAN) of Sometribove; it has a single amino acid substitution of methionine for alanine at position 191 and leucine at position 127.[15] All of these recombinant variants were tested in vivo for oral activity and found to have none in laboratory rats.[11] Recombinant variants have pharmacokinetics identical to pituitary variants of bST.[17] Since the pharmacokinetics of rbST in vivo does not differ from pituitary BST, it is reasonable to assume that the degradation pathways are essentially the same for both molecules. Also, it is assumed that highly purified fragments of pituitary bST would not differ from similar fragments of rbST in biological activity. Data from lactation studies in cattle indicated no difference in response between recombinant and pituitary-derived forms of bST.[11,17] Bovine somatotropin is marketed as an oil/zinc formulation and delivered for use in dairy cattle at a label dosage of 500 mg SC every 14 days (approximately 37 mg/day) for a 500-kg cow. In safety studies, up to 300 µg/kg/day was injected into cattle.[19]

Biological actions of intact ST are well described.[11,20,21] The definition of ST's biological role has changed over time. Although first described as a regulator of growth, the term *somatotropin* does not nearly describe the pleiotropic actions of this molecule. A better term for ST is "homeorhetic regulator." Homeorhesis is "the coordinated control of metabolism in support of a dominant developmental or physiological process."[5] Somatotropin is a key player in regulating metabolism across a variety of physiologic states and has many target tissues. Key developments contributing to our understanding of ST as a homeorhetic regulator are the identification of heterogeneity of the receptor population in both distribution and form of the receptor and its ability to alter tissue responses to acute homeostatic signals.[5,9,12,20] However, the actions of ST described to date are those initiated by the intact molecule. There are many cell types that have been identified as targets of ST, including hepatocytes, ovarian luteal cells, cells of the small intestine, bone, adipocytes, muscle, immune system cells, and cardiac cells.[21-24] The liver appears to be a key target for ST owing to its central role in regulating metabolism and its secretion of the ST mediators, insulin-like growth factors (IGFs), and their binding proteins, in response to ST binding. Binding of ST to its receptor is followed by activation of JAK, MAP, and tyrosine kinases and transfer of the cytoplasmic domain of the receptor to the nucleus while the extracellular domain, also called the somatotropin binding protein, is cleaved and enters circulation as a complex with its bound somatotropin.[27-29] Because one of the actions of ST is to increase plasma levels of IGF-1 and the IGF-1 molecule in cattle is identical to the IGF-I molecule in humans, there was great interest in the levels of IGF-1 in milk and its potential impact on the human population.[18,26] This is covered in the section on human safety.

In regard to bST activity in humans, the bovine and human growth hormones are of similar size and differ by 35% in amino acid sequence.[18,25] It is well established that although primate growth hormones can bind and activate nonprimate growth hormone receptors, the reverse is not true. The amino acid sequence required for specificity of human somatotropin for its receptor has been identified with the key interaction occurring between arg-43 of the primate receptor and asp-171 of primate somatotropin.[28-30] In nonprimate receptors this position is replaced by leucine, and histidine occupies the place of aspartate.[28-30]

Metabolism and degradation of bSTresults in a variety of "fragments" of differing molecular weights and size. Many of these have been reported to have partial growth hormone like activity.[27,31-33] However, no studies have examined kinetics of metabolism and clearance of these fragments. It is important to note that since these fragments have low affinity for the growth hormone receptor or the binding protein, they would likely reside in the plasma pool with a short half-life.[32,33]

Production Responses and Mechanism of Action

The production of rbST represented an exciting development that improved our understanding of lactation biology and offered the opportunity for commercial use. The production and management aspects of rbST have been extensively investigated with over 500 scientific publications reporting results of controlled experiments and field trials. Several excellent reviews have summarized production and management dimensions of the response to rbST.[34-39] From a producer prospective, the use of rbST makes all cows more like the best cows in the herd. This highlights the importance of comprehensive management programs related to nutrition, reproduction, and cow health, and the need for these programs is the same for cows

VetBooks.ir

of comparable production regardless of whether rbST is used to achieve that production.

As a brief overview, Posilac is the commercial oil/zinc formulation of rbST approved in the United States for lactating dairy cows. It is administered by subcutaneous injection at 14-day intervals commencing on the 9th to 10th week post calving and continuing until the end of lactation.[40] Use of rbST before the 9th week of lactation is not recommended because safety studies were not conducted during this interval and because milk yield responses are more difficult to assess during this period because milk yield is still increasing, making it difficult to determine what the cow would have produced had she not been treated. There is an immediate increase in milk production when rbST treatment is initiated, which persists until rbST supplementation is discontinued. Published results from controlled experiments and field trials indicate that the increased milk production response typically ranges from 4 to 6 kg/day.[11,34-36,40] However, a lower response or even no response will occur under conditions of poor management or when animal well-being is compromised. Milk responses have been observed for all breeds and cows regardless of genetic merit. Across experiments the variation between unsupplemented and supplemented cows is similar, indicating that all cows are responding to endogenous pituitary bST and exogenous rbST in a similar manner. Some producers have injected the rbST formulation at 10-day intervals in order to increase the milk yield response. This is considered off-label use and is not recommended. However, the net effect of injecting rbST formulation at 10-day intervals is to increase the dose of rbST from 50 mg/day over a 14-day interval. This dose was included in the safety evaluation, and the milk yield response is linear over a range of doses from 0 to 750 mg/14 days.[35]

Milk composition is of special importance, and controlled experiments and field studies have demonstrated that the nutritional components and manufacturing characteristics of milk are unaltered by the use of rbST supplementation.[12,37,41,42] Milk composition is affected by many factors including breed, genetics, diet, stage of lactation, and environment; these factors affect milk composition in an identical manner in rbST-treated cows.

Somatotropin alters the partitioning of nutrients to allow for an increase in mammary synthesis of milk.[9,12,43] Thus, effects on nutrient use in other physiologic situations were of interest. Investigations have demonstrated that lactating primparous heifers that have not attained mature growth will still do so during rbST treatment. Likewise, rbST-supplemented cows simultaneously lactating and pregnant will still shift nutrient partitioning to support fetal growth and replenishment of body reserves during the later stages of pregnancy.[37,38] Furthermore, the increase in milk yield and persistency that occurs with rbST use continues to be observed when lactation is extended in nonpregnant cows.[44]

Feed is a major expense in the dairy enterprise and a major consideration in the management of dairy cows. Compared with the immediate milk response, voluntary feed intake gradually increases over the first few weeks of rbST treatment and the magnitude of the increase matches the nutrient requirements for the extra milk.[37,38,45] Bioenergetic studies have demonstrated that nutrient requirements for maintenance and per unit of milk are not different in rbST-supplemented cows. Thus, rbST alters the partitioning and use of absorbed nutrients with little or no effect on digestive processes. Overall, dairy cows receiving rbST need to be allowed access to adequate amounts of a balanced ration, but no special diets are required.[37] Extra nutrients are required to support the increase in milk production, but these extra nutrients are all used for milk synthesis. The increase in productive efficiency that results from use of rbST is further discussed in the Sustainability section.

Milk yield per cow has progressively increased over the past 75 years, and this gain in productivity is due to adoption

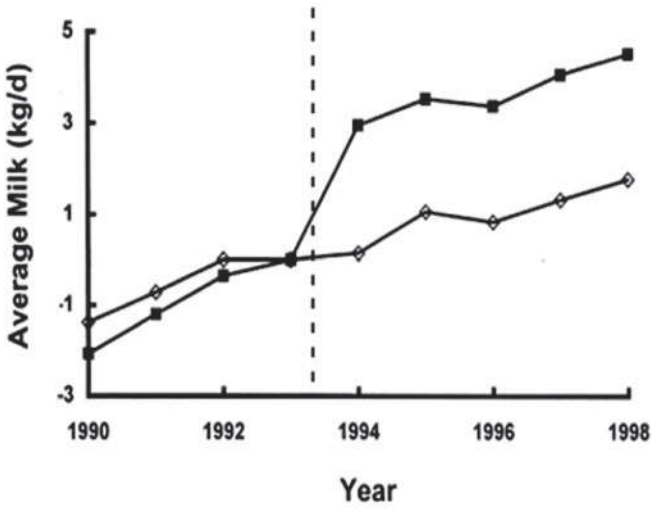

FIG. 41.30 Improvements in average daily milk yield in Northeast dairy herds. Posilac use commenced February 1994 (dashed line) and data encompass preapproval (1990 through 1993) and postapproval (July 1994 through 1998) periods. Control herds (open diamonds) never purchased Posilac, and bST herds (closed squares) used Posilac continuously throughout the postapproval period. Data represent 340 herds with over 80,000 cows and 200,000 lactations; for comparison, daily yields are expressed relative to 1993, the year before commercial approval of rbST. *(Adapted from Bauman DE, Everett RW, Weiland WH, et al: Production responses to bovine somatotropin in Northeast dairy herds. J Dairy Sci 2:2564–2573, 1999.)*

of new technologies and improvements in management practices. Data from a large field study demonstrate the annual gain in daily milk per cow over an 8-year period during the interval of rbST approval.[48] Herds had the characteristic annual gain in daily milk per cow during the 4-year preapproval period, but in herds that adopted rbST the yield was increased by a similar additional increment each year during the postapproval period when rbST was used (Fig. 41.30). When adjusted for the proportion of supplemented cows, the incremental increase due to rbST was relatively constant and equal to approximately 4 to 5 kg milk per day.

Thus, the use of rbST did not alter the rate of genetic progress in herds using rbST and the response is not altered by relative genetic merit of cows receiving rbST.

The regulation of nutrient use for milk synthesis involves two types of controls—homeostasis and homeorhesis.[5,49] Homeostatic controls regulate metabolic processes on an acute, minute-by-minute basis to maintain steady state conditions; insulin is a key homeostatic control, and its regulation of glucose utilization is of critical importance in lactation. Homeorhesis operates on a chronic, long-term basis and can be defined as the "coordinated regulation of metabolic processes to support the needs of a physiologic state."[5] Homeorhetic controls are analogous to a symphony conductor who coordinates the contributions of all the various instruments that make up the orchestra to produce a harmonious symphony. Somatotropin is a major homeorhetic control; during lactation, somatotropin regulates the partitioning of nutrients to support milk synthesis by altering tissue responses to homeostatic signals.[9,49] This orchestration involves most organs and tissues in the body and includes the metabolism of all nutrient classes—carbohydrates, lipids, proteins, and minerals. Thus, rbST treatment both increases milk synthesis by the mammary gland and orchestrates other body processes in a manner to provide the necessary nutrients to support the enhanced milk synthesis.[9,11,49]

Some of the major coordinated changes that occur with rbST treatment are summarized in Table 41.9. These adaptations are of special importance when rbST is first initiated because the

TABLE 41.9

Effect of Bovine Somatotropin on Specific Tissues and Physiologic Processes in Lactating Cows

Tissue	Process affected during first few days and weeks of treatment
Mammary	↑ Synthesis of milk with normal composition
	↑ Uptake of all nutrients and milk synthesis per secretory cell
	↑ Number and maintenance of secretory cells
	↑ Blood flow and nutrient supply consistent with increase in milk yield
Liver	↑ Rates of glucose production
	↓ Ability of insulin to inhibit glucose production
Adipose	↓ Fat deposition if in positive energy balance
	↑ Fat mobilization if in negative energy balance
	↓ Ability of insulin to stimulate fat deposition
	↑ Ability of catecholamines to stimulate use of body fat reserves
Intestine	↑ Absorption of Ca, P, and other minerals required for milk
Whole body	↓ Oxidation of glucose to spare use for milk synthesis
	↑ Fatty acid oxidation if in negative energy balance
	Φ Energy expenditure for maintenance
	↑ Energy expenditure consistent with increase in milk yield (i.e., energy per unit of milk not changed)
	↑ Cardiac output consistent with increases in milk yield
	↑ Immune response
	↑ Voluntary feed intake to support increased milk
	↑ Productive efficiency (milk per unit of nutrient intake)

Changes (↑ = increased, ↓ = decreased, ϕ = no change) that occur in initial period when metabolic adjustments occur to match the increased milk synthesis.

Adapted from references 9, 11, and 20.

increase in milk yield occurs immediately and the matching increase in voluntary feed intake is more gradual. Glucose provides an excellent example of the coordinated responses.[11,49] Glucose is used for milk synthesis, primarily for milk lactose, and the milk response to rbST includes increased mammary uptake and use of glucose. At the same time, acute tissue responses to insulin are shifted so that liver synthesis of glucose is increased and the use of glucose by adipose and other body tissues is reduced. The net effect is that rbST-treated cows partition more glucose to the mammary gland for increased milk synthesis, but glucose supply and use remain in balance. Thus, glucose homeostasis and the cow's well-being are maintained.[47]

An additional dimension of the mechanism by which rbST increases milk production involves an improvement in the persistency of milk production.[50] Milk production typically peaks at about 60 days postpartum and then declines gradually over the remainder of the lactation cycle. The decline in lactation corresponds to a gradual loss of mammary cells referred to as cell death or apoptosis.[51] Mammary gland cell numbers are better maintained in first-lactation heifers and in cows that have a greater lactation persistency. Supplementation with rbST also improves the maintenance of actively secreting mammary cells.[51] The net effect is that the milk yield is more persistent in rbST-supplemented cows so that differences between cows receiving rbST and untreated cows tend to increase over the course of the lactation.

Health and Well-Being

As the first recombinant protein with potential use in production animals, the animal safety evaluation was extensive. In the United States this included the traditional evaluation by the FDA, as well as public hearings, science evaluations, and legislative reviews.[11,12,52] After a thorough review of well-controlled studies, the FDA Center for Veterinary Medicine (CVM) concluded that rbST could be used safely and effectively by the U.S. dairy industry. Following the initiation of commercial sales, an unprecedented postapproval monitoring program (PAMP) was initiated; this involved intensive monitoring of 28 herds (1213 cows) for the first 12 months post approval to confirm the safety evaluation conducted by the CVM.[40] Results demonstrated that health problems detected in cows treated with bST under commercial conditions were typical health events that normally occur in dairy herds. All of the conditions noted were managed routinely by accepted management practices within high-producing herds. Mastitis incidence was not increased in rbST-treated animals compared with herd-mate controls and was less than estimated from preclinical studies, and reproductive performance was improved compared with preclinical studies.[40]

Health Canada also evaluated rbST; they requested that the Canadian Veterinary Medical Association (CVMA) evaluate if "rbST used in accordance with label directions will increase milk production without resulting in serious health problems which cannot be adequately controlled by current management practices."[53,54] In 1998 the CVMA completed a meta-analysis report,[53] and in 2003 results were published in the Canadian Journal of Veterinary Research; they concluded that use of rbST would increase yields of milk and milk components, but it would also adversely impact cow health and welfare, especially udder health, lameness, body condition, reproduction, and lifespan.[54,55] Other less rigorous evaluations also speculated that catastrophic health and welfare problems would occur in rbST-treated cows.[56,57]

Since the FDA approval, there have been several large-scale rbST investigations relating to various aspects of cow health and welfare.[40,48,58-64] Results from these investigations and over 25 years of commercial experience involving over 35 million cows on U.S. dairy farms agreed with the FDA evaluation but were at odds with the conclusions reached by the CVMA.[48,58,65] To provide an updated evaluation of the efficacy and safety of rbST, a multiuniversity expert panel was formed in 2013; they conducted a set of meta-analyses using data from peer-reviewed studies that used the commercial formulation of rbST according to the label.[66]

Variables that were analyzed to characterize the milk and milk composition responses to rbST included milk yield, percent milk fat, percent milk true protein, percent lactose, 3.5% fat-corrected milk yield, fat yield, and protein yield. Except for the percentage of lactose in milk, responses across studies were heterogeneous, indicating that unidentified factors associated with individual studies affected the magnitude of the response. Treatment with rbST increased milk and 3.5% fat corrected milk yields by about 15% over control cows. Milk composition for fat, protein, and lactose was not affected by rbST (Table 41.10). Thus, yield of these milk components increased in parallel with milk production resulting in increases of daily yields of fat and protein of 13.3% and 15.9%, respectively.[66] The increase in milk yield and the lack of effects on milk composition in this meta-analysis agrees with earlier summaries reviewed in the Production section.

Milk somatic cell count (SCC) is an indicator of inflammation in the mammary gland, and milk SCC will increase in response to both subclinical and clinical mastitis.[67] Therefore, the meta-analysis of udder health included SCC and the incidence of clinical mastitis. Similar to what was observed for the milk responses, tests for heterogeneity indicated significance for

CL, Confidence limit.

both milk log SCC and mastitis incidence rate, indicating that unidentified factors associated with individual studies affected the observed values. In the case of SCC, the control group and rbST-treated groups did not differ and averaged nearly 100,000 SCC/mL (see Table 41.10). Likewise, mastitis incidence rate did not differ between the control and rbST-supplemented groups (see Table 41.10). Only one study[61] has conducted cultures and used intramammary infection status to ensure a balance in treatment group assignment. That study involved four herds (total cows = 555), and results indicated there were no differences between treatment groups in number of cows that developed clinical mastitis or number of days that milk was discarded because of mastitis due to use of rbST.[61]

The recent (2014) JECFA report on the effects of rbST on mastitis incidence and SCC conducted is in agreement with the results of this meta-analysis.[68] Their review of clinical and epidemiologic studies found no effect of rbST on mastitis incidence. In the case of subclinical mastitis, they reported that the "vast majority of studies reported no effect of rbST treatment on SCC values, although a few studies reported small transient increases."[68] These results are also consistent with the conclusions of public hearings conducted by the FDA Veterinary Medicine Advisory Committee.[52,69] Environmental and management factors are major causes of mastitis, and they affect both SCC and mastitis incidence.[67] In addition, genetic studies have demonstrated a small positive relationship between mastitis risk and milk production. However, high-producing herds are better managed so that effects of increased milk production are minimized or negated.[67]

Body condition was of special importance in the evaluation of health since cows need to maintain adequate body condition over the lactation cycle. In particular, it was of interest to determine whether rbST-treated cows would lose body condition due to the use of reserves to support the increased milk production. The meta-analysis consisted of BCS data obtained during and after rbST treatment for 15 studies. Mean BCS was significantly lower in cows treated with rbST compared with control cows with the difference being –0.064 ± 0.031 points (see Table 41.10). As reviewed in St. Pierre and colleagues,[18] published studies indicate that 1 point of BCS represents about 50 kg (110 lb) body weight. Thus, the difference in BCS for the rbST-treated cows observed in the meta-analysis represents about 3.2 kg (7 lb) body weight. Although significant, this difference would not be visually apparent and approximates the change in body weight associated with a typical feeding or drinking episode for a dairy cow. Thus, this updated meta-analysis indicated that treatment with rbST had little or no effect on body condition despite the increase in milk yield. The explanation for this comes from the review by Chilliard, who demonstrated that across studies cows treated with rbST increased voluntary intake in an amount energetically comparable with the rbST-induced increases in milk yield.[45]

Altered locomotion or mobility that occurs with clinical lameness represents a range of foot and leg disorders that can result from disease, management, or environmental factors.[70] Results of the St. Pierre and colleagues[66] meta-analysis for clinical lameness found that treatment with rbST had no effect (see Table 41.10). Wherever possible, data for foot lesions were also separated into two categories—lameness lesions and traumatic lesions. Lameness lesions are lesions that directly cause clinical lameness (e.g., laminitis, sole ulcers, digital dermatitis), whereas traumatic lesions are lesions that rarely cause or result in lameness (e.g., mechanically induced skin lesions).[70] Incidence rates for either lameness lesions or traumatic lesions did not differ between controls cows and rbST-treated cows (see Table 41.10).[66]

[b]Limited response period (first and second AI inseminations).

[c]Extended response period (full duration of the trial).

CL, Confidence limit.

Reproductive variables were of special interest in this evaluation. Previously, results from the PAMP study indicated that use of rbST had no effect on pregnancy rate, days open, fetal loss, cystic ovaries, or successful calving rate.[40] Results from the meta-analysis indicated a significant 5.4% improvement in pregnancy proportion in the rbST-supplemented cows for the first two breeding cycles after the voluntary wait period (Table 41.11). When compared over the full length of the trial, the pregnancy proportion was reduced 5.5% for the group receiving rbST (see Table 41.11), a reduction that was likely due to reduced estrous behavior.[64,66] The fact that rbST-treated cows were more likely to become pregnant during the first two breeding cycles, the period when cows are generally enrolled in a timed-artificial insemination (AI) protocol, suggests that rbST did not impair, and might even have a positive effect on, the reproductive performance of dairy cows during this period. In addition, use of timed AI does not require estrus observation, so the subsequent reduced pregnancy rate when timed AI is not in use again indicates estrus behavior rather than ovarian or uterine function is the issue.

Results from the meta-analysis indicated that there was no effect of rbST on days to pregnancy, inseminations per conception, fetal losses, or twinning incidence (see Tables 41.10 and 41.11). Similarly, the incidence rate of cystic ovaries did not differ between controls and rbST-treated cows (see Table 41.11). The lack of effect on ovulation failure and cystic ovaries in dairy cows is consistent with the results from De La Sota and colleagues[71] in which rbST-treated cows had ovaries with healthy estrogen-active follicles.

Culling was also examined, and meta-analysis results indicated that culling density did not differ between controls and cows treated with rbST (see Table 41.10). Similarly, a longitudinal field study conducted over 8 years on 340 commercial dairy herds in the northeastern United States demonstrated that rbST use had no effect on "stay-ability" or herd-life.[46]

Overall, conclusions from the updated meta-analysis were consistent with FDA evaluations, the minimal reports of adverse drug experiences, numerous scientific reviews, and large-scale studies conducted on commercial dairy operations. To date, an estimated 35 million U.S. dairy cows have received the commercial formulation of rbST and results have confirmed that treatment with rbST results in increased milk yield with no adverse effects on cow health or well-being.

Because somatotropin has been shown to improve nutrient partitioning and glucose availability for milk production, it has been investigated for potential therapeutic use to prevent periparturient metabolic diseases. At the onset of lactation the dairy cow enters a period of energy deficit that is associated with reduced expression of key components of the somatotropin axis, as well as other metabolic regulators such as insulin. For example, the growth hormone 1A receptor population in the liver declines immediately before parturition and rises 3 to 4 days after parturition.[72] The dip in growth hormone receptor population is paralleled by a decline in plasma IGF-I concentration and a rise in plasma growth hormone concentration. These changes are associated with rapid changes in ovarian, placental, and adrenal steroid concentrations during the same time period. Thus, the uncoupling of the somatotropin axis in early postpartum dairy cows is correlated with a decrease in liver GH receptor 1A mRNA, a decrease in liver GH receptor protein, and a decline in IGF-I secretion from the liver. Radcliff and colleagues (2006) demonstrated that partial feed restriction exacerbates the decline in the growth hormone receptor 1A message in the liver and further reduces plasma IGF-I concentrations.[72] Rhoads and colleagues in 2007 further demonstrated that feed restriction depresses growth hormone action in not only liver but adipose tissue as well. Thus, the negative energy balance that occurs in early lactation inhibits the growth hormone axis in liver and adipose tissue during the transition period.[73]

Lucy and colleagues[74] in a review of this area developed the hypothesis that abnormal transition cows had lower hepatic growth hormone receptor 1A population leading to lower plasma IGF-I, which resulted in a number of secondary effects such as poor health and reproduction.

Activation of the growth hormone receptor requires dimerization of two growth hormone receptors with a single growth hormone molecule at a high affinity receptor site.[75] Each growth hormone receptor has one high affinity and one low affinity site. The high affinity sites are required for dimerization and activation of the receptor.[76] If excessive concentrations of growth hormone are present relative to available receptor sites, then all of the high affinity binding sites are occupied by single molecules of growth hormone and the receptors cannot dimerize. This appears to be a likely possibility during the transition period and early lactation when plasma growth hormone concentrations are relatively high and the available receptor population is low. Administration of low but not high doses of somatotropin during this period results in beneficial effects on reproduction and health of cattle.[77-79]

Sustainability Implications

Sustainability is an important consideration in agricultural production, and rbST has positive benefits on the sustainability of the dairy industry. Producer gains from technologies such

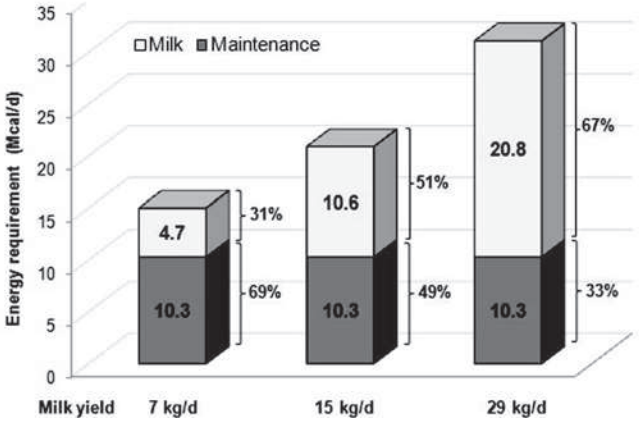

FIG. 41.31 The "dilution of maintenance" effect conferred by increasing milk production in a lactating dairy cow (650 kg body weight, 3.69% milk fat). *(Adapted from Capper JL, Bauman DE: The role of productivity in improving the environmental sustainability of ruminant production systems. Annu Rev Anim Biosci 1:469–489, 2013.)*

as rbST relate to the improvements in efficiency of nutrient use and the related environmental impact. The improvement in productive efficiency with rbST use is a consequence of the "dilution of maintenance,"[80,81] a concept illustrated in Fig. 41.31, in which the nutrient requirements of cows at different production levels are compared. A portion of consumed nutrients is utilized for maintenance; this represents a fixed cost for the cow to live and carry out normal functions. Additional nutrients are required for the synthesis of milk, and this represents a constant quantity for each increment of milk. Thus, nutrient requirements increase as milk output increases, but the fixed costs of maintenance become a smaller percent of the total requirements as milk yield increases (see Fig. 41.31). Likewise, rbST-treated cows require more nutrients to support their increased milk output, but the proportion of total nutrient intake used for milk synthesis increases and the proportion for maintenance is reduced.[5,11,80] To illustrate, consider a dairy herd of 250 cows producing at the 2017 U.S. average per cow; if rbST is used, the same herd milk output can be achieved with only 227 cows and it requires less feed, less waste, and less young stock for replacements. Alternatively, if herd size is maintained at 250 cows, the use of rbST will result in the herd's annual milk output increasing by over 275,000 gallons. Overall, the net effect is the carbon footprint for production of a gallon of milk is reduced by approximately 9% when rbST is used.[82,83]

All food production has an environmental impact. Both producers and consumers gain when the environmental costs of food production are reduced. The environmental benefits of using rbST have been enumerated in national reports by USDA and EPA, as well as a series of scientific publications.[84-90] The preceding paragraph highlighted the value of rbST use for a producer herd, but the environmental benefits are particularly impressive when considered more broadly. Table 41.12 illustrates the impact if rbST is used to produce 20% of the 2017 annual milk output by U.S. dairy farms.The environmental benefits of using rbST include reductions in animal numbers, feedstuffs, water and cropland requirements, manure and animal waste outputs, and inputs of fossil fuels and electricity. Overall, the use of rbST allows the U.S. milk supply to be produced with a lower greenhouse gas and a reduced carbon footprint. To provide perspective, in this example, the reduction in carbon footprint with rbST use is equivalent to removing more than 475,000 autos/year. Furthermore, the gains in productive efficiency and environmental benefits from the use of rbST are similar and additive to those occurring with improvements in management practices and related technologies that increase the milk yield of dairy cows. Overall, these gains play an important role in the sustainability of the dairy industry.

TABLE 41.12

Environmental Impact of Using rbST-Supplemented Cows to Produce 20% of 2017 Annual Milk Production[a,b]

Item	Savings
Animals	Reduced by 183,187 (122,736 cows, 60,451 heifers)
Feed	Reduced by 247 million tons
Cropland	Reduced by 510,000 acres (797 sq. miles)
Water	Reduced by 377 billion gallons (consumed & sanitation)
Manure	Reduced by 3.58 million tons
GHG	Reduced by 2.5 million tons

[a]Table constructed by R.A. Cady based on methods detailed in references.[81,82]

[b]Based on U.S. average calving interval, days dry, 63-day start, 14-day injection interval, last dose before anticipated dry-off date. USDA-NASS Quickstats. Available at: https://quickstats.nass.usda.gov/, Accessed 20 February 18.

Human Safety

The human safety of rbST use was extensively evaluated.When considering the human food safety of bovine somatotropin, the FDA considered the "general nature of protein digestion and absorption in adults and neonates, the effects and mechanism of action of growth hormone, its effects on other growth factors and the potential for biological and oral activity in humans."[18] Thus, oral gavage studies of both somatotropin and IGF-1 were conducted. Relative to the maximum exposure of a 10-kg infant, oral gavage doses of rbST and IGF-I were 50,000 and 200 to 2000 times greater, respectively.[18] In both cases, there were no detectable effects, which strongly indicates that any metabolites produced and taken up across the gut were not active. In agreement, a study where rats were dosed with bovine somatotropin at daily intakes from 0.04 to 4.0 mg per day demonstrated that no detectable immunoreactive bST was identified in serum of these rats.[15] Other evaluations included a Technology Assessment Conference by NIH,[84] an FDA publication in *Science*,[18] and reviews by relevant scientific societies and national medical associations.[92-95] All concluded the use of rbST presented no health or safety concerns for consumers. The human safety of milk from rbST-treated cattle has been established by 56 countries and reviewed three times by the Joint FAO/WHO Expert Committee on Food Additives (JECFA).[68,96,97] In all three reviews the JECFA declared "rbST can be used without any appreciable health risk to consumers" and that there was no need to set an Acceptable Daily Intake or Minimum Residue Level for rbST.[68,97,98] There is no test to identify milk from cows supplemented with rbST, and there are no biological or nutritional differences between milk from rbST-supplemented and unsupplemented cows.[68,90,91] The most recent re-evaluation was in 2014, when JECFA reaffirmed that advancements in somatotropin biology and over 20 years of commercial use provides no evidence of any health concerns or safety risks for humans.[68,96]
