Bronchopleural fistulas develop when necrosis of lung tissue leads to direct communication between the airways and the pleural cavity. Diagnosis may be confirmed by thoracoscopy or by injecting sterile fluorescein dye into the pleural fluid and looking for presence of dye at the nostrils or within the trachea by endoscopy. Horses with bronchopleural fistula will often cough during pleural lavage, and lavage fluid may be noted at the nostrils. Most bronchopleural fistulas seal spontaneously as a result of adhesions to the chest wall or fibrin deposition on the visceral pleura. Sealing may occur rapidly or take several weeks. In one case, partial pneumonectomy was successful at resolving a chronic bronchopleural fistula and pulmonary abscess.[73]

Prognosis The prognosis for survival and return to normal athletic function depends on the severity and duration of clinical signs prior to therapy. Horses with septic inflammatory airway disease or mild to moderate bronchopneumonia have a very good prognosis for a return to previous athletic performance. The prognosis for horses with pulmonary abscesses and without concurrent pleuritis is also good. In one study, 45 of 50 (90%) adult horses with pulmonary abscesses survived.[74] In the same study, 92% of Standardbreds and 52% of Thoroughbreds raced after treatment of pulmonary abscesses.[74] For horses that returned to racing, performance after successful treatment of lung abscesses was not significantly different from that before the illness.[74]

In a retrospective study of 327 horses with pneumonia or pleuropneumonia, the overall survival rate was 75%.[3] In the same study, the survival rate for 81 horses from which anaerobic bacteria were cultured was only 38.3%.[3] However, other studies failed to identify an association between the presence of anaerobic bacteria and decreased survival.[4,75] In cases of pleuropneumonia, retrospective studies have shown survival rates ranging from 43.3% to 87.6%.[4,14,75,76] Differences in survival rates among studies may reflect differences in referral populations as well as advances in therapy in more recent years. Many horses that would have been euthanized because of chronicity and lack of response to medical therapy several years ago are now successfully treated with the surgical approaches described above. This is evidenced by a retrospective of 153 horses with pleuropneumonia in which the survival rate was 95.7% when horses electively euthanized were excluded.[76]

The effect of pleuropneumonia on subsequent racing performance has not been examined extensively. In one retrospective study, 43 of 70 (61%) horses that had recovered from pleuropneumonia returned to racing, and 24 of those 43 (56%) won at least one race.[77] In the same study, horses that required placement of an indwelling thoracic drain did not have a worse prognosis for return to performance compared to horses that did require placement of a drain.[77] In contrast, horses that developed complications such as pulmonary abscesses, cranial thoracic masses, or bronchopleural fistulas were significantly less likely to return to racing.[77]

Rhodococcus equi Infections

Steeve Giguère

Rhodococcus equi, a gram-positive facultative intracellular bacterium, is one of the most common causes of pneumonia in foals between 3 weeks and 5 months of age. *R. equi* has also emerged as a significant opportunistic pathogen in immunosuppressed humans, especially those infected with the human immunodeficiency virus (HIV).[1,2] Although *R. equi* can be cultured from the environment of virtually all horse farms,

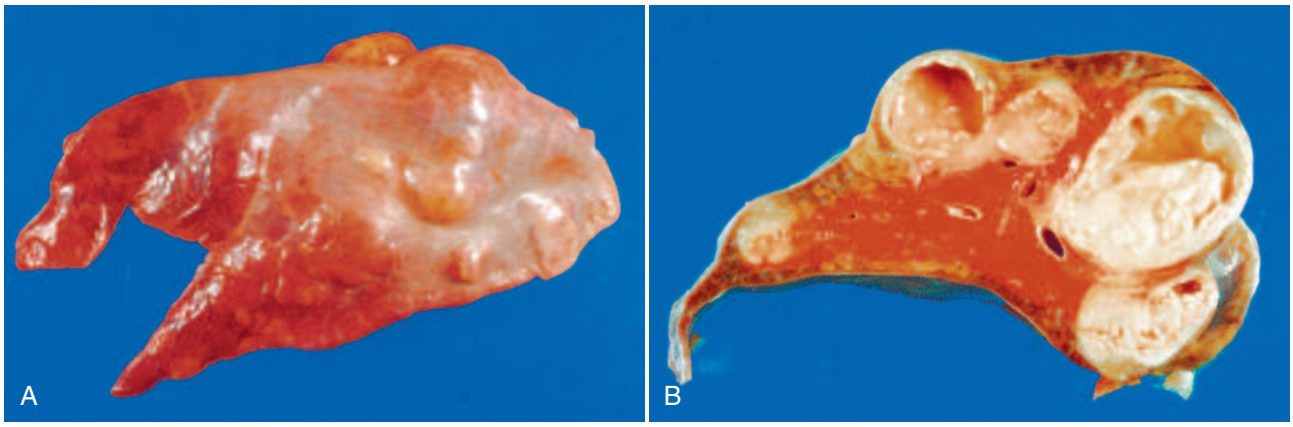

FIG. 31.13 **A,** Left lung from a foal with severe pneumonia caused by *Rhodococcus equi*. There is marked consolidation of the cranial portion of the lung, and multiple abscesses are present caudodorsally. **B,** Cross-section of the same lung showing multiple abscesses filled with caseous material. *(Courtesy Dr. William Castleman., University of Florida, College of Veterinary Medicine, Gainsville, Fla.)*

the clinical disease in foals is endemic and devastating on some farms, sporadic on others, and unrecognized on still others. At farms where the disease is endemic, costs associated with veterinary care, long-term therapy, and mortality of some foals may be very high. This text reviews the clinical manifestations, pathogenesis, epidemiology, diagnosis, treatment, and control of infections caused by *R. equi* in foals.

Clinical Manifestations

PULMONARY DISEASE. The most common clinical manifestation of disease caused by *R. equi* infections in foals is a chronic suppurative bronchopneumonia with extensive abscessation (Fig. 31.13). The slow spread of the lung infection combined with the remarkable ability of foals to compensate for the progressive loss of functional lung make early clinical diagnosis difficult. Early clinical signs often consist of a mild fever, occasional cough, or slight increase in respiratory rate that may not be apparent unless foals are exercised or stressed by handling. If pneumonia progresses, clinical signs may include decreased appetite, lethargy, fever, cough, tachypnea, and labored breathing characterized by nostril flaring and increased abdominal effort. Bilateral nasal discharge is an inconsistent finding. In a recent report of 161 foals affected with *R. equi* pneumonia, the most common clinical signs were cough (71%), fever (68%), lethargy (53%), and increased respiratory effort (43%).[3] A smaller percentage of affected foals present with a more devastating subacute form. These foals might be found dead or, more commonly, are presented in acute respiratory distress with a high fever and no previous history of clinical respiratory disease. Foals with the subacute form of the disease have a poor prognosis despite appropriate therapy.

Because ultrasonographic screening for early detection of pneumonia caused by *R. equi* has become routine practice at many endemic farms, the most frequently recognized form of *R. equi* infection at those farms is a subclinical form in which foals develop ultrasonographic evidence of peripheral pulmonary consolidation or abscessation without manifesting clinical signs.[4,5] At those farms, the cumulative frequency of ultrasonographically visible areas of focal pulmonary consolidation or abscessation considerably exceeds the historical frequency of clinical pneumonia attributed to *R. equi*, indicating that many subclinically affected foals might spontaneously recover without therapy. In two independent studies at breeding farms endemic for *R. equi* infections, 80% to 90% of foals with ultrasonographically visible lesions recovered without antimicrobial therapy.[6,7] The proportion of subclinically affected foals that progress to clinically apparent disease might vary by farm, geographic region, and age at which foals are examined.

EXTRAPULMONARY DISORDERS. Extrapulmonary manifestations of rhodococcal infections are common.[8] In a study of 150 foals with *R. equi* infections admitted to a teaching hospital, at least 1 of 39 different extrapulmonary disorders (EPDs) were recognized in 74% of foals, although some EPDs, particularly abdominal lesions, can be difficult to recognize antemortem and were recognized only during necropsy.[8] Survival was significantly lower among foals with EPDs (43%; 48 of 111) than among foals without EPDs (82%; 32 of 39).[8] Some EPDs (e.g., polysynovitis, uveitis) might be the first clinical manifestation of *R. equi*–associated disease, detected prior to signs of pneumonia.

Intestinal lesions are present in approximately 50% of foals with *R. equi* pneumonia presented for necropsy.[9] However, the majority of foals with *R. equi* pneumonia do not show clinical signs of intestinal disease. In the same study, only 4% of the foals had intestinal lesions without pneumonia.[9] The intestinal form of *R. equi* infection is characterized by a multifocal ulcerative enterocolitis and typhlitis over the area of the Peyer's patches with granulomatous or suppurative inflammation of the mesenteric and/or colonic lymph nodes.[9] In some cases, the only abdominal lesion noted may be a single large abscess (usually in a mesenteric lymph node) that often adheres to the large or small bowel (Fig. 31.14). Foals with abdominal abscesses have a poor prognosis.[8]

Clinical signs associated with the abdominal form of the disease may include fever, depression, anorexia, weight loss, colic, and diarrhea.[8,10] Diarrhea might occur in foals infected with *R. equi* either as an EPD caused by pyogranulomatous typhlocolitis or as a result of antimicrobial treatment. Of 31 foals with ulcerative enterotyphlocolitis identified at necropsy, only 12 foals had diarrhea, whereas 9 foals had diminished growth.[8] Marked GI lymphatic obstruction associated with increased protein concentration in the peritoneal fluid and systemic hypoproteinemia may lead to ascites, giving affected foals a pot-bellied appearance. Such foals have a poor prognosis because of the extensive granulomatous inflammation of the colonic mucosa and submucosa, and mesenteric lymph nodes.

Intermittent or persistent bacteremia with *R. equi* may be more common than recognized and may result in metastatic spread of infection. The proportion of foals that are blood culture–positive and the stages of disease during which bacteremia is most likely to occur are poorly defined. In one study, 6 of 10 foals with naturally acquired pneumonia had positive blood cultures.[11] More recently, *R. equi* was isolated from the blood of 11 of 19 foals, and foals with positive blood culture results were less likely to survive than foals that were culture-negative.[8]

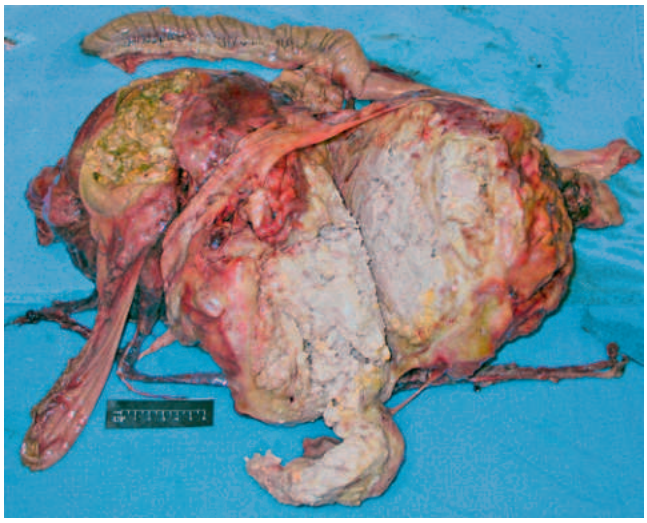

FIG. 31.14 Large abdominal abscess from a 4-month-old foal with a history of weight loss, fever, and mild intermittent episodes of colic. A portion of the small intestine and a portion of the small colon are adhered to the abscess. Culture yielded pure growth of *Rhodococcus equi*.

Polysynovitis, characterized by effusion of multiple synovial structures and absence of lameness, occurs in approximately one fourth to one third of foals with naturally acquired *R. equi* infections.[8,12] Uveitis has also been described in foals naturally infected with *R. equi*.[8] Foals with uveitis might display epiphora, photophobia, aqueous flare, hypopyon, iris discoloration, miosis, and other ophthalmic abnormalities. Detection of immunoglobulins within the synovial membrane or iris by immunofluorescence in a small number of affected foals combined with the fact that *R. equi* is rarely isolated from these sites at the time of diagnosis or necropsy [8,12-14] have led to the widespread hypothesis that polysynovitis and uveitis are immune-mediated disorders.[13-15] However, experimental infection with virulent *R. equi* consistently results in polysynovitis and uveitis, and development of these conditions is associated with the severity of pulmonary disease.[16,17] Culture of synovial fluid and aqueous humor within days of the onset of clinical signs in these foals often yields *R. equi*, and histologic examination of the synovial membrane reveals suppurative inflammation with bacteria.[16,17] Therefore polysynovitis and uveitis are most likely septic processes resulting from bacteremia. However, the infection is eventually cleared from the synovial structures and the eye, resulting in chronic nonseptic inflammation at these sites at the time of diagnosis or necropsy. Regardless of the inciting cause, local therapy of the affected joints in clinical cases of *R. equi*–associated polysynovitis is usually not indicated because the effusion resolves without any apparent consequences if the primary infection responds to appropriate antimicrobial therapy. The presence of polysynovitis or uveitis in a foal between 3 weeks and 6 months of age is highly suggestive of *R. equi* infection and deserves further investigation (see the Diagnosis section later).

Bacteremic spread of the organism from the lungs or GI tract may occasionally result in severe septic arthritis of a single joint or, more commonly, osteomyelitis. However, foals can occasionally develop *R. equi* septic arthritis or osteomyelitis without apparent lung involvement or other source of infection. Foals with septic arthritis typically show moderate to severe lameness, whereas foals with polysynovitis are not lame or only minimally so. In addition to appropriate antimicrobial therapy (see the Treatment section later), foals with *R. equi* septic arthritis and osteomyelitis often require aggressive local therapy. *R. equi* vertebral osteomyelitis or diskospondylitis resulting in spinal cord compression has also been reported.[18-20] Clinical signs of vertebral osteomyelitis or diskospondylitis may include stiff gait, reluctance to move, palpable pain, and sometimes soft-tissue swelling associated with paravertebral abscessation.[8] If the infection or associated swelling extends to the epidural space, neurologic signs of spinal cord disease or nerve root compression might be apparent.[8] Specific neurologic signs vary according to the specific region of the spinal cord that is affected. Foals with vertebral osteomyelitis generally have a poor prognosis. However, there are reports of successful treatment with prolonged antimicrobial therapy alone or in conjunction with surgical débridement of infected bone.[18]

Other less common EPDs associated with metastatic spread of *R. equi* include pericarditis, endocarditis, cellulitis, dermatitis, subcutaneous abscesses, peripheral lymphadenopathy, guttural pouch empyema, pleuritis, sinusitis, ulcerative lymphangitis, myositis, stomatitis, pyometra, and omphalitis.[8,21] Other immune-mediated EPDs include immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, and telogen effluvium.[8,22]

ADULT HORSES. Disease caused by *R. equi* in adult horses is rare, but there are sporadic reports of infection involving primarily the lungs or abdominal lymph nodes (similar to infection observed in foals) and, less common, of wound infection. In one adult horse, acquired combined immunodeficiency of unknown origin led to *R. equi* septicemia and lung abscessation.[23] Occasionally the microorganism has also been isolated from infertile mares and aborted fetuses.[9,24,25]

OTHER DOMESTIC ANIMAL SPECIES. *R. equi* has been isolated from many species other than people and horses. *R. equi* is frequently cultured from the submaxillary lymph nodes of pigs with granulomatous lymphadenitis. However, *R. equi* can also be isolated from the submaxillary lymph nodes of 3% to 5% of apparently healthy pigs, and experimental infection studies in pigs have failed to reproduce granulomatous lymphadenitis.[26,27] The causative role of *R. equi* in granulomatous lymphadenitis in pigs remains unproven. Isolation of *R. equi* from other domestic animal species is rare. *R. equi* can be isolated from lymph node granulomas in 0.008% of cattle at abattoir postmortem inspection.[28] *R. equi* has been cultured also from rare cases of bronchopneumonia, mastitis, metritis, ulcerative lymphangitis, and septic arthritis in cattle. In goats, *R. equi* has been cultured from cases of liver abscesses, bronchopneumonia, subcutaneous abscesses, osteomyelitis, and disseminated infections involving multiple sites.[29,30] In dogs and cats, *R. equi* has been isolated from cases of pneumonia as well as from wound infections, subcutaneous abscesses, vaginitis, endocarditis, endophthalmitis, hepatitis, osteomyelitis, myositis, and joint infections.[31,32] A severe systemic form with suppurative to necrotizing pneumonia and multiple caseating abscesses in mediastinal lymph nodes, liver, and spleen has been observed in camelids (llama and dromedary).[33,34]

Virulence

The ability of *R. equi* to induce disease in foals likely depends on both host and microbial factors. *R. equi* is a facultative intracellular pathogen, and its ability to persist in and eventually destroy alveolar macrophages seems to be the basis of its pathogenicity. Knowledge of the virulence mechanisms of *R. equi* was largely speculative until the discovery of a virulence plasmid in the early 1990s.[35,36] Unlike most environmental *R. equi*, isolates from pneumonic foals typically contain an 80- to 90-kb plasmid. Plasmid-cured derivatives of virulent *R. equi* strains lose their ability to replicate and survive in macrophages.[16] Plasmid-cured derivatives also fail to induce pneumonia and are completely cleared from the lungs of foals within 2 weeks following heavy intrabronchial challenge, confirming the absolute necessity of the large plasmid for the virulence of *R. equi*.[16,37]

VetBooks.ir

Sequencing and annotation of the virulence plasmid obtained from isolates of *R. equi* cultured from pneumonic foals revealed 73 coding sequences[38,39] divisible into four discrete areas based on open reading frame (ORF) amino acid sequence similarity and predicted protein function. The "backbone" sequence of the plasmid is highly similar to that of a plasmid found in the environmental microorganism *Rhodococcus erythropolis* and consists of regions for replication or partitioning, conjugation, and unknown functions.[38] The fourth plasmid region is a 21-kb pathogenicity island (PAI) that is crucial for virulence.[38,39] The 26 coding sequences of the PAI include the unique and *R. equi*–specific virulence-associated protein (Vap) family.[39] There are six full-length *vap* genes, (*vapA*, *vapC*, *vapD*, *vapE*, *vapG*, and *vapH*) and three truncated *vap* pseudogenes (*vapF*, *vapI*, and *vapX*).[38] To date, *vapA*, which encodes an immunodominant, temperature-inducible, and surface-expressed lipoprotein,[40,41] is the only *vap* gene with a demonstrated role in virulence,[42] whereas *vapsC*, *D*, *E*, *F*, *G*, *I*, and *X* are dispensable.[42,43] *VapA* is required for intracellular growth in macrophages,[42] where it disrupts endolysosomes and contributes to preventing maturation of the phagosome to the stage of fusion of *R. equi*–containing vacuoles with lysosomes.[44,45] The functions of the other Vap proteins are unknown.

Although *vapA* is necessary for virulence, it is not sufficient.[16] Two additional regulator genes of the PAI, *virR* and *virS*, are required for intracellular growth in macrophages and virulence.[46-49] Loss of either regulator results in decreased transcription, not only of *vapA*, but also of several chromosomal genes.[46-49] These findings demonstrate the presence of molecular "crosstalk" between the virulence plasmid and the *R. equi* chromosome. All of the *vap* genes as well as five other ORFs within the PAI are upregulated when *R. equi* is grown in macrophage monolayers.[50] Regulation of expression of the genes in the PAI is complex and depends on at least five environmental signals: temperature, pH, oxidative stress, magnesium, and iron.[50-52] The precise role of each of these genes in the pathogenesis of *R. equi* infections remains to be determined. The entire virulence plasmid can be transferred by conjugation from plasmid-containing strains of *R. equi* to plasmid-free *R. equi* strains at a high frequency, and plasmid transmission restores the capacity for intracellular growth in macrophages.[53] Deletion of a putative relaxase-encoding gene *(traA)* located in the proposed conjugative region of the plasmid prevents plasmid transfer.[53]

Virtually all isolates of *R. equi* cultured from diseased foals contain the large circular plasmid described earlier (designated pVapA because it encodes *vapA*), whereas most isolates from swine with granulomatous lymphadenitis contain a similar large circular plasmid (designated pVapB) that encodes a 20-kDa antigen (VapB) that is related to but distinct from VapA.[54] Most isolates from cattle with granulomatous lymphadenitis and from goats with various infections contain a linear plasmid (designated pVapN, with "N" standing for "no-A no-B") unrelated to the circular virulence plasmids pVapA and pVapB.[55,56] In contrast, many environmental isolates of *R. equi* do not contain any of these three plasmids and are referred to as avirulent because they lack the ability to replicate in macrophages and in experimentally infected mice and they cannot induce disease in foals. Isolates carrying pVapB or pVapN have not been isolated from foals with naturally acquired *R. equi* infections. Experimentally, heavy intrabronchial challenge of foals with *R. equi* carrying pVapB results in pneumonia but at a dose much higher than that required for induction of pneumonia with strains containing pVapA.[57] The observation that all *R. equi* isolates obtained from foals carry pVapA, most isolates from swine carry pVapB, and most isolates from ruminants carry pVapN-type plasmid has led to the hypothesis that plasmid type might dictate host species tropism. However, *R. equi* isolates from pigs, carrying pVapB, are able to replicate in a plasmid-dependent manner in macrophages obtained from a variety of species (murine, swine, and equine).[58] Similarly, equine isolates carrying pVapA are capable of replication in swine macrophages.[58] Plasmid swapping between equine and swine strains through conjugation does not alter the intracellular replication capacity of the parental strain.[58] These results demonstrate that, although distinct plasmid types exist among *R. equi* isolates obtained from different species, host tropism is not determined exclusively by plasmid type.

The plasmid profile of *R. equi* isolated from other species is not as straightforward as it is in horses, swine, and ruminants. Analysis of 65 *R. equi* isolates from humans with and without AIDS reveals that approximately 15% of isolates contain pVapA, approximately 17% contain pVapB, and approximately 25% contain pVapN.[59] Most isolates of *R. equi* cultured from humans do not contain pVapA, pVapB, or pVapN.[59-62] Therefore the pathogenesis of *R. equi* infection in immunocompromised human patients appears to be different from the pathogenesis in foals, in which pVapA is always found. Similarly, isolates from cats and dogs can be avirulent or contain any of the three plasmids.[31,63]

Another major advance in the understanding of *R. equi* virulence was the sequencing and annotation of the genome of *R. equi*.[64] The 5.04-Mb *R. equi* genome is most similar to that of the environmental bacterium *Rhodococcus jostii* and then to *Nocardia farcinica* and *Mycobacterium tuberculosis*.[64] As with these other actinomycetes, a large number of the 4598 genes of *R. equi* appear to be involved in lipid metabolism. Like *M. tuberculosis*, lipids are a key component of the outer cell envelope of *R. equi*.[65] This mycolic acid-containing glycolipid barrier might serve to protect the peptidoglycan and plasma membrane from the damaging effects of host-generated enzymes and immune-mediated reactive intermediates. Cell envelope mycolic acid carbon chain length varies among *R. equi* isolates, and notably it was observed that strains with longer mycolic acids were more lethal to mice.[66] This might be explained by the fact that mycolic acid chain length plays a key role in diversion of macrophage phagosome trafficking by *R. equi*.[67] Although it has been firmly established that the virulence plasmid is essential for infection of foals, several chromosomally encoded genes have also been proven to play essential roles in intracellular survival and virulence, notably those involved in various metabolic functions such as fatty acid metabolism, anaerobic metabolism, aromatic amino acid biosynthesis, regulation of secreted proteins, iron acquisition, hydrogen peroxide resistance, and cholesterol catabolic pathways.[64,68-76]

Pathogenesis Inhalation of virulent *R. equi* is the major route of pulmonary infection in foals. The incubation period following experimental intrabronchial challenge varies from approximately 9 days after administration of a heavy inoculum to approximately 2 to 4 weeks when a lower inoculum is administered.[16,77] Lung consolidation can be detected as early as 3 days following heavy intrabronchial challenge.[16] However, the incubation period under field conditions is unknown and likely varies depending on several factors, including the number of virulent bacteria in the air, the age of the foal, and host defense mechanisms. Ingestion of the organism is an important route of exposure, and likely also of induction of an immune response, but rarely leads to hematogenously acquired pneumonia unless a foal has multiple exposures to large numbers of bacteria.[78] Indeed, intragastric administration of live virulent *R. equi* to foals on day 2 and day 7 of life is highly effective in preventing development of pneumonia following subsequent heavy intrabronchial challenge.[79] Despite conferring protection, oral vaccination with live virulent *R. equi* would not be an acceptable strategy to immunize foals, since it would lead to progressive contamination of the environment with virulent bacteria. However, it undoubtedly shows that newborn foals have the ability to mount protective immune responses against *R. equi* (see the Immunity section later).

VetBooks.ir

Epidemiologic evidence suggests that most foals on endemic farms become infected early in life.[80] The median age at the time of diagnosis is approximately 35 to 50 days on most endemic farms.[3,81] Given the fairly long incubation period of the disease, this finding would also support the fact that many foals become infected early in life. In one study, foals between 3 and 13 days of age (mean of 6.4 days) were more susceptible to experimentally induced *R. equi* pneumonia than foals between 14 and 36 days of age (mean of 25 days).[82] In another study, foals between 3 and 42 days of age were experimentally infected with various doses of virulent *R. equi* (10^3 to 10^7).[83] Whereas the youngest foals were highly susceptible to infection, the oldest foals were resistant to thousandfold higher challenge.[83] Collectively, these findings indicate that many foals on endemic farms become infected at a young age and that younger foals are more susceptible than older foals to infection caused by *R. equi*. However, these findings do not necessarily indicate that foals are only susceptible to *R. equi* during the neonatal period. Older foals are also susceptible to experimental infection with *R. equi*, but they require a higher inoculum. In one study, intratracheal administration of *R. equi* to 10 foals between 27 and 67 days of age (mean of 49 days) resulted in disease in all foals.[37] The relative resistance of older foals to infection caused by *R. equi* compared with younger foals is likely the result of immunologic priming after natural exposure to the pathogen.

Epidemiology

Although *R. equi* can be cultured from the environment of virtually all horse farms, the clinical disease in foals is endemic and devastating on some farms, sporadic on others, and unrecognized on still others. This might reflect differences in environmental and management conditions, as well as differences in the virulence of isolates, but the exact basis for the difference in the prevalence of the disease among farms remain unknown. Breeding farms with a large acreage, a large number of mares and foals, a high foal density, and a large population of transient mares and foals have greater odds of being affected by *R. equi* pneumonia.[84,85] In contrast, *R. equi* pneumonia does not appear to be associated with lack of attention to routine preventive health practices.[86]

R. equi is a soil microorganism with simple growth requirements. The highest numbers of *R. equi* are found in surface soil, and the organism cannot be found at depths exceeding 30 cm.[87] *R. equi* can be cultured not only from the soil of all horse farms but also from the soil of areas not inhabited by horses. In one study, *R. equi* was isolated from approximately 74% of soil samples collected from 115 parks and 49 household yards in Japan. The number of *R. equi* in those samples ranged from 10 to 10^5 colony-forming units (CFU) per gram of soil. None of the 1294 isolates from those samples expressed VapA or VapB.[27]

R. equi can be isolated from the feces of most adult horses at concentrations ranging from 10 to 10^4 CFUs/g of feces. The number of *R. equi* in the feces of mares on endemic farms does not increase in the weeks before or after foaling.[88] In one study, virulent *R. equi* could be isolated from the feces of all mares sampled, demonstrating that mares can be an important source of virulent *R. equi* for their surrounding environment.[89] However, dams of affected foals did not shed more *R. equi* in feces than did dams of unaffected foals, indicating that heavier shedding by particular mares does not explain infection in their foals.[89] In another study, *R. equi* could be isolated from the feces of only 19% of the foals at 1 week of age and from all foals by 4 weeks of age.[88] Foals can shed high concentrations of *R. equi* in their feces, reaching numbers up to 10^5 CFUs/g of feces.[90] Virulent *R. equi* present in the sputum of pneumonic foals will be swallowed, and as a result the manure of *R. equi*–affected foals is likely a major source of progressive contamination of the environment with virulent organisms.

In a survey of the prevalence of *R. equi* at horse breeding farms in Japan, the organism was isolated from almost all soil samples, at numbers of 10^2 to 10^5 CFUs/g of soil.[91] Although virulent *R. equi* isolates containing pVapA were cultured from 24 of 31 farms examined, the vast majority of these isolates did not contain plasmids and were avirulent. On those farms, virulent *R. equi* represented 1.7% to 23.3% of all isolates.[91] However, neither the presence nor the concentration of virulent *R. equi* in soil is positively associated with increased cumulative incidence of *R. equi* pneumonia at breeding farms in North America or Australia.[92-94] In addition, soil geochemistry does not appear to be associated with occurrence of *R. equi* pneumonia at farms.[95]

In contrast, airborne concentration of virulent *R. equi* is associated with disease incidence at Thoroughbred breeding farms in Australia.[94] Factors associated with increased air concentration of *R. equi* at these farms included site (higher in holding pens and lanes relative to paddocks), warmer ambient temperature, less soil moisture, reduced grass height, and later date during the foaling season.[94] In Kentucky, concentrations of airborne *R. equi* were lower between midnight and 6 AM, and the presence of horses at the sampling site appeared to increase the airborne concentrations of virulent *R. equi*.[96] These findings suggest that airborne concentrations may be increased by greater activity and density of horses at sites where foals are housed. Also in Kentucky, foals were more likely to be exposed to airborne virulent *R. equi* when housed in stalls versus paddocks and earlier (January and February) versus later (May and June) during the foaling season.[97] Similarly, the odds of detecting airborne virulent *R. equi* at three breeding farms in Ireland were approximately 17 times greater in stables (stalls) than in paddocks of a given farm, and concentrations of virulent *R. equi* were also significantly higher in stables than in paddocks.[98] In a recent study at a breeding farm in Texas, exposure of foals to airborne virulent *R. equi* during the first 2 weeks after birth was significantly associated with subsequent development of *R. equi* pneumonia.[99] The fact that exposure to *R. equi* preceded development of pneumonia suggests that the higher concentration of airborne virulent *R. equi* is likely the cause of pneumonia rather than an effect of it.

In one study, air samples from the breathing zone of pneumonic foals had higher concentrations of virulent *R. equi* than environmental air samples collected from lanes and pens at the same farms.[100] However, concentrations of virulent *R. equi* from air samples collected from the breathing zones were not significantly different between pneumonic foals and healthy controls, indicating that affected foals do not represent a greater risk than other foals for aerosol transmission. In addition, there was no association between virulent *R. equi* in the breathing zone of foals and the subsequent diagnosis of rhodococcal pneumonia.[101] Thus, to date, there is no compelling evidence that *R. equi* infection is contagious among foals and that affected foals should be isolated from other foals.

Considerable genotypic variability has been found among isolates of *R. equi* obtained from the same farm and among isolates from various countries or continents.[102-104] Interestingly, multiple different *R. equi* strains were isolated in five of the six cases in which more than one isolate from a single foal was examined.[103] Similarly, six distinct genotypes were identified among nine *R. equi* isolates from one foal with pneumonia and concurrent abdominal lesions.[105] None of the four pulmonary isolates were identical; however, a pulmonary isolate was found to be identical to an isolate recovered from a small intestinal lymph node, and a second pulmonary isolate was identical to an isolate from a mesenteric lymph node.[105] Therefore foals can be infected with multiple strains of virulent *R. equi*, and with current techniques it is not possible to link infections to a given geographic site or region on the basis of analysis of isolate genotyping.

Rhodococcus equi–Phagocytic Cell Interactions

Once inhaled, *R. equi* is taken up by alveolar macrophages

VetBooks.ir

through a process of receptor-mediated phagocytosis. One of the receptors used by macrophages to engulf complement-opsonized *R. equi* is complement receptor 3 (CR3 or Mac-1).[106] In addition, *R. equi* might use the macrophage mannose receptor for entry, which may recognize lipoarabinomannan (LAM), an outer surface component of the bacterium, either directly or via mannose binding protein or surfactant molecules adhered to LAM.[107] Once engulfed by resident macrophages, virulent *R. equi* are able to modify the phagocytic vacuole to prevent acidification and subsequent fusion with lysosomes.[44,108-110] The ability of *R. equi* to disrupt endolysosome function depends on VapA,[45] and addition of soluble recombinant VapA restores the ability of avirulent *R. equi* mutant lacking the *vapA* gene to survive and replicate in macrophages.[111,112] Uncontrolled intracellular replication of *R. equi* leads to necrosis of the macrophage.[113] If bacteria are opsonized with *R. equi*–specific antibody, presumably promoting bacterial entry via the macrophage Fc receptor, the fate of the *R. equi*–containing phagosome is altered and lysosome fusion occurs.[114] This may explain how the presence of *R. equi* antibody might aid in the prevention of infection. Killing of *R. equi* by mouse macrophages is dependent on the presence of IFN-γ, which activates macrophages to produce both reactive oxygen and reactive nitrogen intermediates. These two radicals combine to form peroxynitrite, which efficiently kills *R. equi*.[115] Neither reactive oxygen nor reactive nitrogen intermediates alone are sufficient to mediate killing of *R. equi*.[115] Macrophage activation and nitric oxide synthesis act at least in part by increasing the ability of macrophages to store iron in a way that it cannot readily be accessed by *R. equi*.[116] Additional cytokines such as tumor necrosis factor (TNF)–α might have similar effects on restricting intracellular growth of *R. equi* in macrophages because both IFN-γ and TNF-α are required for clearance of virulent *R. equi* in mice.[117] In a recent study, priming of equine monocyte-derived macrophages IFN-γ, TNF-α, or IL-6 decreased intracellular survival of *R. equi*, whereas IL-1β or IL-10 enhanced intracellular survival.[118] Neutrophils also play an important role in early host defense against virulent *R. equi*.[119] As opposed to macrophages, neutrophils from foals and adult horses are fully able to kill *R. equi*.[120-122] As seen with macrophages, killing of *R. equi* by neutrophils is considerably enhanced by specific opsonizing antibody.[123,124]

Immunity

ANTIBODY-MEDIATED IMMUNITY. Immunity to *R. equi* pneumonia in foals likely depends on both the antibody and cell-mediated components of the immune system, but its exact basis remains to be determined. The strongest evidence for a role of antibody in protection against *R. equi* is the partially protective effect of passively transferred anti–*R. equi* hyperimmune equine plasma (HIP; see the Control and Prevention of *R. equi* Infections on Farms Where the Disease Is Endemic section later) and the fact that maternal vaccination against poly-*N*-acetylglucosamine protects foals against intrabronchial challenge with *R. equi*.[125] The mechanisms by which antibody confers protection against facultative intracellular bacterial pathogens is an area of active investigation. Opsonization of *R. equi* with specific antibody has been shown to promote phagocytosis and killing of *R. equi* by alveolar macrophages, identifying antibody as a critical component of HIP.[114,126] In most studies evaluating the protective effect of HIP, donors were immunized with whole cell vaccines or a mixture of several soluble antigens, making it impossible to determine the role of antibody against defined antigens of *R. equi*.

A number of studies have focused more specifically against the role of antibody against plasmid-encoded Vaps. First, monoclonal antibody to VapA and serum from horses immunized with partially purified VapA have opsonizing activity.[127] Moreover, purified immunoglobulins obtained from horses vaccinated with partially purified VapA protected mice against intraperitoneal challenge with virulent *R. equi* compared with mice administered immunoglobulins from nonimmunized horses.[128] Finally, intravenous administration of purified immunoglobulins obtained from horses immunized with recombinant VapA and VapC to foals was found to reduce the severity of pneumonia following heavy experimental challenge with *R. equi*.[129] In the same study, the degree of protection conferred by purified anti-VapA and anti-VapC immunoglobulins was similar to that provided by commercially available HIP.[129]

In adult horses, the concentrations of *R. equi*– and VapA-specific IgGa and IgGb antibodies (the IgG isotypes that preferentially opsonize and fix complement in horses) are dramatically enhanced following intrabronchial challenge with virulent *R. equi*. This occurs in conjunction with clearance of the bacteria from the lungs.[130] In foals, production of antibody to VapA and VapC, but not that to other Vaps, increases following natural exposure to *R. equi*.[129] Characterization of the subisotype response in naturally infected foals revealed mainly an increase in IgGa, IgGb, and IgG(T).[129,131,132] Experimental infection of young foals with a low inoculum of virulent *R. equi* that resulted in subclinical pulmonary lesions caused a marked increase in serum IgGa and IgGb levels, resulting in concentrations that were significantly higher than those of adult horses undergoing the same challenge.[133] Infection of foals of the same age with a higher inoculum leading to severe respiratory disease resulted in a switch from a predominant IgGa response to a striking IgG(T) response, indicating that the size of the *R. equi* inoculum can modulate immune responses.[134]

CELL-MEDIATED IMMUNITY. Because of the facultative intracellular nature of *R. equi*, cell-mediated immune mechanisms are thought to be of major importance in resistance to infection. A large part of the knowledge of cell-mediated immunity to *R. equi* infections comes from infection of mice. Deficiencies in the complement component C5 and in natural killer (NK) cells in mice do not impair the pulmonary clearance of virulent *R. equi*.[135] In contrast, functional T lymphocytes are absolutely required for the clearance of virulent (plasmid- and VapA-positive) *R. equi* in mice.[136-138] However, athymic nude mice (lacking functional T lymphocytes) clear plasmid-cured derivatives from their lungs within 1 week of infection, suggesting that, as opposed to virulent organisms, clearance of avirulent plasmid-negative strains in mice does not require functional T lymphocytes and depends mainly on innate defense mechanisms.[137]

The two major mechanisms by which T lymphocytes mediate clearance of intracellular pathogens are secretion of cytokines and direct cytotoxicity. Although both CD4+ (helper) and CD8+ (cytotoxic) T cells contribute to host defense against *R. equi* in mice, CD4+ T lymphocytes play the major role and are absolutely required for complete pulmonary clearance.[138-140] Studies in mice have clearly shown that a type I response, characterized by IFN-γ production by T-helper lymphocytes, is sufficient to effect pulmonary clearance of *R. equi*, whereas a type II response, characterized by IL-4 production, is detrimental.[136,141]

As opposed to foals, adult horses are typically resistant to *R. equi* infections. Thus immune adult horses have been used as a relevant model to better understand what responses are necessary for immunologic protection. Clearance of virulent *R. equi* in adult horses is associated with a significant increase in BAL fluid CD4+ and CD8+ lymphocytes, lymphoproliferative responses to *R. equi* antigens, development of *R. equi*–specific cytotoxic CD8+ T lymphocytes (CTLs), and IFN-γ induction by CD4+ and CD8+ lymphocytes.[130,142,143] *R. equi*–specific CTLs, which are apparently present in all immune adults, are major histocompatibility complex (MHC) class I–unrestricted and appear to recognize unique bacterial lipids from the cell

wall.[143,144] The current thought is that these lipid antigens might be presented to T lymphocytes via the CD1 system, as has been well described in *M. tuberculosis*.[145] How these findings in mice and adult horses relate to the foal is an area of active research.

IMMUNITY TO *R. EQUI* IN FOALS. Virtually all newborn mammals are immunologically immature and have an assortment of immunologic deficits compared with older animals. In general, neonates and perinates have diminished innate immune responses and decreased antigen-presenting cell function and are less able to mount type I immune responses.[146] As a result, neonates of various species demonstrate an increased susceptibility to certain infections.

A number of relative immunologic deficits have been demonstrated in foals. In conjunction with the lack of immunologic memory in newborns, these deficits are postulated to account for the unique age-associated susceptibility of foals to rhodococcal pneumonia. Age-related deficiencies in *R. equi*–specific CTL activity has been documented in 3-week-old foals.[143] Activity of CTLs is improved by 6 weeks of age and is similar to that of adult horses by 8 weeks.[143] Antigen-presenting cells from foals have significantly lower CD1 and MHC class II expression compared with adult horses.[145,147] In addition, several studies have demonstrated that the ability of equine lymphocytes and neutrophils to produce and/or upregulate various cytokines is strongly influenced by age.[146-151] In particular, the finding that young foals are deficient in their ability to produce IFN-γ in response to mitogens has led to the hypothesis that an IFN-γ deficiency and type II bias might be at the basis of their peculiar susceptibility to *R. equi* infections.[148,149] However, foals are also deficient in their ability to produce IL-4 in response to stimulation with mitogens and stimulation with *R. equi* and after vaccination with a killed adjuvanted vaccine, suggesting that a clear polarization toward a type II response is unlikely in neonatal foals.[152-155] Consistent with these findings, experimental infection of young foals with virulent *R. equi* results in IFN-γ induction and antibody responses similar to, or greater than, those of adult horses undergoing the same experimental challenge.[133]

Several studies have investigated various immunostimulants that might enhance host defense mechanisms during the relatively narrow period of susceptibility to *R. equi*. Inactivated *Parapoxvirus ovis*, *Propionibacterium acnes*, and unmethylated CpGs all enhance ex vivo or in vitro phagocytic cell function or cytokine induction in foals.[156-159] However, despite successfully enhancing IFN-γ production in foals, inactivated *P. ovis* failed to decrease the cumulative incidence of pneumonia at an *R. equi*–endemic farm. In the same study, IFN-γ and IL-4 secretion at birth was not associated with subsequent development of pneumonia.[160]

Spontaneous resolution of *R. equi* pneumonia after experimental challenge has been recognized.[82,161,162] Many foals on farms where the disease is endemic do not develop disease or develop subclinical disease that resolves without intervention.[7,163,164] In addition, intragastric administration of live, virulent *R. equi* to newborn foals confers complete protection against subsequent heavy intrabronchial challenge.[79,165] Oral inoculation with virulent *R. equi* results in accelerated development of *R. equi*–specific CTL,[166] providing a potential mechanism for the protection conferred by oral inoculation. Collectively, these findings unequivocally demonstrate that most foals have the ability to mount protective immune responses to *R. equi*. The basis for the peculiar susceptibility of foals to infection with *R. equi* is likely complex and multifactorial rather than involving a simple and single explanation. The number of virulent bacteria in the environmental air, the age of the foal, the level of prior exposure to *R. equi*, and genetic susceptibility likely play a role. Genetic susceptibility to *R. equi* is likely complex, with modest contributions from numerous genes involving various biological pathways and processes.[167]

Diagnosis

The distinction between lower respiratory tract infections caused by *R. equi* and those caused by other pathogens is problematic, especially at farms without previous history of *R. equi* infections. Measurement of WBC or fibrinogen concentrations, ultrasonography, and radiography may help raise the degree of suspicion that pneumonia in a given foal may be caused by *R. equi* rather than another microorganism. However, the definitive diagnosis of bronchopneumonia caused by *R. equi* should be based on bacteriologic culture or amplification of the *vapA* gene by PCR from a TBA obtained from a foal with (1) clinical signs of lower respiratory tract disease, (2) cytologic evidence of septic airway inflammation, and/or (3) radiographic or ultrasonographic evidence of bronchopneumonia. Amplification of *vapA* by PCR is done preferably in conjunction with bacterial culture because the former test does not permit identification of other bacterial pathogens and in vitro antimicrobial susceptibility testing of *R. equi* isolates.[168] The definitive diagnosis of extrapulmonary infections (e.g., abdominal abscess, osteomyelitis) caused by *R. equi* must rely on bacteriologic culture or PCR amplification of *vapA* from samples from the site of infection. The diagnosis of extrapulmonary disorders from sites at which *R. equi* cannot be detected (e.g., uveitis or polysynovitis) should be based on isolation of *R. equi* from TBA or other primary sites of infection. The diagnosis of enterocolitis caused by *R. equi* is problematic because isolation of *R. equi* from feces cannot be taken as evidence of enterocolitis caused by *R. equi*.[168]

CLINICAL LABORATORY TESTS. Hyperfibrinogenemia is the most consistent laboratory finding in foals with *R. equi* pneumonia, although rare cases may have normal fibrinogen concentrations. Neutrophilic leukocytosis with or without monocytosis is also common. One study showed significantly higher fibrinogen concentrations and WBC counts in nonsurvivors than in survivors,[169] whereas other studies showed no difference between the two groups.[12,170] In one study, WBC count higher than 20,000 cells/μL, fibrinogen concentration higher than 700 mg/dL, and evidence of pulmonary abscessation were more likely to be found in foals with pneumonia caused by *R. equi* than in foals with pneumonia caused by other bacteria.[171] However, there is considerable overlap in distributions, which precludes the use of fibrinogen concentrations and WBC counts for diagnosis or prognosis for an individual foal.[171] Similarly, serum amyloid A (SAA) concentrations are significantly higher in pneumonic than in healthy foals.[172] However, many foals with severe *R. equi* pneumonia have SAA concentrations within the reference interval, and there is a poor association between SAA concentration and the severity of pulmonary disease as assessed by radiography.[172]

IMAGING TECHNIQUES. Thoracic radiography is useful in evaluating the severity of pneumonia and in assessing response to therapy. A prominent alveolar pattern characterized by ill-defined regional consolidation is the most common radiographic abnormality.[169] The consolidated lesions are often seen as more discrete nodular and cavitary lesions consistent with pulmonary abscessation (Fig. 31.15). Severity of alveolar pattern and number of cavitary lesions are the radiographic findings significantly associated with a poor outcome in foals with *R. equi* pneumonia.[173] Although nonsurvivors tend to have more severe radiographic lesions than survivors, many survivors have very severe radiographic lesions; thus radiographs should not be used as the sole criterion for prognostication and euthanasia.[12,170,173] Ultrasonography is a helpful diagnostic tool when lung involvement includes peripheral areas but may not be as useful as radiography to evaluate the full extent of lung lesions

VetBooks.ir

because abscesses with overlying aerated lung will not be detected by ultrasonography. However, in most horses and foals with pulmonary abscessation the periphery of the lung is affected, enabling the ultrasonographer to successfully image some of the abscesses.[174] Early ultrasonographic lesions are nonspecific and may include only irregularities of the pleural surface. These lesions may progress to form focal areas of consolidation of various sizes (Fig. 31.16, *A*). In more chronic cases, well-circumscribed, encapsulated abscesses can be detected (Fig. 31.16, *B*). Ultrasonography is very useful in evaluating the severity of pneumonia and in assessing response to therapy, especially for equine practitioners who do not have access to thoracic radiography. Ultrasonography is also a useful tool for detecting some abdominal abscesses (Fig. 31.17) and for screening for *R. equi*–infected foals on farms where the disease is endemic (see the Control and Prevention of *R. equi* Infections on Farms Where the Disease Is Endemic section later). Ultrasonographic or radiographic detection of lung abscesses raises the degree of suspicion that pneumonia in a given foal is caused by *R. equi*. However, detection of pulmonary abscesses, while commonly used as a screening test (see the Screening for Earlier Detection of Affected Foals section later), is not a definitive diagnostic test.

SEROLOGY. Currently available serologic tests should not be used for the diagnosis of pneumonia caused by *R. equi*. Independent studies evaluating the performance of serologic tests available for diagnosis of infection caused by *R. equi* at endemic farms have demonstrated that these tests have low sensitivity, low specificity, or both.[175-178] Improving either sensitivity or specificity of ELISA assays by changing the cutoff value corresponding to a positive or negative test result could only be done to the detriment of the other. The presence of antibodies indicates exposure, subclinical infection, or maternal transfer of antibodies, but it does not necessarily indicate infection leading to clinical disease.

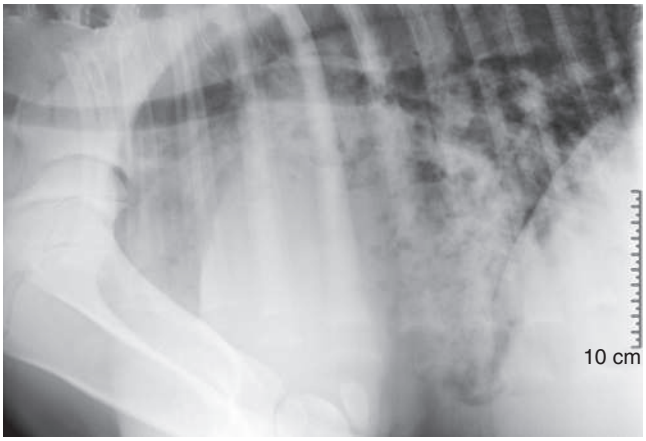

FIG. 31.15 Thoracic radiograph from a 2-month-old foal with pneumonia caused by *Rhodococcus equi*. The study shows a combination of alveolar and nodular interstitial patterns as well as cavitary nodular infiltrates, primarily in the cranioventral and caudoventral thorax. A mild interstitial infiltrate is present in the caudodorsal lung. The trachea is displaced dorsally, suggesting tracheobronchial lymphadenopathy. There is slight narrowing of the tracheal lumen at the thoracic inlet, likely indicating the presence of tracheal secretions.

FIG. 31.17 Sonogram of the abdomen obtained from a 3-month-old Thoroughbred foal with severe pneumonia caused by *R. equi* and multiple abdominal abscesses. The sonogram shows an abdominal abscess *(arrow)*. The pneumonia resolved with therapy, but the abdominal abscesses persisted. The foal was eventually euthanized because of weight loss and intermittent episodes of colic. Postmortem examination confirmed resolution of pneumonia and the presence of abdominal abscesses caused by *Rhodococcus equi*.

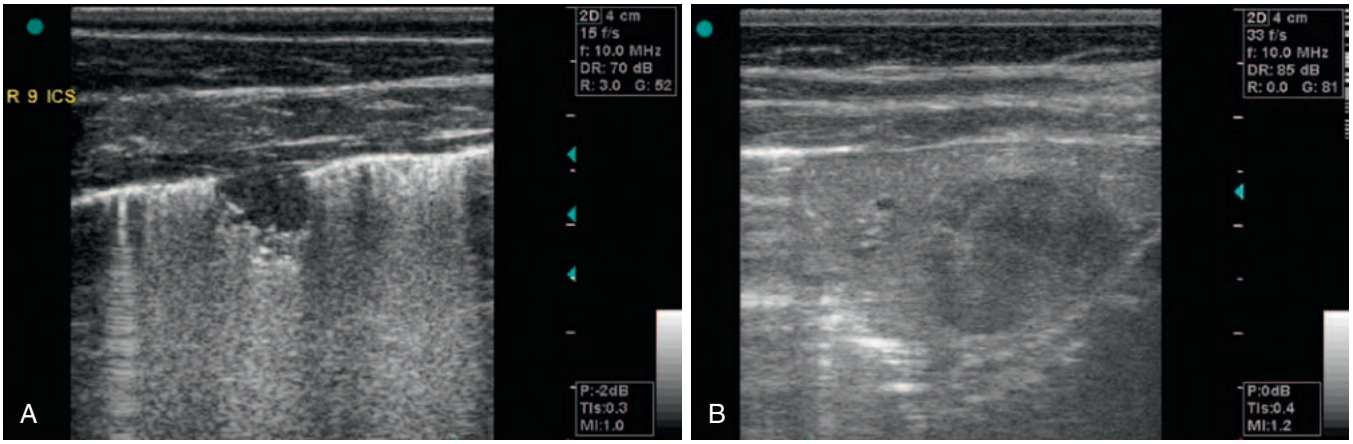

FIG. 31.16 **A,** Sonogram of the right thorax in a foal with mild pneumonia caused by *Rhodococcus equi*. There is an approximately 1 cm^2 area of focal consolidation. **B,** Sonogram of the left thorax in a foal with severe pneumonia caused by *R. equi*. There is consolidation of the ventral aspect of the lung surrounding a large encapsulated abscess.

CYTOLOGY, CULTURE, AND PCR AMPLIFICATION. Bacteriologic culture or PCR amplification of *vapA* from a TBA are the only acceptable ways of establishing a diagnosis of *R. equi* pneumonia. In one study, only 7 of the 11 (64 %) foals with positive *R. equi* culture at necropsy and 57 of the 89 (64 %) foals with radiographic evidence of lung abscessation yielded *R. equi* from culture of a TBA.[179] However, in two other studies, all 17 foals in which *R. equi* was isolated from lung parenchyma at necropsy yielded the organism from culture of TBAs obtained antemortem, suggesting that culture of a TBA is a valid method for diagnosing *R. equi* pneumonia.[180,181] Larger case series are required to more accurately estimate the sensitivity of TBA culture for diagnosis of *R. equi* pneumonia in foals. Specificity of the test must also be considered. Foals without clinical disease may have *R. equi* in their trachea as a result of subclinical disease or, incidentally, from inhaling *R. equi* in contaminated environments. At a farm with endemic *R. equi* pneumonia, 77 of 216 (35%) foals sampled had positive TBA cultures but remained free of clinical signs of respiratory disease throughout the season.[182] For this reason, culture or PCR amplification of *R. equi* from a TBA should always be interpreted in the context of cytologic and clinical findings. Detection of *R. equi* from a foal without clinical signs of respiratory disease, cytologic evidence of septic airway inflammation, or ultrasonographic or radiographic evidence of pulmonary lesions is likely an incidental finding, due to the ubiquitous nature of the organism on horse farms. Amplification of *vapA* by PCR has been shown to be more sensitive than bacterial culture in most but not all studies.[183-185] However, increased sensitivity may also result in a higher incidence of false-positive results due to the detection of very small numbers of *R. equi* present as environmental contaminants. Moreover, culture offers the advantage of detecting other bacterial pathogens present and permits in vitro susceptibility testing of recovered pathogens. As a result, PCR amplification of *vapA* may be done in conjunction with, but should not replace, bacterial culture. The use of PCR assays based on genes other than *vapA* is not recommended, as these assays would also detect environmental isolates lacking the virulence plasmid, which are not known to cause disease in foals.

Isolation or detection of *R. equi* from nasal or fecal swabs cannot be taken as evidence of disease due to infection with *R. equi*. *R. equi* can be cultured from the feces of healthy horses even if they live at farms without history of *R. equi* pneumonia.[90,186,187] Quantitative culture of the feces of foals at weekly intervals has been advocated to aid in early diagnosis of *R. equi* infections because the fecal concentration of *R. equi* increased at the same time as clinical signs of respiratory disease appeared in a few foals.[187] Similarly, concentrations of *R. equi* in feces at the time of clinical diagnosis, as assessed by quantitative PCR amplification of the *vapA* gene, were significantly higher in clinically affected foals than in healthy foals or foals with subclinical lesions at the same farm.[188] However, the assay is not commercially available and it is unknown if the cut-point used in the aforementioned study would be applicable to foals at other farms. Quantification of *R. equi* in a single fecal sample from a foal has little diagnostic value because of individual and farm-to-farm variation in the number of *R. equi* in feces.[90,186,187] Furthermore, a negative fecal culture may not be helpful in excluding *R. equi* infection because only 5 of 30 (17%) foals with confirmed *R. equi* pneumonia had positive fecal cultures.[182] Similarly, bacterial culture and PCR amplification of nasal swabs are insensitive for diagnosis of *R. equi* pneumonia.[183,184,189]

Treatment

Because ultrasonographic lesions in many foals that are clinically healthy will resolve without treatment (see the Screening for Earlier Detection of Affected Foals section later), it is important to consider separately treatment of subclinically affected foals and foals with clinical disease.

FOALS WITH SEVERE CLINICAL PNEUMONIA. A wide variety of antimicrobial agents are active against *R. equi* in vitro. However, many of these drugs are reported to be ineffective in vivo, possibly because of poor cellular uptake and resulting low intracellular concentrations. Randomized, controlled clinical trials comparing the efficacy of various antimicrobial treatments in foals with severe clinical pneumonia caused by *R. equi* are lacking. The only data available regarding treatment comparisons are from retrospective cohort studies and studies using historical controls. In a retrospective cohort of 48 foals referred to a veterinary teaching hospital between 1978 and 1985, all 10 foals treated with erythromycin-rifampin survived compared to 2 of 4 with TMS, 2 of 6 with chloramphenicol, 0 of 4 with oxytetracycline, and 0 of 17 with penicillin-gentamicin.[12] In the aforementioned study, the combination of erythromycin-rifampin was introduced in 1981, and it is unknown if disease severity influenced treatment allocation. In another report, 50 of 57 (88%) foals with culture-confirmed pneumonia caused by *R. equi* and treated with erythromycin and rifampin survived between 1981 and 1986. These reports, in association with the previously reported in vitro activity and synergism of erythromycin and rifampin,[191] became the basis of recommended therapy with erythromycin and rifampin. Since the early 2000s, azithromycin and clarithromycin have replaced erythromycin in the combination with rifampin because of their higher oral bioavailabilities and considerably higher concentrations in pulmonary epithelial lining fluid (PELF) and bronchoalveolar cells.[192-196] The recommended dosages are listed in Table 31.4. Several formulations of erythromycin are commercially available. Although they all show slight differences in bioavailability and elimination, they all result in therapeutic concentrations at recommended dosages. However, the bioavailability of erythromycin in foals is considerably lower when foals are not fasted (mean ± SD: 26 ± 15% when fasted and 8 ± 7% when fed).[194]

Macrolides and rifampin are highly active against *R. equi* in vitro but only exert bacteriostatic activity.[197,198] As a result, macrolides and rifampin exert time-dependent activity against *R. equi* in vitro.[198] Of the three macrolides listed previously, clarithromycin is the most active against *R. equi* in vitro and against intracellular *R. equi* in cell culture.[198,199] The minimum inhibitory concentrations at which 90% of *R. equi* isolates are inhibited (MIC_{90}) are 0.06, 0.5, and 1.0 μg/mL, for clarithromycin, erythromycin, and azithromycin, respectively.[200,201] The combination of a macrolide and rifampin is synergistic both in vitro and in vivo, and the use of the two classes of drugs in combination reduces the likelihood of *R. equi* resistance to either drug.[191,197,198]

Randomized, controlled, prospective studies comparing the relative clinical efficacy of erythromycin, clarithromycin, and azithromycin in pneumonic foals have not been reported. In a retrospective study, the combination clarithromycin-rifampin was significantly more effective than erythromycin-rifampin or azithromycin-rifampin, especially in foals with severe pulmonary lesions.[202] Although data analysis was adjusted for disease severity and age, these results must be interpreted with caution because foals were not randomly allocated to treatment groups and because of potential biases inherent to retrospective data. Nevertheless, these data are the best available evidence to guide macrolide selection in foals with *R. equi* pneumonia.

The discovery that concurrent therapy with rifampin considerably decreases plasma, PELF, and bronchoalveolar cell concentrations of clarithromycin[203,204] has led to questions about the value of the combination. Despite the profound decrease in clarithromycin bioavailability caused by concurrent administration with rifampin, concentrations of clarithromycin in PELF and bronchoalveolar cells are well in excess of the MIC_{90} (0.06 μg/mL) and even the concentration of clarithromycin that prevents emergence of resistant mutants (0.24 μg/mL when combined with rifampin).[203,204] These findings likely

TABLE 31.4

Recommended Dosages, Oral Bioavailability, and Serum Half-Lives of Antimicrobial Agents Commonly Used for the Treatment of *R. equi* Infections in Foals

Class	Drug	Dose (mg/kg)	Route	Frequency (h)	Oral Bioavailability (%)	Serum $t_{1/2}$ (h)	References
Macrolides	Erythromycin[a]	25	PO	6-8	8[b]-25[c]	1	193, 260

explain the apparent clinical efficacy of the combination of macrolides with rifampin despite the decrease in bioavailability. Administration of rifampin 4 hours after administration of clarithromycin results in a statistically significant improvement in the bioavailability of clarithromycin, but the modest improvement is unlikely to be of clinical relevance.[205]

Studies in immunodeficient mice indicate that the combination of a macrolide with rifampin is superior to either drug used in monotherapy. In one study, the combination of erythromycin with rifampin was significantly more effective than either drug used alone.[206] Given that concurrent administration of rifampin considerably decreases bioavailability of clarithromycin in foals, a similar mouse infection model was used to compare the in vivo activity of clarithromycin and rifampin alone or in combination. Despite significantly lower clarithromycin concentrations in mice treated with the combination, treatment with clarithromycin and rifampin in combination significantly decreased the number of *R. equi* in the organs of nude mice compared to treatment with either drug alone.[207] The numbers of *R. equi* in the organs of mice treated with clarithromycin or rifampin alone were either higher or not significantly different from that of saline controls.[207]

A well-designed, large-scale clinical trial is needed to determine the benefit (or detriment) of combining a macrolide with rifampin for treating foals with severe *R. equi* pneumonia. However, such a study is unlikely to be performed because of the very large sample size needed and the logistical and financial requirements involved. In the meantime, we have more than 30 years of experience and retrospective data as well as animal models documenting the superiority of the combination of a macrolide with rifampin, compared to a complete lack of evidence that macrolide monotherapy is effective in foals with severe clinical pneumonia. Until there is solid evidence demonstrating that macrolide monotherapy is not inferior, the combination of a macrolide (erythromycin, azithromycin, or clarithromycin) with rifampin remains the recommended treatment of choice.[168,208]

FOALS WITH MILD TO MODERATE SUBCLINICAL LESIONS. Only studies enrolling foals with lesion scores of 10 cm or greater (see the Screening for Earlier Detection of Affected Foals section later) have documented a significant difference in recovery between foals treated with antimicrobials (i.e., azithromycin with rifampin) and the placebo groups.[164,209] Therefore apparent recovery of foals with mild subclinical lesions with various treatments in uncontrolled studies cannot be taken as evidence of efficacy. In two separate, blinded, placebo-controlled studies, azithromycin alone (10 mg/kg PO q24h) or gamithromycin alone (6 mg/kg IM q7d) were found to be noninferior to the combination azithromycin and rifampin.[164,209] Monotherapy with tulathromycin also was more effective than a placebo, but not as effective as the combination of azithromycin with rifampin.[210] Despite a statistically significant difference between macrolide monotherapy and the control group in these studies, it is important to note that up to 78% of the foals receiving the placebo recovered without the need for antimicrobial treatment.[209] Therefore the apparent efficacy of macrolide monotherapy in foals with subclinical ultrasonographic lesions should not be interpreted as evidence of similar efficacy in foals with severe pneumonia. It is also unknown if macrolide monotherapy is more likely to induce and select for resistance than combination therapy in vivo. In vitro evidence indicates that resistance is less likely to occur with the combination of macrolide with rifampin.[211]

TREATMENT OF FOALS WITH MIXED BACTERIAL INFECTIONS. Various bacteria and fungi are often isolated from TBA along with *R. equi*. The most common concurrent bacterial isolates are β-hemolytic streptococci and *E. coli*.[212] Isolation of multiple types of bacteria or fungi from a TBA does not negatively affect survival, and mixed infections are significantly more likely to be encountered in TBA than in lung tissue, suggesting that many bacteria isolated from a TBA colonize the trachea without necessarily contributing to pulmonary pathology.[212] Some clinicians advocate the addition of a third antimicrobial agent if heavy growth of a gram-negative pathogen is isolated along with *R. equi*. Retrospective data indicate that the use of additional antimicrobial agents with better gram-negative coverage (i.e., gentamicin or ceftiofur) is not associated with increased survival relative to the use of a macrolide with rifampin in foals from which both *R. equi* and gram-negative bacteria are isolated from a TBA.[212] The combination of an aminoglycoside (gentamicin or amikacin) with macrolides or rifampin in vitro is antagonistic against *R. equi* compared with either drug alone.[191,197,198] However, the clinical significance of this in vitro finding has not been established.

TREATMENT OF FOALS INFECTED WITH ISOLATES OF *R. EQUI* RESISTANT TO MACROLIDES AND/OR RIFAMPIN. Although the vast majority of *R. equi* isolates from foals are highly susceptible to macrolides and rifampin in vitro, strains resistant to either drug class have been encountered. Most foals infected with *R. equi* that do not respond to therapy are infected with isolates susceptible to macrolides and rifampin. Therefore failure to

VetBooks.ir

respond to antimicrobial therapy does not provide evidence that a given foal is infected with an isolate resistant to antimicrobial agents. The presence of an isolate resistant to macrolides or rifampin can only be confirmed by in vitro susceptibility testing done by a laboratory following the criteria established by the Clinical and Laboratory Standards Institute (CLSI).

In a recent study, the overall prevalence of macrolide- and rifampin-resistant isolates in Texas and Florida over a 10-year period was 4%.[213] In the same study, the odds of death were seven times higher in foals infected with resistant isolates.[213] In addition, the study demonstrated that isolates of *R. equi* susceptible to macrolides were sometimes misclassified as resistant; therefore it is reasonable to request retesting or validation of resistance by the testing laboratory. More recently, it has been documented that mass antimicrobial treatment of subclinically affected foals has selected for antimicrobial resistance over time, with isolates of *R. equi* resistant to all macrolides and rifampin being cultured from as many as 40% of the foals at some farms.[104] Macrolide resistance in *R. equi* is conferred by acquisition of a newly identified ribosomal RNA methylase gene designated *erm*(46).[214] This gene confers resistance to all macrolides, lincosamides, and streptogramins type B but not to other classes of antimicrobial agents.[214] The gene can be transferred from resistant to susceptible isolates of *R. equi* by conjugation.[214] Most macrolide-resistant isolates of *R. equi* that have been identified to date are also resistant to rifampin. Rifampin resistance in *R. equi* is the result of mutations in the *rpoB* gene.[201,215-217]

Therapy of foals infected with isolates confirmed to be resistant to macrolides, rifampin, or both is problematic because of the limited range of effective alternatives. Macrolide- and rifampin-resistant isolates of *R. equi* are susceptible in vitro to fluoroquinolones, gentamicin, linezolid, and vancomycin.[213,218,219] In one study, 18 of 24 isolates were also susceptible to chloramphenicol, minocycline, and TMS.[213] Currently there are no data to indicate the preferred antimicrobial agents for the treatment of foals infected with isolates resistant to macrolides and rifampin. Vancomycin, imipenem, or linezolid in foals should be used only for the treatment of life-threatening *R. equi* infections caused by isolates confirmed to be resistant to all other possible alternatives. The use of systemic and/or nebulized gentamicin is a reasonable consideration for foals infected with macrolide- and rifampin-resistant isolates. Historically, the efficacy of gentamicin in foals infected with *R. equi* has been widely reported as being poor. This belief is based on the results of a retrospective case series of foals with pneumonia caused by *R. equi* in which all 17 foals treated with gentamicin died, whereas all 10 foals treated with erythromycin in combination with rifampin survived.[12] In contrast, in another retrospective case series of 39 foals with pneumonia caused by *R. equi*, all 19 survivors were treated with gentamicin, whereas nonsurvivors were treated with a variety of other antimicrobial agents, including erythromycin, kanamycin, or chloramphenicol.[169] These studies were not controlled and did not account for lesion severity at the time of initiation of therapy. In addition, the dosages of gentamicin used in those studies were lower than dosages currently recommended based on the fact that gentamicin effectiveness is now known to be concentration dependent. Gentamicin is one of the few drugs that is bactericidal against *R. equi*, and it is highly active against intracellular *R. equi*.[220] Intravenous or nebulized gentamicin administered at a dose of 6.6 mg/kg once daily results in pulmonary epithelial and bronchoalveolar cell concentrations well in excess of the MIC_{90} for isolates of *R. equi*. Additional studies will be necessary to assess the clinical efficacy of gentamicin intravenous or nebulized in foals infected with *R. equi*.

DURATION OF THERAPY. Resolution of clinical signs and radiographic or ultrasonographic resolution of lung lesions are commonly used to guide the duration of therapy, which generally ranges between 2 and 12 weeks, depending on the severity of the initial lesions and response to therapy. Foals treated based on subclinical lesions identified during ultrasonographic screening typically do not require as long a treatment period as foals in respiratory distress with severe pulmonary lesions. In fact, as addressed later, many foals with subclinical ultrasonographic lesions clear the infection without therapy.[7,163]

ADVERSE EFFECTS. Although well tolerated by most foals, macrolides commonly cause diarrhea. The diarrhea is often self-limiting and does not necessitate cessation of therapy. However, affected foals should be monitored carefully because some may develop severe diarrhea, leading to dehydration and electrolyte losses that necessitate intensive fluid therapy and cessation of oral macrolides. The incidence of diarrhea in foals treated with erythromycin-rifampin has ranged between 17% and 36%.[202,221] In one study, foals treated with clarithromycin had a higher incidence of diarrhea (28%) than those treated with azithromycin (8%), although in most cases diarrhea was mild and self-limiting.[202] In the same study, the incidence of severe diarrhea necessitating administration of IV fluids was not significantly different between groups of foals treated with azithromycin-rifampin, clarithromycin-rifampin, or erythromycin-rifampin.[202]

Hyperthermia and tachypnea have been described in foals treated with erythromycin during periods of very hot or humid weather.[221] Anecdotal reports suggest that these reactions occur occasionally with newer macrolides as well. Recent studies demonstrate that azithromycin, clarithromycin, and erythromycin suppress sweating in foals, with erythromycin inducing more severe sweating dysfunction.[222,223] In contrast, rifampin does not impair sweating.[222]

Severe enterocolitis also has been reported in mares whose foals are treated with erythromycin, presumably caused by disruption of the mare's normal colonic microflora following ingestion of small amounts of active drug during coprophagia or by contamination of feeders or water buckets with drug present on the foal's muzzle. This complication seems to be rare. Enterocolitis in mares has been reproduced experimentally by administration of subtherapeutic doses of erythromycin.[224] In some cases, the severe enterocolitis in the mares of treated foals is associated with *Clostridium difficile*.[225]

ANCILLARY THERAPIES. Nursing care, provision of adequate nutrition and hydration, and maintaining the foal in a cool and well-ventilated environment are important. Humidified oxygen delivered by pharyngeal insufflation in moderately hypoxemic foals or by percutaneous transtracheal oxygenation in severely hypoxemic patients is indicated.[226] Judicious use of NSAIDs might reduce fever and improve attitude and appetite in febrile, lethargic, anorectic foals. Nebulization with saline, antimicrobial agents, or bronchodilators have been advocated, but there are no data to either support or refute these therapeutic practices. In addition to appropriate systemic antimicrobial therapy, foals with *R. equi* septic arthritis or osteomyelitis often require aggressive local therapy such as joint lavage, surgical débridement, and IV or intraosseous regional limb perfusion with antimicrobial agents.

Prognosis

Prior to the introduction of the combination of erythromycin and rifampin as the treatment of choice in the early 1980s, the prognosis of *R. equi*–infected foals was poor, with survival rates as low as 20%.[227] Using erythromycin and rifampin, Hillidge reported a successful outcome (as assessed by survival) in 50 of 57 (88%) foals with confirmed *R. equi* pneumonia.[179] Studies from referral centers, where severely affected cases are likely more prevalent, have revealed survival proportions ranging between 59% and 72%.[170,202,228] The

VetBooks.ir

prognosis for foals with abdominal abscesses is poor, although rare cases will respond to long-term antimicrobial therapy.[8,229] Surgical removal or marsupialization have been attempted in some foals, but abdominal adhesions usually result in inability to resect the abscess.

In contrast, the survival rate at farms that use a screening program to identify and treat foals with subclinical lesions has resulted in survival proportions of nearly 100%.[4,230] However, recent evidence indicates that many of these foals would have recovered without therapy.[6,7,163,231] Controlled studies have shown that approximately 88% of foals with ultrasonographic lesion scores (sum of the diameter of each abscess) of 10 cm or less recover without antimicrobial therapy. In the same studies, treatment of affected foals with antimicrobial agents did not provide a clear benefit over administration of a placebo.[7,163]

The impact of *R. equi* infections on future athletic performance has been examined. No significant differences in total earnings, average earning index, or age at first race were observed when comparing 30 horses that previously had *R. equi* pneumonia with either their dams' other progeny or the North American averages.[232] In another study, 54% of 83 foals that survived *R. equi* pneumonia had at least one racing start as compared with 65% of their birth cohort, suggesting that horses contracting *R. equi* pneumonia as foals might be somewhat less likely to race as adults. However, consistent with a previous report,[232] the racing performance of those foals was not different from that of the U.S. racing population.[170] In summary, prognosis for performance after successful treatment of uncomplicated *R. equi* pneumonia should be regarded as very good.

Control and Prevention of *R. equi* Infections on Farms Where the Disease Is Endemic

Methods for control and prevention include using screening tests for early detection of *R. equi* pneumonia, environmental management, chemoprophylaxis, and prevention through use of either passive or active immunization. Currently there is inadequate evidence to recommend environmental interventions to control or prevent *R. equi* pneumonia.[233] Further evaluation of certain practices, such as foaling at pasture and reducing either airborne concentrations of virulent *R. equi* or density of mares and foals, is merited.

SCREENING FOR EARLIER DETECTION OF AFFECTED FOALS. *R. equi* pneumonia is often not recognized until it is well advanced and therefore difficult to treat. To a casual observer, even severely affected foals may appear to suckle and behave normally. The rationale for screening is the assumption that detecting foals in the early stages of disease and implementing appropriate treatment of affected foals will improve outcomes. It is important to emphasize that screening methods are not diagnostic tests. A useful screening test is one in which the probability of disease is high with a positive test result (high positive predictive value) and very low with a negative test result (high negative predictive value). The higher the prevalence of disease is at a given farm, the higher the positive predictive value of a given test will be. Therefore depending on the prevalence of *R. equi* infections at a given farm, a positive result on a screening test could be a basis from which to perform a diagnostic test (low to moderate prevalence) or to initiate therapy (high prevalence). Uncontrolled studies suggest that screening may reduce the mortality attributable to *R. equi* pneumonia.[4,234] Thus in the absence of a vaccine or other effective methods for preventing this devastating disease, screening is a reasonable approach to control *R. equi* at endemic farms. Implementing screening testing at farms that are only sporadically affected by *R. equi* pneumonia may not be warranted.

A variety of screening techniques performed serially have been described, including visual inspection of foals for clinical signs of pneumonia, rectal temperature monitoring, hematologic variables, serology, and thoracic imaging using either radiography or ultrasonography, with empirical recommendation that screening begin around 3 weeks of age.[235] Systematic comparisons of these tests have not been performed. Thus a specific recommendation for any particular screening test cannot be made, and it is likely that the optimal approach for screening may vary among farms on the basis of cumulative incidence of disease, resources available for control and prevention, and preferences of the attending veterinarians and farm management.

Studies have shown that serial PCR amplification of *vapA* in feces and serum measurement of serum concentrations of either antibodies against *R. equi*, serum amyloid A, or plasma fibrinogen are not useful screening tests.[172,176,178,236,237] WBC concentrations performed at monthly intervals had clinically acceptable sensitivity and specificity for early detection of *R. equi* pneumonia at one farm (sensitivity of 79% and specificity of 91% at a cutoff value of 15,000 cells/μL).[175] However, serial measurement of WBC or neutrophil concentrations resulted in limited performance for prediction of subsequent development of clinically apparent *R. equi* pneumonia at another farm.[238] In addition to conflicting data regarding the benefit of this approach, additional limitations of using WBC concentration for screening are the time and effort required to collect blood samples from foals, the lag from time of submission to availability of results, and the potential for false-positive results attributable to stress-associated leukocytosis or other infectious or inflammatory conditions that may be common among foals.

Over the past decade, control of *R. equi* infections at many farms where the disease is endemic has relied on early detection of subclinical pulmonary disease using thoracic ultrasonography and initiation of treatment with antimicrobial agents prior to development of clinical signs.[4,5,239] Ultrasonography of the chest offers several advantages over other screening tests: (1) results are specific for the presence of pulmonary pathology; (2) the procedure can be performed relatively quickly for an individual foal; (3) results are available immediately; and (4) the procedure may be more sensitive than radiography for detecting lesions in their early stages of development or in certain regions where soft-tissue structures are superimposed over regions of the lung.[174] Periodic ultrasonography of the chest has been reported to decrease mortality due to *R. equi* pneumonia at some farms relative to historical controls, but contemporaneously controlled studies are lacking.[4,5,239] Historically, antimicrobial treatment was recommended for all foals with pulmonary lesions 1 cm or greater in diameter.[4,5,239] This approach of ultrasonographic screening resulted in a considerabe increase in the number of foals treated for presumptive *R. equi* pneumonia. The temporal association between widespread use of macrolides and rifampin consequent to ultrasonographic screening and a perceived increase in the frequency of detection of antimicrobial-resistant isolates of *R. equi* in the last decade suggests that this practice is not innocuous. Emergence of widespread macrolide and rifampin resistance at a farm after widespread use of these drugs was implemented on the basis of an ultrasonographic screening program has been documented.[104]

Several uncontrolled studies have reported the apparent efficacy of various antimicrobial agents in foals with mild subclinical lesions. Recently reported blinded, randomized, placebo-controlled studies, however, indicate that approximately 88% of foals with lesion scores (defined as the sum of the largest diameter of all pulmonary lesions ≥1 cm) between 1 and 10 cm recover without antimicrobial therapy.[7,163] Furthermore, antimicrobial treatment of foals with such ultrasonographic lesions does not significantly hasten lesion resolution compared to administration of a placebo.[7,163] In another study,

VetBooks.ir

270 foals at an endemic farm were subjected to thoracic ultrasonography every 2 weeks for the entire season. The veterinarian making treatment decisions was unaware of ultrasonographic findings. Forty-six foals (17%) developed clinical signs of pneumonia and were treated; all 46 foals had ultrasonographic lesions.[6] Fifty-four foals (20%) remained clinically healthy and free of ultrasonographically visible pulmonary lesions, whereas 170 foals (63%) remained clinically healthy but had pulmonary lesions of various degrees of severity.[6] Optimal cut-point of the sum of the maximal diameters of all lesions observed sonographically at a given examination to maximize sensitivity and specificity in that study was 20 cm. This high sum of lesion diameters as a cut-point for lesion score would have yielded a relatively high sensitivity (89%) but poor specificity (62%) for the diagnosis of clinical pneumonia.[6] Despite using such a high cut-point to initiate therapy, the number needed to treat was 3, meaning that approximately three foals would be treated with antimicrobial agents unnecessarily for every one foal benefiting from therapy.

Because ultrasonography only allows the detection of lesions at the periphery of the lung and because of individual variation in disease susceptibility and host defense mechanism, there is no lesion score cut-point that will perfectly differentiate foals requiring therapy from foals that will spontaneously recover. Although it is probably indicated to treat foals with clinical signs of lower respiratory tract disease, the evidence reviewed earlier indicates that treatment of all foals with small subclinical pulmonary lesions is unnecessary. By being more selective and treating only foals with larger lesion scores (e.g., >10 cm) and monitoring the foals weekly or twice weekly both clinically and ultrasonographically, one farm was able to decrease antimicrobial drug use considerably without an increase in mortality.[209,210] Additional studies at multiple other endemic farms will be required to determine whether this approach should be widely recommended.

PASSIVE IMMUNIZATION. Intravenous administration of HIP obtained from horses vaccinated against *R. equi* using various antigens has generally proved effective in significantly reducing the severity of *R. equi* pneumonia in foals following experimental challenge.[79,127,240,241] However, studies evaluating the efficacy of various HIP preparations under field conditions have given equivocal results. Although the data are conflicting and not all trials have shown a statistically significant reduction in the cumulative incidence of *R. equi* pneumonia, 5 of 7 studies have demonstrated reduction of relative risk, suggesting some benefit of HIP.[3,81,181,242-245]

Intravenous administration of purified immunoglobulins obtained from horses immunized with recombinant VapA and VapC to foals reduced the severity of pneumonia following high-dose experimental challenge with *R. equi* to a degree similar to that provided by commercially available HIP.[129] This demonstrates that immunoglobulins, predominantly against VapA and VapC, are responsible for the protection conferred by HIP. Therefore administration of plasma obtained from horses that are not hyperimmunized against *R. equi* is not recommended for protection against *R. equi*. Because endemicity of *R. equi* at farms does not appear to be explained by farm-specific isolates and because foals may be infected with multiple strains at once,[102] there is no need to administer plasma that is produced from immunizing horses with isolates of *R. equi* obtained from a given farm; transfusion of plasma from horses that have been immunized against any virulent (i.e., VapA-positive) strain of *R. equi* should suffice.[233] Use of HIP licensed as an aid in the control of *R. equi* pneumonia is recommended (rather than plasma simply obtained from horses hyperimmunized against *R. equi*) because licensure ensures standards of potency, purity, and safety. Currently there is insufficient information to recommend one brand of licensed antibody product over another.

The optimal amount of plasma to be transfused and the optimal age at which transfusion should occur remain to be determined. Administration of HIP 9 days after aerosol infection of foals with *R. equi* did not confer protection,[246] suggesting that administration of HIP prior to infection is important. Because of evidence that many foals become infected early in life,[80] it is commonly recommended that foals receive transfusion of at least 1 liter of HIP no later than the second day of life. Because early administration may result in the decline of passively transferred antibody to a nonprotective level at a time when foals are still susceptible to *R. equi* and when environmental challenge is high, it is common practice to administer a second liter of HIP at 2 to 4 weeks of age.

Transfusion of HIP is not completely effective and therefore does not eliminate the need for careful monitoring of foals at risk. In addition to being incompletely effective, transfusion of HIP carries some risk to foals, such as trauma that may occur during handling and adverse reactions to transfusions. The process is also time intensive, labor intensive, and expensive. Thus the cost-effectiveness of transfusion depends on the value of the foals and the prevalence of disease at a given farm.

ACTIVE IMMUNIZATION. It would be convenient to control *R. equi* pneumonia on endemic farms by active immunization of mares or foals with a protective antigen. To date, however, this approach has been largely unrewarding. The role of antibody in partial protection against *R. equi* infection suggests that vaccination of mares could confer at least some degree of protection. However, in both a field study and an experimental challenge, vaccination of mares with live or killed whole cell *R. equi* did not provide protection against *R. equi* pneumonia despite a significant increase in colostral *R. equi*–specific antibody and transfer of these antibodies to foals.[244,247] Vaccination of a small number of mares with VapA associated with a water-based nanoparticle adjuvant led to high anti-VapA IgG concentrations in mares and foals and might have conferred protection against natural challenge compared with nonvaccinated controls.[248] More recently, vaccination of mares against poly-*N*-acetylglucosamine protected foals against intrabronchial challenge with *R. equi*.[125] Large-scale studies at endemic farms will be necessary to confirm these preliminary findings before widespread vaccination of mares can be recommended.

Because cell-mediated immunity is of paramount importance for protection against *R. equi*, active immunization of foals likely will be required for complete protection. Oral or nasal immunization with *S. enterica* serotype Typhimurium expressing the VapA antigen protects mice against *R. equi* infection.[249,250] Studies in mice indicate that DNA immunization with *vapA* protects against *R. equi* infection and that the IgG subisotype response is consistent with a type I–based immune response.[251] A similar DNA vaccine containing the *vapA* gene induced strong cell-mediated immune responses in adult horses, but responses were poor in foals.[252] Intrabronchial immunization of neonatal foals with a live, fully attenuated, riboflavin auxotroph strain of *R. equi* stimulated immune responses but did not confer protection against subsequent intrabronchial challenge with live *R. equi*.[253] The fact that live, avirulent plasmid-cured *R. equi* does not elicit adaptive immunity and is cleared rapidly indicates that bacterial replication is needed for induction of strong cell-mediated immune responses.[254] Intrabronchial immunization with a deletion mutant of *R. equi* lacking the chromosomal genes isocitrate lyase *(icl)* and cholesterol oxidase *(choE)* conferred protection against subsequent challenge in three foals.[255] However, two foals developed pneumonia caused by the mutant strain.[255] More recently, oral vaccination of foals with a live attenuated *R. equi* strain lacking genes involved in the steroid catabolic pathway elicited substantial protection against subsequent intrabronchial challenge with live virulent *R. equi*.[73] Collectively, the aforementioned

studies indicate that there is a fine line between sufficient replication of *R. equi* for induction of strong cell-mediated immune responses and development of disease from the vaccine strain. Additional challenges are that immunization in foals will need to be initiated very early in life and an effective vaccine will have to overcome the relative immaturity of the naive neonatal immune system. Currently there is inadequate evidence to recommend active immunization of mares or foals to control or prevent *R. equi* pneumonia, but promising vaccine candidates are under development.

CHEMOPROPHYLAXIS. Because an effective vaccine is lacking, prophylactic administration of antimicrobial agents to all foals during the period when they are most susceptible to infection has been suggested as another approach for the prevention of *R. equi* infections on endemic farms. Azithromycin is an attractive choice for chemoprophylaxis because of good oral bioavailability, long half-life, and high and sustained concentrations in PELF, bronchoalveolar cells, and neutrophils. Two studies have evaluated the use of azithromycin for chemoprophylaxis. In a randomized, controlled trial conducted in the United States among 338 foals at 10 farms, the cumulative incidence of *R. equi* pneumonia was reduced from 21% among untreated foals to 5% among foals that received azithromycin (10 mg/kg PO q48h for the first 14 days of life).[256] In contrast, in a study conducted among 70 foals at a large breeding farm in Germany, the incidence of abscessing pneumonia was not significantly different between foals that received azithromycin (10 mg/kg PO q24h for the first 28 days of life) for prevention of abscessing pneumonia (cumulative incidence = 60%) and foals that did not receive azithromycin for chemoprophylaxis (cumulative incidence = 69%); however, the age at onset of abscessing pneumonia was delayed in treated foals.[230] The reason for the discrepancy between studies is unknown. Regardless, use of azithromycin is not considered an acceptable approach for chemoprophylaxis because widespread use of this drug would create greater pressure for emergence of macrolide resistance among bacteria.[168]

Gallium maltolate is a metal-based compound with antimicrobial properties that has been demonstrated to reduce replication of *R. equi* in pure culture[257] and within macrophages,[258] to reduce tissue concentrations of *R. equi* in mice following experimental infection,[257] and to be bioavailable[259] and safe in foals.[260] Unfortunately, chemoprophylaxis with gallium maltolate (30 mg/kg PO q24h for the first 14 days of life) failed to reduce the incidence of *R. equi* pneumonia in a placebo-controlled trial of 438 foals at 12 farms in the United States.[3]

Pneumonia in Foals

Daniela Bedenice

Equine pneumonia is a significant cause of morbidity and mortality in both the newborn and the older foal.[1-4] Although the causative agents and the mode of lung infection are generally different for each age-group, foal pneumonia is commonly associated with a compromise in the immunologic protection of the host. The exact immunologic basis of the foal's inherent susceptibility to opportunistic respiratory pathogens needs to be further elucidated.

Failure of passive transfer of immunity (FPT) is a well-known risk factor of neonatal infection, including respiratory disease,[4] because not only are affected foals deprived of specific maternal antibody protection but their neutrophil function is also seriously impaired.[5] Although foals can respond immunologically in utero to bacterial or viral infections, their ability to do so is less than that of adults. Reduced complement values and defective chemotaxis (directed migration of neutrophils or macrophages) and killing capacity of the neonatal neutrophil contribute to a relatively decreased defense against invading bacteria. Furthermore, an immature ciliary apparatus and the presence of fewer alveolar macrophages in neonates in comparison with adult horses lead to decreased bacterial clearance from the lungs.[6] The number and distribution of the bronchoalveolar cells approach adult levels only at approximately 3 to 6 weeks of age.[7]

It has been suggested that a natural cellular immunodeficiency may also occur in foals at 2 to 4 months of age.[8] Although the exact association between age-related cellular immunodeficiency and the defense against intracellular pathogens such as *Pneumocystis carinii (Pneumocystis jiroveci)* and *R. equi* of foals still needs to be clarified, CD4+ and CD8+ T-lymphocytopenia was documented in a filly with *P. carinii* pneumonia.[9]

Etiology

NEONATAL PNEUMONIA (<1 MONTH OF AGE). In contrast to the older foal, infectious lung disease in the neonate is usually part of a multiple-organ systemic infection or sepsis, which may be acquired via the placenta in utero or perinatally through environmental bacteria leading to hematogenous (ascending) infection (e.g., omphalophlebitis). *E. coli*, *Klebsiella* spp., *Actinobacillus equuli*, *Salmonella* spp., and *Streptococcus* spp. are some of the more common bacteria involved in neonatal foal pneumonia.[10]

Descending lung infections may be caused by inhalation of viral, bacterial, or opportunistic fungal agents. Furthermore, iatrogenic aspiration (oil, medication, oral supplements) or aspiration of gastric reflux, milk, meconium, or contaminated amniotic fluid after placental infection may seed the foal's lung. Meconium aspiration occurs in utero in foals that experience fetal distress (perinatal asphyxia). Although the meconium is commonly sterile at this time, it creates mechanical airway obstruction, surfactant inactivation, and pulmonary inflammation (caused by vasoactive mediators and chemotactic and inflammatory cytokines, including TNF-α, interleukin [IL]–1β, and IL-8).[11] The resulting edema and vasoconstriction may lead to hypoperfusion of the pulmonary parenchyma, with damage to type II pneumocytes and decreased production of surfactant.[12] This type of "secondary surfactant deficiency" also may be induced by other forms of generalized pulmonary inflammation, including diffuse bacterial pneumonia. Neurologic dysfunction, severe inflammation, or structural abnormalities of the upper airways (congenital cysts, dorsal displacement of the soft palate, laryngeal paralysis, pharyngeal weakness, etc.) may predispose to aspiration pneumonia postpartum. The prognosis of foals with dysphagia due to pharyngeal dysfunction is considered favorable for life and fair for athleticism, based on a 2012 study by Holcombe and colleagues.[13] In the latter report, 8 of 16 (50%) affected foals were premature and/or diagnosed with neonatal encephalopathy, and 12 of 16 (75%) had aspiration pneumonia.

Equine viral arteritis (EVA) and equine herpesvirus infections (EHV-1 and EHV-4) have been implicated in in utero viral infections leading to lung disease.[14] Although involvement of adenovirus in the pathogenesis of pneumonia has also been reported in a Thoroughbred foal, fatal adenoviral pneumonia is primarily related to severe combined immunodeficiency (SCID) in Arabian foals.[15,16] In addition, equine influenza virus (EIV) infection has been associated with fatal bronchointerstitial pneumonia in young foals that do not have maternal immunity.[17]

PNEUMONIA IN OLDER FOALS (1 TO 6 MONTHS OF AGE). *S. equi* subsp. *zooepidemicus* and *R. equi* are the most important pathogens associated with pneumonia in older foals, although plurimicrobial infections (*Actinobacillus* spp., *B. bronchiseptica*, *E. coli*, *Klebsiella pneumoniae*, *Pasteurella* spp., *Pseudomonas* spp., *Salmonella* spp., and *Staphylococcus* spp.) are not uncommon.[18,19] *S. equi* subsp. *zooepidemicus* was isolated from 87% of

uncomplicated lower respiratory tract infections in foals (1 to 8 months old) on selected farms[20] and was documented as the most common cause of pulmonary abscesses in a second study.[21] In contrast, anaerobes appear to be infrequently involved in primary pneumonia of foals.[20] *Corynebacterium* spp. pneumonia due to aerosol infection is a rare cause of diffusely increased interstitial and peribronchial radiographic densities, indicative of pulmonary abscesses in foals[22]; it is possible that the isolates in this study were *R. equi*. More recently, acute respiratory failure was associated with *Leptospira* spp. infection in five foals (3 weeks to 5 months of age). Pulmonary hemorrhage and interstitial pneumonia with infiltration of red blood cells, hemosiderophages, and inflammatory cells were observed at necropsy, similar to observations in people.[23]

Although respiratory viruses are often believed to be primary offending agents that lead to secondary bacterial lung invasion, they have limited importance in nursing foals.[20,24] Equine adenoviruses (EAdVs) and EHV-2 are ubiquitous in the general equine population, with little apparent pathogenicity in immunocompetent foals. Although adenoviruses are the most common respiratory pathogens in Arabian foals with SCID, the role of EHV-2 in the respiratory disease complex of foals remains unclear. It has been suggested that EHV-2 exerts its effects on the host indirectly through predisposition to secondary infections, such as *R. equi* pneumonia. Dunowska and colleagues evaluated serial blood samples from 43 foals on a single farm over a period of 10 months, where all but 2 foals were seropositive for EHV-2 on at least one occasion. The majority (88%) of these foals became infected with EHV-2 within the first 2 months of life.[25]

Because of the complexity of the disease, in-depth discussions of *Rhodococcus* pneumonia and ARDS are presented elsewhere in this chapter.

INTERSTITIAL PNEUMONIA. Acute, severe interstitial or bronchointerstitial pneumonia is a sporadic, rapidly progressive disease of foals of 1 to 6 months of age that is characterized by a sudden onset of respiratory distress, tachypnea, fever, high mortality, and histopathologic evidence of severe, diffuse, necrotizing bronchiolitis, alveolar septal necrosis, and neutrophilic alveolitis on necropsy.[26-28] Although no definitive causative agents or factors of this disease have yet been identified, suspected causes include viruses, *P. carinii*, heat stroke, environmental toxins, and bacteria.[26-29] Enteric gram-negative organisms, *R. equi*, *Pseudomonas aeruginosa*, and *P. carinii* have all been cultured from the lungs of affected foals.

The reported cases are usually sporadic, affecting a single foal within a herd,[26] although rare clusters of cases have also been described.[28] The disease is generally rapidly progressive and may lead to sudden death as a result of fulminant respiratory failure. Severe respiratory distress, hypoxemia, hypercapnia, and respiratory acidosis are the most striking clinicopathologic signs. The hypoxemia of bronchointerstitial pneumonia is relatively resistant to supplemental oxygen therapy, indicating a pulmonary shunt. Thoracic radiographs commonly demonstrate caudodorsally distributed interstitial and bronchointerstitial pulmonary opacities. With advanced disease, the radiographic pattern progresses to include patches of a coalescing alveolar nodular pattern with air bronchograms.[30] As with bacterial pneumonia, many foals demonstrate hyperfibrinogenemia and neutrophilic leukocytosis on hematology.

Therapy is symptomatic, including antiinflammatory therapy, broad-spectrum antibiotics, thermoregulatory control, bronchodilation, and supplemental oxygen. Surviving foals may develop a proliferative epithelial and interstitial response, including bronchiolar and alveolar epithelial hyperplasia, type II cell hyperplasia, and hyaline membrane formation.[30]

Chronic pulmonary disease (1 to 3 months' duration) with marked radiographic interstitial opacities was reported in 12 foals, ages 3 to 9 months, that were examined at a veterinary teaching hospital.[31] Evaluation failed to yield a consistent pathogen from tracheobronchial aspirates. The authors proposed that chronic interstitial pneumonia occurring in foals is associated with a good prognosis and considered corticosteroid therapy as a potentially useful treatment.

***PNEUMOCYSTIS JIROVECI* (CARINII) INFECTION.** Rare opportunistic fungal pathogens of the lung may include *P. carinii* (renamed *P. jiroveci* in humans), *Aspergillus* spp., *Candida* spp., and *Mucor* spp. *P. carinii* is a unicellular eukaryote that has been classified as a fungus after DNA studies.[32] It is most commonly seen in humans and animals that suffer from a concurrent immunodeficiency. It was first recovered in Arabian foals with SCID.[33] It has since been recovered from foals of other breeds with no specific history of immunodeficiency, although for the most part no direct testing for immunocompetence was performed in the reported cases. However, one more recently documented case demonstrated a low number of circulating CD4+ and CD8+ lymphocytes in a filly with *P. carinii*.[33]

In several reports the onset of clinical signs in affected foals ranged from a 3-week history of weakness, weight loss, and nasal discharge to acute dyspnea. Half of the reported non-Arabian cases had concurrent infections with *R. equi*, *Enterobacter cloacae*, *E. coli*, or *S. equi* subsp. *zooepidemicus*. A severe interstitial, sometimes miliary and alveolar pattern was seen on radiographs of the lungs. The majority of the reported foals died, and the diagnosis of *P. carinii* was obtained at necropsy.[29,33-36] On postmortem examination the lungs were uniformly heavy and consolidated, and a diffuse interstitial pneumonia was found. Trophozoites and cysts were observed in the alveolar epithelial cells, and macrophages were observed within the alveoli. Fluorescent in situ hybridization, silver staining, and streptavidin-biotin immunolabeling of histologic sections provide better identification of the organisms in the pulmonary tissue.[34] A few foals were also diagnosed by visualization of the organism on a BAL sample in the latter report. Two surviving foals responded to TMS therapy.

Clinical Presentation and Diagnosis of Foal Pneumonia

The clinical manifestation of pneumonia in the newborn foal can be variable and depends on the disease severity and underlying or associated problems. Early in life, localizing clinical signs of respiratory infection may be absent even in the presence of extensive disease. Dyspnea may be seen in severely affected foals and may manifest as an increase in respiratory rate, effort, or thoracoabdominal asynchrony (paradoxical breathing). However, signs of respiratory distress and hypoxemia are frequently vague. Even some severely hypoxemic foals may show only restlessness, considerable resistance, and struggling when being handled or restrained. Abnormal respiratory sounds (crackles or wheezes) may be heard on auscultation of ill foals. However, even normal foals may show crackles on the down lung after having remained in lateral recumbency for a prolonged period of time. Furthermore, foals with no auscultable abnormalities may still have extensive pulmonary disease.[37,38] Similar to other species, cyanosis is a sign of severe hypoxemia in foals. The arterial PaO_2 (partial pressure of oxygen), however, must reach very low levels (35 to 45 mm Hg) before clinical cyanosis is observed. Approximately 5 g/dL of unoxygenated hemoglobin in the capillaries generates the dark-blue color that is appreciated as cyanosis in humans. Therefore severely anemic foals may never appear cyanotic even in the face of profound hypoxemia. Weakness, depression, anorexia, weak or absent suckle reflex, dehydration, and fever may also be noted in newborn foals with respiratory disease. Cough and nasal discharge are usually absent in the early stages of neonatal pulmonary disorders.[10] The older foal, on the other hand, will generally exhibit clinical

signs that focus on the respiratory tract, such as abnormal auscultation of the lungs, nasal discharge, cough, fever, tachypnea, and increased respiratory effort.

Thoracic radiographs and arterial blood gas analysis are important in confirming the presence and evaluating the extent and distribution of foal pneumonia. Because radiographic findings may precede or lag behind alteration of respiratory function, repeated diagnostic imaging is recommended. A recent study documented that radiographic abnormalities involving the caudodorsal lung region were most common in neonatal foals admitted to a referral center.[39] Bedenice and colleagues showed that the presence of dyspnea, tachypnea, a fibrinogen concentration greater than 400 mg/dL, systemic inflammatory response syndrome (SIRS), hypoxemia, or FPT in neonatal foals may be a predictor of underlying respiratory disease and should prompt an early radiographic evaluation of the thorax, even in the absence of other localizing clinical signs.[4,39] Thoracic ultrasonography has become a popular diagnostic tool for the assessment of equine lung and pleural disease and is particularly useful in determining the side(s) of the thorax affected, as well as the precise location of the lesion in many cases.[4]

Diagnostic sampling of the respiratory tract is less commonly performed in neonatal foals compared with older foals and adult horses. However, transtracheal aspirate, BAL, protected catheter brush (PCB), or protected aspiration catheter (PAC) sampling is important in stabilized patients, irrespective of age, to direct antimicrobial therapy and evaluate therapeutic efficacy. Lung biopsies are rarely performed and are limited to patients with chronic disease or suspected fungal pneumonia.[38]

Treatment The treatment goals in dealing with bacterial pneumonia in either age-group are similar and directed at maintaining adequate gas exchange to ensure patient survival, limit progressive pulmonary damage, and ultimately eradicate infection. Long-term goals should aim to maintain optimal pulmonary function and conserve adult athletic performance. Specific treatment strategies for septic pneumonia may include goal-directed antimicrobial therapy, treatment of inflammation independent of antimicrobial therapy, respiratory therapy (oxygen therapy, ventilation, bronchodilation), and cardiovascular support.[37]

Broad-spectrum antimicrobial treatment, with consideration of the drugs' anticipated sensitivity and lung penetration, should be initiated before culture results are available. Third- or fourth-generation cephalosporins (ceftiofur and cefepime, respectively) show good penetration into lung tissues.[40] Ceftiofur administered intramuscularly at 6.6 mg/kg in weanling foals provided plasma and pulmonary epithelial lining fluid concentrations above the therapeutic target of 0.2 µg/mL for at least 4 days, and would thus be expected to be an effective treatment for pneumonia caused by susceptible pathogens such as *S. equi* subsp. *zooepidemicus*.[41] Alveolar delivery of antibiotics typically occurs via diffusion of a free, nonprotein-bound drug and is usually satisfactory if plasma concentrations and alveolar perfusion are adequate.[42] Aminoglycosides penetrate lung tissue at 10% to 45% of serum levels. However, the acidic environment of infected airways may reduce the drug's activity below levels sufficient to eradicate the offending bacteria in some cases.[43,44] Antibiotic therapy should not be discontinued prematurely in neonatal foals because pulmonary infection is commonly well established before its diagnosis.[45]

Outcome The survival of neonatal foals with septic pneumonia is contingent on the underlying disease conditions, a prompt diagnosis, and the cause and severity of lung dysfunction. Few studies have objectively evaluated the outcome of foal pneumonia.[38] One report documented that 65% of foals with radiographic evidence of pulmonary disease were discharged alive from the hospital, in contrast to 86% survival of foals without respiratory illness. The presence of diffuse radiographic infiltrates (caudodorsal, caudoventral, and cranioventral lung involvement) or concurrent alveolar patterns within the caudodorsal and caudoventral lung indicated lower survival rates.[38] Pneumonia is also considered one of the greatest causes of morbidity and mortality in foals older than 1 month of age.[2]

The long-term effects on athletic performance have thus far predominantly been evaluated in older foals that survived *Rhodococcus* pneumonia. *R. equi* infection in foals was associated with a decreased chance of racing as adults. However, the performance of foals that went on to race was not significantly different from that of the general U.S. racing population.[46] It remains speculative whether severe equine neonatal pneumonia will most likely limit future peak athletic performance. Human studies have shown that many hosts develop long-lasting or permanent lung changes after recovery from neonatal pneumonia, which may significantly affect quality of life and susceptibility to later infections. Case-based evaluations in horses have demonstrated that functional and structural pulmonary abnormalities may occur in survivors of severe neonatal pneumonia. However, the clinical significance of this finding currently remains unclear.

Fungal Infections of the Equine Respiratory Tract

Allison Jean Stewart

Definition and Etiology Fungi are eukaryotic organisms with a definitive cell wall made up of chitins, glucans, and mannans. Within the fungal cell wall, the plasma membrane contains ergosterol, a cell membrane sterol that is frequently targeted by antifungal agents. There are more than 70,000 species of fungi, but only 50 species are known to cause disease in people or animals. Pathogenic fungi can be divided into three groups: multinucleate septate filamentous fungi, nonseptate filamentous fungi, and yeasts. Dimorphic fungi are able to interchange between forms depending on environmental conditions. Examples of dimorphic organisms include *Blastomyces dermatitidis*, *Histoplasma capsulatum*, and *Coccidioides immitis*, which exist in yeast form in vertebrate host tissue and in hyphal or mycelial form in vitro. In soil and decaying matter, the mycelial form usually is present and is composed of a collection of hyphae. The mycelia produce infective spores that are capable of inoculating vertebrate tissue.

Fungal infections in horses are relatively uncommon, although geographic prevalence is highly variable. Fungi are ubiquitous, and their constant aerosol exposure to respiratory tissue is inevitable. Upper respiratory and pulmonary disease caused by fungi is frequently acquired by the inhalation route, with the sporular diameter small enough to allow penetration into the distal airways and alveoli. In most samples of stable air, more than 90% of particles visible under a light microscope are spores of fungi or actinomycetes.[1] One study found that if a horse stood quietly in its stable without access to hay, the mean concentration of dust was very low (approximately 12 particles/cm^3 [of particles less than 5 mm in diameter]). When the bedding was disturbed during the normal "bedding down" operation, the concentration of respirable dust increased sixfold.[2] Systemic fungal infections and some cases of fungal pneumonia are thought to arise through a compromised GI tract, by inhalation, or via open wounds.

Tissue invasion of pulmonary tissue usually occurs in the immunocompromised host, although on occasion the normal individual may be affected. Important predisposing factors for fungal pneumonia include (1) qualitative and especially quantitative granulocyte abnormalities and (2) the presence of devitalized tissue. In most cases of upper respiratory tract fungal granuloma, there are no obvious predisposing causes.

VetBooks.ir

Primary pathogenic fungi such as *B. dermatitidis*, *H. capsulatum*, *C. immitis*, *Cryptococcus neoformans*, and *Conidiobolus coronatus* usually infect immunologically normal horses. However, in a report of cryptococcosis in seven horses, five had a history of illness that may have predisposed them to cryptococcosis.[3] A separate group of fungal pathogens tends to infect only those equine patients with abnormal host defenses. Opportunistic fungi, including *Aspergillus* spp., *Candida* spp., *Fusarium* spp., *Emmonsia crescens*, and *P. carinii* (renamed *P. jiroveci* in humans), have caused fungal disease in horses that are immunocompromised or neutropenic; have neoplasia, colitis, enteritis, or bacterial pneumonia; or have been treated with corticosteroids.[4-15] In vitro studies support the critical role of phagocytic cells in host defense against opportunistic fungi.

Clinical Signs

Mycotic granulomas have been found in nasal passages, paranasal sinuses, nasopharynx, guttural pouch, trachea, bronchioles, lungs, and mediastinum of infected horses. The most common clinical signs of upper respiratory tract fungal infection include unilateral or bilateral serosanguineous or mucopurulent nasal discharge, as well as inspiratory or expiratory noise. Other clinical signs include coughing, facial deformation, and dyspnea caused by partial blockage of nasal passages by granulomatous masses. Differentials for fungal granulomas of the respiratory tract include ethmoidal hematoma, squamous cell carcinoma, amyloidosis, and exuberant granulation tissue.

Fungal plaques in the guttural pouch often are located over the arterial blood supply. Horses with guttural pouch mycosis usually present with episodic serosanguineous nasal discharge that may progress to potentially fatal epistaxis if there is erosion into an artery. The duration of clinical signs can vary from days to many months. Guttural pouch mycosis is discussed in detail later in this chapter.

Pulmonary fungal infections causing granulomas, diffuse pneumonia, or pleuropneumonia can present with signs similar to those of bacterial infection. There may be cough, nasal discharge, tachypnea, respiratory distress, hemoptysis, and, if chronic, weight loss. Radiographic appearance of fungal pneumonia may reveal virtually any infiltrative pattern. Although miliary patterns are occasionally seen, the most common initial finding is a patchy bronchopneumonia. Multiple focal sites are common, and lesions tend to be peripheral in distribution. Differentials include bacterial pneumonia, equine asthma, silicosis, equine pulmonary nodular fibrosis (associated with EHV-5), granulomatous disease complex, and neoplasia.

Systemic infections can have variable clinical signs depending on the location and extent of the infection. Fungal infections can affect multiple organ systems and body cavities. Weight loss, colic, or diarrhea can often occur with infection within the abdominal cavity.

Diagnostic Sampling

Lesions in the nasal passages, nasopharynx, guttural pouch, trachea, and bronchioles usually can be observed directly during endoscopic examination. Masses in paranasal sinuses and lungs may be observed radiographically. CT or MRI provide detailed imaging of the equine skull (and thorax, depending on the size of the animal and gantry) and can be used to determine the extent of lesions and bony invasion. An 8- to 20-mm trephine (Michelle 8-mm trephine or 14- to 20-mm Galt trephine [Jorgensen Laboratories, Inc., Loveland, Colo.]) can be drilled into the nasal or maxillary sinus, through which a sterile rigid arthroscope or flexible endoscope can then be passed to directly view some lesions within the paranasal sinuses.

For nasal and nasopharyngeal lesions, specimens for cytology, histopathology, and culture can be obtained by using an endoscopically guided biopsy instrument; however, these samples tend to be small, superficial, and often nondiagnostic. Mucosal contaminants may overgrow the organism of interest. Larger biopsy samples from the nasal passages or nasopharynx often can be obtained by using a uterine biopsy instrument (Jorgensen Laboratories, Inc., Loveland, Colo.) passed nasally with visual guidance from a flexible endoscope. Excisional biopsy or surgical debulking may be performed through a sinus flap or via laryngotomy.

Fungal pneumonia may be diagnosed from samples obtained by tracheal wash or bronchoalveolar lavage fluid, or via a lung biopsy. Lung biopsy is associated with significant risk if a large pulmonary vessel is accidentally punctured. The biopsy should be performed ideally after radiographic evaluation or with concurrent ultrasound guidance and should be obtained from the periphery of the lung; however, some horses have experienced fatal hemorrhage associated with puncture of a vessel only 2 cm from the periphery. The lung is rich in plasminogen, so bleeding complications may be severe. Spring-loaded biopsy needles (4-gauge × 20-cm biopsy needle [Temno Products Group International, Lyons, Colo.] or Magnum biopsy needle) are safer for lung biopsy compared with Tru-Cut biopsy instruments (Cardinal Health, Dublin, Ohio).[16] Ultrasound evaluation can be used to monitor for bleeding after the procedure.

CYTOLOGY. Fungal hyphae may be identified in airway fluid or in impression smears obtained from biopsied masses. Clinicians must be careful in attributing significance to presence of fungal elements in a transtracheal aspirate. Fungal hyphae are often present either free or in large mononuclear cells in tracheal aspirates from healthy horses.[17] A study of healthy Thoroughbred racehorses showed that 70% had fungal elements detected in their tracheal aspirates without evidence of fungal pneumonia.[18] Barn fungus such as *Alternaria* spp. are nonpathogenic and rarely incite an inflammatory response in the host. The organisms often have a blocklike appearance and may be colored (Fig. 31.18). A normal predominance of macrophages, lymphocytes, and nondegenerate neutrophils (<5% to 10%) would be expected.

To be significant cytologically, large numbers of fungi should be involved in the inflammatory process within the lung. With fungal pneumonia, aspirates may contain predominantly neutrophils that often are degenerate and may contain intracellular fungal hyphae. If processing of the sample is delayed, extracellular fungi may be phagocytized, and this makes interpretation more difficult. Some fungi have characteristic morphologic features that can give an early presumptive identification (Table 31.5).

HISTOPATHOLOGY. Hyphae of certain fungi may be poorly visualized using routine hematoxylin and eosin (H&E) stains; therefore special stains such as periodic acid–Schiff (PAS), Gridley fungus, and Grocott-Gomori methenamine–silver nitrate (GMS) can be useful to stain histopathologic specimens. With chronicity, there is often evidence of extensive fibrosis.

MICROBIOLOGICAL CULTURE. Fungi can be found in tracheal aspirates from healthy horses. Sixteen percent of healthy horses are reported to have fungal growth on the tracheal aspirate bacterial culture plates; therefore results of fungal culture must be interpreted with caution.[19] Some fungi have fastidious growth requirements. They may be outcompeted by contaminant bacteria and may take up to several weeks to grow on culture media. For transport of tissue for microbiological culture, the sample should be placed in a prepared culture medium (BBL Port-A-Cul Vial [Becton, Dickinson and Company, Sparks, Md.]) and transported at room temperature. Specific culture media such as Sabouraud dextrose agar (Remel, Inc., Lenexa, Kan.), inhibitory mold agar, or Mycobiotic (Neogen, Lansing, Mich.) containing cycloheximide and chloramphenicol are useful.

MOLECULAR TECHNIQUES. Serologic tests that use immunodiffusion, radioimmunoassays, complement fixation, and ELISAs are available to detect circulating antibodies against several fungal organisms (see Table 31.5). These titers often decrease with resolution of disease; therefore repeated measurements can be used to help monitor response to treatment. Immunohistochemistry,[10,20-22] fluorescent in situ hybridization,[21] and DNA probes[23] can be used to positively diagnose fungal organisms in histopathology sections. A panfungal RT-PCR assay (University of California, Davis, Calif.) can be used to detect a variety of fungal organisms in body fluids and fungal isolates, followed by species-specific RT-PCR to positively identify the organism.[5]

IMMUNE FUNCTION TESTING. Several fungal infections have been associated with host immune suppression caused by severe malnutrition, congenital immunodeficiency, or acquired immunodeficiency.[13-15] Blood can be tested for immunoglobulin quantification by radial immunodiffusion (Cornell University, Ithaca, N.Y.) and lymphocyte subpopulation phenotyping via flow cytometry (Kansas State University, Manhattan, Kan.).[15,24]

Treatment

Treatment of fungal granulomas of the upper respiratory tract may involve surgical options (debulking, laser therapy, or cryotherapy) and/or medical therapy (systemic, topical, or intralesional). Treatment of *Aspergillus* spp. pneumonia is usually frustrating, as diagnosis is often late in the course of disease and the horse frequently has severe underlying illness. Successful therapy has been reported for other causes of fungal pneumonia.[5,25-28] Several pharmacokinetic studies on antifungal drugs have been performed,[29-34] and as these medications become more affordable, the success rate of therapy is likely to increase. The drug of choice depends on the site of infection, the fungus involved, and the financial resources of the owner. Specific antifungal agents used in horses have been reviewed.[35] Therapy may not be attempted because of the severity of the primary disease, the expense, or the poor prognosis.

Prevention of invasive fungal pneumonia is difficult. It is impossible for the horse to avoid large inhaled inocula, given its environmental conditions. Improving ventilation and minimizing exposure to inspired spores are most beneficial in immunocompromised patients. The most important methods of disease prevention are treating predisposing illnesses promptly and effectively and judiciously avoiding overuse of corticosteroids and broad-spectrum antibiotics.

ANTIFUNGAL THERAPEUTICS (Table 31.6)

Amphotericin B. Amphotericin B deoxycholate is a polyene antibiotic that combines with ergosterol in the fungal cell membrane, resulting in an increase in cell permeability. Intravenous amphotericin B can cause nephrotoxicity and phlebitis. Other possible side effects include anorexia, anemia, cardiac arrhythmias, hepatic and renal dysfunction, and hypersensitivity reactions.[36] Amphotericin B also has been used successfully to treat histoplasmosis and pulmonary aspergillosis and cryptococcosis.[25,26,37] A high dose of oral amphotericin B successfully treated mucormycosis caused by *Absidia corymbifera*.[38] Topical amphotericin B has been successful in treatment of nasopharyngeal *C. coronatus*.[39-42]

Azoles. Benzimidazole derivatives in the class *azoles*, such as miconazole, enilconazole, ketaconazole, itraconazole, fluconazole, and voriconazole, destroy fungi by inhibition of ergosterol biosynthesis in the fungal cell membrane. Azole antifungals inhibit cytochrome P450–dependent 14 α–sterol demethylase, which is essential for the formation of ergosterol. Topical 2% miconazole was used in the resolution of four cases of guttural pouch mycosis[43] and as part of successful multimodal therapy against nasopharyngeal *Pseudallescheria boydii*.[44] Enilconazole is not commercially available in the United States but has been used topically in the successful treatment of guttural pouch mycosis.[45-47] Aerosolization of 1.2 mg/kg enilconazole q12h in 125 mL saline resolved *Scopulariopsis* pneumonia.[28] Ketoconazole is absorbed poorly in the nonacidified form[29] but can be acidified for better absorption (30 mg/kg via nasogastric tube q12h mixed with 0.2 normal HCl).[28]

Itraconazole (Sporanox solution [Janssen, Titusville, N.J.]) is absorbed well orally (bioavailability 60%). A dose of 5 mg/kg PO q24h maintains concentrations above mean inhibitory concentration (MIC) for susceptible yeasts (*Histoplasma* spp.

TABLE 31.5

Characteristic Morphologic Features and Availability of Serologic Tests for Fungal Organisms Reported to Cause Fungal Granulomas in Horses (March 2018)

Agent	Cytologic Appearance: Tissue Form	Serologic Test: Method	Serologic Test: Veterinary Laboratory
Cryptococcus neoformans	Round, thin-walled, yeastlike fungus (5-10 µm) with a large heteropolysaccharide capsule (1-30 µm in diameter) that does not take up common cytologic stains. Capsule is best stained using Mayer's mucicarmine stain. Organisms show narrow-based budding and lack endospores.	Capsular antigen ELISA (antigen) or latex agglutination (antigen)[26,58,61]	$41.00 UT $27.00 CU $23.00 CSU $18.00 UGA $29.50 NMDA $33.00 MDL
Conidiobolus coronatus	Broad, thin-walled, highly septate, irregularly branched hyphae (5-13 µm in diameter).[53,56] Often surrounded by acidophilic staining glycoprotein antigen-antibody complex known as Splendore-Hoeppli material.	Immunodiffusion is highly sensitive and specific. Decreasing titer is correlated to disease resolution in horses.[51,55]	Serologic testing not widely available.
Pseudallescheria boydii	Hyaline, nonpigmented, septate, randomly branched hyphae (2-5 µm in diameter) with regular hyphal contours. Asexual form has nonbranching conidiophores with terminal conidia. Sexual form in culture has cleistothecium (large, round body) and ascospores.[44]		
Coccidioides immitis	Spherules have a double-contoured wall, are variable in size, but can be large (20-80 µm, up to 200 µm). The mature spherules (sporangia) contain endospores (sporangiospores) 2-5 µm in diameter. In the environment, mycelium are thick walled with barrel-shaped arthroconidia.	AGID (antibody) for IgM and IgG[27,77,80,81] MVista Quantitative EIA (antigen)	$27.00 UT $20.00 CSU $21.00 CU $43.00 NMDA $60.00 MDL
Aspergillosis spp.	Broad (2-4 µm in diameter) septate hyphae with parallel sides and acute right-angled branching.	Platelia *Aspergillus* Galactomannan EIA (sandwich immunoassay) Some reactivity to *Penicillium*, *Alternaria*, and *Paecilomyces*. AGID (antibody) *Aspergillosis fumigatus* only *Aspergillus* spp. panel	$60.00 MDL $27.00 UT $20.00 CSU $21.00 CU $48.00 NMDA $105.00 UT (send out)
Blastomyces dermatitidis	Yeasts are spherical (15-17 µm in diameter) with basophilic protoplasm and unstained, uniformly shaped refractile walls. Unilateral, broad-based budding is characteristic. Yeasts are often located within multinucleated giant cells.	AGID (antibody)[23] MVista Quantitative EIA (antigen)	$27.00 UT $20.00 CSU $21.00 CU $48.00 NMDA $60.00 MDL
Histoplasma capsulatum	Yeasts (2-4 µm in diameter) have a thin, clear halo surrounding a round or crescent-shaped basophilic cytoplasm.	AGID (antibody)[74] MVista Quantitative EIA (antigen) Antigen	$27.00 UT $20.00 CSU $21.00 CU $48.00 NMDA $60.00 MDL $80.00 UT
Acremonium strictum	Mononuclear cells contain single, spherical, intracytoplasmic encapsulated spores 3-5 µm in diameter.[5]		
Candida spp.	Ovoid budding yeast cells (2-4 µm in diameter) with thin walls, or they can occur in chains that produce septate pseudohyphae when blastospores remain attached after budding division. Filamentous, regular, true hyphae also may be visible.		
Pneumocystis carinii	Trophozoite (yeast form) is a 2- to 5-µm in diameter ameboid with filopodia that attach to the surface of type I pneumocytes. Sporangia (cystic form) are encapsulated spores (4 to 6 µm in diameter) containing 8 uninucleate spores (intracytic bodies).[14,15,20,85]		
Fungal serology panel	Antibody to *Histoplasma*, *Blastomyces*, *Coccidioides*, *Aspergillus* (AGID) The CU panel also includes *Cryptococcus* antigen		$69.00 CU $68 CSU $48.00 NMDA
Fungal culture			$52.00 CU $30 CSU
Fungal susceptibility	Per isolate		$73.00 CU $168 UT

TABLE 31.6

Pharmacokinetic Studies of Antifungal Drugs Performed in Horses

Drug and Relative Cost	Dosage	Source	Susceptible Organisms, Equine Reports, Comments
Ketoconazole $ = Moderate	30 mg/kg q12h mixed with 0.2 normal HCl via nasogastric intubation[29]	LH Tablets (200 mg) (Nizoral [Janssen, Raritan, N.J.])	*Scopulariopsis*,[28] *Coccidioides*, *Cryptococcus*, *Candida*, *Malassezia*, *Histoplasma*, *Sporothrix*, *Microsporum*, *Trichophyton*
Itraconazole $ = Very expensive	5 mg/kg/day solution PO[31] (bioavailability 60%, compared to 12% for capsules)	Sporonox solution (10 mg/mL oral or injectable solution) Sporanox capsules (100 mg) (Janssen, Raritan, N.J.)	*Aspergillus*,[45,68] *Histoplasma*, *Bastomyces*, *Coccidioides*, *Cryptococcus*, *Candida*, *Paracoccidioides*, *Paecilomyces*, *Scopulariopsis*, *Sporothrix*, *Alternaria*, *Sporotrichum*, *Prototheca*. Not active against *Fusarium*, *Mucor*, *Rhizopus*. Very unstable and lipophilic, therefore compounded substances are not recommended.
Fluconazole $ = Inexpensive	14 mg/kg PO loading followed by 5 mg/kg/day PO[30]	LH Injectable solution (2 mg/mL) (Bedford Labs, Bedford, Ohio) Tablets (200 mg) (Pfizer, New York, N.Y.) Generic available Powder (100 g) (Spectrum Chemicals, New Brunswick, N.J.)	*Histoplasma*, *Bastomyces*, *Coccidioides*,[27] *Cryptococcus*,[60,61] *Mucor*, *Rhizopus*, *Candida*,[12] *Conidiobolomycosis*,[54,56] *Parracoccidia*, *Paecilomyces*, *Scopulariopsis*, *Sporothrix*, *Alternaria*, *Sporotrichum*, *Prototheca*. Minimal activity against *Aspergillus* and *Fusarium*.
Voriconazole $ = Very expensive	4.0 mg/kg/day PO[32-34]	Vfend (Bedford Labs, Bedford, Ohio) Tablets (200 mg)	Drug of choice for invasive *Aspergillus*,[67] *Candida*, *Cryptococcus*, *Scedosporium apiospermum*, *Bipolaris*, and *Fusarium* species in human patients that are unable to tolerate or are refractory to other therapeutic agents.

HCl, Hydrochloride; *LH*, local wholesaler; *PO*, by mouth.

and *Blastomyces* spp.) and *Aspergillus* spp., with no detectable side effects.[31] The use of compounded itraconazole is not recommended. It is very unstable (requires low pH), and owing to its lipophilic nature it is difficult to formulate in aqueous solution.

Oral fluconazole at a loading dose of 14 mg/kg, followed by 5 mg/kg q24h, yields concentrations in plasma, cerebrospinal fluid (CSF), synovial fluid, aqueous humor, and urine above the MIC reported for several equine fungal pathogens.[30] Fluconazole, however, reportedly has minimal activity against filamentous fungi (*Aspergillus* spp. and *Fusarium* spp.). Low-dose oral fluconazole (1 mg/kg PO q24h) for at least 10 to 15 days anecdotally has been successful in treatment of fungal keratitis. Compounded fluconazole formulations are very stable. The cost of fluconazole has been markedly reduced since the availability of generic products.

Voriconazole, a broad-spectrum triazole antifungal agent, was approved for use in human medicine in 2002. It is now considered the drug of choice for initial treatment of invasive aspergillosis, candidiasis, cryptococcosis, *Bipolaris hawaiiensis*, and serious fungal infections caused by *Scedosporium apiospermum* and *Fusarium* spp. in patients that are unable to tolerate or are refractory to other therapeutic agents.[46-49] An initial single-dose pharmacokinetic study in horses recommended a dose of 4 mg/kg PO q24h.[32] Voriconazole distributes widely into body fluids and reached therapeutic concentrations in peritoneal, synovial, and cerebrospinal fluids; aqueous humor; periocular tear film; epithelial lining fluid; and urine.[33-34]

SYSTEMIC IODIDE THERAPY. The exact mode of action of iodides is unknown; however, they seem to have a beneficial effect on the granulomatous inflammatory process. Iodides have very little if any direct in vitro antibiotic effect.[50] Although several successful cases are reported in which iodides were used as primary or adjunctive therapy, overall efficacy is considered limited at best. Treatment is inexpensive, but iodide toxicity can occur and is characterized by excessive lacrimation, nonproductive cough, increased respiratory secretions, and dermatitis.[50] The recommended dose of 20% sodium iodide is 20 to 40 mg/kg/day IV for 7 to 10 days.[39,42,51,52] Orally administered iodine is available in two forms. Inorganic potassium iodide (10 to 40 mg/kg/day) is available only as a chemical grade and is unstable in the presence of light, heat, and excessive humidity.[42,52] Organic ethylenediamine dihydriodide (EDDI) (0.86 to 1.72 mg/kg of EDDI is equivalent to 20 to 40 mg/kg/day of the 4.57% dextrose powdered form [Butler Co., Columbus, Ohio]) is commercially available.[52] Administration of iodine in the diet of pregnant mares may cause congenital hypothyroidism in foals and thus should be avoided.

ETIOLOGIC AGENTS

Conidiobolomycosis. *Conidiobolus coronatus* is a saprophytic fungus that causes granulomatous lesions of the upper respiratory tract in horses. Single to multiple granulomatous lesions in the nasal passages, trachea, or soft palate can be observed endoscopically (Fig. 31.19). Histologic appearance of conidiobolomycosis is similar to that of pythiosis and of basidiobolomycosis. Hyphae of *C. coronatus* are thin-walled, highly septate, and irregularly branched (see Table 31.5).[53] The lesions typically have large numbers of eosinophils and fewer macrophages, neutrophils, plasma cells, and lymphocytes surrounding hyphae. Definitive diagnosis is based on microbiological culture, immunodiffusion, or PCR.[54] Detection of serum antibodies by immunodiffusion is considered highly sensitive and specific[51,55] and can be used to monitor response to treatment.[55]

Conidiobolomycosis lesions can be treated with surgical excision, laser therapy, cryotherapy, or long-term administration of iodides or antifungals.[39,51,54] Amphotericin B has been

FIG. 31.19 Endoscopic image of mycotic granulomas caused by *Conidiobolus coronatus* in the nasopharynx of a horse.

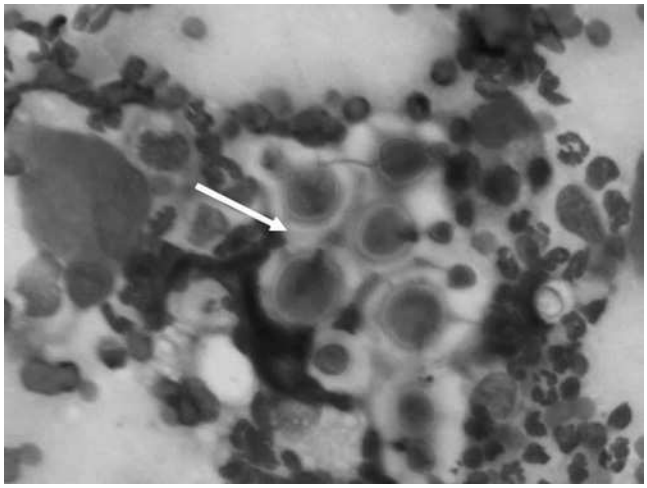

FIG. 31.20 Photomicrographs of an impression smear from a biopsy of a mass in the nasal passage of a horse. The smear is extremely cellular with abundant neutrophils and macrophages. Round yeast cells with large nonstaining capsules and occasional narrow-based budding consistent with cryptococcal organisms *(arrow)* are shown. (Modified Wright stain, ×100.) *(Courtesy Elizabeth Welles, Auburn University, Auburn, Ala.)*

administered intralesionally or topically in combination with dimethyl sulfoxide (DMSO) to treat *C. coronatus*.[39-42] It is important to remember that long-term therapy and reevaluation are essential, as recurrence can occur.[42] Oral fluconazole would be considered the drug of choice for the treatment of conidiobolomycosis, with treatment length varying between 4 and 16 weeks based on endoscopic reevaluation.[56] A vaccine using *C. coronatus* antigen from broth cultures was unsuccessful in treating seven horses with conidiobolomycosis.[54]

Cryptococcosis. Cryptococcosis is caused by *Cryptococcus neoformans* (var. *neoformans* and var. *gattii*) and is a ubiquitous, saprophytic, round, basidiomycetous yeastlike fungus with a large heteropolysaccharide capsule that does not take up common cytologic stains (see Table 31.5; Fig. 31.20). The capsule forms a clear halo when stained with India ink. The capsule is immunosuppressive and antiphagocytic. A relatively high frequency of equine cryptococcosis occurs in Western Australia.[3,57,58] There is an epidemiologic relationship between *C. neoformans* var. *gattii* and the Australian river redgum tree *(Eucalyptus camaldulensis)*, whereas *C. neoformans* var. *neoformans* has historically been associated with bird (particularly pigeon)

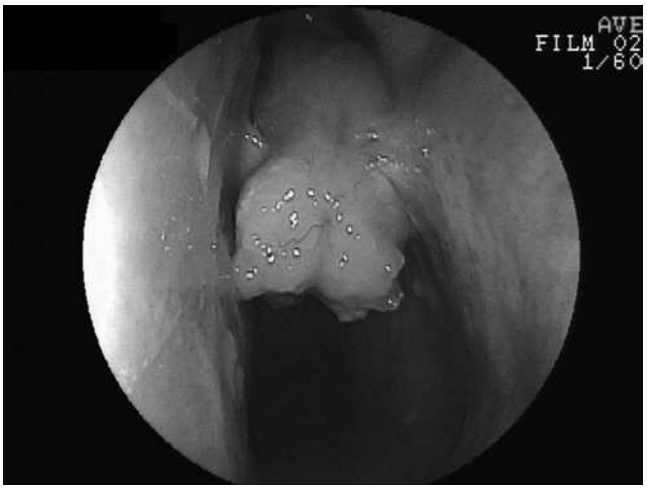

FIG. 31.21 Endoscopic image of a *Cryptococcus* granuloma in the nasal passages of a horse.

excreta.[3] Cytologic or histopathologic identification is very reliable for diagnosis because of the characteristic morphology.[59] Serologic testing with latex agglutination to identify cryptococcal capsular antigen is useful, with resolution of lesions correlated with declining serum titers.[26]

Cryptococcosis in horses is associated primarily with pneumonia, rhinitis (Fig. 31.21), meningitis, and abortion. Pulmonary *Cryptococcus* has been successfully treated with daily intravenous infusions of amphotericin B over 1 month.[26] However, four more cases from the same institution were recently successfully treated with oral fluconazole for 7 to 18 months, with declines in cryptococcal antigen titers corresponding to disease resolution.[58] Sinonasal cryptococcosis was successfully treated in two horses after extensive surgical débridement and long-term treatment with oral fluconazole.[60,61]

Cryptococcosis should be treated with fluconazole, amphotericin B, or voriconazole (Table 31.7).

Pseudallescheriosis. *Pseudallescheria boydii* is a saprophytic ascomycete. Infection most commonly involves the extremities, and in human patients it is known as Madura foot. Hyphae within tissue cannot be differentiated from *Fusarium* spp. or *Aspergillus* spp. unless cultured. *P. boydii* cultured from the nasal cavity and sinus of a horse with chronic, malodorous nasal discharge was susceptible in vitro to miconazole, ketaconazole, natamycin, and clotrimazole. After débriding and flushing the plaque, miconazole cream was infused twice daily for 4 weeks through lavage tubing that had been passed into the nasal passage through a hole drilled in the frontal bone and sinuses. Adjunctive iodide therapy was also administered and the lesions resolved.[44]

Nasal mycosis caused by *P. boydii* has been reported in two other horses, both of which were euthanized.[62,63] *P. boydii* has also been isolated from the pharynx of 2 of 60 normal donkeys.[64]

Aspergillosis. *Aspergillus* spp. have broad septate hyphae with parallel sides and acute right-angled branching (see Table 31.5). They have a propensity for vascular invasion. Definitive diagnosis is by culture or staining by immunohistochemistry or immunofluorescence. *Aspergillus* spp. are very common in the environment, especially in moldy feed and bedding.[37] They are opportunistic pathogens and often cause disease in horses that are immunosuppressed from debilitating disease such as enterocolitis, septicemia, neoplasia, Cushing's disease, and equine protozoal myeloencephalitis (EPM); that have undergone surgery; or that have been treated with immunosuppressive drugs[4,6,8-10] (Fig. 31.22).

Infection is by inhalation of an overwhelming number of spores, resulting in fungal proliferation and invasion of the

TABLE 31.7

Treatment of Common Fungal Infections in Humans and Horses

Infection	Recommended Treatment in Humans[87]	Treatments Tried in Horses	Comments
Cryptococcosis	Induction with amphotericin B 0.7-1 mg/kg, plus 5-fluorocytosine 100 mg/kg/day for 2 weeks then consolidation with fluconazole 400 mg/day for >10 weeks.	Daily infusions of amphotericin B (initially 0.35 mg/kg, increasing over 8 days to 0.5 mg/kg in 1 L 5% dextrose in water over 1 h IV for 1 month) successfully used to treat pulmonary cryptococcosis. Flunixin meglumine (0.25 mg/kg IV) was administered before each treatment.[26,61] Successful treatment with long-term fluconazole (14 mg/kg loading then 5 mg/kg PO q24h) for sinonasal cryptococcosis after surgical débridement[60,61] and pulmonary infection.[58]	Reported dosages range from 0.3-0.9 mg/kg in saline IV over 1 h. Long-term oral fluconazole is recommended as sole treatment or after 2 weeks of IV amphotericin B.
Histoplasmosis	Amphotericin B 0.7-1.0 mg/kg/day for 2 weeks then itraconazole 200-400 mg/day for 4-18 months.	Successful treatment of histoplasmosis in a filly using amphotericin B (0.3-0.6 mg/kg eod IV infused over 1 h) with a total cumulative dose of 6.75 mg/kg administered over 1 month. After each treatment the filly became lethargic for 18-24 h. Polyuria and polydipsia occurred during the fourth week, but urine-concentrating ability was maintained and azotemia did not occur.[25]	In vitro susceptibility to fluconazole is poor.
Blastomycosis	Amphotericin B 0.7-1.0 mg/kg/day to 1.5-2.5 g total or to 0.5 g total then itraconazole 200-400 mg/day		
Aspergillosis (invasive pulmonary)	1. Voriconazole 200-400 mg PO q12h, 3-6 mg/kg IV q12h 2. Amphotericin B 1.0-1.5 mg/kg/day until desired response, then itraconazole 400 mg/day when disease progression slows	Voriconazole 4 mg/kg PO q24h. Successful treatment of a neonatal foal with pulmonary aspergillosis after lung lobe resection.[67]	Fluconazole has limited efficacy. Oral itraconazole or voriconazole would be the drugs of choice, possibly after 2 weeks of IV amphotericin B.
Candidiasis	1. Amphotericin B 0.7-1.0 mg/kg/day for 2 weeks 2. Fluconazole 6 mg/kg for 2 weeks 3. Caspofungin 70 mg ×1, then 50 mg/day for 2 weeks 4. Voriconazole	Two foals were treated with IV amphotericin B for 8 days (total dose 2.6 mg/kg) and 29 days (total dose 10.3 mg/kg), respectively. Fluconazole (5.5 mg/kg PO q24h) for 6 weeks and (4 mg/kg PO q24h) for 28 days was used to treat two other foals.[12]	Fluconazole is generally considered the drug of choice against *Candida* spp., although *Candida krusei* is resistant to fluconazole.
Pneumocystis	1. TMS 2. Pentamidine isethionate 3. Trimetrexate	TMS (25-30 mg/kg PO q12h) is the treatment of choice.[86] Dapsone[a] (3 mg/kg PO daily for 2 months) was used to successfully treat a foal with *Pneumocystis carinii* that developed *Salmonella* enterocolitis after treatment with TMS.[24]	Lacks ergosterol, therefore antifungals are not effective.

[a]Jacobus Pharmaceutical Co. Inc., Princeton, N.J.

eod, Every other day; *IV*, intravenous; *PO*, by mouth; *TMS*, trimethoprim-sulfamethoxazole.

small airways, or by translocation of organisms across an inflamed GI tract leading to lesions centered around large blood vessels as a result of hematogenous spread. In two retrospective studies of invasive pulmonary aspergillosis, 41 of 49 cases were associated with enterocolitis.[4,6] *Aspergillus* spp. pneumonia is almost uniformly fatal, often with no or mild respiratory signs. Antemortem diagnosis of pulmonary aspergillosis is made rarely. In a retrospective study of 30 cases of *Aspergillus* spp. pneumonia, only 2 cases were diagnosed or suspected antemortem.[6] Transtracheal aspirates or bronchoalveolar lavages may not be helpful because hyphae and spores are often present extracellularly or within macrophages in aspirates and lavages from healthy animals.[4] False-negative results also can occur. Cytologic examination of a transtracheal wash specimen obtained from the foal shown in Fig. 31.22, *A* 2 days prior to euthanasia failed to identify *Aspergillus* spp. hyphae. Serologic diagnosis occasionally has been useful,[65] but it is often unreliable because many horses have titers to *Aspergillus* spp. Development of a commercially available ELISA is promising.[8,37]

In human medicine, 50% to 90% of patients with invasive aspergillosis die despite treatment. Amphotericin B has been the mainstay of treatment for invasive aspergillus for decades, but it is associated with nephrotoxicity in about 50% of human patients. Nephrotoxicity is reduced with the use of liposomal amphotericin B. Voriconazole, an azole antifungal, is now considered the drug of choice against human aspergillosis, and caspofungin (in the new class of echinocandin antifungals)

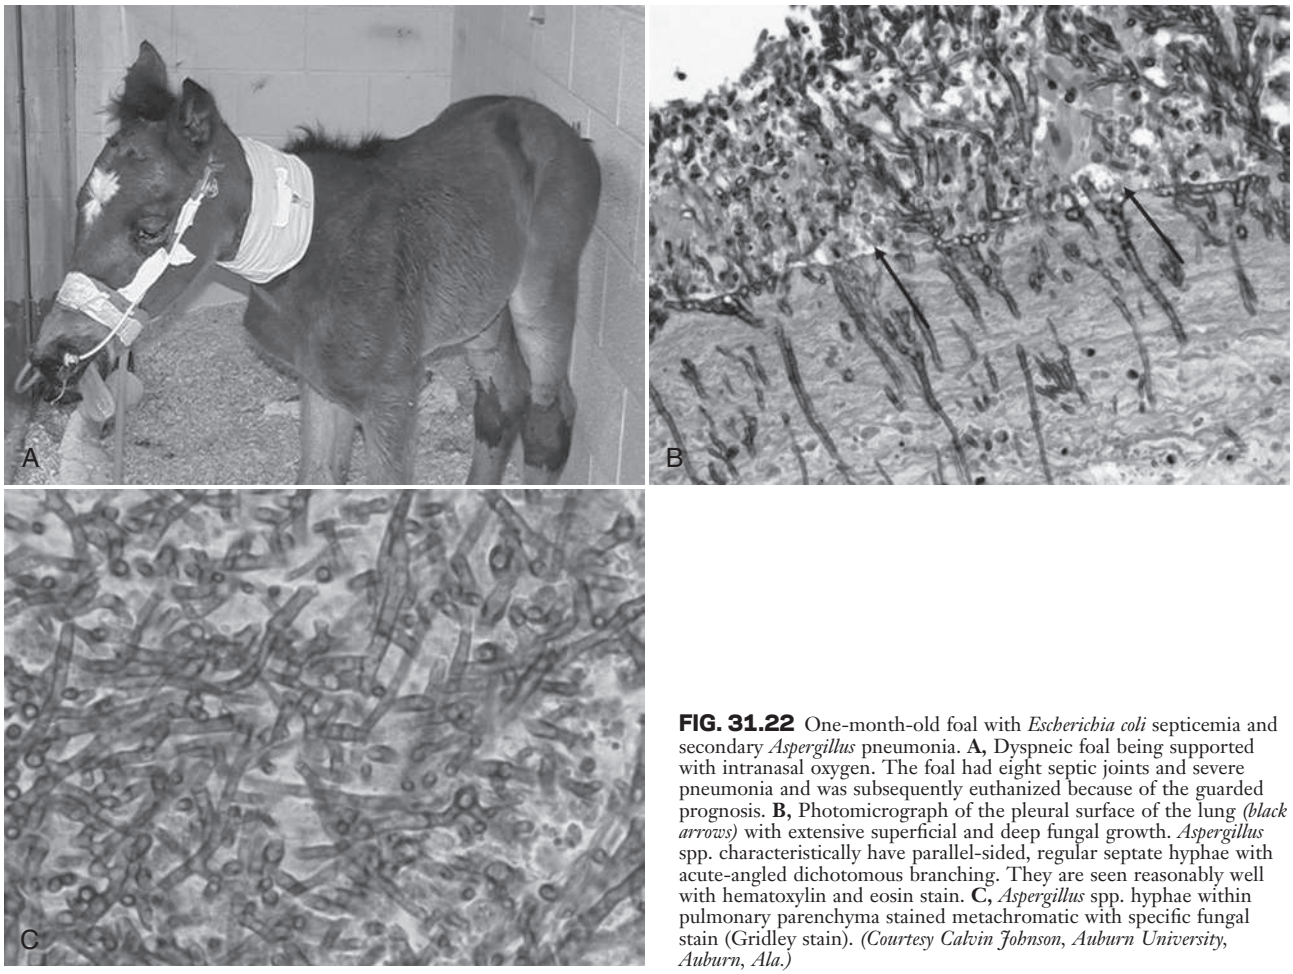

FIG. 31.22 One-month-old foal with *Escherichia coli* septicemia and secondary *Aspergillus* pneumonia. **A,** Dyspneic foal being supported with intranasal oxygen. The foal had eight septic joints and severe pneumonia and was subsequently euthanized because of the guarded prognosis. **B,** Photomicrograph of the pleural surface of the lung *(black arrows)* with extensive superficial and deep fungal growth. *Aspergillus* spp. characteristically have parallel-sided, regular septate hyphae with acute-angled dichotomous branching. They are seen reasonably well with hematoxylin and eosin stain. **C,** *Aspergillus* spp. hyphae within pulmonary parenchyma stained metachromatic with specific fungal stain (Gridley stain). *(Courtesy Calvin Johnson, Auburn University, Auburn, Ala.)*

shows promising results in patients with refractory infections.[66] Oral voriconazole and itraconazole are currently the treatments of choice for aspergillosis in horses. In human medicine, itraconazole has shown comparable response rates to those of amphotericin B.[66] *Aspergillus* spp. are usually resistant to fluconazole. There are limited reports of horses surviving pulmonary aspergillosis.[37] A neonatal foal with pulmonary aspergillosis was successfully treated by lung lobe resection followed by treatment with systemic voriconazole.[67]

Treatment of mycotic aspergillus rhinitis and sinusitis in horses has been more successful. It is important, however, to rule out concomitant invasive pulmonary aspergillosis. Oral itraconazole,[68] topical natamycin (flushed via an endoscope or indwelling catheter placed into the sinus), nystatin powder (insufflated up the nostril), and topical enilconazole have been curative.[69,70]

Blastomycosis. Blastomycosis is caused by inhalation of conidiae of the thermally dimorphic saprophytic fungus *Blastomyces dermatitidis. Blastomyces* yeasts can be identified on cytologic examination, often within multinucleated giant cells. They are spherical, with basophilic protoplasm and unstained, uniformly shaped refractile walls. Unilateral, broad-based budding is characteristic (see Table 31.5).

Blastomycosis was reported to cause pyogranulomatous pleuropneumonia, pulmonary abscessation, peritonitis, and abscesses in a 5-year-old horse.[23] *B. dermatitidis* was positively identified from transtracheal wash fluid by use of a DNA probe, and serologic testing was strongly positive. The horse was euthanized without treatment.[23] Disseminated blastomycosis was diagnosed in a miniature horse with subcutaneous infections associated with a chronic pectoral wound. The pony had pulmonary consolidation and pleural effusion. Yeasts were observed histologically in many tissues, and *B. dermatitidis* was cultured after 6 weeks.[71] Disseminated blastomycosis was diagnosed in a mare with unresponsive mastitis that progressed to subcutaneous lesions on the ventrum.[72]

Treatment with amphotericin B, itraconazole, or fluconazole is recommended (see Table 31.7).

Histoplasmosis. Histoplasmosis is caused by the saprophytic, dimorphic fungus *Histoplasma capsulatum* and is most prevalent in moist soil containing bird or bat waste. Yeast organisms are 2 to 4 μm in diameter, with a thin clear halo surrounding a round or crescent-shaped basophilic cytoplasm. *H. capsulatum* has been reported in fewer than 10 equine cases,[25] and thus horses are considered to be relatively resistant to disease. *H. capsulatum* may occur in an enteric, pulmonary, or disseminated form.[25] *H. capsulatum* was identified in pulmonary granulomas in a horse dying of chronic *Yersinia* colitis.[73] It has also been associated with abortions and severe granulomatous pneumonia in neonatal foals (Fig. 31.23) and a yearling.[74] Successful treatment with amphotericin B was reported in a filly with pulmonary histoplasmosis diagnosed by cytologic identification of the organism on a tracheal wash smear and from a lung aspirate.[25] Treatment with amphotericin B or itraconazole is recommended (see Table 31.7).

Epizootic lymphangitis is caused by *Histoplasma capsulatum* var. *farciminosum*. It was eradicated from a number of European and Asian countries by slaughter, but it is still considered an

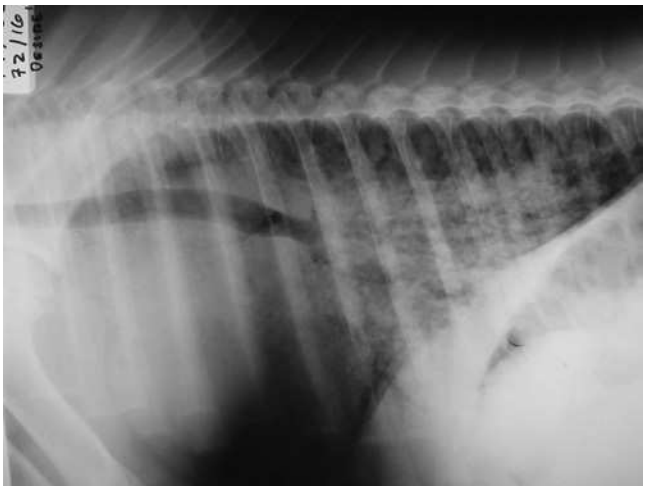

FIG. 31.23 Lateral thoracic radiographs from a foal with *Histoplasma* pneumonia. *(Courtesy Carol Clark, Peterson and Smith Equine Hospital, Ocala, Fla.)*

economically important disease in Ethiopia, Senegal, South Africa, Chad, and Gambia, and it is likely still endemic in other African countries and parts of the Middle and Far East.[75] Although four forms of the disease—ocular, cutaneous, respiratory, and asymptomatic—are described, they are not distinct clinical entities, and combinations can occur.[75] The respiratory form can involve nodules in the mucous membranes of the nares and extend up the nasal passages, down the trachea, and into the pulmonary parenchyma. There is often a mucopurulent nasal discharge, with stertorous noise during respiration in advanced stages. This form causes cough, progressive weakness, and weight loss and is difficult to differentiate clinically from glanders. Control of the disease is gained usually by destroying infected horses and through application of strict hygiene practices to prevent spread of the organism. Organisms can be identified cytologically and definitively diagnosed by culture, but the organism is slow growing, and overgrowth by contaminants is common. Culture on Sabouraud dextrose agar supplemented with glycerol and chloramphenicol is recommended.[75] There is a skin test known as the "Histofarcin" test that is useful for field diagnosis, with a sensitivity of 90.3% but a specificity of only 69%; however, the false-positives may be due to subclinical disease.[76] Serologic tests were developed but are not commercially available. PCR testing shows promise but is currently not very practical in the field.[75] Treatment with systemic iodides, surgical excision, and topical treatment with amphotericin B is variably successful. A cost-effective and currently recommended protocol in impoverished areas consists of lancing all visible nodules under sedation and flushing with 4% tincture of iodine daily; in addition, oral potassium iodine (30 g for a 200- to 250-kg horse by stomach tube or orally in feed is administered daily for 5 days, then every other day for 3 to 4 weeks). This protocol is effective in early cases, but would be unlikely to resolve pulmonary disease.[75] Fluconazole would likely be effective, but would be economically prohibitive in most cases.

Coccidiomycosis. *Coccidioides immitis* is a soil saprophyte that grows in semiarid areas with sandy, alkaline soils.[77] Inhaled arthroconidia enlarge to form nonbudding spherules, which incite an inflammatory reaction in the lungs and lymph nodes.[78] Horses infected with this fungus have weight loss, fever, abdominal pain, and signs of respiratory disease. Localized, recurring nasal granulomas also have been reported.[79] Diffuse infections, with granulomas in the lungs, liver, kidney, or spleen, have a grave prognosis.[78] Przewalski's horses may be more susceptible.[79]

C. immitis is difficult to culture, and spherules may not be observed histologically from antemortem lung biopsies. However, serology is very useful for diagnosing infection, and decreasing titers are associated with clinical improvement.[27,77] Serum antibodies are detected rarely in healthy horses.[80] Higher serologic antibody titers are associated with a poorer prognosis for survival.[81] Horses with disseminated disease and pneumonia with thoracic effusion usually have severe clinical disease and frequently die (19 of 21 cases).[81] Antifungal agents successful in treating infected horses include itraconazole and fluconazole.[27]

Scopulariopsis. *Scopulariopsis* pneumonia was diagnosed by culture of bronchoalveolar lavage fluid in a 2-year-old Quarter Horse filly with pleuropneumonia. The infection resolved following multimodal therapy with ketaconazole and aerosolization of enilconazole.[28]

Adiaspiromycosis. Adiaspiromycotic miliary fungal pneumonia caused by the saprophytic soil mold *Emmonsia crescens* was diagnosed in a horse by percutaneous lung biopsy. Euthanasia was performed without treatment.[11]

Acremonium strictum. A diagnosis of interstitial fungal pneumonia caused by *Acremonium strictum* was made based on cytologic evaluation, culture, and PCR testing of bronchoalveolar lavage fluid in a 10-year-old horse. The horse made an uneventful recovery with supportive treatment that included 1 month of fluconazole.[5] In general, fluconazole has been shown to have poor activity against *A. strictum* in vitro.[82] The isolate cultured from the horse was found to be resistant to fluconazole based on in vitro sensitivity testing that was performed after the course of treatment. It is therefore uncertain if the fluconazole assisted in disease resolution.[5]

Candidiasis. In human medicine, candidemia is the most common fungal infection in burn patients, neutropenic patients with malignancies, patients undergoing complex abdominal surgery, and patients receiving total parenteral nutrition and long-term corticosteroid therapy.[67] In humans, *Candida* spp. account for 8% to 10% of all blood culture isolates and rank fourth in the list of most frequently isolated pathogens from blood cultures.[67] The mortality rate in patients with candidemia is 40% to 75%.[67] More than 60% of isolates are *Candida albicans*.[67] Fluconazole is generally considered the drug of choice against *Candida* spp., although *Candida krusei* is resistant to fluconazole. Itraconazole, amphotericin B, caspofungin, and voriconazole are alternative antifungal agents (see Table 31.7).[67]

Systemic candidiasis was diagnosed and successfully treated in four neonatal foals. Each foal had prior sepsis attributable to gram-negative bacteria that had been aggressively treated with numerous antibiotics and parenteral nutrition. *C. albicans* was cultured from a transtracheal wash from one of the foals. Three of the foals had *Candida* glossitis, and one had panophthalmitis and fungal keratitis. Two of the foals were treated with intravenous amphotericin B, and oral fluconazole was used on the other two foals.[12]

Superficial *Candida* spp. infections of the mucous membranes (thrush)[83] can occur in isolation or as part of a systemic infection, and further microbiological culturing of the blood, tracheal wash, urine, or joint fluid may be indicated to rule out systemic infection.[12] *Candida* spp. glossitis can be treated by rinsing the mouth either with potassium permanganate (0.025% q24h) or nystatin (0.3 g in 10 mL of water q8h).

Pneumocystosis. *Pneumocystis carinii* (renamed *P. jiroveci* in humans) has been reclassified from a protozoan to a saprophytic fungus based on the DNA sequence of its 16S-like RNA subunit, but some researchers consider it to be a plant because it lacks ergosterol, the major fungal sterol.[84] It exists as an ameboid yeast or as a cystic sporangia. *P. carinii* cannot be cultured, and diagnosis is based on the cytologic identification of characteristic morphologic features using specimens obtained by bronchoalveolar lavage rather than tracheal wash. A fluorescent in situ hybridization method with an oligonucleotide

VetBooks.ir

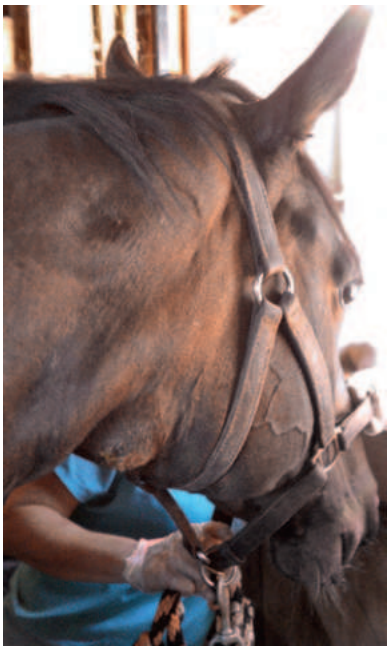

FIG. 31.24 Horse with retropharyngeal lymphadenopathy resulting in head and neck extension characteristic of *Streptococcus equi* infection.

probe that targets the 18S ribosomal RNA has been developed recently to detect *P. carinii* in histologic sections.[21] Immunohistochemistry also can be used.[20]

P. jiroveci is the most common organism to cause opportunistic infection in people with HIV, and people undergoing immunosuppressive therapy after organ transplantation are predisposed. *P. carinii* causes diffuse interstitial pneumonia, especially in immunocompromised patients such as Arabian foals with SCID.[13] It also has been diagnosed in immunocompromised adult horses,[14,15] as well as in an immunocompetent foal.[20] TMS (25 to 30 mg/kg PO q12h) is the treatment of choice (see Table 31.7).[85,86] Dapsone (3 mg/kg PO daily for 2 months; Jacobus Pharmaceutical, Princeton, N.J.) was used to successfully treat a foal that developed *Salmonella* enterocolitis after treatment with TMS.[24]

Streptococcus equi subsp. *equi* Infection (Strangles)*

Ashley G. Boyle

The highly contagious *S. equi* subsp. *equi* infections in horses, commonly referred to as *strangles*, were first described in early veterinary science literature by Jordanus Ruffus in 1251.[1] The causative organism will be referred to as *S. equi* in this section.

Clinical Signs

Strangles is characterized by sudden onset of fever followed by upper respiratory tract catarrh, as evidenced by mucopurulent nasal discharge and acute swelling with subsequent abscess formation in submandibular and retropharyngeal lymph nodes (Fig. 31.24). The term *strangles* was coined because affected horses sometimes suffocated as the lymph nodes became enlarged and obstructed the airway. Strangles is currently a reportable disease in many U.S. states.

Fever is the first clinical sign and remains as lymphadenopathy develops and abscesses mature. Pharyngitis makes swallowing painful, and affected animals may become anorectic or reluctant to eat and stand with the neck extended.

*Previous contributions by Corinne Sweeney are acknowledged.

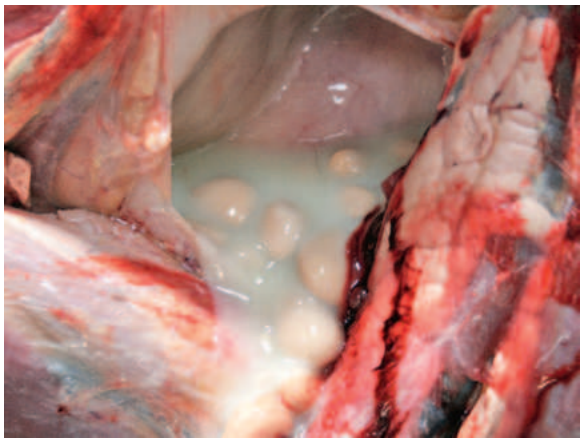

FIG. 31.25 Guttural pouch *Streptococcus equi* empyema with chondroids at postmortem. *(Courtesy Dr. Julie Engiles, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.)*

FIG. 31.26 Horse with the unique presentation of periorbital abscessation with concurrent ocular discharge that cultured positive for *Streptococcus equi*. *(Courtesy Dr. Erica Koch, Wentworth Equine Veterinary Services, Wolfeboro, N.H.)*

Lymphadenopathy is a major clinical sign. The submandibular and retropharyngeal lymph nodes are about equally involved in *S. equi* infections. They usually become swollen and painful approximately 1 week after infection. Other lymph nodes of the head region (parotid, cranial, and cervical) are also frequently involved and may abscess. Retropharyngeal lymph nodes may drain into and cause empyema of the guttural pouch (Fig. 31.25). Periorbital abscesses can cause marked swelling of the eyelids and result in ocular discharge that will culture positive for *S. equi* if sampled (Fig. 31.26). Abscesses of the lymph nodes at the thoracic inlet can cause severe tracheal compression, asphyxia, and death. Clinical severity and progression varies greatly depending on the immune status of the animal.

Pathogenesis

S. equi is of the Lancefield group C streptococcal diseases and enters via the mouth or nose and attaches to cells in the crypt of the lingual and palatine tonsils and to the follicular-associated epithelium of the pharyngeal and tubal tonsils. There is no evidence of colonization before penetration. After a few hours, the organism is difficult to detect on the mucosal surface but is visible within cells of the epithelium and subepithelial follicles. Translocation to the mandibular and suprapharyngeal lymph nodes that drain the pharyngeal and tonsillar region occurs in a few hours.[2]

VetBooks.ir

Complement-derived chemotactic factors attract large numbers of polymorphonuclear neutrophils (PMNs), although gross evidence of abscessation is not visible for 3 to 5 days after *S. equi* enters the lymph nodes. Failure of neutrophils to phagocytose and kill the streptococci appears to be a result of a combination of the hyaluronic acid capsule, antiphagocytic SeM protein, Mac protein, and other undetermined antiphagocytic factors released by the organism. Depending on the immune status of the patient and the degree of exposure to *S. equi* bacterial load, clinical signs may develop 3 to 14 days after exposure.[1]

Although strangles involves predominantly the upper airways, including the guttural pouches and associated lymph nodes, metastasis to other locations occasionally occurs. Spread may be hematogenous or via lymphatic channels, which results in abscesses in lymph nodes and other organs of the thorax and abdomen. This form of the disease is known as *bastard strangles.*

Nasal shedding of *S. equi* usually begins 2 to 3 days after onset of fever and persists for 2 to 3 weeks in most animals. Some animals never shed. In others, nasal shedding may last at least 6 weeks after purulent discharges have stopped. Persistent guttural pouch infection may result in intermittent shedding for years.[3,4] Systemic and mucosal immune responses are evident 2 to 3 weeks after infection and coincide with mucosal clearance.

As long as they were not treated with antimicrobials, approximately 75% of horses develop a waning immunity to strangles that lasts about 5 years after recovery from the disease. A small percentage of these horses become susceptible to a second attack of the disease within months, which probably represents a failure to produce or maintain an adequate level of the appropriate mucosal and systemic antibodies. Older horses with residual immunity have limited susceptibility and develop a mild form of strangles often called *catarrhal strangles.* These animals shed virulent *S. equi* that will produce severe disease in more susceptible, often younger horses. Colostral antibodies ingested during the first 24 hours of life have also been shown to recirculate to the nasopharyngeal mucosa, thus providing an additional source of protection to the foal during its first weeks. Foals that suckle immune mares are usually resistant to *S. equi* infection until weaning.[1]

Epidemiology

TRANSMISSION. Outwardly healthy horses that still shed organisms are a source of infection when introduced into a new population of horses. Definitive determination of carrier status requires endoscopic examination of the guttural pouches as well as PCR testing of guttural pouch lavage fluid.[1,5,6] *S. equi* may originate from outwardly healthy horses such as the following:

- Horses that are incubating the disease and go on to develop signs themselves
- Horses that are recovering from recent disease but that continue to harbor the organism after full clinical recovery for some weeks
- Horses that are fully recovered from the disease but continue to be potentially infectious for prolonged periods through periodic shedding of *S. equi* (carriers)

ENVIRONMENTAL PERSISTENCE OF *STREPTOCOCCUS EQUI*. Currently there is a lack of definitive field-based evidence for prolonged environmental persistence. *S. equi* is known to be sensitive to bacteriocins from environmental bacteria and does not readily survive in the presence of other soil-borne flora. Modeled environmental field conditions revealed that the organism was found to persist for less than 4 days, but moist environments (e.g., water buckets) may allow the organism to persist for extended periods (up to 34 days) when protected by cold conditions.[7,8]

Diagnosis

Early definitive diagnosis is essential for containing this highly infectious disease. Sampling may be unsuccessful during the incubation and early clinical phases. *S. equi* is normally not present on the mucosa until at least 24 to 48 hours after the onset of fever, so infection in horses monitored by daily measuring of rectal temperatures during an outbreak may be recognized early and isolated to limit transmission of *S. equi*. Samples can be obtained via nasopharyngeal swab, nasopharyngeal wash, and guttural pouch wash. A comparison of *S. equi* sample type is found in Table 31.8.[1] Cytologic evaluation reveals gram-positive extracellular cocci in long chains,

TABLE 31-8

Comparison of Sample Type for Diagnosis of *Streptococcus equi*[1]

S. equi Sample	Pros	Cons
Aspirate of mature abscessed lymph node	High yield of bacterial organisms	Requires this stage of disease
Moistened rostral nasal swab[a]	Ease of sampling	Animal needs to have active mucopurulent discharge
Moistened nasopharyngeal swab[a]	Ease of sampling	False negatives possible in early febrile state (not shedding yet) False negatives possible due to intermittent shedding from guttural pouch
Nasopharyngeal wash	Ease of sampling	False negatives possible in early febrile state (not shedding yet)
	Sampling more surface area	False negatives possible due to intermittent shedding from guttural pouch
	Was found to be more sensitive than nasopharyngeal swab[9]	
Guttural pouch lavage[b]	Best for detection of carrier animals	Special equipment needed Experience needed entering the guttural pouch More time consuming False negative if lymph nodes have not yet ruptured into the pouch

[a]Synthetic microfiber flocked swabs have not shown increased detection rates over traditional rayon or cotton swabs.

[b]The committee recommends guttural pouch lavage quantitative polymerase chain reaction (qPCR) for the detection of carriers with concurrent visual inspection of the guttural pouch via endoscopy. To limit the contamination of the environment and the veterinarians, we recommend collection directly from the guttural pouch, rather than via free catch from the nasal passage.

supporting a general diagnosis of a β-hemolytic streptococcus organism. Common hematologic findings of horses with *S. equi* are hyperfibrinogenemia, neutrophilic leukocytosis, and mild anemia.[9]

CULTURE. Culture is the preferred method on aspirates of mature abscesses, but it takes a minimum of 24 hours to obtain results. Culture is inexpensive, sensitive, and accurate for samples that have large numbers of bacteria, such as those collected from animals with obvious disease. Unfortunately, up to 40% of samples can be falsely negative on culture, especially in patients sampled too early in the course of disease or during convalescence.[10]

POLYMERASE CHAIN REACTION. Multiple gene targets are available for the detection of *S. equi* via quantitative polymerase chain reaction (qPCR), and this technique has been shown to be more sensitive than culture as a diagnostic tool.[1,9-12] Nasopharyngeal washes (Fig. 31.27) are preferable to nasopharyngeal swabs due to a larger sampling area,[1] but guttural pouch sampling is 50 times more likely to detect carrier animals.[1] Absence of obvious guttural pouch pathology on endoscopic evaluation combined with negative guttural pouch lavage qPCR is recommended to remove a horse from quarantine.[1] To prevent contamination of the environment, it is recommended to aspirate the sample via polyethylene tubing through the instrument channel of a 1-meter endoscope.[5,6] The endoscope should be sterilized after and between sampling of suspect horses.

SEROLOGY. Serologic testing involves the use of ELISA to detect the SeM protein. Serology is useful for detecting recent but not current infection; assessing the need for vaccination; identifying horses that may be predisposed to purpura hemorrhagica; and diagnosing *S. equi*–associated purpura hemorrhagica and metastatic abscessation (SeM titers often are = 1:12,800 but have been seen as low as 1:3200 and 1:6400 in confirmed cases).[1,10] It has been suggested that horses with high serum SeM-specific antibody titers (≥1:3200) may be predisposed to developing purpura hemorrhagica when vaccinated against *S. equi*.[1] A 2009 study reported safely vaccinating horses with SeM titers of 1:1600[13] or less with the Pinnacle® I.N. (Zoetis, Parsipanny, N.J.) vaccine. A 2017 study suggested that horses should be tested with the SeM serology for 1 year after a strangles outbreak to determine when it is safe to vaccinate.[14]

The Animal Health Trust in the United Kingdom has developed a combined serologic test that detects two surface antigens, Antigen A (SEQ_2190 N-Terminal Fragment) and Antigen C (SeM N-Terminal Fragment), and has similar sensitivity but greater specificity when compared to the whole SeM antibody titer.[15] This test can be used to identify unvaccinated horses with strangles exposure as recent as 2 weeks previously and to identify animals without clinical signs that may be carrying *S. equi* for the purposes of isolation and further evaluation via endoscopic guttural pouch examination.[1,15,16]

FIG. 31.27 Infusing 50 mL of 0.9% saline for a nasopharyngeal wash on a sedated horse with a uterine pipette. The pipette is punctured through one side of the rectal sleeve.

VACCINATION. Most horses develop a solid immunity during recovery from strangles, which persists but wanes in more than 75% of animals for up to 5 years as long as the animal was not treated with antimicrobials during the primary infection. This indicates that stimulation of a high level of immunity is biologically feasible given appropriate presentation of protective immunogens. There is evidence that immunity in horses resistant to reinfection is mediated at the mucosal level and functions to block entry of *S. equi*. However, systemic immunity after parenteral inoculation of avirulent live *S. equi* is also protective. Together these findings indicate that optimum immunity may require both systemic and mucosal responses.

Vaccine should be administered only to healthy nonfebrile animals free of nasal discharge. Although controversial, vaccination should be considered only in horses with no known contact with animals with strangles during an outbreak.[1] The American Association of Equine Practitioners (AAEP) Infectious Disease Committee does not recommend vaccination during an outbreak due to the increased risk of purpura hemorrhagica.

USE OF EXTRACT VACCINES. Extract vaccines (Strepvax II [Boehringer Ingelheim Vetmedica, Inc., St. Joseph, Mo.]) are given intramuscularly and elicit serum antibody responses 7 to 10 days later. Naive horses and foals require a schedule of two or three doses at an interval of 2 weeks. Booster doses are given once annually. Pregnant mares may be boostered a month before the expected date of foaling. Extract vaccines have been associated with cases of purpura hemorrhagica.[17]

USE OF ATTENUATED LIVE INTRANASAL VACCINE. Attenuated live vaccine (Pinnacle I.N. [Zoetis, Parsipanny, N.J.]) is given in a schedule of two doses at 2- to 3-week intervals. Annual booster doses are recommended. The mode of application should be such that an adequate amount of vaccine reaches the pharyngeal and lingual tonsils but does not enter the trachea. Careful handling of live vaccine is recommended to prevent inadvertent injection intramuscularly via either the vaccine directly or contamination of other vaccines given at the same time. A temporary pharyngitis is possible secondary to administration of this vaccine, and it is not recommended in horses younger than 1 year of age because of the possibility of them developing vaccine-associated clinical disease.[18]

FUTURE VACCINES. It is likely that more effective and safer vaccines will be developed based on genomic sequence information from *S. equi* and other *Streptococcus* species, *and* there is a need for vaccines that are DIVA (differentiating infected from vaccinated animals) in order to identify recently infected horses from those already vaccinated via serology. Recent experimental trials in Europe have evaluated the use of recombinant multicomponent subunit vaccines that may be promising for broader clinical applications in the future.[19,20]

CONTROL OF OUTBREAKS. Most outbreaks are thought to originate from introduction of an infected horse to a naive population. All new horses should be isolated for 3 weeks and monitored for any signs of disease, including fever. Many farms with repeated infections have resorted to screening for infection via a single endoscopic evaluation and PCR testing of guttural pouch lavages, a procedure considered by many as the "gold standard" for carrier detection.[5,6] A series of three nasopharyngeal swabs, collected 1 week apart, will result in detection by a positive culture on at least one of the swabs in only 60% of carrier animals. Concurrent testing of these swabs by PCR increases the likelihood of detection to more than 90% of carrier animals.[6]

A practical disease-control strategy should then be agreed on and implemented. The general aims and measures for such a strategy are outlined in Table 31.9, and a flow chart is shown in Fig. 31.28.[1,21]

Treatment

The goal of treating strangles is to control transmission and eliminate infection while providing future immunity to the disease. Appropriate treatment of horses with strangles usually depends on the stage and severity of the disease, and veterinary opinion as to whether to use antibiotic treatment remains markedly divided.[22]

HORSES WITH EARLY CLINICAL SIGNS. During an outbreak, immediate antibiotic therapy for new cases in the early acute phase with fever and depression may be curative and may prevent focal abscessation and shedding. Because abscesses have not developed at this early stage, the antibiotics have adequate access to the bacteria. Immediate treatment of horses that show the earliest clinical sign, fever, could be an effective way of controlling strangles outbreaks in racing stables or riding barns, although the disadvantages of treatment should be weighed.[1]

TABLE 31.9

Aims and Measures Used to Control Transmission of *Streptococcus equi* on Affected Premises

Aim	Measure
1. To prevent the spread of *S. equi* infection to horses on other premises and to new arrivals on the affected premises	Quarantine new arrivals for 3 weeks. Additional screening for subclinical carriers by guttural pouch endoscopy, culture, and qPCR testing should be part of any screening program. Stop all movement of horses on and off the affected premises immediately and until further notice. Horses with strangles and their contacts should be maintained in well-demarcated "dirty" (i.e., *S. equi*–positive) quarantine areas. Clustering of cases in groups should allow parts of the premises to be allocated as "dirty" (red), "exposed" (amber), and "clean" (green) areas. Perform twice-daily monitoring of rectal temperatures of the amber and green groups to identify temperature increases in horses early and move them to the red area prior to the start of shedding.
2. To establish whether convalescing horses are infectious at least 3 weeks *after* clinical recovery	Testing horses that have been treated with antibiotics should not commence prior to 3 weeks after the cessation of antibiotic treatment. If nasal discharge persists longer than 2 weeks, guttural pouch examination is indicated to identify horses that may have empyema and require additional treatment. A single endoscopically guided guttural pouch lavage qPCR on cases and their contacts to screen for carriers provides increased efficiency and sensitivity over three nasopharyngeal washes over 3 weeks. All equipment must be disinfected between horses when sampling multiples on a farm. Horses are considered safe to move out of isolation on the basis of absence of obvious guttural pouch pathology in conjunction with negative guttural pouch lavage qPCR results.
3. To eliminate *S. equi* infection from the guttural pouches	Remove pathology through a combination of flushing and aspiration with saline, and remove chondroids using endoscopically guided instruments. Perform topical and systemic administration of antimicrobials to eliminate *S. equi* infection. A minimum of 3 weeks should pass before retesting a treated, previously positive guttural pouch via qPCR.
4. To prevent indirect cross-infection by *S. equi* from horses in the "dirty" area to those in the "clean" area of the premises	Personnel should use dedicated protective clothing when dealing with infectious animals and should not deal simultaneously with susceptible animals. If this is unavoidable, infectious horses should be dealt with *after* susceptible animals. Strict hygiene measures are introduced, including provision of dedicated clothing and equipment for each area, disinfection facilities for personnel, and use of thorough stable cleaning and disinfection methods. When cost is not a factor, consideration should be given to destruction of the dedicated equipment after eradication of the infection. After removal of organic material from stables, all surfaces should be cleaned first with detergent and then be thoroughly soaked in an appropriate liquid disinfectant (bleach, phenols, quaternary ammonium compounds) and allowed to dry. Manure and waste feed from infectious animals should be composted (disinfected by heat) in an isolated location. Pastures used to hold infectious animals should be rested for 4 weeks. Care should be taken to clean and disinfect water troughs at least once daily during an outbreak. Horse vans should be cleaned with detergent and then disinfected after each use.

qPCR, Quantitative polymerase chain reaction.

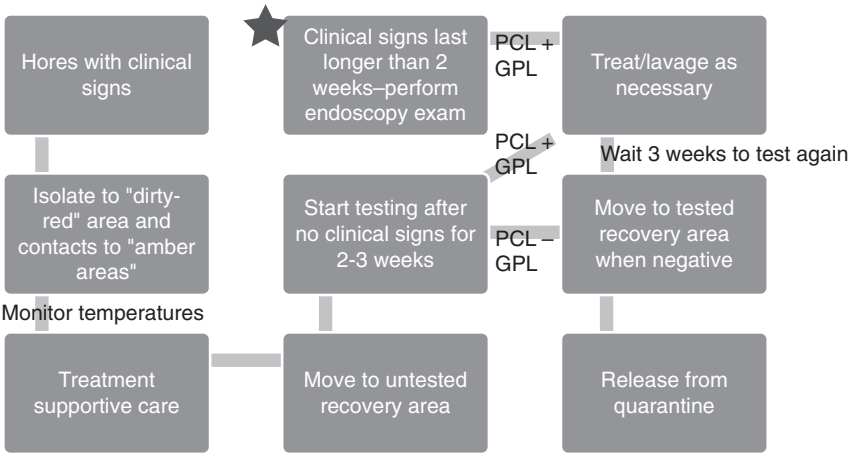

FIG. 31.28 Flow chart of recommended steps in the management of an outbreak of *Streptococcus equi*. Briefly, horses that present with clinical signs of strangles will be isolated to a "dirty" or "red" zone and all of these horses' contacts should be in placed in an "amber" zone. Temperatures are monitored, and horses are moved to the "dirty" zone if the temperature is 101.3° F (38.5° C) or higher. Supportive care and treatment of affected animals should be provided. Once clinical signs have resolved in affected horses, they are moved to a recovery area for untested horses. It is recommended that guttural pouch endoscopy and *S. equi* polymerase chain reaction *(PCR)* and culture combination testing of the guttural pouch lavage *(GPL)* should start a minimum of 2 to 3 weeks after the resolution of clinical signs. If a horse is positive on GPL or has an abnormal endoscopy, copiously lavage the guttural pouch and treat with topical and possibly systemic antibiotics. If the GPL is negative, move the horse to a tested recovery area ("green" zone). If a horse remains clinical for longer than 2 weeks, perform a guttural pouch examination at that time to determine if the horse has significant empyema and requires lavage to remove physical contamination of the pouch in order to shorten time to resolution.[20]

HORSES WITH LYMPH NODE ABSCESSATION. Uncomplicated cases of strangles are often left to run their course with supportive care, providing lasting immunity. Affected horses should be isolated in a clean, dry stall and fed moist, palatable food. NSAIDs should be used judiciously to decrease swelling and promote eating. Hot compresses or topical 20% ichthammol can be used to accelerate maturation of abscessation. Mature external abscesses should be lanced to allow drainage, followed by daily lavage of open abscesses using dilute povidone-iodine solution. This speeds resolution of abscessation as well as alleviation of compression of the pharynx.

Although the use of antimicrobials for treating strangles is controversial, if the horse is febrile, depressed, anorectic, and particularly if manifesting dyspnea, antibiotic therapy is indicated to decrease abscess size and prevent complete airway obstruction. In rare cases, affected horses may require intensive supportive therapy, including IV fluids, feeding by nasogastric tube, and tracheostomy. An animal requiring a tracheostomy should be given systemic antimicrobial drugs to prevent secondary bacterial infections of the lower respiratory tract.

DRUGS OF CHOICE FOR THERAPY. Penicillin G (procaine penicillin [22,000 to 44,000 IU/kg IM q12h] or aqueous potassium penicillin [22,000 to 44,000 IU/kg IV q6h]) is considered the drug of choice for the treatment of nonpneumococcal streptococcal disease, with alternative drugs used depending on ease of administration or the site of infection. Other agents for therapy include cephalosporins and macrolides. Anecdotally, trimethoprim-sulfadiazine treatment failure has been seen, and there are no studies determining its effectiveness against *S. equi*.[23] Use of antimicrobials during any phase of the disease may prevent the development of lasting immunity.

Complications

GUTTURAL POUCH EMPYEMA AND CARRIER STATUS. The percentage of carriers per outbreak could be as high as 10%. Endoscopic examination is required for identification of guttural pouch empyema. The SeM ELISA and the combined indirect ELISA (iELISA) do not detect empyema or carrier status.[5] Elimination of guttural pouch empyema requires repeated lavage with a solution of 20% acetylcysteine in buffered saline via polyethylene tubing through an endoscope or via a Chambers catheter. Chondroids are particularly difficult to remove, possibly requiring manual removal with endoscopic equipment such as a memory helical polyp retrieval basket, repeated lavage via indwelling catheters, or surgical removal. Successful elimination of *S. equi* in these carriers requires local treatment of the guttural pouch with a penicillin gel after removal of the material within the guttural pouch in addition to systemic treatment with procaine penicillin or potassium penicillin for 7 to 10 days. Eradication of this disease will not be possible until the subpopulation of carriers is eliminated.[24]

COMPLICATIONS ASSOCIATED WITH METASTATIC SPREAD OF INFECTION. *S. equi* spreads hematogenously or lymphatically, resulting in metastatic abscessation that can affect any organ system in 2%[25] to 20%[26] of cases. Aspiration of mucopurulent discharge or hematogenous or lymphatic spread to the lungs can cause pneumonia. Abscessation in the mesentery, liver, spleen, and kidneys is common, leading to peritonitis and clinical signs of colic. Abscessation of the cranial mediastinal lymph nodes can cause tracheal compression and respiratory distress. Neurologic signs are present when abscessation occurs in the brain.[1] The mortality rate of horses with strangles is less than 2%, but the presence of bastard strangles can increase the mortality rate to as high as 62%.[27,28] Attempted culture and sensitivity from the affected body cavity provides direction for the appropriate antibiotic treatment, which has included penicillin, ceftiofur, chloramphenicol, and doxycycline. An average of 2.5 months of antibiotic treatment was needed for resolution.[27] Some horses have been treated via surgical drainage along with systemic antibiotics.[28]

PURPURA HEMORRHAGICA. Purpura hemorrhagica is an aseptic necrotizing vasculitis that can occur in mature horses after repeated natural exposure to infection or after vaccination of horses that have had strangles. The actual incidence of this type III hypersensitivity response secondary to strangles or vaccination is unknown. Clinical signs range from mild to life-threatening, including pitting edema of the head, trunk, and distal limbs, as well as petechiae and ecchymoses. In some cases, antigen-antibody complexes affect other sites, including

the GI tract, muscles, lungs, myocardium, and kidneys. In addition to prolonged treatment with penicillin, cases of purpura hemorrhagica also require the use of systemic corticosteroids (dexamethasone, 0.1 to 0.2 mg/kg IV or IM q12-24h; prednisolone, 0.5 to 1 mg/kg PO q24h) for an average of 3 weeks to reduce systemic vasculitis.[13] Significant rhabdomyolysis with progressive atrophy has been identified in some Quarter Horses, after exposure to *S. equi*, without other signs of purpura.[17]

Acute Respiratory Distress Syndrome and Acute Lung Injury (Acute Bronchointerstitial Pneumonia)

Bettina Dunkel

Definition and Pathophysiology Acute respiratory distress syndrome (ARDS) describes a condition of severe pulmonary dysfunction and respiratory failure caused by physical or chemical injury or an exaggerated pulmonary immune response. In human medicine, the current definition, the so-called Berlin definition, defines ARDS as respiratory distress that is acute in onset (within a week of a known insult) and combined with the presence of bilateral pulmonary opacities and respiratory failure not fully explained by cardiac failure or fluid overload. Based on the degree of hypoxemia, measured by the ratio of partial arterial oxygen pressure (PaO_2) to fraction of inspired oxygen (FiO_2), three severities of ARDS are differentiated: mild (PaO_2/FiO_2 >200 and ≤300 mm Hg), moderate (>100 and ≤200 mm Hg) and severe (≤100 mm Hg).[1-3]

In the first definition from 1994, the term *acute lung injury (ALI)* was used to describe a less severe form of the disease, now corresponding to the mild form of ARDS.[4] This term is no longer used in human medicine. It still features in the current definitions for veterinary acute lung injury (VetALI) and veterinary acute respiratory distress syndrome (VetARDS) that were developed during a consensus meeting predating the Berlin definition (Box 31.1).[5] Due to lack of available data, no species-specific definitions were established, but the physiologic differences in arterial oxygenation in foals younger than 1 week of age were addressed by introducing different inclusion criteria for this age-group (Table 31.10). The consensus definition also acknowledged the disease presentation in neonatal foals, with presumed pulmonary surfactant deficiency (called neonatal equine respiratory distress syndrome) secondary to very early gestational age, induction of parturition, or cesarean section as an entity distinct from VetALI and VetARDS.[5]

BOX 31.1

Veterinary Acute Lung Injury (VetALI) and Veterinary Acute Respiratory Distress Syndrome (VetARDS)

At least one each of the first four criteria must be met; criterion 5 is recommended but optional (Wilkins et al., 2007).

1. Acute onset (<72 hours) of tachypnea and labored breathing at rest
2. Exposure to a known risk factor
3. Evidence of pulmonary capillary leak without increased pulmonary capillary pressure[a] (any one or more of the following):
   a. Bilateral/diffuse infiltrates on thoracic radiographs (>1 quadrant/lobe)
   b. Bilateral dependent density gradient on computed tomography
   c. Proteinaceous fluid within the conducting airways
   d. Increased extravascular lung water
4. Evidence of inefficient gas exchange (any one or more of the following):
   a. Hypoxemia without PEEP or CPAP and known FiO_2
      i. PaO_2/FiO_2 ratio
         1. <300 mm Hg VetALI (PaO_2 ≤63 mm Hg at room air[b])
         2. <200 mm Hg VetARDS (PaO_2 ≤42 mm Hg at room air[b])
      ii. Increased arterial-alveolar (A-a) gradient
      iii. Venous admixture (noncardiac shunt)
   b. Increased "dead-space" ventilation
5. Evidence of diffuse pulmonary inflammation
   a. Transtracheal wash/bronchoalveolar lavage cytologic neutrophilia
   b. Transtracheal wash/bronchoalveolar lavage biomarkers of inflammation
   c. Molecular imaging (positron emission tomography)

[a]No evidence of cardiogenic edema (one or more of the following):
Pulmonary arterial occlusion pressure <18 mm Hg (adult horse)
No clinical or diagnostic evidence supporting left heart failure, including echocardiography

[b]FiO_2 room air: 21%.

CPAP, Continuous positive airway pressure; *FiO_2*, fraction of inspired oxygen; *PaO_2*, partial arterial oxygen pressure; *PEEP*, positive end-expiratory pressure.

TABLE 31.10

Equine Neonatal Acute Lung Injury/Respiratory Distress Syndrome (Eq NALI/NARDS)[a]

Postnatal Age	Normal PaO_2	Normal PaO_2/FiO_2 Ratio	Eq NALI	Eq NARDS
60 minutes	60.9 ± 2.7 mm Hg	>300 mm Hg	<175 mm Hg	<115 mm Hg
12 hours	73.5 ± 3.0 mm Hg	>350 mm Hg	<200 mm Hg	<140 mm Hg
24 hours	67.6 ± 4.4 mm Hg	>350 mm Hg	<200 mm Hg	<140 mm Hg
48 hours	74.9 ± 3.3 mm Hg	>350 mm Hg	<200 mm Hg	<140 mm Hg
4 days	81.2 ± 3.1 mm Hg	>400 mm Hg	<250 mm Hg	<160 mm Hg
7 days	90.0 ± 3.1 mm Hg	>430 mm Hg	<280 mm Hg	<190 mm Hg

[a]As for VetALI/VetARDS but adhering to the following age-dependent adaptation of the PaO_2/FiO_2 ratio in term foals in lateral recumbency breathing room air (FiO_2 = 0.21) based on age-dependent normal values for PaO_2 under similar conditions (Wilkins et al., 2007).

FiO_2, Fraction of inspired oxygen; *PaO_2*, partial arterial oxygen pressure.

VetBooks.ir

VetBooks.ir

ARDS arises as a complication after major infectious or noninfectious bodily injury. The triggering event can be an intrapulmonary (viral or bacterial pneumonia, smoke inhalation, near drowning, or food aspiration) or extrapulmonary (trauma, multiple transfusions, systemic inflammatory response, or sepsis) insult. During injury or infection, the body mounts a protective response that involves controlled activation of the inflammatory and coagulation system.[6,7] The pathophysiology of ARDS centers around dysregulation of this initially protective response. Uncontrolled pulmonary inflammation and coagulation lead to accumulation and activation of leukocytes and platelets in the lungs, altered permeability of the pulmonary endothelial and epithelial barrier, and ultimately accumulation of extravascular protein-rich edema fluid within the alveoli and airways.[7,8] Although not temporally distinct and largely overlapping, the pathophysiologic events can be divided into an initial exudative phase, a fibroproliferative phase, and if the patient survives, a resolving or fibrotic phase.[9] The exudative phase is characterized by uncontrolled released of inflammatory mediators and influx of inflammatory cells into the pulmonary tissue. Activated platelets, neutrophils, and alveolar macrophages marginate in the microcirculation and extravasate into the pulmonary tissue where they release oxidants, reactive oxygen species, proteases, and cytokines, amplifying and perpetuating inflammation and coagulation.[10] A variety of mediators, pathways, and molecular systems ultimately contribute to the breakdown of the alveolar endothelial and epithelial barrier, causing flooding of the alveoli once the edema safety factors are exhausted. The barrier tends to collapse suddenly, resulting in rapid filling of the alveoli with proteinaceous exudate, leukocytes, and red blood cells and destruction of the surfactant layer.[11] The fast onset of pulmonary edema may correspond with the clinically observed acute onset of respiratory distress in foals. The prothrombotic and anti-fibrinolytic environment favours formation of thrombi in the pulmonary microvasculature and deposition of intraalveolar fibrin-rich hyaline membranes.[12] The fibroproliferative response, which can begin within 24 hours of the onset of ARDS, is characterized by type I pneumocyte necrosis and proliferation of the more resilient type II pneumocytes in an attempt to restore the epithelial surface.[11,13] Fibroblasts invade the pulmonary interstitium and alveolar walls and deposited collagen, which can result in fibrosis and significant impairment of pulmonary mechanics and gas exchange. The extensive pulmonary pathology leads to severe hypoxemia with hypocapnia or hypercapnia caused by ventilation-perfusion (V/Q) mismatch and decreased pulmonary compliance. Alveolar edema creates areas of a low V/Q ratio (adequate perfusion but no ventilation) causing hypoxemia, whereas areas with deceased perfusion generate hypoxemia and eventually hypercapnia by increasing dead space ventilation (high V/Q ratio; adequate ventilation with minimal perfusion).[11] The coexistence of areas with high and low V/Q ratios adjacent to normal lung tissue makes mechanical ventilation of patients with ARDS extremely challenging and predisposes the patient to ventilator-induced lung injury.

The resolution of ARDS requires repair of endothelial and epithelial barriers, reabsorption of alveolar edema, and removal of inflammatory exudate and cellular debris.[7] Transepithelial ion flux generates an osmotic gradient, allowing water absorption through aquaporin-5 channels located on type I epithelial cells. If damage to the pulmonary epithelium is minor, pulmonary edema can be cleared swiftly, pulmonary function improves rapidly, and chances of survival increase. If large areas of alveolar epithelium are destroyed, gradual re-epitheliazation by proliferation of type II cells and potentially also by recruitment of progenitor cells must occur first.[7,14] Severe damage to the epithelium corresponds to prolonged respiratory failure, slow recovery, and high mortality.[15] Recovering patients may have complete resolution of pulmonary compromise or may suffer from residual functional impairment such as muscle weakness, decreased pulmonary function, restrictive or obstructive changes, and low diffusion capacities.

Environmental and individual risk factors may predispose certain patients to the development of ARDS. Recently identified environmental factors in people include long-term ozone exposure and vitamin D deficiency.[16] Individual gene variants regulating inflammation, coagulation, and endothelial cell function and genetic polymorphism predisposing individuals to the pathogenic effects of specific bacteria and viruses are also thought to influence the development and outcome of ARDS in humans.[7]

VetALI and VetARDS, in earlier reports also referred to as acute interstitial or bronchointerstitial pneumonia, have been described in foals and weanlings up to 7 months of age and other small and large animal species, including an alpaca cria.[17-25] Extensive searches for a common pathogen were conducted until with increasing understanding of the pathophysiology it became evident that multiple infectious and noninfectious agents are capable of initiating the inflammatory response.[19-22] In foals the most common risk factor appears to be intrapulmonary injury, namely bacterial or rarely viral pneumonia.[19-22,24-26] There are no clinical reports of VetALI and VetARDS in adult horses, although descriptions in case reports and small studies suggest its occurrence. Buergelt and colleagues[19] reported respiratory distress in six adult horses, but the description better fits the heterogenous group of interstitial pneumonias than VetALI and VetARDS. Two adult horses with respiratory distress after near drowning met the criteria for VetALI,[27,28] and two horses affected by smoke inhalation experienced fulminant pulmonary inflammation and most likely VetALI.[29] Experimentally, VetARDS has been induced by IV injection of perilla mint ketones[30,31] and was observed after experimental gram-negative sepsis.[32] However, most of the animals in the latter study were in an agonal state, making interpretation of the observed pulmonary changes difficult.[32] Further risk factors recognized in other species that may also occur in the horse include systemic inflammation, severe trauma, multiple transfusions, aspiration of stomach content, drugs, and toxins.[5] The discovery of genetic predispositions to dysregulation of inflammation and coagulation in people is intriguing, as a similar predisposition in equids could potentially explain why of many foals affected by infectious pneumonia, only very few develop VetALI and VetARDS.

Clinical Signs and Differential Diagnoses

Clinical signs include profound depression, fever and respiratory distress with tachycardia, tachypnea, nostril flare, and cyanotic mucous membranes. Auscultation of the lungs can reveal a variety of abnormal sounds or complete silence over nonventilated areas. Clinically it is almost impossible to differentiate foals with VetALI and VetARDS from foals with severe bacterial, chiefly advanced *R. equi*, pneumonia, particularly as the syndrome can be triggered by an underlying bacterial infection.

Clinical Pathology and Necropsy Findings

Laboratory findings include severe hypoxemia with hypocapnia or hypercapnia and, depending on the underlying disease process, leukocytosis or leukopenia and hyperfibrinogenemia. Abnormal coagulation parameters may be observed, and signs of disseminated intravascular coagulation were present in two foals with VetALI and VetARDS in one report.[21] Transtracheal lavage fluid demonstrates neutrophilic inflammation with or without signs of infection, depending on the underlying cause. Thoracic radiographs show a diffuse, dense bronchointerstitial pattern often coalescing to a focal or diffuse alveolar pattern with prominent air bronchograms. The initial radiographic appearance of the lungs may worsen dramatically within hours due to rapid progression of pulmonary edema. On the other

hand, absorption of the alveolar fluid may result in impressive improvement of the radiographic appearance within days.[21,22] A thoracic sonogram is useful in foals that cannot be safely transported to a radiography unit and reveals multiple coalescing comet-tail artefacts predominately in the caudodorsal lung field.

On gross pathologic examination, the affected lungs are wet and firm and fail to collapse, and airways contain variable amounts of pink, foamy liquid. Histologically, necrosis of alveolar and terminal bronchial epithelium is observed with extensive filling of the alveolar spaces with neutrophils, macrophages, hemorrhage, protein-rich edema fluid or hyaline membranes. Occasionally microthrombi can be detected in interstitial capillaries. In more chronic cases, diffuse proliferation of cuboidal pneumocytes and fibroblasts and beginning fibrosis may be present.[19-22]

Diagnosis The diagnosis can be established if the criteria outlined in Box 31.1 and, depending on the age, Table 31.10 are met, cardiac disease is absent, and the extent of the respiratory distress cannot be attributed solely to a primary disease process (e.g., almost complete destruction of the pulmonary parenchyma by a primary disease process). CT has been described in heathy foals and will allow more detailed assessment of lung pathology.[33,34] However, risks and benefits of the procedure need to be carefully assessed in these precarious patients. Presence of bacterial or viral pneumonia does not rule out concurrent VetALI or VetARDS.

Treatment and Prognosis A recent reduction in mortality in human ARDS has largely been attributed to more widespread use of lung-protective ventilation with lower tidal volumes (6 mL/kg) and airway pressures and conservative fluid therapy.[35] Antiinflammatory, antioxidant, anticoagulant, and surfactant therapy and treatment to enhance alveolar edema removal (aerosolized or intravenous β-adrenergic agonists such as salmeterol, terbutaline, or epinephrine to stimulate active transepithelial ion transport) have largely failed to improve survival.[7] A recent meta-analysis showed promise for antiplatelet drugs, including clopidogrel, but whether this will be confirmed in future studies remains to be seen.[36] However, considering that, in contrast to human medicine, most equine patients die as a direct result of respiratory failure, some of those therapeutic options may still benefit the equine patient. Because mechanical ventilation is, with few exceptions,[37] feasible only in neonates, the most important treatment remains intranasal insufflation of humidified oxygen via unilateral or bilateral intranasal cannulas. Large-bore tubing systems minimize the resistance to airflow, and FiO_2 as high as 70% and 75% has been measured at the carina in adult horses and foals, respectively, using bilateral flow rates of 15 L/min (10 L/min in foals; combined 30 L/min in adults or 20 L/min in foals).[38,39] Alternatively, use of intratracheal oxygen insufflation has been described, achieving results similar to high bilateral intranasal flow rates.[40] Administration of methylprednisolone at 1 to 2 mg/kg/day is much debated but still frequently used in acute cases of human ARDS for up to 2 weeks, followed by a gradual decrease of the dose.[16] Considering that ventilation is rarely an option and that in two reports all but two foals surviving ARDS received corticosteroids, anecdotal evidence is in favour of steroid administration (IV prednisolone sodium succinate or methylprednisolone at 1 to 2 mg/kg/day divided in 2 to 4 doses). Antimicrobial treatment, if required, should be directed against the underlying disease process. Bronchoconstriction is not a prominent feature of ARDS, and therefore bronchodilators are most likely of limited use. Care should be taken when administering bronchodilators, as they can induce sudden worsening of V/Q mismatching and can lead to acute decompensation of the severely hypoxic patient. Judicious IV fluid therapy may be necessary in dehydrated patients, but overhydration or rapid changes in circulating blood volume should be avoided, as capillary hydrostatic pressure is the main determinant of pulmonary edema formation when endothelial and epithelial permeability is increased. On the other hand, a suboptimal hydration status decreases cardiac output and worsens oxygen delivery to the peripheral tissue. Measurement of central venous pressure may aid in determining the patient's hydration status. If foals are too depressed to nurse or eat, nutritional support is essential.

Based on the limited information available, the prognosis for survival and future athletic performance is guarded, with survival rates ranging from 60% to 69% in two clinical reports.[21,22] It is difficult to extrapolate long-term outcomes of pulmonary function from human patients due to the extensive use of mechanical ventilation with associated injury and the frequent presence of preexisting morbidities such as smoking.[41] Experimental induction of ARDS in horses did not result in any lasting histologic changes or fibrosis despite severe clinical signs.[30] The few long-term reports of equine survivors have so far suggested little noticeable lasting respiratory compromise, and successful careers as racehorses have been reported even in severely affected animals.[22] More information is clearly needed to determine the long-term effects of severe pulmonary injury in horses.

Interstitial Pneumonia and Endogenous and Toxic Conditions

Pamela A. Wilkins

Interstitial pneumonia is an uncommon cause of acute or chronic disorders of the lower respiratory tract of horses.[1-8] However, because of the severity of the process, it becomes important to recognize and definitively diagnose this entity as early as possible in its clinical course. The term *interstitial pneumonia* defines a number of diseases that are acute to chronic and progress to pulmonary fibrosis. The course is insidious and morphologically characterized by alveolar structural derangements that lead to loss of functional gas exchange units of the lung and altered mechanical properties of the lung, characterizing the pneumonia as a restrictive lung problem.

Etiology Multiple agents have been implicated in the genesis of interstitial pneumonia in animals, but fewer than 20 have been confirmed in horses (Box 31.2). Chief among these are infectious agents and ingested toxins. Frequently the etiologic agent cannot be identified due to the insidious nature of the process, and the final diagnosis is idiopathic interstitial pneumonia. The lung responds in a rather stereotypical manner to injury, and our limited ability to identify infectious, toxic, and immunologic causes frequently hinders our current ability to make an accurate identification of a specific etiology. All efforts should be made to identify an etiologic agent early in the course of the disease, but the practitioner needs to be aware that treatment frequently will be nonspecific and supportive.

INFECTIOUS AGENTS. Infectious causes of interstitial pneumonia in horses and foals include viral, bacterial, parasitic, protozoal, and fungal agents. Typically the pneumonia is acute and severe, characterized by severe damage to the lung parenchyma (alveolar region).

Viral agents are frequently implicated or suspected but rarely identified by the usual serologic, histopathologic, and virus isolation methods. The advent of more sensitive and specific techniques, such as in situ PCR and monoclonal antibody immunohistochemistry (IHC), may partially resolve the current diagnostic challenge. Most recently, a novel gamma equine herpesvirus, equine herpesvirus 5 (EHV-5), has been found to

BOX 31.2

Causes of Interstitial Pneumonia in Horses

Acute

Infections (systemic viral, bacterial, parasitic)
Inhaled chemicals
- Oxygen (FiO_2 >50%)
- Smoke

Ingested toxins or precursors
- Perilla mint *(Perilla frutescens)*, Crofton weed *(Eupatorium adenophorum)*, *Crotalaria* spp., *Senecio* spp.

Adverse drug reactions
- Uncertain

Hypersensitivity
- Acute hypersensitivity pneumonitis

Endogenous metabolic or toxic conditions
- Shock—particularly endotoxic (acute respiratory distress syndrome, or ARDS)
- Disseminated intravascular coagulation (DIC)
- Uremia

Idiopathic or cryptogenic

Chronic

Infections (systemic viral, bacterial, parasitic)
Inhaled inorganic dust (pneumonoconioses)
- Silicosis

Hypersensitivity
- Hypersensitivity pneumonitis

Ingested toxins or precursors
- Perilla mint *(P. frutescens)*, Crofton weed *(E. adenophorum)*, *Crotalaria* spp., *Senecio* spp.

Collagen-vascular disorders
- Uncertain

Idiopathic or cryptogenic

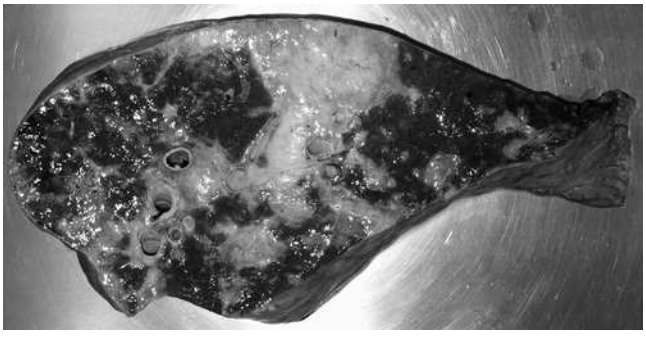

FIG. 31.29 Cut section of lung from a horse with equine multinodular pulmonary fibrosis (EMPF). Note the large areas of fibrous tissue within the pulmonary parenchyma. *(Courtesy Dr. Fabio Del Piero, Louisiana State University, Baton Rouge, La.)*

be associated with a nodular form of interstitial pneumonia of horses characterized by pulmonary interstitial fibrosis, suggesting that these rather unusual cases may have an underlying infectious etiology.[9-11] This disease has been called equine multinodular pulmonary fibrosis (EMPF) by the authors describing the pathology of the disease (Fig. 31.29). Horses affected generally have a history of fever, cough, and weight loss accompanied by exercise intolerance and finally respiratory distress. They can present as acutely affected animals or as having a more chronic, progressive problem. Typical radiographs reveal multiple discrete to coalescing nodular densities overlying a diffuse interstitial pattern. Histologic appearance is diagnostic of this disease (Fig. 31.30). EHV-5 has been identified in both BAL fluids and lung biopsy samples from affected patients by

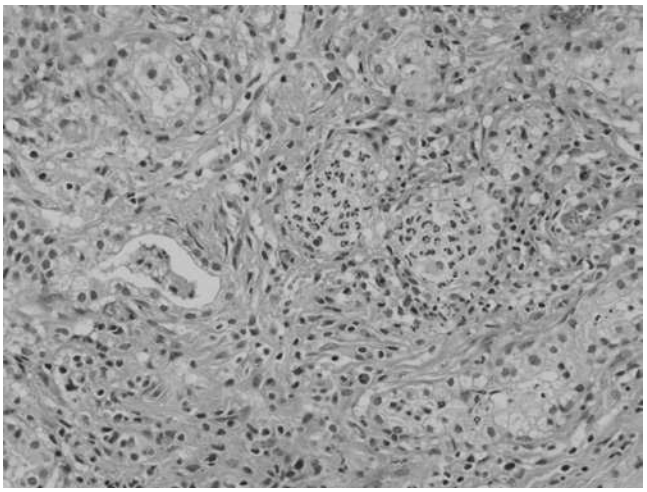

FIG. 31.30 Postmortem histopathology specimen from a horse with severe equine multinodular pulmonary fibrosis (EMPF). This is the histologic appearance of one of the fibrotic nodules. The alveoli are constricted within dense neoformed fibrotic tissue. Alveoli have an abnormal cuboidal epithelium (type 2 pneumocytes), and the lumen contains macrophages, sloughed epithelial cells, and neutrophils. Denser and diffuse fibrotic areas are present. *(Courtesy Dr. Fabio Del Piero, Louisiana State University, Baton Rouge, La.)*

both PCR and IHC. Influenza infection resulting in severe, fatal interstitial pneumonia in unvaccinated or naive horses and foals has been described in single case reports and as outbreaks.[12-14] There is a single report of a fatal pneumonia in a young horse secondary to EHV-1 infection.[15] Both adenovirus and equine arteritis virus have been described as causes of severe bronchointerstitial or interstitial pneumonia in foals and adult horses.[16-19]

In some horses with bronchointerstitial pneumonia of unknown cause, bacterial agents have been isolated from the lung. The usual distribution of bacterial bronchopneumonia in the horse is cranioventral, frequently associated with transportation, whereas the distribution in interstitial pneumonia is diffuse. In the latter cases the bacteria may be either opportunistic or primary pathogens and may not represent the primary causative agent.[20,21] An exception is *R. equi* pneumonia of foals, which can cause ARDS in older foals. *R. equi* has been cultured from foals with severe, acute bronchointerstitial pneumonia with a diffuse pulmonary distribution.[22] Interstitial pneumonia associated with *P. carinii* has been described in the foal, and *Mycoplasma* spp. have been isolated from the respiratory tract of adult horses.[23-25] The significance of the *Mycoplasma* isolates remains a matter of debate.[25] *P. carinii* pneumonia is thought to occur primarily in immunocompromised foals as a complication of some other serious disease, such as infectious pneumonia or SCID. It is characterized by a plasmacytic, lymphocytic interstitial pneumonia with flooding of alveoli with foamy acidophilic material.

Parasitic pneumonia, an uncommon cause of chronic bronchointerstitial pneumonia, usually occurs in young foals secondary to migration of *Parascaris equorum* larvae through the pulmonary parenchyma.[26]

INGESTED CHEMICALS. Ingested chemicals rank second only to infectious agents as potential causes of interstitial pneumonia in horses. Ingestion of pyrrolizidine alkaloids from a variety of plants (mostly genera *Crotalaria*, *Trichodesma*, and *Senecio*) can cause interstitial pneumonia in horses.[27] This toxicity is associated with production of a toxic metabolite activated in the liver that then circulates to the lung. The toxic alkylating agents damage capillary endothelial cells, although the amount

of alkyloid required to damage the lung is generally less than that required for hepatotoxicity. Crofton weed *(Eupatorium adenophorum)*, a poisonous plant found primarily in Australia and Hawaii, produces interstitial pneumonia in horses.[28] Toxicity is associated with ingestion of the flowering plant, but the nature of the toxin is not known. Perilla ketone, derived from the plant *Perilla fructans*, produces acute respiratory distress within 1 week of ingestion in ponies.[29] The lesions include diffuse alveolitis and Type II pneumocyte proliferation with sparing of the bronchioles. Toxicity depends on additional metabolism of the 3-substituted furan by the mixed function oxidase system, which occurs directly in the lungs of the horse.

INHALED CHEMICALS. Direct pulmonary injury by inhaled chemicals is an uncommon cause of interstitial pneumonia in horses. In humans this type of pneumonia is primarily related to occupational exposure. Smoke inhalation causes acute, diffuse interstitial pneumonia in horses, frequently followed within a few days by opportunistic bacterial pneumonia.[30] Oxygen toxicity can theoretically produce interstitial pneumonia and alveolar Type II cell proliferation. This problem is more likely to be seen in neonatal foals mechanically ventilated with increased levels of oxygen (FiO_2 >50%) for several days, although this may in fact be a form of ventilator-associated lung injury (VALI) related to mechanical stretch of the airspaces. Damage is thought to be due to production of reactive oxygen metabolites, which attack a lung that may already have been injured by barotrauma, resulting from a ventilator-driven increase in airway pressure. Agrichemicals or herbicides, such as paraquat, may cause acute interstitial pneumonia (AIP) in horses and should be considered in horses with a history of possible exposure.[31] Silicosis is a specific chronic granulomatous pneumonia of horses associated with inhalation of silicon dioxide crystals.[32] This syndrome has been described in horses originating from the Carmel Valley region of California. The inhaled particles are ingested by alveolar macrophages and result in lysis of the macrophage, chronic alveolitis, and fibrosis. Multiple granulomas are present, and submicron intracytoplasmic crystalline particles can be identified in macrophages.

HYPERSENSITIVITY REACTIONS. In the most specific sense, hypersensitivity pneumonitis refers to pulmonary disease caused by inhalation of organic antigens. Lymphocytic, plasmacytic bronchitis and bronchiolitis, combined with lymphocytic interstitial pneumonia, characterize the disease in the horse lung. Granuloma formation and fibrosis can be observed. Chicken dust and fungi have been implicated as a cause of severe, chronic bronchointerstitial pneumonia, but the syndrome itself is quite rare.

ENDOGENOUS METABOLIC AND TOXIC CONDITIONS. A variety of conditions cause acute pulmonary injury with inflammatory edema or severe alveolar wall damage and serofibrinous exudation similar to that described for AIP. Acute uremia, shock, burns, and trauma can produce an acute pulmonary injury called acute lung injury (ALI) or acute respiratory distress syndrome (ARDS), depending on severity. Although endotoxin does not directly injure the lung, endotoxemia in the horse initiates inflammatory and metabolic cascades that can lead to pulmonary injury. Activation of these pathways produces vasoactive and chemoattractant molecules that increase vascular permeability, activate complement, produce proinflammatory cytokines, and release neutrophil enzymes that can adversely affect the lungs of horses. Horses, as a species, are quite sensitive to the negative effects of endotoxemia, and their lungs are particularly sensitive, perhaps due to the presence of intravascular macrophages, which further amplify the inflammatory cascade. Both ALI and ARDS have been defined for veterinary patients but require updating.[33]

Pathophysiology

Interstitial pneumonia progresses through four phases.[7,11,34] During the first phase, the initial insult causes parenchymal injury and alveolitis. This is followed by a proliferative phase characterized by cellular and parenchymal alterations in tissues of the lung. Chronic cases progress to the development of interstitial fibrosis, and the final stage results in end-stage irreparable fibrosis of the lung.

The structural changes that occur in the lung reduce the number of functional alveoli, adversely affecting ventilatory function of the lung and altering V/Q relationships. There is reduced lung compliance associated with the loss of distensible alveoli, presence of pulmonary edema, and fibrosis. Total and vital lung capacity are decreased in association with the loss of functional gas exchange units and reduced lung compliance. The work of breathing is increased, resulting in exercise intolerance and difficulty breathing. Pulmonary hypertension and cor pulmonale may present as complications of interstitial pneumonia and fibrosis. Although the origin of pulmonary hypertension is unclear, hypoxic vasconstriction and generation of vasoactive compounds (such as endothelin-1) that alter pulmonary vascular resistance acutely, and vessel anatomy chronically, may play a role.

Clinical Signs

Horses affected with interstitial pneumonia frequently present with fever, cough, weight loss, nasal discharge, exercise intolerance, severe dyspnea, cyanosis, and a restrictive breathing pattern. A "heave line" may be present; nostril flare and an anxious expression are usual. The history can be acute or chronic. Although affected foals are frequently depressed and anorectic, adults may be bright and alert with a variable appetite. The disease proceeds toward death in many cases, with progressive respiratory compromise, although some may also slowly improve with time. More than one foal at a farm may be affected.

Diagnosis

In older horses, the primary differential diagnosis of RAO may be excluded by the leukocytosis and hyperfibrinogenemia that commonly occurs in horses with interstitial pneumonia and fibrosis but does not occur in horses with heaves. However, these abnormal features are common in horses with infectious bronchopneumonia, and thoracic radiography is of paramount importance in establishing a definitive diagnosis. Typically, thoracic radiographs reveal extensive interstitial and bronchointerstitial pulmonary patterns (Fig. 31.31). Nodular infiltrates, either large or miliary, may be present but are always diffusely distributed.

Culture of transtracheal or BAL aspirates often yields no significant growth of viral, bacterial, or fungal pathogens. Cytologic evaluation of tracheal or BAL fluid shows increased numbers of neutrophils and macrophages. If *P. carinii* is involved, BAL fluid may reveal trophozoites or intracystic bodies with special stains, such as toluidine blue or methenamine silver. Using PCR, EHV-5 has been found in BAL fluid from horses with EMPF.[9] EHV-5 PCR has been found to be closely associated with EMPF in BAL fluid or a combination of whole blood and nasal secretions.[35]

Histologic examination of a transthoracic lung biopsy specimen is the definitive diagnostic test for chronic interstitial pneumonia and fibrosis and for EMPF (see Fig. 31.30) . Care must be taken to ensure that the biopsy is obtained from a representative area, and ultrasound guidance has been useful in the hands of the author. Clinically important complications from this technique are uncommon but can occur. Biopsy can both define the causative agent and confirm the clinical diagnosis in EMPF when evaluated for EHV-5.

Additional diagnostics could include arterial blood gas analysis, abdominocentesis, and thoracocentesis to rule out metastatic neoplastic disease; pulmonary function testing; viral isolation; serologic testing for antibody to fungi and chicken

serum if hypersensitivity pneumonitis is suspected; and immunohistochemical evaluation of lung tissue for suspected infectious agents. A complete cardiac evaluation should also be conducted, as pulmonary hypertension and cor pulmonale are not uncommon sequelae.

Treatment Treatment of these cases is often unrewarding. Therapeutic goals are (1) treatment of any underlying or secondary infection; (2) suppression of inflammation; (3) maintenance of tissue oxygen delivery within appropriate limits; (4) relief of any associated bronchoconstriction; and (5) prevention or treatment of complications. Environmental management, with appropriate temperature and humidity control and good ventilation, is beneficial.

Parenteral corticosteroid therapy is the mainstay of treatment, with early and aggressive therapy providing the best long-term outcome, particularly in foals. In one report of 23 foals affected with acute bronchointerstitial pneumonia, 9 of 10 treated with corticosteroids survived, whereas none of those not receiving steroid treatment lived.[4] Foals with a diagnosis of ARDS have the best prognosis when treated with corticosteroids and antimicrobial therapies as indicated by diagnostics.[36]

Broad-spectrum antimicrobial treatment should be instituted initially, particularly in foals, as described for the treatment of infectious bronchopneumonia. The choice of antimicrobial and duration of therapy should be dictated finally by the culture and sensitivity results from the transtracheal aspirate and by the patient's clinical course. Anecdotally, horses with EMPF have responded to treatment with acyclovir or other antiviral agents and corticosteroids. The course of therapy is generally prolonged, 6 to 12 weeks; clinical and radiographic improvement has been noted in a few cases to date.

Foals, in particular, and adults with severe respiratory distress may benefit from nasal insufflation of humidified oxygen, with flow rates of 5 to 15 L/min for foals and 15 L/min for adults.[37] If necessary, as determined by persistent hypoxemia in the face of intranasal insufflation at the rates given, a second nasal canula can be placed in the opposite nostril to increase the FiO_2. Care must be taken to avoid obstruction of the nasal passages. Alternatively, intratracheal or transtracheal insufflation can be considered to further increase FiO_2 and improve oxygenation (see Fig. 31.31).[38]

Systemic bronchodilator therapy may or may not be indicated in these cases. If used, bronchodilators may worsen V/Q inequalities. Thus bronchodilator therapy should be accompanied by supplemental oxygen, and the effects should be monitored with serial blood gas measurements and discontinued if hypoxemia worsens. Nebulized or aerosolized bronchodilator therapy may be more judicious, and beneficial effects are evident in some foals with respiratory distress. Aminophylline and theophylline should not be used due to their narrow therapeutic range. Furosemide may be appropriate for its bronchodilator effect and its effect on reducing pulmonary artery pressure, particularly if cor pulmonale develops.

Prognosis The prognosis of interstitial pneumonia in horses is generally poor to guarded. Affected foals, when treated early and aggressively with corticosteroid and antimicrobial therapy, have the best outlook for life. The disease is usually progressive in adults and eventually results in the demise of the horse, although the occasional horse recovers sufficiently to return to previous performance levels. A fair number of adult horses, with continuous intense management, will live for a period but be severely compromised,. Exceptions to the poor prognosis may be seen in cases of *P. carinii* and parasitic pneumonia in foals if they are treated early and aggressively and, possibly, also in cases of idiopathic interstitial pneumonia/EMPF in adult horses that are treated early with corticosteroids and antivirals. A trial of treatment for peracute interstitial disease for 48 hours is warranted, and chronic interstitial pneumonia should be treated for a minimum of 6 weeks before discarding the possibility of recovery.

Equine Respiratory Viruses

Gabriele A. Landolt

Viral respiratory infections in horses are major causes of respiratory disease resulting in impaired health, poor performance, and financial losses. Although vaccines are available for many of the etiologic agents, viral respiratory disease has remained among the most commonly encountered equine health concerns worldwide.

Infection with equine respiratory viruses can lead to serious respiratory illness with potentially fatal consequences, yet the clinical significance of some of the viruses that have been detected in equine respiratory tract secretions remains largely unknown (e.g., EHV-2, EHV-5, equine coronavirus).[1] The severity of equine viral respiratory disease depends on the agent, virulence of the circulating virus, infectious dose,

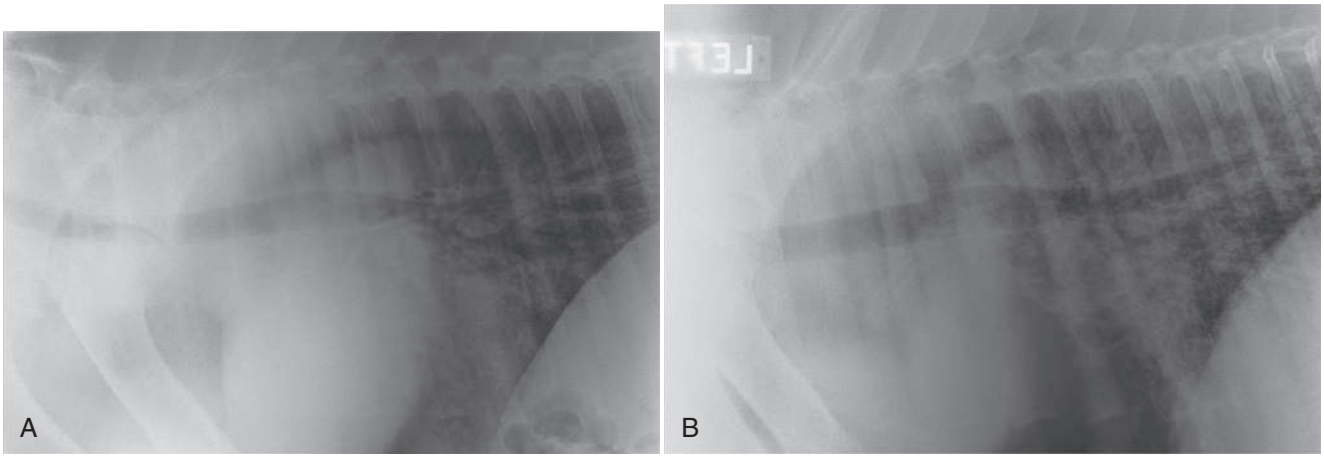

FIG. 31.31 **A**, Midthoracic/caudal dorsal thoracic radiograph of a foal younger than 2 months that presented with *Pneumocystis* spp. pneumonia and acute respiratory distress syndrome (ARDS). Immune function testing was within normal limits. Note the predominant interstitial pattern with patchy alveolar component. **B,** Similar radiographic view of the foal in A following 4 weeks of treatment with antimicrobials and corticosteroids. This foal was also treated with inhaled antimicrobials, inhaled corticosteroids, and intranasal oxygen insufflation over the first 2 weeks of treatment. The foal was significantly improved clinically and radiographically.

VetBooks.ir

management and environmental conditions, and degree of immunity of the individual animal. In a group of susceptible horses, equine viral respiratory disease is often characterized by the rapid spread of an acute, febrile respiratory disease that may be accompanied by a cough and serous nasal discharge. Therefore a presumptive diagnosis of viral respiratory disease can often be made based on history and clinical signs. However, to confirm and differentiate among the potential etiologic agents, laboratory diagnosis is required.

Diagnosis of Equine Respiratory Viruses

The basic approaches for the laboratory diagnosis of equine viral respiratory disease are the isolation of the etiologic agent (virus isolation); demonstration of the virion, the virus genome, or the viral products in clinical specimens (detection of virus particles by electron microscopy; detection of viral antigens by immunofluorescence, ELISA, or immunoperoxidase; detection of the viral genome); and the detection of virus-specific antibodies (serology). Because each of these methods has merits as well as disadvantages (e.g., lack of sensitivity, long turnaround time, high costs), it may be necessary to combine several of them to identify the etiologic agent accurately and rapidly. The World Organisation for Animal Health (OIE; http://www.oie.int) publishes the *Manual of Diagnostic Tests and Vaccines for Terrestrial Animals*, which provides an in-depth review of current diagnostic testing strategies.

VIRUS ISOLATION. Virus isolation from clinical samples is crucial for epidemiologic investigation and for vaccine production and generally is carried out in cell culture. The notable exception is equine influenza virus, for which embryonated chicken eggs have remained the culture system of choice. Because virus shedding in secretions of the respiratory tract is typically greatest within the first few days after infection, the best results for virus isolation are often achieved by culturing nasal or nasopharyngeal swab samples collected in the first 24 to 48 hours after onset of clinical disease. Because the duration of nasal virus shedding is often brief in partially immune animals, it may prove useful to sample immunologically less protected individuals in a group (e.g., younger horses, poorly vaccinated or unvaccinated animals) to increase the likelihood of demonstrating infectious virus. Nasopharyngeal or nasal swab samples are best collected using polyester-tipped swabs instead of cotton swabs because certain viruses (e.g., influenza A virus) have been found to adhere to the cotton fibers. Preferably, the swab samples should be placed in a small amount of sterile viral transport medium and kept on ice.

ANTIGEN DETECTION. The most important advantages of diagnostic tests aimed at the detection of viral antigen over traditional virus isolation are the faster turnaround time as well as the ability to detect virions that have lost their infectivity. Immunofluorescence (fluorescent antibody [FA] test) is based on the detection of virus-infected cells using virus-specific fluorochrome-labeled antibodies. The technique is used to detect viral antigen in a broad range of clinical samples (e.g., frozen sections of tissues, tissue imprints, cells obtained from nasal scrapings or tracheal washes) and has been shown to be highly sensitive. A number of antigen-capture ELISA-based assays have been developed for the detection of equine respiratory viruses.[2-6] Frequently, a solid-phase system is used for virus detection. Specific antibody is first adsorbed to the surface of a microtiter plate, and the sample containing the suspected virus is then added. If the virus is present, it binds to the adsorbed antibody. After washing, specific enzyme-labeled antibodies are added. Detection of virus in the sample is achieved by addition of the enzyme substrate, which results in a color reaction. Commercially available ELISA-based test kits (e.g., Flu OIA® assay [Biostar, Boulder, Colo.]; Directigen Flu-A assay® [Becton Dickinson Microbiology Systems, Cockeysville, Md.]) have been validated for the rapid, stall-side detection of equine influenza virus. Many investigators found these commercial diagnostic kits to be highly specific and rapid, and their sensitivity approaches that of egg-based virus isolation.[7-11] Since the discovery of PCR, the technique has found wide application in diagnostic laboratories. By choosing appropriate oligonucleotide primers, a selected region of the viral genome can be amplified. PCR-based assays are extremely sensitive and theoretically can detect a single copy of the target nucleic acid in a sample.[12-14] Due to the assay's high sensitivity, the greatest challenge facing the diagnostic application of PCR is the production of false-positive results. Nevertheless, PCR-based techniques offer a more sensitive tool for the diagnosis of equine respiratory viruses than conventional techniques such as culture or immunoassays. To increase the diagnostic capacity of PCR, multiplex PCR assays have been developed. By including more than one pair of primers in the reaction mixture, these assays are designed to simultaneously detect a panel of respiratory pathogens. RT-PCR–based assays are widely used for the detection and quantification of equine respiratory pathogens.[15-17] By using a target-specific fluorescent probe, RT-PCR–based assays eliminate the need to distinguish the target by PCR fragment size on electrophoresis or hybridization with probes post PCR. The advantages of RT-PCR include high specificity, sensitivity, and a rapid turnaround time.

ANTIBODY DETECTION. Detection of virus-specific antibodies has been and continues to be a key tool in the diagnosis of equine viral respiratory disease. Detection of specific antibody can provide support that an animal has been exposed to a given antigen. Although this is often used as circumstantial evidence of infectious disease, a diagnosis of active infection requires the demonstration of at least a fourfold increase in antibody titers (seroconversion) in samples collected during acute infection and during convalescence. Therefore serology typically provides only retrospective information. Yet as most serologic assays are fairly easy to perform and cost-effective and because large numbers of samples can be collected and tested simultaneously, serologic testing is particularly useful for large-scale population surveillance. Commonly used techniques for antibody detection include ELISA-based assays, virus neutralization tests, single radial hemolysis, complement fixation tests, and hemagglutination inhibition assays. Due to the inherent variability of immunoassays, paired samples always should be run by the same laboratory. Lastly, it is important to recognize that antibody is not always detected in the presence of active infection. The most common reason for a negative result despite infection is that insufficient time has passed between infection and measurement of an antibody response. Alternatively, immunocompromised horses may fail to produce a detectable antibody response despite active infection.

Treatment

The treatment of horses suffering from viral respiratory disease is primarily symptomatic. It is important to ensure that sick animals are kept in a clean, well-ventilated, and stress-free environment. Morbidity caused by pyrexia and myalgia may be reduced by administering NSAIDs. It is important to monitor affected horses for development of complications such as pneumonia and myocarditis, and animals exhibiting signs of respiratory disease beyond 10 days should be reevaluated to rule out secondary bacterial infections.

Antiviral drugs, such as amantadine, rimantadine, oseltamivir, and the chain-terminating nucleoside analogs (e.g., acyclovir, valacyclovir, cidofovir), have been evaluated for prophylaxis and treatment of horses during outbreaks of equine influenza and EHV-1, respectively. In addition, there are several published reports describing the use of acyclovir in horses diagnosed with EMPF.[18,19]

VetBooks.ir

Clinical trials with the influenza virus M2 ion channel blockers amantadine and rimantadine have shown that both drugs appear to be equally effective in reducing the severity and duration of clinical illness.[20,21] In addition, oral administration of rimantadine (30 mg/kg q12h) was shown to reduce the virus load in nasal secretion, although the duration of nasal virus shedding was similar to that in the untreated controls.[20] However, the therapeutic and prophylactic benefits of M2 ion channel blocker antiviral therapy during outbreaks of equine influenza may be limited due to the potential for the rapid development of drug resistance. In vivo and in vitro studies have demonstrated that drug-resistant influenza virus mutants can develop as early as 1 day after start of treatment.[22] Subsequent isolation of the drug-resistant virus from susceptible contacts showing signs of clinical disease indicates that acquisition of drug resistance is not associated with attenuation of the virus.[23,24] Treatment of horses with amantadine has also been associated with adverse effects and poor oral bioavailablity.[25] Oseltamivir, a neuraminidase inhibitor with demonstrated antiviral activity against equine influenza in vitro, was also found to reduce the magnitude of nasal virus shedding and severity of clinical signs in horses following experimental inoculation.[26] In addition, oseltamivir administration reduced the counts of *S. equi* subsp. *zooepidemicus* in bronchoalveolar fluid samples collected 7 days after influenza infection compared to the untreated controls.[26] Despite these findings, the use of antivirals during an equine influenza outbreak should be carefully deliberated, as their use can result in the development of antiviral resistance among influenza A viruses.[27-29] Hence the indiscriminate use of these drugs can possibly reduce the effectiveness of treatment during an outbreak.

Acyclovir, valacyclovir, ganciclovir, valganciclovir, and other chain-terminating nucleoside analogs have been shown to be efficacious against various strains of abortigenic and neuropathogenic EHV-1 viruses in vitro.[30-33] Despite the fact that the oral bioavailability of acyclovir in horses is low,[34] anecdotal reports suggest a potential benefit of acyclovir administration (10 mg/kg PO five times daily) in horses with clinical signs of EHV-1 infection (e.g., herpes myeloencephalopathy and neonatal infection).[35-37] Studies examining the effectiveness of oral valacyclovir, a prodrug of acyclovir with enhanced oral absorption, in the treatment of horses infected with EHV-1 have demonstrated controversial results. Although administration of valacyclovir (27 mg/kg q8h followed by 18 mg/kg q12h) to aged mares either prior to experimental EHV-1 inoculation or at the onset of fever reduced the severity of clinical signs, virus shedding, and viremia in one study,[38] another study found no effect on clinical signs, nasal virus shedding, or viremia in ponies treated (40 mg/kg q8h) compared to the untreated control ponies.[39]

Equine Influenza Virus

Equine influenza is the most frequently diagnosed cause of viral respiratory disease of the horse.[40,41] It is a highly infectious disease that affects horses, donkeys, mules, and zebras. Outbreaks of a disease resembling influenza have been reported as early as 1751; however, the etiologic agent was not isolated until 1956.[42,43]

Etiology Equine influenza viruses are members of the family *Orthomyxoviridae*, which contains enveloped viruses with segmented, single-stranded, negative-sense RNA genomes.[44] The *Orthomyxoviridae* comprise the following genera: influenza A, B, and C viruses; thogotoviruses; and isaviruses.[44] Influenza D virus was isolated from pigs and cattle,[45,46] and serologic evidence for influenza D virus infection in humans and horses has recently been established.[47,48] Despite this, the clinical significance of this finding is currently unknown.

Equine influenza viruses are members of influenza A viruses. In contrast to influenza B and C viruses, which appear to have a fairly narrow host range, influenza A viruses can infect a wide variety of species (e.g., horses, humans, wild and domestic birds, pigs, sea mammals, dogs, and cats). It has long been recognized that influenza A viruses exhibit partial restriction of their host range,[43] indicating that viruses from one host species occasionally can transmit to infect another host. Although horses have often been regarded as isolated or "dead-end" hosts for influenza,[43] events of recent years clearly indicate that the species barrier for viruses jumping either to or from horses is not absolute. For example, the severe influenza epidemic in horses occurring in 1989 in the Jilin and Heilongjiang provinces in the northeast of the People's Republic of China was caused by a virus with avian-like genetic features, suggesting that the virus had spread directly to horses from birds.[49] Another, more recent example is the transmission of an equine-lineage H3N8 virus to dogs in the United States.[50]

Although the viral and host factors that determine the host range of influenza viruses and the mechanisms by which species barriers are overcome are not completely understood, a large body of research highlights the importance of the viral hemagglutinin (HA) glycoprotein in determining host specificity.[43,51,52] The HA serves as the viral receptor-binding protein and is embedded, along with the neuraminidase (NA) and the ion channel M2 protein, in a host cell–derived lipid envelope. Mediated by binding of the HA to sialic acid residues on the host cells, the virion envelope and the host cell membrane fuse. This interaction subsequently promotes the release of the viral genome into the cytoplasm of the host cell. The NA is responsible for the cleavage of the α-ketosidic linkage between a sialic acid molecule and an adjacent sugar D-galactose or D-galactosamine. Biologically, the NA facilitates the mobility of the influenza virus virion by assisting in the release of the budding virus particle from the host cells.[53,54] Both HA and NA are major surface antigens of the influenza virus virion. Partly due to the host immune pressure, these proteins can undergo substantial antigenic variation (antigenic drift), which allows the mutant viruses to escape neutralizing antibodies.

Based on antigenic properties of the HA and NA, influenza A viruses are divided into subtypes. To date, eighteen HA subtypes (H1 to H18) and eleven NA subtypes (N1 to N11) have been described.[55,56] With the exception of two HA and NA subtypes (H17, H18, N10, N11) that have been isolated only from bats, all other subtypes have been isolated from wild waterfowl.[55,57-59] In contrast, only a limited number of subtypes have been associated with infection of mammals. In humans, only viruses of H1, H2, H3, N1, and N2 subtypes have circulated widely in the population,[43,60] and only H1, H3, N1, and N2 subtypes have been consistently isolated from pigs.[61-63] In horses, two influenza subtypes have been described: H7N7 (A/equine/1) and H3N8 (A/equine/2).[42,64,65] Although there are a few reports of horses with serologic evidence of H7N7 exposure,[42,66,67] the H7N7 viruses have not been isolated from horses since the late 1970s[11,57,68] and are considered to be extinct. In contrast, despite intensive vaccination programs, equine H3N8 viruses continue to circulate in large parts of the world. Since the 1980s, a number of severe, widespread influenza outbreaks in horses have occurred in South Africa,[69] India,[70] the People's Republic of China,[49,71] the United Kingdom,[72] and most recently South America.[73,74] In 2007 an equine influenza outbreak occurred for the first time in Australia, a country previously considered to be free of the disease.[75] The outbreak was caused by an equine-lineage H3N8 virus that was thought to have been introduced by importation of influenza-infected horses from Japan.[75,76] Stringent control measures, consisting of movement restrictions and vaccinations, allowed for the eradication of the virus from the Australian

horse population, and Australia regained its equine influenza–free status in December 2008.[77,78]

Since the early to mid-1980s, the equine H3N8 viruses have diverged into two distinct evolutionary lineages: Eurasian and American. Although the circulation of both lineages initially centered largely on their geographic origin,[79] introduction and apparent maintenance of American lineage viruses in horses in Europe initially resulted in the co-circulation of both lineages in Europe. In contrast, only a few reports support sporadic infection of horses in North America with viruses originating in Europe.[80-82] Continued genetic divergence of the American lineage viruses resulted in the formation of three antigenically distinct American-like sublineages (a South American lineage, a Kentucky lineage, and a Florida lineage).[82] Since the early 2000s the Florida sublineage has further evolved into two antigenically distinct groups, referred to as Florida sublineage clades 1 and 2. Whereas clade 1 viruses primarily circulate in North America, clade 2 viruses have mainly been identified in Europe and parts of Asia.[80,82] Despite the fact that the rate of genetic diversion of equine viruses is small compared to human and swine influenza viruses, this sustained genetic and antigenic evolution continues to have an impact in terms of immunization.

Epidemiology Experimentally, horses of all age-groups are susceptible to infection.[83] However, although sporadic infection in foals has been described, there exists only one published report of a widespread influenza outbreak in foals younger than 6 months of age.[84] The lower incidence of disease in young foals is most likely due to the presence of maternally derived antibodies. Influenza-specific serum antibody concentration (particularly antibody titers measured by single radial hemolysis) is often used as a correlate for protection against infection and disease, and animals with high concentrations of homologous antibody are by and large protected against experimental challenge.[85,86] After natural infection, ponies were reported to be protected from infection for 8 months, with partial protection persisting for more than 1 year.[87] Although vaccination does not always provide full protection against clinical disease, immunization has reduced the frequency of influenza outbreaks and the frequency and severity of clinical signs when influenza occurs among vaccinated animals.[83,88,89]

Equine influenza outbreaks occur most often when susceptible animals are congregated and housed in close contact with each other (e.g., horse shows, racetracks, sale barns). It is thought that spread of virus among susceptible animals occurs through three modes: direct contact with infected animals or fomites, droplet transmission (droplets larger than 10 μm and capable of being projected over moderate distances by coughing and sneezing), and aerosol transmission (droplet nuclei smaller than 5 μm, capable of wide dissemination and of reaching the lower respiratory tract).[90] Although aerosol transmission clearly has the greatest impact in regard to influenza virus infection control, the importance of bioaerosol transmission in the spread of influenza virus is poorly understood. Depending on the prevailing environmental conditions (humidity, temperature, exposure to sunlight, etc.), the virus can remain infectious for days on contaminated surfaces.[91] Meteorologic factors associated with an increased risk of spread of equine influenza virus between premises during a recent outbreak were relative humidity of less than 60% and wind speeds greater than 30 km/h from the direction of a barn with infected horses.[92]

Once the virus has been introduced into a group of immunologically naive animals, disease can spread rapidly (in a matter of hours to days). Such effective spread is enhanced by a short (~2 days) incubation period, high concentrations of virus shed in nasal secretions, a forceful cough, as well as the practice of housing horses in confined spaces.[91] In partially immune animals, the spread of disease is often considerably slower, and outbreaks may last as long as 3 to 4 weeks.[93] Following experimental infection, horses typically shed virus for 6 to 7 days.[94-97]

Pathogenesis Influenza A viruses replicate and induce pathologic changes throughout the respiratory tract, with the most significant lesions typically occurring in the lower airways. After inhalation of the virus, the virion attaches to sialic acid receptors on the surface of the respiratory epithelial cell and enters the cell by receptor-mediated endocytosis. Following replication and release from the host cell, the virus spreads quickly throughout the respiratory tract. Largely through apoptosis,[98-100] influenza virus replication leads to cell death. The loss of the ciliated respiratory epithelium in the trachea and bronchial tree[101] results in the impairment of tracheal mucociliary clearance.[64,102,103] In addition, the disruption of the superficial layers of the respiratory epithelium allows opportunistic bacteria to invade the deeper tissues of both the upper and the lower respiratory tract. The combination of reduced airway clearance and erosion of the respiratory epithelium predisposes affected horses to the development of secondary bacterial complications such as bacterial bronchopneumonia.[101,104] In uncomplicated cases, regeneration of the respiratory epithelium begins about 3 to 5 days after onset of illness,[104] yet resolution of the epithelial damage takes a minimum of 3 weeks.[103,105]

Clinical Presentation Clinical signs of influenza virus infection in horses are often seen 48 hours after exposure to the virus. In vaccinated animals, the disease is rarely fatal, but deaths have been reported during some epidemics, particularly in donkeys and rarely in neonatal foals.[42,106] The typical clinical presentation of equine influenza consists of pyrexia, anorexia, lethargy, nasal discharge, and cough. Pyrexia is often the first symptom present, with body temperatures peaking somewhere between 48 to 96 hours after infection. In some cases, a second peak of pyrexia may occur around 7 days after infection. Nasal discharge is typically serous in the first few days of illness but may become mucopurulent by 72 to 96 hours after infection. Concurrently, a dry, hacking cough develops. Coughing tends to persist long after pyrexia and nasal discharge have resolved and may still be present 3 weeks post infection. The majority of affected animals are anorexic during the initial pyrexia. Uncomplicated cases of equine influenza can resolve within 7 to 14 days post infection. Complications of equine influenza can be severe and include secondary bacterial pneumonia, myositis, myocarditis, and limb edema.[65,102,103] Neurologic disease as a result of a nonsuppurative encephalitis has also been described.[107] Finally, it has been hypothesized that influenza infection may predispose horses to the development of equine asthma and exercise-induced pulmonary hemorrhage.[65,101,102] The effects of influenza virus infection can be significantly exacerbated by even moderate exercise.[108]

Hemogram abnormalities associated with equine influenza infection can include a moderate normocytic, normochromic anemia and a leukopenia, which may result from both a neutropenia and lymphopenia. Monocytosis during early convalescences is a variable finding.

Control Control of equine influenza primarily is based on adequate husbandry procedures and vaccination. Introduction of equine influenza virus into a group of horses likely can be prevented by following the biosecurity guidelines (e.g., isolation of horses for 4 weeks prior to introduction into the horse population) published by the OIE (published in the *Terrestrial Animal Health Code*, Volume II, 2013; http://www.oie.int/). Because these biosecurity measures may be difficult to implement for most barns, 2 weeks of strict isolation and adequate vaccination may serve as an adequate compromise. Unfortunately, even these measures are often not taken, and vaccination is the primary modality used for infection control.

VetBooks.ir

Although a wide variety of vaccine formulations, including modified live and recombinant vaccines, are commercially available, inactivated vaccines remain the most common type of vaccine used. Despite the fact that the vaccines are generally very efficacious, outbreaks of equine influenza continue to occur. One of the reasons for this is that the virus undergoes antigenic drift, which results from the accumulation of amino acid changes in the antigenic sites of the hemagglutinin protein. Studies have shown that even a single amino acid difference in one of the five antigenic sites of the hemagglutinin protein between the vaccine and infecting virus strain can result in a reduction of the protection induced by the vaccine.[109,110] In addition, vaccination seldom induces the same immunity as natural infection, and vaccine-induced antibodies may not persist for very long.[100] This is particularly true for vaccines that are based on inactivated whole virus. In contrast, vaccines using modified live virus and recombinant vectored virus technologies (e.g., canary poxvirus–based vaccines) stimulate both humoral and cellular immune responses and mimic immunity elicited by natural infection more closely.[100]

Similar to human influenza virus vaccines, equine vaccines need to be updated periodically to include relevant contemporary virus strains. Vaccine strain recommendations are based on epidemiologic, genetic, and antigenic data that are analyzed by a panel of equine influenza specialists overseen by the OIE.[111] With the divergence of the Florida sublineage, current recommendations are that killed vaccines should include strains representative of both Florida clade 1 and clade 2.[112] Because the sustained genetic evolution of the equine H3N8 viruses will continue to result in vaccine failures in the future, inclusion of viral antigens representative of contemporary circulating viruses must remain a priority.

Studies have demonstrated that an intranasal, cold-adapted, modified live virus vaccine was able to confer protection for up to 12 months after a single administration. Despite this, only a 6-month claim is made on the product data sheet.[97,113] While the vaccine contains only one modified life virus strain, which is based on the H3N8 A/Eq/KY/91 isolate, the vaccine appears to protect against both European and American lineage isolates.[114] Lastly, a recombinant canary poxvirus vector-based vaccine has also shown excellent performance against recent influenza virus strains.[115]

Recommendations for equine vaccination are available from a variety of sources. Due to the presence of maternally derived antibodies, foals should not be vaccinated before at least 6 months of age.[116-118] For inactivated vaccines, initial vaccination series should include three doses even when the data sheets recommend only two initial doses.[117] An interval of 3 to 4 weeks between the first and second doses is recommended, but a longer interval of 3 to 4 months between the second and third doses is preferred. This results in the third dose of the initial series being administered when the antibody response to the second vaccine dose has waned, and the amplitude of the antibody response to the third dose is consequently much greater.[119] For high-risk populations (show horses, racehorses, etc.), booster vaccinations should be given at 6-month intervals.[117,120] Additional booster doses may be administered 1 to 2 weeks prior to potential exposure if a higher risk of infection is anticipated. The modified live intranasal vaccine requires only a single initial dose, followed by booster doses at 6-month intervals.

Equine Herpesviruses

Equine herpesvirus infection is a common infection of equids throughout the world, with at least nine herpesviruses identified to date.[121,122] The equine herpesviruses with the most clinical importance are the *Alphaherpesvirinae* EHV-1 and EHV-4, which both cause respiratory disease. EHV-1 commonly infects horses, donkeys, and other equids and occasionally infects domestic cattle, captive camelids, cervids, and zebras; EHV-4 is restricted to horses.[121] EHV-3, also a member of the subfamily *Alphaherpesvirinae*, is the cause of equine coital exanthema, a venereally transmitted disease characterized by superficial lesions on the epithelium of the external genitalia of mares and stallions.

Members of the *Gammaherpesvirinae* subfamily, both EHV-2 and EHV-5 have been associated with a range of clinical diseases, including respiratory disease. Whereas EHV-2 has been associated with poor athletic performance, respiratory disease, and keratoconjunctivitis,[123-126] EHV-5 has been hypothesized to be the causative agent of EMPF and equine lymphoma.[127-129] EMPF is a progressive pulmonary disease characterized by coalescing nodules of fibrosis and interstitial pulmonary fibrosis and pneumonia.[127] Results from a recent study in which EMPF was experimentally induced after inoculation of horses with virus isolated from EMPF lesions provides added support for the causal relationship between EHV-5 infection and the disease.[130]

Studies aimed at determining the clinical significance of EHV-2 and EHV-5 infection are complicated by the ubiquitous nature of infection in the equine population. EHV-2 and EHV-5 have been detected in horses throughout the world.[131-133] As both viruses can frequently be detected in samples obtained from healthy horses as well as from horses with clinical disease, the relevance of the finding remains unknown.[134-137]

Etiology

Both EHV-1 and EHV-4 are members of the *Alphaherpesvirinae* subfamily of herpesviruses, in the genus *Varicellovirus*. These two viruses have very similar antigenic and genetic characteristics, although they are quite distinct from the gammaherpesviruses EHV-2 and EHV-5.[121] Both viruses are easily inactivated by solvents, detergents, disinfectants, and other common veterinary means of decontamination but in favorable environmental conditions can persist for as long as a month and in refrigerated liquids for much longer.

Both EHV-1 and EHV-4 have a linear double-stranded DNA genome of 145 and 150 kbp encoding 79 and 80 open reading frames (ORFs), respectively,[138-140] which can code for 77 proteins. Amino acid homology of EHV-1 and EHV-4 is 55% to 96%.[138] The gene products of EHV-1 and EHV-4 are classified as immediate early, early, or late (which include the major glycoproteins).[141-144] In recent years, a single nucleotide polymorphism (N752/D752) in the EHV-1 ORF 30, encoding the catalytic subunit of the viral DNA polymerase, was suggested to be significantly associated with the neuropathogenic potential of EHV-1 strains.[145,146] In support of the increased neuropathogenic potential of the N to D substitution at position 752 are the results of a recent study using recombinant viruses with either genotype.[145] Although results of several recent studies indicate that the less virulent genotype (N752) appears to be more prevalent in the equine population at this time,[147-149] viruses with D752 have increased in prevalence in recent decades.[150] It has been hypothesized that the link between the substitution of asparagine (N) and aspartic acid (D) at position 752 and its neuropathogenic potential is due to the higher magnitude and duration of viremia that was found after experimental infection of horses with virus carrying this mutation.[151] In contrast, a recent study found no significant difference in viral loads in nasal secretion and blood between the two genotypes in horses with natural EHV-1 infection.[149] The discovery of this mutation and its association with neuropathogenic potential led to the development of PCR-based diagnostic assays that are able to detect strains carrying the N752D mutation. Despite this, it should be taken into consideration that infection with an EHV-1 strain encoding D at position 752 does not inevitably result in neurologic disease. Likewise, although D752 is present in the large majority of EHV-1 viruses causing neurologic disease, equine herpesvirus myeloencephalopathy (EHM) has also been

VetBooks.ir

caused by strains with N at position 752. Lastly, glycoprotein D, an essential protein in the viral entry process, has recently been shown to be another important virulence factor of EHV-1 in horses.[152]

Epidemiology EHV-1 infection causes significant suffering in horses and extensive economic losses through frequent outbreaks of a range of diseases, including respiratory disease, abortion, neonatal foal death, EHM, and chorioretinopathy.[121] EHV-4 can cause respiratory disease outbreaks but only sporadic cases of abortion rather than abortion storms. Infections caused by EHV-1 and EHV-4 are particularly common in young performance horses and frequently result in establishment of latent infection within the first weeks or months of life.[153] Establishment of latency with subsequent viral reactivation resulting in clinical disease and viral shedding during periods of stress is a characteristic of herpesviruses in general, including EHV-1 and EHV-4,[121] and makes eliminating these pathogens from the equine population a difficult if not impossible endeavor. Latency and reactivation are critical features of the epidemiology of EHV-1 and EHV-4 infection, allowing the virus to persist for lengthy periods, and in all likelihood as a lifelong infection, in the majority of previously infected horses before reactivating. Reactivation and subsequent nasal virus shedding can result in infection of new susceptible horses and possibly in disease in the latently infected horse itself. Although the true prevalence of latent equine herpesvirus infection is unknown, as more sophisticated methods of detecting latent infection with EHV-1 and EHV-4 are developed,[154] the detectable prevalence of infection continues to rise with the implication that EHV-free horses are a very rare occurrence.

Pathogenesis The pathogenesis of EHV-1 infection has been comprehensively reviewed.[121,155,156] Primary EHV-1 or EHV-4 infection occurs at the respiratory epithelium, resulting in erosion of the upper respiratory mucosal surface and viral shedding for 4 to 7 days post infection; shedding can occur for longer at lower levels and possibly beyond 14 days. Cell-to-cell spread results in the presence of virus in respiratory tract lymph nodes within 24 to 48 hours post infection. In contrast to EHV-4 infection, which is mostly limited to the respiratory tract, EHV-1 establishes a lymphocyte-associated viremia, which is responsible for the delivery of virus to the pregnant uterus and other tissues. Spread of virus from leukocytes to endothelial cells at these secondary sites results in vasculitis, hemorrhage, thrombosis, and ischemic tissue necrosis. Viremia can persist for up to 21 days and is a prerequisite for abortion, chorioretinopathy, and EHM. Moreover, there appears to be a positive correlation between the development of EHM and the magnitude and duration of viremia.[157] Despite this, only a small percentage of horses with viremia develops EHM, indicating that the clinical outcome of infection in the individual animal is influenced by other factors (e.g., age, sex, breed, virus strain).[146] In pregnant mares, EHV-1 infection can result in abortion subsequent to vasculitis of the small arteriolar branches of the glandular layer of the endometrium with subsequent thrombosis, microcotyledonary infarction, perivascular cuffing, and transplacental spread of virus.[121] Abortion typically occurs in the last 4 months of pregnancy but has been reported to occur as early as the second trimester. There are usually no signs of impending abortion, and the foal is typically expelled in the amniotic membrane, having just died from asphyxia due to placental separation. Some fetuses survive initially but then die from respiratory failure due to infection of the lungs. EHV-1 myeloencephalopathy results from widespread vascular injury after damage to the vascular endothelium of the blood-brain barrier and thrombo-ischemic necrosis in the spinal cord and the brain. It is possible that the immunopathologic response to EHV-1 infection of the vascular endothelium of the central nervous system may play a part in the etiology of the thrombo-ischemic necrosis. In this regard, a recent study has found an increased concentration of D-dimers in the bloodstream during EHV-1 viremia, suggesting that viremia can result in activating the coagulation cascade and the fibrinolytic system.[158] EHV-1 chorioretinopathy is also caused by a vascular endotheliopathy with subsequent ischemic injury to the chorioretina, and it is characterized clinically by focal or multifocal "shotgun" lesions.[159] While the incidence of ocular lesions has been reported to be more than 50% following EHV-1 infection, most ocular infections remain subclinical.[159] Moreover, these lesions are typically not detectable in acute disease and take weeks following infection to become visible. Latency is established in the lymphoreticular system and in the trigeminal ganglion.[121,147,160] Reactivation of latent virus frequently results in reinfection of the upper respiratory tract and shedding of virus in nasal secretions.

Immunity to EHV-1 and EHV-4 has been extensively reviewed.[161] The protective immune response following infection is short lived (3 to 6 months), although this may increase with age and repeated exposure. High titers of virus-neutralizing (VN) antibody before infection can reduce the amount and duration of virus shed from the nasopharynx[162] but fail to prevent infection or the development of EHM or abortion.[163] The reason for this failure is likely to be related to the rapid intracellular translocation of the virus,[164,165] thereby escaping the effects of VN antibody. However, intracellular virus is susceptible to cytotoxic T lymphocytes (CTLs), which can lyse virus-infected cells. This CTL activity is MHC class I restricted and mediated by CD8+ lymphocytes.[166] Ponies with high frequencies of CD8+ CTLs show a reduction in the clinical and virologic outcome of infection[167] and are protected against abortion.[168] Control of EHV-1 infection requires an immune response that not only limits primary infection but also controls reactivation of latent infections.[163] Although circulating and mucosal antibodies each play some role in protection,[162,169] the most important component of a protective immune response to EHV-1 is the CTL response.[168,170,171] Another important aspect of EHV-1 pathogenesis and immunity is the capacity of the virus to evade the immune response.[172] Strategies of immunoevasion used by EHV-1 include modulation of cytokine responses with subsequent effects on T- and B-cell responses, modification of the CTL responses, interference with antigen presentation by downregulation of MHC class I expression, inhibition of antibody-dependent cytotoxicity, alteration of NK-cell lysis, and loss of efficient chemoattraction of professional antigen-presenting cells.[173-176]

Clinical Presentation Clinical diseases associated with EHV-1 and, to a lesser extent, EHV-4 infection include respiratory disease, abortion, EHM, chorioretinopathy, and neonatal foal death. Infection with both EHV-1 and EHV-4 causes respiratory signs, but clinical signs are likely more severe for EHV-1, as is the likelihood of viremia. Respiratory disease is often more severe in young horses than in older, previously exposed horses. Clinical signs of EHV-1 or EHV-4 respiratory tract infection include pyrexia, which may be biphasic, with a first peak at 24 to 48 hours associated with upper respiratory tract infection and a second peak occurring at 4 to 8 days if viremia develops. Lethargy and anorexia are often mild, and nasal discharge, serous at first, becomes mucopurulent by days 5 to 7. Conjunctivitis, lymphoadenopathy of the submandibular lymph nodes, and edema or vasculitis of the distal limbs are variable findings. Respiratory disease, particularly affecting a large number of animals, is uncommon in horses older than 2 years of age presumably due to recurrent exposure to the virus and development of sufficient immunity to suppress clinical signs of airway disease.

Neonatal foals infected with EHV-1 in utero may be normal at birth but quickly become weak, lethargic, and develop

profound respiratory distress. Prognosis is poor for survival. The abortion and EHM forms of EHV-1 are discussed elsewhere under the appropriate system.

The clinical signs resulting from infection with EHV-2 and EHV-5 remain poorly described and established, although these viruses may be a cause of acute respiratory tract disease with clinical signs of nasal discharge, reactive submandibular lymph nodes, and coughing.[123,177] There is mounting support of a potential association of EHV-5 infection and EMPF. However, the exact nature of the relationship between the virus and the disease has not yet been fully elucidated.[127,128,178-180]

Prevention Due to the ability of equine herpesviruses to establish latency within their host, the elimination of these pathogens from the equine population is not a feasible approach to infection control. Therefore strategies that prevent dissemination of the virus from horses undergoing active virus shedding must be used. Vaccines are an attractive tool for this, but currently there are no products that can provide comprehensive protection against equine herpesvirus infection and its potential sequelae. Inactivated EHV-1 vaccines are capable of eliciting circulating VN antibody responses, which can limit respiratory disease and nasal viral shedding, and the use of some of these vaccines has been associated with a reduction in the incidence of abortion storms.[161-163,181] Vaccines containing higher antigen loads, and typically those licensed for control of abortion, can generate high-titered VN antibody responses and even EHV-1–specific interferon-gamma responses.[181] Such vaccines are likely to outperform other inactivated products with lower antigen loads. Using an optimized vaccination regime (vaccination was performed on days 0, 27, and 97) and virus challenge at the peak of the resulting immune response, a recent study was able to demonstrate a significant reduction in days of viremia in addition to a reduction of clinical signs and nasal virus shedding after administration of a commercially available high-antigen load killed vaccine.[182] A commercially available modified live EHV-1 vaccine (MLV) generates limited EHV-specific cellular immunity[183] and has been demonstrated to reduce respiratory disease and viral shedding but no protection against viremia.[184] The use of current commercial vaccines of proven efficacy is recommended at 6-month intervals for control of respiratory disease and shedding of EHV-1 and EHV-4. Generally, vaccines effective against EHV-1 will cross-protect against EHV-4. There is no evidence that any commercial or experimental vaccine can prevent the occurrence of EHM.

No attempts are made to control EHV-2 or EHV-5 infection with vaccination. However, the proposal that concurrent EHV-2 infection may play a role in the etiology of *R. equi* pneumonia has led some clinicians to attempt vaccination of foals with killed EHV-2 vaccines.[185]

Biosecurity measures following detection of EHV-1 and EHV-4 infection should include the use of strict hygiene and barrier precautions as well as isolation of affected and in-contact horses for periods of up to 28 days. The virus is thought to spread primarily through contact, with limited airborne droplet spread compared to equine influenza virus. Extensive codes of practice have been described for control of the spread of EHV-1 in facilities both in publications[121] and in online resources (http://www.hblb.org.uk; http://www.aaep.org).

Equine Arteritis Virus

Equine viral arteritis (EVA), named after the characteristic inflammatory changes found in the walls of small arteries, is a contagious disease of horses caused by equine arteritis virus (EAV).[186] While EVA is a disease with worldwide distribution, the seroprevalence varies substantially between countries and equine populations. Despite the fact that the vast majority of EAV infections are subclinical, occasional outbreaks occur that result in respiratory disease in adult horses, abortion, and fatal pneumonia in foals. These disease outbreaks have significant costs in terms of animal suffering and economic loss. Recent examples of larger outbreaks with substantial impacts on animal health and economic losses include a multistate EAV outbreak in 2006–2007 in the United States as well as a 2007 outbreak in the Normandy region of France.[187-189]

Etiology EAV is an enveloped positive-strand RNA virus and is a member of the family *Arteriviridae*, order *Nidovirales*.[190] The *Arteriviridae* comprise the following genera: *Equartevirus* (equine arteritis virus [EAV]), *Rodartevirus* (porcine reproductive and respiratory syndrome virus [PRRSV], lactate dehydrogenase-elevating virus [LDV] of mice), *Simartevirus* (simian hemorrhagic fever virus [SHFV] and others), and *Dipartevirus* (wobbly possum disease virus [WPDV]).[191] The polycistronic genome of EAV is approximately 12.7 kb and contains at least 10 functional ORFs.[192-194] ORFs 1a and 1b encode two replicase polyproteins that are posttranslationally processed by three proteinases to produce at least 13 nonstructural proteins. The remaining eight ORFs encode eight structural proteins, two (M and GP5) of which serve as the major viral envelope proteins. The GP5 envelope glycoprotein carries the major neutralization determinants of the virus, and four neutralization sites (A to D) have been identified.[195] Based on phylogenetic analyses of the EAV-ORF5, the viruses are divided into two distinct clades: North American and European clades that share approximately 85% nucleotide identity.[196,197] Despite the fact that only one serotype has been identified, there are extensive variations in virulence of different isolates of the virus. While the molecular determinants of EAV virulence have not been fully elucidated, recent data suggest that amino acid substitutions in the replicase and/or the structural proteins (GP2, GP4, GP5, and M) result in attenuation of a virulent strain of EAV.[198] The virus is readily inactivated by lipid solvents and disinfectants, although it can remain infectious for 75 days at 4° C, for years in tissue samples stored at –20° C, and for decades in semen, embryos, and tissue samples stored at –70° C.[199]

Epidemiology EAV is spread by the respiratory and venereal routes, and the persistently infected carrier stallion is central to the persistence of the virus in the horse population.[186] As a consequence, disease outbreaks frequently follow the importation of carrier stallions or their semen. With the increasing internationalization of the horse industry, this has become an important factor in the spread of the virus throughout the world in recent years and highlights the fact that identification of the carrier stallion is a key component of EVA control programs.[187,200] Virus transmission may also occur through direct or indirect exposure of seronegative animals to aborted fetuses and fetal membranes, by carrier stallions to susceptible stallions by masturbation, and from EAV-infected donor mares to naive recipient mares via embryo transfer.[201,202]

Following infection, a variable percentage (10% to 70%) of stallions infected become carriers and shed the virus for a variable period, ranging from several months to years, in their semen.[200,203] The virus persists primarily in the ampulla of the vas deferens, and the carrier state has been shown to be testosterone dependent, as castration resolves infection.[200] Some carrier stallions spontaneously eliminate the virus from their reproductive tract. During replication of the virus in the carrier stallion, genetically and phenotypically distinct variants of the virus can emerge, and these variants subsequently can be found in the semen of these stallions.[188,204,205] When one of these variants is transmitted to a mare through breeding, or occasionally through contaminated fomites, a new outbreak can occur.[186] Transmission by the venereal route is associated with infection rates in mares as high as 85% to 100%, and

VetBooks.ir

disease outbreaks often result from breeding a seronegative mare with EAV-containing semen.[190] Subsequent spread of the virus to other horses on the premises is by respiratory droplets and the airway route.[190] During these outbreaks the EAV strain remains stable with minimal genetic change.[186] Seroprevalence varies among breeds and between countries and geographic regions, with a reported seroprevalence of up to 85% in U.S. Standardbreds but less than 6% in Thoroughbreds in the United States.[206] While it has been hypothesized that differences in seroprevalence are due to genetic susceptibility to EVA, it is likely that the difference is a consequence of the number of actively shedding carrier stallions in different breeds. The virulence of strains in specific breeds can vary, however, and the strains shed by Standardbreds are typically highly attenuated, causing minimal disease.[186] Interestingly, recent research suggests that a correlation exists between the host's genotype (i.e., CD3+ T-cell susceptibility to EAV infection) and the clinical outcome of infection, including the potential to become a carrier of the virus.[207-209]

The immune response to infection is strong, leading to protective immunity with a duration of several years.[190] Foals born to immunized mares are protected by colostral antibodies for 2 to 6 months.

Pathogenesis Virus transmission occurs via both the venereal and the respiratory routes. After respiratory infection the virus invades the respiratory epithelium and infects bronchial and alveolar macrophages, reaching bronchial and other regional lymph nodes by 48 hours post infection.[190] Nasal virus shedding is typically detected for 7 to 14 days after infection but can last for up to 21 days.[210] The establishment of viremia leads to dissemination of the virus throughout the body and further replication of the virus in the adrenals, thyroid, liver, and testes. Following infection, virus can be detected in the buffy coat for 2 to 21 days and in the plasma and serum for 7 to 9 days. The virus infects and replicates in endothelial cells, causing direct injury to the vascular endothelium and adjacent muscularis media, and subsequently gains access to the media of affected vessels. Vasculitis is characterized by fibrinoid necrosis of small muscular arteries, leukocyte infiltration, and perivascular hemorrhage and edema. With the exception of the carrier stallion, virus is eliminated by 28 days post infection and coincides with the appearance of virus-neutralizing antibodies.[211] Reports exist where virus has been recovered for up to 180 days post infection from the accessory sex glands of prepubertal colts.[190,212,213]

Clinical Presentation The great majority of infected horses are asymptomatic. When disease does occur, the clinical signs of EAV infection can vary from fever and leukopenia to severe disease and death. In general, the severity of EVA tends to be greater in very young and old horses. The incubation period is 2 to 14 days (6 to 8 days following venereal exposure). Horses may show some of the following signs. Typically the affected animals are pyrexic, with temperatures reaching 40.5° C (105° F) for 1 to 5 days. Anorexia, lethargy, serous nasal and ocular discharge, and coughing may occur. Conjunctivitis ("pink eye") with ocular discharge and periorbital and supraorbital edema; dependent edema of the limbs, prepuce, scrotum, and mammary glands; urticaria (localized to the sides of the neck and face or generalized); photophobia; petechial hemorrhage in the nasal, conjunctival, and oral mucous membranes; and submandibular lymphadenopathy have also been reported.[190]

In stallions, acute infection can cause short-term subfertility characterized by reduced libido, decreased sperm motility, sperm concentration, and normal sperm morphology. These changes in semen quality are transient but can persist for up to 16 weeks.[187] In contrast, persistent infection does not appear to have an effect on sperm quality in carrier stallions.[187]

Abortions in pregnant mares occur in the acute or early convalescent phases of infection and are often not preceded by premonitory signs. It is thought that abortion occurs as a consequence of placental dysfunction secondary to vasculitis affecting myometrial blood vessels.[214] Abortion can occur from 2 to 10 months of gestation, with abortion rates ranging from 10% to 70%. Fetuses are typically partially autolyzed at the time abortion occurs. Commingling of mares recently bred by an infected stallion with pregnant mares is a common scenario leading to abortion.

Neonatal foals infected with EAV show severe respiratory signs and high mortality. In foals that survive more than 24 hours, fever and leukopenia or thrombocytopenia are present. Interstitial pneumonia, lymphocytic arteritis or periarteritis, renal tubular necrosis, and fibrinoid necrosis of the tunic media are seen on pathologic examination.[186]

Prevention EVA control programs are aimed at eliminating the risk of abortion, neonatal foal death, and the establishment of the carrier status in stallions.[199] Control measures include identification of carrier stallions, isolation and testing of horses prior to introduction into the resident horse population, segregation of pregnant mares and newborn foals, vaccination, and the establishment of biosecurity measures. Prevention of the development of carrier status in future stallions can be accomplished through vaccination of all colts with breeding potential in the first year of life and annual revaccination thereafter.[190] Identification of the carrier stallion can be accomplished by virologic and serologic testing (taking into account previous vaccination history) and should be carried out prior to introducing a stallion to a new premises.[199] Serologic testing should be performed in all stallions prior to the breeding season, and if seropositivity is detected in a stallion with no known vaccination history, virologic testing of the semen should be conducted. If the carrier status has been identified, these stallions should be managed separately under strict hygiene protocols to prevent spread of the virus to naive in-contact animals.[187,200] Mares being bred to carrier stallions should be vaccinated against EAV. Fresh and frozen semen from carrier stallions is also infective, and negative mares receiving this semen should be vaccinated. Extensive codes of practice have been produced by both the U.S. Department of Agriculture (http://www.aphis.usda.gov) and the Horserace Betting Levy Board (http://www.hblb.org.uk) to assist in control of EVA. Moreover, guidelines for vaccination of horses against EAV have been established by the American Association of Equine Practitioners (AAEP; http://www.aaep.org).

Both a modified live and a killed vaccine against EAV have been developed.[186,190] In the United States, the MLV vaccine has been available since the mid-1980s. The vaccine was derived from an experimental vaccine that was created by serial passage of the virulent Bucyrus strain in primary horse kidney and primary RK cells. The MLV vaccine provides complete or partial protection against the clinical signs of EVA, but viral replication still occurs after challenge. Despite the fact that only a single serotype of EAV has been described, recent in vitro studies demonstrated that antibodies raised subsequent to vaccination with the MLV vaccine do not neutralize all strains with equal efficiency.[215,216] The duration of vaccinal protection appears to be as long as 2 years, although annual revaccination of breeding stallions is recommended before the start of the breeding season. The MLV vaccine has been used successfully to limit outbreaks of infection in racecourses after initial diagnosis.[190] The manufacturer does not recommend the use of this vaccine in foals younger than 6 weeks of age and in pregnant mares. Vaccination of pregnant mares during the last 2 months of gestation has been associated with the risk of abortion.[217]

Equine Rhinitis Virus

Etiology Equine rhinitis viruses (formerly equine rhinoviruses) are a known cause of clinical and subclinical respiratory infections in horses worldwide. The viruses are classified as members of the family *Picornaviridae*, which includes small ("pico"), nonenveloped, single-stranded RNA viruses. Among the equine rhinitis viruses, at least two serotypes have been isolated from horses: equine rhinitis A virus (ERAV) (formerly equine rhinovirus 1 [ERV-1]), and equine rhinitis B virus (ERBV) (formerly equine rhinovirus 2 [ERV-2]).[218,219]

Considerable uncertainty has surrounded the classification of the equine rhinitis viruses. Because the illness caused by these viruses resembles the common cold brought about by rhinoviruses in humans, they initially were included in the genus *Rhinovirus*. However, subsequent studies demonstrated that ERAV differed from other members of the *Rhinovirus* genus as well as from ERBV.[219-222] For example, while rhinoviruses generally demonstrate a narrow host-cell range in vitro and in vivo, ERAV is able to infect and replicate in a broad range of cell types and host species. For instance, intranasal inoculation of a human volunteer with ERAV resulted in pharyngitis, lymphadenitis, fever, and viremia.[223] Furthermore, the presence of systemic signs and viremia during ERAV infection, the occurrence of persistent infections, and the physical properties of the virus are all more reminiscent of foot-and-mouth disease virus (FMDV). Based on these characteristics, along with similarities in protein sequences, ERAV was placed alongside FMDV in the *Aphtovirus* genus of the picornavirus family. Subsequently, ERBV has been reclassified as the sole member of the new genus *Erbovirus*. To date there are three known serotypes of ERBV: ERBV1, ERBV2, and ERBV3 (acid-stable equine picornavirus).

Epidemiology First isolated from horses in the United Kingdom,[224] ERAV infection occurs worldwide and is a recognized cause of acute respiratory disease.[218,225-227] The incidence of neutralizing antibody to ERAV varies according to the age of the horse, and most horses appear to become infected during their second year of life. In a study by Studdert and Gleeson, only 16% of horses between the age of 6 and 12 months were seropositive.[221] However, studies conducted in older horses found that a high percentage (50% to 90%) of horses 5 years of age have antibodies to equine rhinitis virus.[225,228-230] As with many other respiratory pathogens, young horses entering a large population in frequent contact with other horses are most susceptible to infection.[225] In addition, there appears to be a seasonal distribution, with most of the ERAV infections occurring in late winter and spring.[231,232] Stress (e.g., transportation and training) and concurrent disease resulting in immunosuppression may predispose to infection.[233] The virus is fairly resistant to inactivation and is thought to survive in the environment for a considerable time. As for human rhinoviruses, virus spread occurs most likely through direct and indirect contact (fomites).[234]

The clinical significance of ERBV1, ERBV2, and ERBV3 is not well defined. Several recent surveillance studies indicate that the prevalence of ERBV1- and ERBV2-neutralizing antibodies is between 24% and 80% of horses.[123,229,230,235] However, the consequences of infection with ERBV1 and ERBV2 are unclear, as these viruses have been isolated from horses both with and without signs of acute respiratory illness.[229,236,237]

Clinical Presentation Although ERAV is generally considered a respiratory pathogen, the clinical signs associated with infection may be quite variable. Following experimental infection with ERAV, horses may develop pyrexia, anorexia, nasal discharge, pharyngitis, and lymphadenitis involving at least the submandibular and pharyngeal lymph nodes.[238] On some occasions, laryngitis or mild bronchitis can develop.[228] Based on serologic studies, subclinical ERAV infection may also occur and may be important in the dissemination of the disease.[221,231,234,238,239]

Horses infected with ERAV may also develop viremia. On average, viremia lasts for 4 to 5 days, and the disappearance of virus from the blood coincides with the appearance of neutralizing antibodies.[238] Although the relationship between antibody levels and protection against disease has not been established, immunity is thought to be solid, and antibodies persist for a long time.[234]

Infection with ERAV may be accompanied by long-term urinary and fecal shedding as well as virus persistence.[238,240] The recognition of the potential for ERAV persistence has important implications for disease diagnosis. Highly sensitive diagnostic methods (e.g., immunofluorescent antibody [IFA] or RT-PCR) may be able to detect persistent ERAV in horses suffering from respiratory disease, which may not be associated with the observed illness. This notion is underlined by the recent finding that the ERAV genome was detected by RT-PCR in nasopharyngeal swab samples obtained from two clinically healthy horses 1 year after acute ERAV infection.[219]

Control Similar to other respiratory viruses, infection control should be based on adequate husbandry and biosecurity measures. Recently, a conditionally licensed ERAV vaccine has become available in the United States. Based on data provided by the manufacturer, the initial vaccination series should include three doses administered with a 3- to 4-week interval between each dose. Booster vaccinations should be administered at yearly intervals or prior to an anticipated virus exposure.

Equine Adenovirus

Etiology Adenoviruses (family *Adenoviridae*) comprise a group of nonenveloped, icosahedral DNA viruses. Although most vertebrate species harbor an adenovirus, the viruses are highly species specific. In humans, adenoviruses are extremely prevalent and represent a significant cause of acute respiratory, ocular, and GI disease. Infections of immunocompetent individuals usually stay localized and often take a mild or subclinical course.[241] Similarly, equine adenoviruses have been isolated from clinically healthy adult horses[242] and foals.[243,244] Equine adenoviruses consist of two species, equine adenovirus 1 (EAdV1) and equine adenovirus 2 (EAdV2), which appear to have evolved from separate lineages within the adenoviruses.[245] EAdV1 has been implicated as the cause of acute respiratory tract disease[246,247] and conjunctivitis, as well as a progressive, fatal pneumonia in Arabian foals with SCID.[248-250] EAdV2 has been incriminated as a cause of intestinal infection[251,252] and diarrhea in immunocompetent foals.[253,254]

Epidemiology First isolated in 1969 from a foal with respiratory disease,[255] equine adenoviruses have a worldwide distribution.[256] While serologic evidence from Australia, the United Kingdom, the United States, the Netherlands, and Nigeria indicates that adenovirus infection occurs at a high frequency in the general horse population,[257-260] the role of equine adenovirus in respiratory disease in adult horses remains unclear. In this regard it is interesting that a number of studies found no apparent association between clinically apparent respiratory disease in young adult horses and infection with adenovirus, as diagnosed by subsequent seroconverison.[237,239,261]

In contrast, fatal and nonfatal adenovirus pneumonia has been well documented in foals, particularly of the Arabian breed. Fatal respiratory disease is predominantly seen in foals with SCID. Other foals may develop respiratory disease but usually do not succumb to disease.

VetBooks.ir

VetBooks.ir

In general, adenovirus transmission is thought to occur via direct contact with secretions from infected animals or indirectly via fomites or infected premises. In adult horses, the virus can persist in the upper respiratory tract, and these animals can act as a reservoir host for the virus. Adenoviruses are highly stable and have been found to remain infectious at 4° C for up to 1 year.

Clinical Presentation The clinical signs recorded after experimental intranasal infection of a Thoroughbred yearling were confined to a serous nasal discharge that lasted from 4 to 12 days post inoculation. Peak levels of serum antibodies were found at 13 days after inoculation and dropped by approximately 2 months after experimental infection.[262]

In foals, clinical signs generally occur between 10 and 35 days of age.[263] After experimental inoculation at 24 hours of age, clinical signs appeared 3 to 5 days after infection and consisted of intermittent pyrexia, nasal and ocular discharge, tachypnea, and cough. All foals recovered by day 10 post inoculation. The majority of foals developed a mild and transient lymphopenia that was followed by lymphocytosis. Typically, about 25% of infected foals also develop diarrhea.[263] Gross pulmonary lesions found in animals euthanized at 14 to 21 days post inoculation included atelectasis, involving up to 25% of the pulmonary parenchyma, and suppurative bronchopneumonia. Histologically, swelling and hyperplasia of the airway epithelium, as well as intranuclear inclusion bodies in the respiratory epithelial cells, were a consistent finding up to 11 days post infection.[264]

Foals with SCID show a progressive decline in health despite intensive therapy. In necropsy, conjunctivitis, rhinitis, tracheitis, and bronchopneumonia are present. Intranuclear inclusion bodies are readily demonstrated in the respiratory epithelial cells. Areas of interstitial pneumonia surround affected bronchi. Acute pancreatitis characterized by inclusion bodies in acinus and ductal cells, as well as adenoviral sialoadenitis involving labial and parotid salivary gland can often be demonstrated.[252,265]

Control No vaccine is available to control adenovirus infection in horses. However, except in immunocompromised animals, the virus appears to be of little clinical importance.

Hendra Virus

Hendra virus is described in detail later in this chapter.

Equine Lungworm

Scott M. Austin

Dictyocaulus arnfieldi is a nematode parasite that affects donkeys, mules, horses, and asses. Infection occurs most frequently in cold, damp climates. This parasite appears to be well adapted to the donkey, as large numbers of parasites are associated with minimal clinical signs.[1] In contrast, infections in horses produce intense tissue reaction to parasites, resulting in clinical signs of a cough and arrested development of the adult worms. It has been suggested that donkeys are the natural host and that horses require cohabitation with donkeys to acquire the infections. Although it is true that patent infections are rare in the horse, horses may be infected without any history of exposure to infected donkeys.[2,3] *D. arnfieldi* has a direct life cycle. Infection begins with the ingestion of infective L3 larvae from contaminated pastures. Larvae migrate from the intestines to the lungs via the lymphatics and then infiltrate the alveoli. Adult worms may reach 8 cm in length and can block smaller airways. There is no evidence that links infection in donkeys to pulmonary fibrosis; however, lungworm infections may exacerbate other coexisting pulmonary disease.[1] The lungworms have a prepatent period of about 8 to 13 weeks.[3,4] Embryonated eggs produced from patent infections are coughed up, swallowed, and passed in the feces. The eggs hatch into first-stage larvae in the feces and spread onto pastures with the assistance of the fungus *Philbolus*.[1] The larvae congregate on or in the sporangiophore of this fungus, which colonizes the surface of the manure. Fluid within the sporangiophore increases in pressure until it explodes at midday, spreading parasitic larvae up to 3 meters from the site of origin. The dispersion of larvae away from feces increases the odds of ingestion by a susceptible host. The L1 larvae can survive for up to 7 weeks in the environment with suitable warmth and moisture but die rapidly in the cold.[5,6] Maturation of L1 larvae into infective L3 larvae can happen in as little as 5 to 7 days under permissive conditions. In contrast to infections in donkeys, larval development is usually arrested in the early fifth stage in horses, and patent infections are rare.[7,8] In horses, infections are more frequently encountered when pastured with donkeys, but infections have been identified in closed horse herds without exposure to donkeys or mules.[1,6,9,10]

Although *D. arnfieldi* infections have been common in donkeys, more recent surveys indicate a significant decline in the prevalence of this parasite.[11] Three decades ago, a survey of horses and donkeys in central Kentucky identified an infection rate of 54% for donkeys and 25% for horses.[9] In a separate study of a single Kentucky farm, lungworm larvae were found in 93% of donkeys and 50% of Thoroughbreds.[12] A more recent survey of 735 new donkeys at admission to a sanctuary in the United Kingdom (2004-2008) demonstrated a prevalence of only 4% in donkeys.[11] Necropsy surveys of horses in central Kentucky from 2000 to 2001 failed to identify any *D. arnfieldi* infections.[13] The macrocyclic lactones, which are highly effective against *D. arnfieldi*, were introduced after these initial studies and are probably responsible for the decline in incidence of this parasite.[1]

Donkeys rarely show clinical signs associated with infection, and pathology is usually limited to areas of overinflation surrounding affected bronchi and to the tip of the caudal lung lobe. In contrast, more significant lesions are seen in infected horses and are associated with a more robust inflammatory response to lungworm infections.[1] In the horse, larvae within the bronchi stimulate a marked eosinophilic and lymphocytic exudate.[14] Damage from the adult worms causes focal edema and hemorrhage and results in hyperplasia and thickening of occupied bronchi.[15] The adult parasites also impair local defenses as they disrupt the mucociliary apparatus and cause a decrease in alveolar macrophage numbers, allowing for opportunist bacterial infections.[7] Exudate, adult parasites, and airway hyperplasia cause obstruction of small bronchioles and secondary air trapping. Examination of affected lungs demonstrates interstitial pneumonia, focal necrosis, and areas of pulmonary overinflation in the lung periphery.[4,14]

Parasitic pneumonitis can affect horses of any age, but clinical signs are most frequent in horses between 5 and 8 years of age.[9] Clinical signs can develop as rapidly as 12 days after ingestion of infective larvae.[7] Chronic cough is the most common manifestation in the horse, along with exercise intolerance and mucopurulent nasal discharge.[10] Affected horses are rarely inappetant or dull.

Diagnosis in donkeys relies on the modified Baermann technique to detect larvae in the feces. Fifty grams of feces are required for this test. Accurate results require the feces to be evaluated quickly or to be kept cool, as temperatures greater than 16° C are associated with the loss of 50% of the larvae in 24 hours and the loss of 80% in 48 hours.[15] Since patent infections are rare in horses, endoscopic or transtracheal examination for larvae or proof of eosinophilic inflammation may be required to make a diagnosis. Hematologic and serum chemistry results are frequently normal in horses with uncomplicated parasitic

pneumonitis. Mature neutrophilia and hyperfibrinogenemia are usually seen only when there is a secondary bacterial infection.[16] Supportive evidence for parasitic pneumonia can be obtained by transtracheal wash, BAL, and possibly direct visualization through an endoscope. Cytology of aspirates demonstrates abnormally elevated eosinophil counts (greater than 2%). Eosinophil percentages as high as 88% have been recovered from horses with *Dictyocaulus* infections. Larvae or eggs can be found during examination of the fluid.[16] Radiographic examination is nonspecific and may reveal a mixed bronchointerstitial pattern.[5,16] Centrifugal flotation, modified McMaster technique, and Baermann technique have all been used to identify eggs or larvae in the feces of infected animals. Confirmation of infections in horses is difficult, as patent infection is rare.

Historically, thiabendazole (440 mg/kg/day for 2 days) and mebendazole (20 mg/kg/day for 5 days) were effective in reducing parasite load and larval shedding, but neither product is currently available.[17] Fenbendazole, a benzimidazole that is still available, only reduces larval numbers in feces of donkeys by 50% to 70% when administered at 15 mg/kg PO once.[18] The larvicidal dose of fenbendazole (10 mg/kg/day for 5 consecutive days) is not effective against adult *D. arnfieldi*.[18] Macrocyclic lactones such as moxidectin (400 µg/kg) or ivermectin (200 µg/kg) have been demonstrated to be effective against mature and immature stages of *Dictyocaulus* spp., and these drugs are the most frequently used products to treat parasitic pneumonia.[19] It is recommended that new donkeys be tested for *Dictyocaulus* and treated accordingly before introduction to a herd. Horses that graze pastures shared with donkeys are more likely to acquire infections, so it is important to control infections in donkeys and limit exposure of horses to the parasite.[20]

Thoracic Trauma

Scott M. Austin

Thoracic injuries in the horse are uncommon but are often associated with high mortality. These injuries result from either penetrating or blunt trauma.[1,2] Collision with fences is the most common cause of penetrating thoracic wounds, but running into trees and farm implements, gunshots, goring by horned animals, and impalement by high-velocity debris during tornadoes have also been reported.[3,4] While penetrating wounds are usually obvious, blunt force injuries can be more difficult to diagnose and may occur after collisions with stationary objects, kicks from other horses, and athletic mishaps such as falls. Significant internal injuries may be present in the absence of external wounds.[5] Frequently, damage occurs to both internal and external structures, and a complete physical examination and ancillary diagnostic tests are necessary to determine the extent of the damage. Potential trauma includes pectoral or axillary lacerations, penetrating wounds or impalement of the thorax, rib fractures, flail chest, and lung contusions or lacerations and leads to potentially life-threatening complications such as pneumothorax, pneumomediastinum, hemothorax, pleuritis, and diaphragmatic hernia.[6,7]

External injury can cause extensive muscle damage, rib fractures, laceration of large vessels, and significant shock and pain. Internal injuries such as pneumothorax and thoracic hemorrhage will have the additional signs of respiratory distress characterized by nostril flaring, dyspnea, tachypnea, and exaggerated thoracic excursions.[1,2] In addition, horses with diaphragmatic hernias may present with signs of abdominal discomfort.[1-3] Patient stabilization to alleviate life-threatening complications must be undertaken first. Initial treatment ensures a patent airway, restores ventilation and oxygenation, controls hemorrhage, addresses shock, and reestablishes circulatory volume.[7]

After the patient is stabilized, a complete examination of the thorax will include careful auscultation and percussion, chest wall palpation, wound exploration, blood gas analysis, diagnostic thoracentesis, radiography, and ultrasonography. Decreased lung sounds with increased resonance over the dorsal lung field is characteristic of pneumothorax, whereas diminished lung sounds with decreased resonance over the ventral thorax is characteristic of hemothorax or pleural fluid accumulation.[2] Ultrasonography is extremely valuable for evaluation of the pleural space and lung surface and can detect air, blood, or fluid. Thoracentesis can be used in conjunction with ultrasound to further characterize any abnormalities. Arterial blood gas provides information regarding ventilation and oxygenation, and serial samples can be used to evaluate response to therapy. Because of the size of the equine chest, radiography usually requires referral to a hospital with equipment sufficient to image the equine thorax.

Wounds of the Axilla

Deep wounds of the axilla occur frequently because of wire cuts, running into fences, or being impaled by sharp objects.[6] Axilla wounds may cause direct penetration of the thorax or develop significant subcutaneous emphysema potentially leading to pneumomediastinum and pneumothorax.[6,7] Wounds should be explored and thoroughly lavaged, but excessive pressure is discouraged, as this may drive contaminants further into the wound.[6] To limit subcutaneous emphysema, wounds should be packed with gauze and a stent applied to hold packing in place. Packing should be changed every 24 to 48 hours until a granulation bed has formed.[7] As with any wound, broad-spectrum antibiotics, pain relief, and tetanus prophylaxis are recommended. Activity should be restricted, and cross-ties have been recommended. If severe subcutaneous emphysema develops, secondary pneumomediastinum and potentially pneumothorax may occur weeks after the initial injury.[3]

Penetrating Thoracic Wounds

When penetrating chest wounds are suspected, the clinician must perform careful auscultation and observe the respiratory cycle for several breaths. Splinting, paradoxical movement of a chest wall segment, and obvious incongruities of the chest wall suggest serious problems in ventilation.[6,8] Careful palpation may identify local pain, fractures, flail segments, or subcutaneous emphysema. Ultrasound can confirm abnormalities detected during physical examination.[6] Serial exams are necessary, as signs of pneumothorax may take time to develop. If full-thickness penetration of the chest wall is suspected, arterial blood gases should be performed to evaluate oxygenation. Chest radiographs can be used to determine if pneumothorax, pneumomediastinum, or rib fractures are present.

Pneumothorax

Pneumothorax is an uncommon event and is classified as open, closed, or tension.[2,3,9,10] Penetrating wounds through the chest wall result in an open pneumothorax, and air moves freely into and out of the chest during inspiration and expiration. In contrast, the chest wall is intact in closed pneumothorax, and air entering pleural space originates from lung parenchyma secondary to infection, rib fractures, or ruptured lung bulla.[6] Tension pneumothorax occurs when a one-way valve develops in either the chest wall or lacerated lung parenchyma. Air is drawn into the pleural space upon inhalation but does not escape during exhalation, resulting in intrapleural pressures that surpass atmospheric pressure and causing compromise of ventilation and cardiopulmonary collapse.[5]

In a review of 40 cases of pneumothorax in horses, the causes were divided between open and closed trauma and surgery of the upper and lower respiratory tract.[10] Closed pneumothorax secondary to pleuropneumonia (17 of 40 cases)

VetBooks.ir

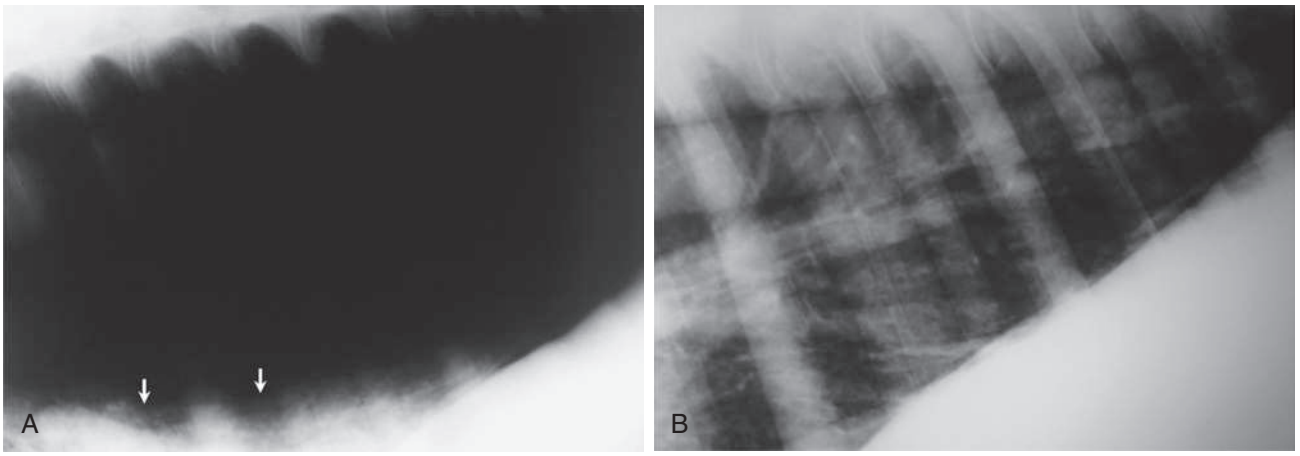

FIG. 31.32 **A,** Lateral radiograph of the caudodorsal thorax of a horse with bilateral pneumothorax. The dorsal borders of the lung margin are marked by arrows. **B,** Same view as A after thoracocentesis and resolution of the pneumothorax.

and blunt force trauma of the thorax (7 of 40) accounted for the majority. Penetrating wounds resulting in open pneumothorax accounted for 9 of 40 cases. Pneumothorax was bilateral in 19 of 40, unilateral in 17 of 40, and not stipulated as unilateral or bilateral in 4 of 40.[10] Bilateral and tension pneumothorax compromise ventilation and result in obvious clinical signs, whereas unilateral pneumothorax is well tolerated in the horse.[7] Unilateral pneumothorax is more likely encountered secondary to pleuropneumonia, whereas trauma usually results in bilateral pneumothorax.[3,10] The survival rate was 69.6% for traumatic causes of pneumothorax as opposed to 35.3% for infectious causes.[10] Clinical signs of pneumothorax include tachypnea, cyanosis, lack of lung sounds upon auscultation in the dorsal lung fields, fever, tachycardia, decreased activity, depression or anxiety, and cough. While history and clinical signs are suggestive, the diagnosis can be confirmed with radiography and ultrasonographic examinations.[10] Thoracic radiographs are often not possible in the field, but ultrasonography can be used effectively. Radiographic signs of pneumothorax include retraction of normal pulmonary parenchyma, hyperlucency within the caudodorsal thorax, and visualization of the dorsal margin of the lung lobes below the bodies of the thoracic vertebrae (Fig. 31.32). Radiography and ultrasonography have been reported to have 74% agreement, with most discrepancies occurring when the volume of air in the thorax was small.[11] Ultrasonography is superior to radiography for detecting small volumes of air in the pleural space.[12]

Normal aerated lung is characterized as a hyperechoic line on the ultrasound image. Ribs are visualized as hyperechoic curved lines that cast acoustic shadows. The appearance of two ribs with acoustic shadowing in the superficial plane and the pleural line deep is defined as the "bat sign."[12] Absence of the bat sign is characteristic of subcutaneous emphysema. Static images of air within the pleural space and the normal air-filled lung may appear similar; however, synchronous movement of the pleural line relative to the chest wall or "gliding lung sign" is characteristic of normal lung. Air that doesn't move with the respiratory cycle is seen with pneumothorax. M-mode ultrasonography can also be used to evaluate the pleural space. Normal lung on M-mode ultrasonography is represented by a series of horizontal lines representing the skin, muscular layers, and pleura. Below the pleura the normal lung appears as a granular layer. With pneumothorax, the granular layer is replaced by a continuum of horizontal lines above and below the pleura line.[12] In experimentally induced pneumothorax, two-dimensional ultrasonography can detect as little as 50 mL of air within the pleural space and is superior to M-mode ultrasonography and radiography for identification of pneumothorax.[12]

FIG. 31.33 Emergency stabilization of a horse with an open thoracic wound and subsequent pneumothorax. Plastic wrap has been placed around the chest to prevent air from entering the thoracic cavity, and a Heimlich drainage valve has been attached to the dorsally placed chest tube. Intravenous fluids and intranasal oxygen are being administered.

Arterial blood gas analysis should be performed when pneumothorax is suspected. Severe alterations indicate the need for immediate support of perfusion and ventilation. Pulse oximetry can provide a continuous indicator of response to treatment.[6] Common complications include hypoxemia and possible metabolic and respiratory acidosis.[13]

Treatment for pneumothorax focuses on eliminating air from the pleural space and preventing recurrence. Obvious penetrating chest wounds should be sealed with a sterile, airtight dressing.[2,4,7] Temporary wound closure, packing, petroleum dressings, and application of plastic wrap have been recommended to stop air leakage (Fig. 31.33). Stent bandages or complete circumferential bandages should be applied for added security of closure. However, bandages around the chest should

not be used when flail chest is present.[14] In most instances, pain is significant and can cause inadequate ventilation and hypoxemia (PaO_2 <80 mm Hg).[1-3] Nasal or tracheal insufflation of oxygen is necessary in hypoxemic or cyanotic patients until correction of ventilation can be accomplished.[1,2,15,16] Intratracheal oxygen has been demonstrated to be superior to intranasal oxygen for increasing inspired oxygen concentrations but may also provoke coughing, which can be counterproductive.[7] Treatment of pneumothorax includes dorsal chest tube placement (10- to 14-gauge) in the twelfth intercostal space and suction of air. All wounds should be explored, cleaned, and packed. Removal of air allows reestablishment of ventilation and helps control hemorrhage from low-pressure pulmonary vessels.[2,7] Antibiotics, pain relief, and tetanus prophylaxis are indicated in most cases.[3,6,10] Simple observation of spontaneously occurring pneumothorax indicates that air is slowly resorbed with time. Approximately 1.25% of the volume of a hemithorax is resorbed in 24 hours, which means that a 20% pneumothorax would take 16 days to eliminate.[5]

Pleuritis or pleuropneumonia are potential sequelae to open chest wounds and necessitate culture and sensitivity to guide antimicrobial selection and ventral drainage to manage fluid accumulation. Mixed bacterial infections are expected after penetrating wounds. In a case series evaluating acute and chronic pleuritis or pleuropneumonia, pleural fluid accumulation secondary to penetrating injury was rare (3 of 43 cases).[17] Prognosis is satisfactory in most cases, with a reported 73% survival rate; however, horses that develop secondary pleuropneumonia have a guarded prognosis of 50% survival.[3,6,17,18]

Pneumomediastinum

Contents of the mediastinum include the trachea, esophagus, heart and great vessels, nerves, lymph nodes, and thoracic duct. Pneumomediastinum occurs secondary to extensive subcutaneous emphysema secondary to axillary wounds or trauma to the trachea or esophagus at the thoracic inlet. Classic radiographic features include visualization of the thoracic esophagus, great vessels, and outer margins of the trachea.[4,6] Specific treatment is not described except for limiting aspiration of air through an axillary wound, broad-spectrum antibiotics, and monitoring for pneumothorax.

Hemothorax

Bleeding secondary to thoracic trauma may be sufficient to cause hemorrhagic shock in addition to compromising ventilation. Expected clinical signs include tachycardia, tachypnea, pale mucous membranes, weakness, trembling, and respiratory distress. Occasionally a systolic murmur may be present. It should be noted that the degree of tachycardia may not correlate with severity of pain. If heart rate is higher than expected for the apparent pain level, hemorrhage should be suspected.[7] In a survey of horses with thoracic trauma, hemothorax was identified in 40% and was not life threatening, indicating that minor vessels are most often involved.[3] Hemorrhage is severe when the heart and great vessels are damaged, and most horses with massive hemothorax do not survive.[1,2] Treatment of blood loss consists of arresting hemorrhage, restoration of circulatory fluid volume, and if indicated, whole blood transfusion.[19-21] Intravenous, polyionic crystalloids are administered at a rate of 20 to 80 mL/kg over several hours to restore circulatory volume, improve cardiac output, and increase tissue perfusion. The goal is normal to slightly low blood pressure (permissive hypotension) if hemorrhage can be stopped. Hypertonic saline (7.2%) can be administered at 2 to 4 mL/kg in horses with hemorrhagic shock but should not be used in horses with uncontrolled hemorrhage, as the increase in blood pressure may disrupt clot formation.[7] Hypertonic saline will need to be followed by isotonic fluid therapy. Colloids such as hetastarch are not recommended in horses with acute hemorrhage due to potential interference with coagulation.[21] When severe bleeding persists and signs of hypotension ensue, blood transfusion is often necessary. Losses of up to 20% of the blood volume (8% to 10% of body weight) can be tolerated without a significant drop in blood pressure. Acutely, alterations in packed cell volume (PCV) and total protein will not be evident, so the need for transfusion must be based on clinical signs such as tachycardia, poor pulse quality, pale mucous membranes, cool extremities, depression and anxiety, and weakness.[7] Alterations in blood lactate (>4 mmol/L), venous oxygen tension (<30 mm Hg), venous hemoglobin saturation (<50%), and blood pressure may further indicate the need for transfusion.[4,20] The recommended volume of blood to transfuse is 6 to 8 L in an adult horse, which represents 30% to 40% of the estimated or calculated blood loss.[20] Blood loss estimation can be conducted using the following formula:

$$\text{Liters of blood lost} = \frac{\text{Normal PCV} - \text{Patient PCV}}{\text{Normal PCV}} \times 0.08 \times \text{Patient weight (kg)}$$

When the hemorrhage is controlled or originates from smaller vessels, removal of blood from the thorax improves ventilation and avoids secondary septic pleural effusion, pleural adhesions, and constricting fibrothorax. Patient stabilization prior to removal is necessary.[7]

Rib Fractures

Rib fractures are most commonly seen in foals and occur during birth. In a postmortem review of 760 foals, thoracic trauma was evident in 8.8%. Nineteen had fractured ribs that were believed to be the cause of death.[22] Asymmetry of the chest wall was seen in 55 of 263 foals in another study, and dystocia and a primiparous dam were identified as factors that increased the risk of thoracic trauma.[23] The percentage of rib fractures in foals admitted to referral centers may be as high as 65%.[22,24] The most common site of rib fractures in foals appears to be the costochondral junction and involves ribs 3 through 8.[22] Death in foals is usually secondary to hemothorax with respiratory collapse, myocardial lacerations, pneumothorax, diaphragmatic hernia, and hemopericardium.[22] Clinical signs of rib fractures include lethargy and recumbency, groaning and grunting, plaques of subcutaneous edema over the affected area, flinching upon palpation, and audible or palpable crepitus or clicking upon digital palpation or simultaneous auscultation.[4,24] Ultrasonography is very useful in identifying fractures and assessing underlying pulmonary injury (Fig. 31.34). Fractured ribs in foals may be reduced and stabilized using plates, self-tapping cortical screws, cerclage wire, or zip ties.[25,26] Foals with rib fractures that do not overlie the heart may be managed by complete stall rest for 2 weeks. If injuries are more severe, analgesia, thoracentesis, nasal insufflation of oxygen, whole blood transfusions, sedation, and positive pressure ventilation may be necessary.[6]

Rib fractures in adult horses generally occur after blunt force or penetrating trauma. Thirty percent of horses with penetrating wounds may have concomitant rib fractures.[3] Radiographic identification of minimally displaced rib fractures in adult horses may be difficult because of the large mass of the horse and superimposition of ribs on the opposite side. Indeed, in many instances, rib fracture may not be apparent until a callus has formed. Fortunately, single fractures appear to heal well without surgical intervention.[2] Surgical intervention is reserved for displaced fractures that are a risk to lacerate lung, heart, or diaphragm.

Flail chest, while more common in neonates, is rarely observed in adult horses. Flail chest is defined as fracture of three or more ribs in at least two sites allowing a free-floating

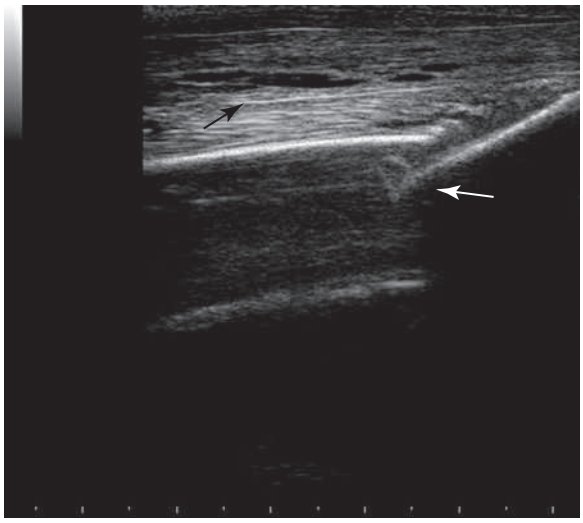

FIG. 31.34 Fractured rib *(white arrow)*, saggital view. Note the edema surrounding tissues *(black arrow)* and around the fracture site.

rib segment and a characteristic paradoxical movement of the rib segment during respiration. The segment of chest wall moves inward during inhalation and outward during exhalation.[6] Diagnosis is rare in the adult horse, as the trauma sufficient to cause a flail chest is often fatal. Flail chest causes severe respiratory compromise and often leads to severe hemorrhage due to trauma to the underlying heart and lung. Stabilization of the flail segment is essential, and suturing ribs in the affected segment to an external splint provides stability during healing.[7]

Abdominal Injury

When there is extensive thoracic trauma, the abdominal cavity should also be thoroughly evaluated. The cupula of the diaphragm can extend as cranial as intercostal space 6 during expiration, making the diaphragm vulnerable to injury with thoracic trauma. Diaphragmatic hernias can occur secondary to thoracic trauma but are rare.[27] Clinical signs may include exercise intolerance, respiratory compromise, and tachypnea. In some horses, abdominal discomfort may dominate and be consistent with either a strangulating or nonstrangulating obstruction of the intestine.[28-31] Thoracic radiography and ultrasonography may identify herniation of the diaphragm, and abdominocentesis may identify intestinal perforation or bowel rupture. Often tears are not identified until exploratory laparotomy, and they frequently occur along the ventral midline just dorsal to the xiphoid process.[4] Conservative management of diaphragmatic hernias often results in euthanasia, so surgical repair is recommended.[32,33] Multiple methods of surgical repair have been reported, and all require mechanical ventilation intraoperatively.[27,32] Aftercare is similar to that for patients with colic; however, pneumothorax should be resolved before recovery.[4]

Summary

Injuries to the thorax of the horse can be managed with surgical or conservative strategies.[3,7,18,34] Initially patients require stabilization, and the extent and complicating factors of the wounds must be defined. Horses with simple rib fractures, small chest wounds, and modest pneumothorax or hemothorax are candidates for conservative management. Medical therapy includes broad-spectrum antibiotics and appropriate pain relief, thoracentesis or thoracic drain placement, second intention wound healing, and bandaging. More severe wounds require surgical intervention to exploration, lavage of wounds and body cavities, stabilization of fractures, control of hemorrhage, and removal of foreign bodies.[34]

Pulmonary Edema

Pamela A. Wilkins

Pulmonary edema rarely occurs as a primary event in the horse and, when present, is usually secondary to some other pathologic process. Extravascular fluid accumulates within the lung after events that alter hydrostatic and colloid osmotic interstitial and vascular forces change the surface area and pore size of the blood-gas barrier or diminish lymphatic drainage.[1] Pulmonary edema can be classified as cardiogenic or noncardiogenic. Pulmonary capillary pressure can be increased by any increase in left atrial or pulmonary artery pressure. In horses, this can occur secondary to acute renal failure, left heart failure, or very high cardiac output conditions, such as extreme exercise. Increases in microvascular permeability may occur with sepsis, disseminated intravascular coagulation, hypoxic acidosis, allergic responses such as transfusion reactions, or primary pulmonary pathology, resulting in the release of mediators of inflammation that increase vascular endothelial or alveolar epithelial permeability. Pulmonary edema associated with airway obstruction has been termed *negative pressure pulmonary edema* (NPPE) and has been reported in horses.[2-7] NPPE occurs secondary to inspiratory efforts against a closed glottis that result in a precipitous fall in intrathoracic pressure. The large decrease in intrathoracic pressure increases the transmural pressure gradient for all intrathoracic vascular structures, favoring movement of water into the extravascular space. Transient pulmonary obstruction may be a root cause of fatal exercise-induced pulmonary hemorrhage (EIPH) in racehorses and other horses performing at maximal exercise; these horses are predisposed because of already large transmural pulmonary vascular pressures and large intrathoracic pressure swings associated with breathing (Wilkins and Del Piero, unpublished data) (Fig. 31.35).

Diagnosis is based on clinical examination, history of predisposing causes, and radiographs. Horses have a shallow rapid respiratory pattern and may be dyspneic. Arterial blood gas analysis may reveal hypoxemia and hypercapnia. Fine crackles or wheezes may be audible on auscultation. Patients with volume overload (associated with renal failure or, rarely, too-rapid fluid administration) or primary cardiac problems may have an increased central venous pressure with pronounced venous distention. Fluid (clear or slightly yellow or pink-tinged) may drip from the nostrils and can increase in volume without necessarily becoming frothy. Continuous coughing and production of frothy blood-tinged or bloody fluid production warrants a very grave prognosis. Radiographic findings are nonspecific but include peribronchial and perivascular cuffing, increased prominence of vessels, and a hazy reticular interstitial pattern (Fig. 31.36). Underlying pulmonary disease may obscure signs of edema, and radiographs of sufficiently high quality to show relatively subtle changes may not be obtainable in mature horses. Numerous diffuse comet-tail artifacts are seen with thoracic ultrasound examination (Fig. 31.37). Noncardiogenic pulmonary edema (capillary leak) is a component of the definition for VetALI and VetARDS (see the Acute Respiratory Distress Syndrome and Acute Lung Injury [Acute Bronchointerstitial Pneumonia] section earlier).

■ ***Treatment*** Treatment consists of correcting the cause, reversing hypoxemia, decreasing plasma volume and left atrial pressure, and increasing plasma colloid osmotic pressure. Intranasal oxygen and even positive ventilation may be needed in severe cases. Improvement in oxygenation can be monitored by sequential arterial blood gas analysis or by using transcutaneous

TABLE 31.11

Pharmacologic Treatments for Pulmonary Edema in Horses

Treatment	Reason	Route	Dose/Rate	Comments
Oxygen	Hypoxemia	Intranasal insufflation	5-15 L/min	Aim for PaO_2 >85 mm Hg, O_2 sat >90%
Furosemide	Diuresis	Intravenous	1 mg/kg	Repeat as needed; monitor acid-base status, hydration, and electrolyte concentrations
Furosemide	Bronchodilation	Nebulization		Will not be effective with concurrent NSAID administration
Bronchodilators (various)	Bronchodilation	Nebulization Oral Intravenous	See the Summer Pasture–Associated Obstructive Pulmonary Disease section	Many will be effective, described in depth elsewhere
Flunixin meglumine	Antiinflammatory	Intravenous	1 mg/kg	bid; monitor renal function
Diphenhydramine	Antihistamine	Intravenous	0.1-1 mg/kg	bid; monitor for excessive drowsiness
Epinephrine	Anaphylaxis	Intravenous	3-5 mL IM for 450-kg horse	Use ONLY for treating anaphylaxis

bid, Twice a day; *IM*, intramuscularly; *NSAID*, nonsteroidal antiinflammatory drug; *O_2 sat*, percentage oxygen saturation; *PaO_2*, partial arterial oxygen pressure.

oxygen saturation monitoring equipment (pulse oximetry) applied to the nasal mucosa, tongue, or other available nonpigmented mucous membrane. In cases of NPPE, maintaining an adequate, low-resistance airway is very important to prevent further damage, and tracheostomy may be necessary. IV fluid therapy should be guided by the patient's needs and monitored by serial measurement of central venous pressure if necessary. Furosemide may be given intravenously or intramuscularly at a dose of 1 to 2 mg/kg and repeated in 1 hour (Table 31.11). If helpful, the dose can be titrated for each patient. At a dose of 1 mg/kg, approximately 8 L of urine is produced in approximately 1 hour.[8] A few studies have been conducted on the effects of furosemide on pulmonary hemodynamics in the horse.[8-12] Furosemide provides some relief to RAO-affected horses within 20 minutes of administration, increasing dynamic compliance without affecting PaO_2.[13] The beneficial effects appear to be mediated by prostaglandin E2 (PGE2), derived from either the renal or the airway epithelium, resulting in bronchial smooth muscle relaxation. Prior treatment with flunixin meglumine prevents the furosemide-induced bronchodilation.[14] The effect in horses with pulmonary edema has not been reported. Colloid solutions should be administered cautiously or in conjunction with use of diuretics because they can initially increase vascular pressure. Plasma may be safer than other colloid preparations such as dextrans or hetastarch. Colloid solutions may be of little benefit in raising intravascular osmotic pressure in patients with increased microvascular permeability.

Antiprostaglandin drugs (flunixin meglumine, phenylbutazone) and antihistamines may help and are indicated particularly in cases of anaphylactic reaction, as are diphenhydramine and epinephrine (see Table 31.11). Bronchodilators may be of benefit (see Table 31.11). The use of corticosteroids remains controversial; if they are used, antimicrobial coverage is advisable, as pulmonary edema has been shown to impair pulmonary bacterial defense mechanisms.

Smoke Inhalation

Peggy S. Marsh

Smoke inhalation injury is typically associated with exposure to fires, and there are often concurrent problems in other body systems from thermal injury. Thermal injury, along with smoke inhalation, leads to both local and systemic lesions. Diffuse tissue edema may occur and can create organ dysfunction. Severely affected patients may develop complex problems, including life-threatening sepsis, systemic inflammatory response syndrome, and in some cases, multiple organ system failure.[1]

Insult to the respiratory system by smoke inhalation depends on the fuels that burned, the completeness of combustion, the heat intensity, and the duration of exposure. In general, lesions are initiated by three mechanisms. The first is direct thermal injury, which is often limited to the upper respiratory tract by laryngeal reflexes and efficient heat exchange within the nasal passages.[2] Second, toxic chemicals in the smoke can cause damage, both directly and indirectly, through inflammatory mediators. Carbon monoxide intoxication is commonly associated with human injuries from smoke and is a product of incomplete combustion.[3] Finally, with combustion there is consumption of oxygen, and the resulting low PaO_2 can lead to pulmonary vasoconstriction as well as generalized hypoxia.

Three phases of pulmonary dysfunction have been described in the horse.[4,5] The first stage is acute pulmonary insufficiency caused by several mechanisms. Carbon monoxide may be present in sufficiently high concentration to cause toxicity within a short time after exposure. Carbon monoxide combines with hemoglobin to form carboxyhemoglobin. Hemoglobin has a 200 to 250 times greater affinity for carbon monoxide as compared with its affinity for oxygen.[3] High levels of circulating carboxyhemoglobin result in a shift of the oxyhemoglobin dissociation curve to the left, thereby decreasing oxygen release at the tissue level and leading to tissue hypoxia. Other processes occurring during this acute phase include progressive edema and necrosis in the upper respiratory tract, leading to airway obstruction; bronchoconstriction in the lower respiratory tract, caused by the irritating effects of noxious products; and altered pulmonary blood flow.[6]

These insults produce the second stage: formation of pulmonary edema, lower airway obstruction, and pulmonary parenchymal lesions. Within 48 to 72 hours after exposure, driven by pulmonary macrophages, neutrophils are called into the area of insult. They release cytokines, proteolytic enzymes, and oxygen-derived free radicals. Expression of the inflammatory cascade in excess of balance causes microvascular damage, leading to increased extravascular lung water. Local insult also results in the release of tissue factor, initiating the coagulation cascade to produce fibrin. Debris from the inflammatory cascade, along with fibrin and material directly deposited from smoke inhalation, create pseudomembranous casts, which may obstruct the small airways. Widespread plugging of the airways may significantly increase airway pressure, causing barotrauma and alveolar damage.[6] The last stage, bronchopneumonia, occurs

as a result of local and systemic impairment of the host immune system. This phase may take up to 1 to 2 weeks after the initial injury to develop.

It is common for horses with smoke inhalation injury to also have burn injury. A complete description of this process in horses has been reported.[7] Thermal injury causes a local response that includes microvascular insult and direct tissue coagulation leading to inflammation, local edema, and finally necrosis. Extensive local injuries will drive a systemic response. An initial decrease in systemic organ blood flow is followed by the formation of generalized edema. The pathophysiology of edema formation is complex and involves protein shifts, endothelial damage, and alteration of the interstitial architecture, all leading to a net accumulation of fluid in the interstitial spaces.[8] Over time, major thermal injury is characterized by high cardiac output, increased oxygen consumption, and protein and fat wasting, all of which may create a hypermetabolic state.[9,10] Loss of skin as a barrier, release of inflammatory mediators, and hypermetabolism play a role in the development of immunosuppression. Other features noted with burn injury in the horse include acute hemolysis, renal failure, laminitis, and myositis.[11]

Horses exposed to smoke will have a variety of clinical signs depending on the duration and type of exposure and the length of time from the insult. Acutely in more severe cases, within the first 6 hours, signs of carbon monoxide toxicity and shock may occur. The patient shows signs of severe hypoxemia and may be depressed, disoriented, irritable, ataxic, or even moribund. As edema and necrosis progress in the upper respiratory tract, dyspnea and stridor may develop. Auscultation of the thorax may reveal decreased air movement, crackles, or wheezes, but these may not become apparent for 12 to 24 hours. If edema of the airways is sufficiently severe, airflow may be severely restricted. Edema fluid may be visible at the nostrils and later may be replaced by inflammatory exudate. Concurrent edema formation may be occurring systemically. Hypoxia and generalized edema may lead to dysfunction of distant organs such as the kidneys and muscles. Signs of infection may be difficult to ascertain from other signs. All that may be noticed is a fever and a worsening of respiratory signs after initial improvement. As noted in a recent report, clinical signs may become more complex when there is thermal injury.[12] Exposure to smoke without thermal injury can also occur, as with unhealthy air created by large wildfire smoke and associated debris. Clinical signs of an irritated respiratory tract are seen, similar to horses with chronic inflammatory airway disease.[13]

Diagnosis is typically based on history and physical examination. A normal initial examination does not rule out exposure because the onset of clinical signs may be delayed several days. Within a short time after exposure, carboxyhemoglobin concentration in venous blood can be measured. A level above 10% is consistent with carbon monoxide toxicity.[3] Various diagnostic tests are useful in determining the extent of respiratory injury. These tests include endoscopy of the upper respiratory tract and tracheobronchial tree, thoracic radiographs, blood gas analysis, hematology, and cytologic evaluation of tracheal aspirates. Any or all of these tests can be performed on a serial basis as prognostic aids. Diagnostic tools for other organ injury include blood pressure monitoring, measurement of central venous pressure, serial hematologic and serum chemistry analyses, and monitoring of urine production.

Treatment depends on the stage and extent of injury. Initially, oxygen support is of benefit. It is a treatment for carbon monoxide toxicity and helps reduce hypoxemia.[14] Humidified oxygen can be supplied by nasal insufflation or via transtracheal catheter. Upper respiratory tract obstruction may necessitate a tracheostomy. Attention should be paid to keeping the airways clear, and nebulization may help. Bronchodilators may be useful in counteracting reflex bronchoconstriction. Decreasing inflammation and pulmonary edema may necessitate the use of diuretics and NSAIDs. Use of corticosteroids is controversial because of the potential for immunosuppression and laminitis.[4] Where available, hyperbaric oxygen therapy has been used.

Secondary complications require attention. Cardiovascular compromise and burn-induced edema may necessitate the judicious use of intravenous fluids. To prevent infection, strict hygiene, meticulous nursing care, and optimal nutritional support should be provided.[1,7] Prophylactic antimicrobial use is not recommended in human patients. Documented infection should be treated with appropriate antimicrobial agents based on results of culture and sensitivity patterns.[1,7] Proper management of chronic smoke exposure includes limiting exercise and a full veterinary examination of the respiratory tract before return to work.[13]

Recurrent Airway Obstruction

Dorothy M. Ainsworth

In a recent American College of Veterinary Internal Medicine (ACVIM) consensus statement, it was suggested that because of their similarities to human asthma, recurrent airway obstruction (RAO), summer pasture–associated obstructive pulmonary disease (SPAOPD), and equine inflammatory airway disease (IAD) now be classified under the umbrella term *equine asthma*.[1] In recognizing that differences in the clinical severity of these three inflammatory conditions exist, it was further suggested that horses with RAO or SPAOPD (either symptomatic or in remission) be referred to as having severe equine asthma; those horses with IAD should be diagnosed as mild or moderate equine asthmatics.[2] For simplicity, the terms RAO and SPAOPD are used in the following sections.

Definition and Etiology

RAO is a pulmonary inflammatory condition that affects mature horses usually older than 7 years of age. It is characterized by excessive mucus production, airway neutrophilia, bronchial hyperreactivity, and in most cases, reversible bronchospasm. Previously, the condition has been called heaves, chronic obstructive pulmonary disease (COPD), broken wind, hay sickness, and small airway disease.[3]

RAO typically occurs in adult horses residing in the northeast and midwest regions of the United States and Canada, as well as in Great Britain and in Europe—locales where the climate is wet and cool and horses are stabled and fed hay. RAO also occurs in horses pastured outdoors but fed dusty hay, especially from round bales. It rarely occurs in horses maintained in warm, dry climates, such as those found in California or in Australia.[4] In North America the prevalence of RAO diagnosed at veterinary teaching hospitals positively correlated with rainfall, minimum temperatures, and total pollen and mold counts occurring 1 to 3 months previously.[5] These findings suggest that environmental conditions are integral to the development of the disease in genetically susceptible horses.

RAO reflects a hyperreactivity to inhaled molds and organic dusts contained in the feeds, hay, and straw. It resembles occupational (neutrophilic) asthma found in humans exposed to organic dusts typically found in animal husbandry operations.[6] Identifying the *specific* causative agents within the hay dust that induce the equine disease has been a challenge, as stable dust contains more than 50 species of molds, large numbers of forage mites, endotoxins, and other inorganic components.[7] Inhalation challenge with endotoxin induces airway neutrophilia but not all of the characteristic pulmonary function changes of RAO.[8,9] Likewise, inhalation challenge with aqueous extracts of *Aspergillus fumigatus*, *Faenia rectivirgula (Micropolyspora faeni)*, or *Thermoactinomyces vulgaris* partially induces RAO in susceptible horses.[10-12] Complete experimental induction of RAO in susceptible horses requires inhalation of hay dust particulates

either by natural challenge (hay feeding) or by nebulization of a hay dust solution or a solution containing fungal spores, endotoxin, and silica microspheres.[13-17]

Development of Pulmonary Inflammation

Within hours of hay dust exposure, airway neutrophilia and excessive mucus production are evident endoscopically and cytologically.[18,19] Alveolar macrophages, isolated from RAO-susceptible horses just 6 hours after nebulization of a hay dust solution,[20] have upregulated gene expression of TNF-α, IL-1β, and IL-8. The trigger for gene transcription may reflect activation of nuclear factor kappa B (NF-κB) by Toll-like receptors 2 and 4 (TLR2 and TLR4) following exposure to fungal wall components, endotoxin, or other bacterial cell products.[21] The expression of hypoxia-inducible factor 1α (HIF-1α) is thought to enhance TNF-α, IL-8, and vascular endothelial growth factor (VEGF) expression through the NF-κB pathway.[22]

MACROPHAGES. The initial upregulation of macrophage-derived proinflammatory gene transcription is to be transient, with mRNA levels returning to preexposure levels 24 hours after hay dust challenge.[20,23,24] With continuous, chronic hay dust exposure, protein and the gene expression levels of IL-8, IL-1β, and TNF-α in the BAL cells remain upregulated, which probably reflects contributions from recruited neutrophils and other cells.[25-28] The net effect of these proinflammatory cytokines (and others such as IL-17, see below) is to enhance the chemokinetic gradient existing within the airways and to promote neutrophilic extravasation.[29,30] The neutrophil intracellular signaling pathways required for extravasation into the airways involve mitogen-activated protein kinases (MAPKs) and/or phosphoinositide 3-kinase (PI3K) as inhibition of these pathways attenuates neutrophil chemokinesis.[30] In RAO-affected horses, at least one mechanism that tempers neutrophil chemotaxis, secretoglobin production, is attenuated. These are mucosal epithelial-derived proteins that reduce IL-8–stimulated chemotaxis of blood-derived neutrophils. They also sequester calcium and phosphatidylcholine, a cofactor and substrate, respectively, both of which are required for phospholipase A2 activity.[31] RAO-affected horses have reduced secretoglobin concentrations in their BAL, suggesting an absence of an inflammatory braking mechanism.[31-33]

LYMPHOCYTES. The role of lymphocytes, especially T-helper cells, in the development of the pulmonary inflammatory response remains uncertain. Data that support the hypothesis that RAO is an IgE-mediated (T-helper type 2 [Th2]) disorder include the findings of elevated allergen-specific IgE concentrations in the serum[34] and in the BAL fluid of RAO-susceptible or affected horses,[35,36] increased numbers of IL-4 and IL-5 (mRNA-positive) BAL fluid cells (detected by in situ hybridization techniques) in RAO-affected horses,[37,38] and genetic studies that suggest a phenotypic association (at least in one family of Swiss Warmblood horses) with a locus on equine chromosome 13 that contains the IL-4 receptor gene.[39] Although Th2 disorders are typically characterized by eosinophilic infiltrates, it has been hypothesized that IL-4 activates its receptor on neutrophils to inhibit neutrophil apoptosis, to increase protein synthesis, and to upregulate the expression of the IL-9 receptor.[40] This results in enhanced IL-8 production and neutrophil influx.[40,41] Although the gene expressions of IL-4 and IL-9 receptors are upregulated in peripheral blood neutrophils isolated from RAO-prone and RAO-affected horses, linking this pathway to the Th2 limb in horses requires additional investigation and confirmation.

Other data suggest that RAO does *not* reflect a polarized Th2 immune response. There are no significant differences in IgE-protein–positive cells in the lung tissue samples or in the BAL cells of RAO-affected horses compared with control horses.[42,43] Second, in those two well-studied Swiss Warmblood families classified as healthy or RAO-affected (based on a horse owner assessed respiratory signs index [HOARSI]), no significant differences in serum IgE concentrations against recombinant *A. fumigatus* antigen were found.[44] Third, results of IgE serologic and intradermal testing failed to detect a difference between RAO-affected and control horses.[45] Fourth, cytokine profiles of BAL cells[27,28] or of pulmonary CD4+ and CD8+ cells[46] isolated from RAO-affected horses during the first 24 or 48 hours after hay dust exposure fail to demonstrate an upregulation of IL-4, IL-5, or IL-13. Furthermore, chronic (3-week) hay dust exposure is associated with an increase in the gene expression of IFN-γ in the BAL fluid cells,[26,27] although in one trial, but not in the second trial of the same chronically affected horses, the gene expression of IL-4 was upregulated.[26] Fifth, GATA3, the transcription factor required for IL-4 gene expression, is not upregulated in the bronchial cells of RAO-affected horses.[47] Sixth, IL-4 gene expression in the pulmonary lymph nodes isolated from chronically affected RAO horses is significantly downregulated compared to controls.[48] Importantly, these data *do not* provide evidence that RAO is a Th1 immune response because (1) concomitant increases in the gene expression of T-bet, the transcription factor for IFN-γ expression in CD4+ cells, does not occur.[27] Interestingly, in other species TLR stimulation leads to the production of proinflammatory factors, including IL-12, and subsequent IFN-γ synthesis.[49,50]

In RAO-affected horses there is evidence that, as occurs in human asthmatics, Th17 cells (a subset of T-helper cells) contribute to the immunopathogenesis of RAO.[28,29,48] IL-17, secreted by Th17 cells and some granulocytes, promotes maturation, chemotaxis, and activation of neutrophils. IL-17 also upregulates the gene expression of IL-8 in the airway epithelium and promotes airway neutrophilia. Following chronic (≥2 weeks) hay dust exposure, IL-17 gene expression in BAL cells is upregulated in RAO-affected horses.[28,29] Increased IL-17 protein expression, detected immunohistochemically, is also found in the pulmonary lymph nodes of RAO-affected horses compared to controls.[48]

Currently little is known about the role of regulatory T cells (Tregs) in the immunopathogenesis of RAO. In mice and humans, this subset of CD4+ cells helps control immune responses to viral, bacterial, fungal, and parasitic infections.[51] In a study of RAO-affected horses during remission and exacerbation (4 days of hay challenge), the percentage of Tregs (CD4+, CD25+, Foxp3+) in the BAL increased from a baseline value (remission) of 1.5% to 4% (exacerbation).[52] Investigators hypothesized that the increase in Tregs may help resolve immune-mediated bronchial inflammation.

EPITHELIAL CELLS. The airway epithelium not only serves as a physical barrier but also plays a key role in the secretion of cytokines needed to recruit inflammatory cells, to direct tissue-resident or circulating antigen-presenting cells, and/or to promote lung remodeling. It is likely that the inhaled microbial components bind to the airway epithelium via pattern recognition receptors and initiate an innate immune response with synthesis of inflammatory cytokines and chemokines.[17] In RAO-affected horses, bronchial epithelial IL-8 gene and protein expression is upregulated at least 24 hours after hay challenge,[28,53] potentially contributing to airway neutrophilia. Bronchial gene expression of other chemokines (CXC chemokine ligand 1 [CXCL1], granulocyte-macrophage colony-stimulating factor [GM-CSF], granulocyte colony-stimulating factor [G-CSF]) or cytokines (IL-5, IL-6, IL-10, IL-17, and transforming growth factor [TGF]–β1) is not different between control and diseased horses.[28,53] In a recent transcriptome analysis of endobronchial biopsies from affected horses, investigators reported an upregulation of genes involved in neutrophil chemotaxis (IL-8, CXC chemokine receptor type

2 [CXCR2]) and immune and inflammatory responses (matrix metalloproteinase [MMP]–1, MMP-8), suggesting that bronchial epithelium is an important contributor to the inflammatory process of RAO.[54]

OTHER INFLAMMATORY MEDIATORS. As airway neutrophils and other cells accumulate, other inflammatory mediators are released and contribute to the inflammation. Histamine, released by degranulated mast cells, increases vascular permeability and produces bronchoconstriction. Although mast cell degranulation is typically attributed to IgE-mediated crosslinking of high-affinity receptors (FceRI) on mast cells, leukotrienes, prostaglandin E, acetylcholine, substance P, endothelin, and peptidoglycan induce mast cell degranulation.[55,56] Despite increased histamine concentrations in the BAL of RAO-affected horses, histamine-1 receptor antagonists provide little therapeutic relief for affected horses, suggesting that it is not a predominant inflammatory mediator in RAO.[57] The potential role of prostaglandins, with their bronchoconstrictive ($PGF_{2\alpha}$, PGD_2, thromboxane A2 [TXA2]) and/or bronchodilatory capabilities (PGE2, PGI_2), has also been examined. In a differential gene expression study of lung tissue from RAO-affected horses, PGF synthase, an enzyme that reduces PGD_2 and PGH_2 to $PGF_{2\alpha}$, and PTGDR, a PGD_2 receptor, were upregulated.[58] In diseased horses, increases in BAL PGE2 and $PGF_{2\alpha}$[59,60] and in serum TXB2 (a metabolite of TXA2) occur.[61] Although administration of a cyclooxygenase inhibitor prevents the increase in the serum TXB2 in RAO-affected horses, it does not inhibit the development of airway hyperresponsiveness or bronchospasm in susceptible horses. This suggests that eicosanoids are not the major contributor to clinical signs. Lipoxygenase metabolites have also been investigated in RAO-affected horses. In humans, these compounds are bronchoconstrictors (leukotriene [LT] B4, LTC4, and LTD4), mucus secretagogues (LTC4 and LTD4), and chemokines (LTB4).[62] Inhalation of LTB4 or LTD4 induces airway neutrophilia and bronchoconstriction, respectively, in normal and RAO-affected horses.[63] BAL cells isolated from RAO-affected horses during the first 48 hours of hay dust exposure and stimulated ex vivo produce increased concentrations of LTB4 and LTC4.[62] However, actual BAL concentrations of LTB4 and LTC4 are not elevated in chronically affected horses[60] despite the finding of the enhanced gene expression of LTA4 hydrolase (which metabolizes LTA4 to LTB4) in RAO-affected horses.[58] Pretreatment of RAO-susceptible horses with either a 5-lipoxygenase inhibitor or a LTD4 receptor antagonist before hay dust exposure does not prevent the development of airway neutrophilia or alterations in lung mechanics.[64,65] In addition, treatment of clinically affected horses with the leukotriene receptor antagonist montelukast (LTC4, LTD4, LTE4 antagonist) also fails to improve pulmonary function test results, clinical scores, or arterial blood gas tensions.[66]

Reactive oxygen species derived from pulmonary macrophages and granulocytes contribute to the inflammatory process of RAO.[67] Oxidative stress occurs when enzymatic (superoxide dismutase, glutathione peroxidase, glutathione *S*-transferase) and nonenzymatic antioxidants (glutathione [GSH], ascorbate, α-tocopherol, bilirubin, albumin, and transferrin) are depleted.[68] Evidence of an oxidant stress within the airways of RAO-affected horses is based on the findings of (1) increased levels of oxidized glutathione (glutathione disulfide [GSSG]), (2) increased glutathione redox ratios (GSSG/GSSG + GSH), and (3) decreased ascorbic acid concentrations in the pulmonary epithelial lining fluid of RAO-affected horses.[67-69] Tan and colleagues also reported that both red blood cell and white blood cell glutathione peroxidase activities were significantly increased in RAO-affected horses during exacerbation compared with controls, suggesting a systemic response to the pulmonary inflammation.[68] (Systemic responses are discussed below.) Changes in these indices of oxidant stress correlate with lung dysfunction parameters (pulmonary [R_L], C_{dyn}, and PaO_2) in RAO-susceptible and RAO-affected horses.[70] Although reactive oxygen species (ROS) are well recognized for their microbicidal activities, they also upregulate proinflammatory gene expression by activating NF-κB.[71]

Proteases derived from airway phagocytes, lymphocytes, and epithelial cells may propagate the inflammatory reaction of RAO. MMPs with elastolytic and collagenolytic activities have been identified in the respiratory tract secretions of RAO-affected horses and include MMP-1, MMP-8, MMP-9, and MMP-13.[72-77] The degradative effect of MMP-9 on the basement membrane and on the extracellular matrix components facilitates the extravascular movement of neutrophils into the airways. The collagenase activity of MMP-8 and MMP-13 contributes to airway remodeling during disease exacerbation.[76] In vitro, tetracycline derivatives effectively inhibit MMP activity detected in tracheal epithelial lining fluid,[77] but their efficacy in ameliorating or preventing the inflammatory response of RAO-susceptible horses exposed to hay dust remains to be determined.

Epidemiology and Genetics

RAO occurs in both ponies and horses, but no gender or breed predisposition has been identified.[78,79] The prevalence of RAO is dependent on the geographic region examined. Bracher reported that 60% to 80% of Swiss horses older than 8 years of age suffer from some degree of this disease. In North America and in Europe the prevalence of RAO is estimated to range from 12% to 50%.[78] Although exposure to hay particulates is integral to the development of the disease, the role of a prior viral (or bacterial) infection in inducing susceptibility to hay dust hypersensitivity remains to be established. Horses with IAD (mild to moderate equine asthma) share some of the clinical features of RAO,[80] yet the relationship of IAD to the development of RAO is unknown. Currently there is no evidence that IAD progresses to RAO.[1,3]

A heritable component of RAO disease susceptibility exists. Marti and colleagues examined families of RAO-affected warmblood and Lipizanner horses and found that the risk of developing RAO was 3.2 times higher when one parent (dam or sire) had RAO and 4.6 times higher when both parents did.[81] In segregation and genomic analyses of two families of Swiss Warmblood horses, the mode of inheritance of RAO is characterized by major gene effects but the potential candidate genes differ between the two families.[39,82] In one family of Swiss Warmblood horses, RAO was transmitted in an autosomal recessive mode with the major association of microsatellites or single nucleotide polymorphisms and affected cases being found on equine chromosome 13 (ECA13).[83] In the other family of Swiss Warmblood horses, an autosomal dominant mode of inheritance was found, with the major association found on ECA15.[82] Investigators suggested that the observed genetic heterogeneity between the two families of Swiss Warmblood horses may reflect etiologically distinct subgroups of RAO that are not distinguished phenotypically. Proposed potential candidate genes on ECA13 were those encoding receptors for IL-4 *(IL4R)* and IL-21[39]; on ECA15, a potential gene of interest was *SOCS5* (suppressor of cytokine signaling 5). Using a high-density SNP chip to re-genotype a subset of that same Swiss Warmblood family, Schnider identified an association (single SNP) located in an intron of *TXNDC11;* this locus was separate from the other previously identified regions.[84] *TXNDC11* encodes a thioreductase involved in the degradation of glycoproteins and, in cell cultures, mucin expression by *MUC5AC* gene. However, this SNP association failed to reach Bonferroni corrected genome-wide significance threshold. Although the results are intriguing, it remains to be determined if RAO genetic susceptibility maps to loci on ECA13 and

ECA15 in other horse breeds. Lastly, as copy number variations may help identify candidate genes involved in disease processes, Ghosh and colleagues investigated this in a genomic analysis of RAO-affected and control horses (multiple breed types). Although 20 RAO-specific copy number variant regions were identified in 9 of 16 horses, they were distributed on 15 autosomes, and none was on ECA13.[85]

Clinical Signs and Differential Diagnosis

The severity of clinical signs in RAO-affected horses is variable and is exacerbated by stabling, exposure to dusts, hay, and ammonia fumes. Winter is considered a risk factor for disease exacerbation. However, RAO-susceptible horses kept outdoors during hot, humid summer weather—which may reflect a period of high concentrations of airborne pollen and spores—also exhibit a worsening of clinical signs.[86] In a study of 148 cases of RAO presented for evaluation to a veterinary referral hospital in the United Kingdom, the chief complaints (median duration of which was 7 months) were coughing (84% of cases), bilateral nasal discharge (54%), exercise intolerance (51%), and postexercise breathing difficulty (23%).[87] In a review of 16 cases presented to a veterinary teaching hospital in western Canada, the most common historical complaint (88% of cases) was coughing.[88] In a review of 65 cases presented to a veterinary teaching hospital in the northeastern United States, the primary problems were abnormal breathing effort (68% of cases), nasal discharge (50%), and a spontaneous cough (46%).[89]

On physical examination, mildly affected horses are typically afebrile and exhibit a bright demeanor and a normal or slightly accentuated (abdominal) breathing effort, respiratory rate, and heart rate. Nasal discharge may not be evident in all cases, perhaps because horses swallow excessively the expectorated exudate. When the horse is exercised, a thick white nasal discharge and a cough become apparent. The frequency of coughing increases when horses are stabled, often exceeding 10 to 15 coughs per hour.[90] More severely affected horses exhibit tachypnea (respiratory rate >40 breaths/min), nostril flaring, and a markedly accentuated expiratory effort (heave). The thoracic expiratory component may precede that of the abdominal compartment, producing a "double effort."[91] Abdominal pressure swings may be large enough to cause the anus to protrude with expiration. Paroxysmal coughing, bilateral nasal discharge, anxious facial expression, flatulence during coughing, reluctance to move, inappetence, and weight loss occur in the most severely affected cases.

Although RAO is a diffuse lung disease, auscultation of mild cases may not reveal abnormal lung sounds unless a rebreathing bag is used to induce a hyperpnea. In one survey, abnormal thoracic (47% of cases) and tracheal (63% of cases) auscultation occurred.[87] In the latter, abnormal lung sounds and "mucus clicks" (tracheal exudate) were detected by tracheal auscultation. In mildly affected horses, only regional areas of adventitious lung sounds (crackles or high-pitched expiratory wheezes) may be detected. In contrast, in severely affected horses, wheezes and mucus clicks may be heard at the horse's nostrils without the use of a stethoscope. Depending on the severity of the disease, thoracic percussion may be normal or may reveal expansion of the caudal lung fields beyond the normal line of pleural reflection.

Researchers have developed clinical scoring systems to categorize the severity of RAO. In moderately to severely affected horses, there is a very good correlation between the clinical signs and alterations in R_L or C_{dyn},[92] but in mild cases, clinical scores underestimate the severity of changes in the pulmonary function tests. In another study of 30 RAO-affected horses and 10 controls, investigators found that the severity of some clinical signs (e.g., cough, nostril flare, abdominal lift but not breathing frequency, thoracic auscultation, exercise intolerance) correlated with tracheal mucus scores, BAL neutrophil percentages, and thoracic radiographic evidence of bronchial and tracheal thickening.[93]

In rare cases, horses with long-standing RAO develop cor pulmonale, evidenced by jugular distention, pulsation, ventral edema, and tachycardia.[94,95] Although RAO-susceptible horses exhibit echocardiographic alterations during acute episodes of RAO (characterized by an increase in pulmonary artery diameter, a decrease in left ventricular diameter, and an abnormal septal motion), serum troponin measurements remain normal.[96] Because the echocardiographic parameters (reductions in the circumferential ratio of the aorta to the pulmonary artery and in the mass ratio of the left ventricle and septum to the right ventricle) return to normal when horses are in remission, it is likely that the reversibility of the airway disease reduces the risk of permanent myocardial disease.[95,97]

Laboratory Aids and Diagnostic Tests

The diagnosis of RAO is based on the history, the clinical signs, demonstration of the reversibility of airway obstruction following bronchodilator administration, and the response to therapy. A definitive diagnosis may be challenging in asymptomatic or mildly affected cases necessitating a "hay challenge" to precipitate clinical signs. Endoscopic examination of the respiratory tract of RAO-affected horses demonstrates excessive amounts of tracheobronchial secretions (mucus) that originate from most of the bronchial segments. Distal airways are edematous and inflamed, and airways easily collapse during expiration. Expectorated secretions from the lower respiratory tract coat the pharynx, larynx, and other structures of the upper respiratory tract. Cytologic analysis of lower respiratory tract secretions (BAL) is helpful in symptomatic cases. During periods of clinical remission, BAL cell populations obtained from RAO-susceptible horses consist predominantly of mononuclear cells (90% macrophages and lymphocytes) and do not differ from those found in healthy horses.[98] BAL from symptomatic horses contains more than 25% nondegenerative neutrophils and often exceeds 90% of the total nucleated cell count. Yet the extent of pulmonary neutrophilia alone is not correlated with severity of clinical signs.[99] In most cases the percentage of eosinophils or mast cells is not increased in affected horses. Thus cytologic analysis of BAL in RAO-affected horses reflects a suppurative nonseptic inflammation with increased mucus concentrations, distinguishing this disorder from lungworm infections (pulmonary eosinophilia), bacterial pneumonia (degenerative neutrophils, intracellular bacteria), or fungal pneumonia (degenerative neutrophils, hyphae, erythrocytes). In rare cases, infectious bronchitis may complicate RAO.

In general, the complete blood cell count (CBC) and serum biochemistry profiles are usually normal in RAO-affected horses.[89] In severely affected horses, a mature neutrophilia and lymphopenia may be evident on the leukogram. The "stress leukogram" reflects the effects of increased plasma cortisol concentrations that occur at least 6 hours after RAO-susceptible horses are exposed to a high-dust environment.[100] Significant increases in serum haptoglobin, amyloid A, and functional fibrinogen concentrations in RAO-affected horses (maintained in dusty environments for >30 days) occur, challenging the conventional idea that RAO is a compartmentalized inflammatory response.[101,102]

Arterial blood gas analyses are normal in approximately 25% of the cases[103]; other cases exhibit hypoxemia (PaO_2 <85 mm Hg) with or without evidence of arterial hypercapnia.[104] In symptomatic horses that are exercised, at a given work effort the arterial oxygen tensions are reduced compared with blood gas values obtained from the same horses during clinical remission.[105] The prognostic value of arterial blood gas alterations in RAO-affected horses has not been examined.

Digital thoracic radiographs of RAO-affected horses demonstrate an unstructured interstitial and/or bronchointerstitial

VetBooks.ir

pattern. The diaphragmatic silhouette may be flattened or concave in some horses, presumably due to lung hyperinflations.[106] Yet radiographs are of limited value in diagnosing RAO because the accentuated bronchointerstitial pattern can be detected in healthy aged horses. Radiographs are useful in *ruling out* thoracic neoplastic or infectious disorders (e.g., interstitial or bronchopneumonia pneumonia, equine multinodular pulmonary fibrosis) in horses that have clinical signs resembling RAO (cough, nasal discharge, abnormal breathing effort). In severely affected horses that repeatedly fail to respond to medical interventions, radiographs should be taken to determine if bronchiectasis (dilation or deformation of the bronchi or bronchioles) exists.[107] Bronchiectasis causes irreversible airway obstruction due to collapse of affected airways; it is a relatively uncommon complication of RAO.

Ultrasound evaluation of RAO-affected horses confirms a shift of the caudal lung border caused by alveolar hyperinflation.[108] However, gas in the large colon (left side) or in the cecum (right side) may preclude complete imaging of the most caudal extent of the lung fields at the sixteenth intercostal space. Thoracic ultrasonograms demonstrate small hypoechoic areas of irregularity on the lung surface. Ultrasonography is not useful in detecting airway inflammation.

Lung biopsies, although not typically performed to diagnose RAO, demonstrate bronchiolar goblet cell metaplasia, bronchiolar luminal exudate, peribronchiolar lymphoplasmacytic cell infiltration, and accumulations of neutrophils within the airways.[88] The potential disadvantages of performing a lung biopsy include the risk of inducing hemorrhage (hemothorax, epistaxis) and the chance of obtaining a nonrepresentative tissue sample.

Intradermal skin testing of RAO-affected horses has been investigated extensively with the aim of diagnosing RAO and identifying the offending allergens. In separate studies, Evans and Jose-Cunilleras found that the total number of positive intradermal skin tests evaluated at 0.5, 4 to 6, and 24 hours after allergen injection was greater in RAO-affected horses compared to controls but that this difference in skin reactivity did not permit discrimination between a diseased horse and a healthy horse.[109,110] In contrast, others have failed to find a significant difference between RAO-affected and control horses in the number of positive skin responses to a variety of molds at either the early (0.5, 4 hours) or the late (24 hours) phases.[111-113] Wong and colleagues, evaluating the skin responses to intradermal histamine and *Aspergillus* antigens, found that compared with the controls, the RAO-affected horses had a heightened response to histamine (evaluated at 0.5 hours post injection) and a delayed resolution of the skin wheal (after 24 hours) to the *Aspergillus* antigens.[114] In general, positive skin tests and serum precipitins to fungal and thermophilic actinomycete antigens are found in many normal as well as RAO-affected horses, reflecting a level of exposure of the horse rather than a susceptibility to disease. Skin testing does not allow identification of RAO-susceptible or RAO-affected horses or of the specific inhaled particulate that is inciting the pulmonary inflammation.[115]

Serum allergy tests such as the radioallergosorbent test (RAST) or IgE-based ELISA, which aim to identify the allergen that is inciting the hypersensitivity, are of limited value in the diagnosis of RAO. Lorch and colleagues compared the results of three serum IgE quantitation assays—the spot test (a RAST), an ELISA that uses a recombinant human FceRIα chain as the IgE readout reagent (Allercept [Heska, Loveland, Colo.]), and an equine ELISA that uses a polyclonal antiserum to detect equine IgE—with intradermal skin test responses in RAO-affected horses. They concluded that based on the poor performance of all three tests, none should be used as a screening test for allergen hypersensitivity.[116] Similar conclusions were reached by Tahon and colleagues, who compared the Allercept test and the CAST test (Alpco [Windham, N.H.]), which measures IgE-mediated release of sulfidoleukotrienes from peripheral blood basophils, with intradermal testing in RAO-affected horses and controls. None of the tests showed a significant difference in responses between diseased and control horses, and thus these tests did not support an IgE-mediated basis for RAO.[45]

Conventional pulmonary function tests (PFTs), used primarily in research investigations to confirm the diagnosis of RAO, require measurements of transpleural pressure changes (obtained via an intrathoracic esophageal balloon catheter system) either alone or in combination with airflow measurements (detected by a flow meter attached to a sealed face mask worn by the horse). Horses with RAO exhibit a decrease in dynamic lung compliance or lung distensibility (C_{dyn}), an increase in pulmonary resistance (R_L), an increase in maximum pleural pressure changes (ΔP_{plmax}), and an increase in peak inspiratory and expiratory flow rates.[117] In general, C_{dyn} reflects changes in peripheral airway function, whereas R_L reflects central, larger airway function. RAO-affected horses also exhibit bronchial hyperreactivity: The dose of aerosolized histamine or methacholine required to reduce C_{dyn} to 65% of its baseline value is much less in diseased horses than in controls.[118] During periods of clinical remission, PFTs are not different from those of healthy age-matched horses. Yet when using more sensitive tests of airway disease, horses in remission still maintain some degree of bronchial hyperreactivity and airflow obstruction,[119,120] demonstrating that conventional PFTs lack sensitivity.[121,122]

The changes in respiratory mechanics and the development of clinical signs are consequences of the influx of inflammatory cells, the contraction of smooth muscle in the airways, the production and accumulation of mucus, and possibly remodeling of the lung parenchyma (see below). Bronchoconstriction probably results from the cumulative effects of (1) released inflammatory mediators (histamine, serotonin, eicosanoids, leukotrienes, endothelin) and (2) activation of muscarinic receptors on the smooth muscle by released acetylcholine.[123] In addition to their direct effects on smooth muscle tension, histamine and serotonin also augment the release of acetylcholine from parasympathetic nerves.[124] Based on in vitro muscle bath studies, there is evidence that RAO-affected horses lack inhibitory nonadrenergic-noncholinergic innervation of the peripheral (but not central) airways, further contributing to the development of bronchospasm.[125] However, the expression or distribution of airway muscarinic receptor subtypes (M_1, M_2, M_3) is unaltered in RAO-affected horses.[126]

As noted earlier, excessive mucus is evident endoscopically and cytologically in RAO-affected horses. This may be the result of increased mucus viscoelasticity[127,128] and an impairment of the mucociliary apparatus damaged from epithelial cell destruction.[129,130] An increase in the number of mucus cells and their delayed apoptosis may also be contributory.[122] An upregulation of two mucin-producing genes, *MUC5AC* and *MUC2*, in airway tissues of RAO-affected horses has not been detected.[131,132]

Airways that are narrowed, obstructed, or both (as a result of inflammatory cells, mucus, and alterations in pulmonary surfactant)[133,134] increase R_L and fail to participate in efficient gas exchange. Low ventilation-perfusion lung regions contribute to a widening of the alveolar-arterial oxygen-difference ($AaDO_2$) gradient and the development of arterial hypoxemia.[135,136] High ventilation-perfusion regions (dead space) also increase in affected horses, but normal arterial $PaCO_2$ levels can be maintained in some horses through increases in the total minute ventilation.[137] Changes in minute ventilation are usually due to an increase in breathing frequency, as tidal volume changes little with the disease. In general, there are no significant changes in cardiac output, heart rate, and mean systemic arterial pressure, but pulmonary artery systolic and mean pressures

VetBooks.ir

and pulmonary vascular resistances are significantly increased in diseased horses.[137] The combination of airway inflammation and hypoxemia, if severe enough, stimulates the respiratory controller in the ventral medulla to increase the respiratory drive and to activate inspiratory and expiratory muscles (abdominal heave). Recruitment of respiratory muscles increases the maximum pleural pressure excursion (ΔP_{plmax}), the work of breathing, and the total body oxygen consumption.[138] However, much of the increased expiratory effort (and increased intrathoracic pressures) collapses the noncartilaginous airways, further compounding gas trapping and impairing gas exchange.

Pathology The lungs obtained from RAO horses in remission at the time of death appear normal.[135] In symptomatic horses, the lungs are pink, soft, hyperinflated, and imprinted with rib impressions. Lungs fail to collapse when the chest is opened because of gas trapping distal to occluded airways.[111] Emphysematous bullae are usually lacking, but accumulations of mucus and cellular debris occlude the small airways, forming spiral-shaped casts known as *Curschmann's spirals*. Light and electron microscopic examinations of lung segments from diseased horses demonstrate that the peripheral airways are the most severely affected but central airways are not spared.[129,130] Histologic changes include goblet cell hyperplasia, epithelial cell damage, bronchial and bronchiolar epithelial cell hyperplasia, smooth muscle hypertrophy and hyperplasia, increased collagen and elastin deposition in the lamina propria, and overinflation of the alveoli.[139-141] Pathologic changes occur in response to pulmonary inflammatory mediators (release of neutrophil-derived exosomes, ROS, MMPs)[142] and mechanical loads on the airways. Peribronchiolar infiltrates consist of lymphocytes and plasma cells, along with collagen deposition[143]; eosinophils are rarely observed either within the airways or in the lung parenchyma. Airway remodeling (changes in airway smooth muscle [ASM] mass and collagen) as a function of antigen exposure, avoidance (pasture), and/or antiinflammatory and bronchodilator therapy have been extensively studied. Compared to age-matched controls, the ASM mass in the peripheral airways of RAO horses in remission is increased two- to threefold.[144] When RAO-affected horses are treated with either pasture turnout (antigen avoidance) or daily inhaled fluticasone for 12 months, a 30% reduction in peripheral ASM mass is observed.[145] A similar reduction in ASM mass occurs when RAO-affected horses are maintained in an antigen avoidance environment (pasture) while receiving daily inhaled fluticasone/salmeterol for 3 months,[146] an effect attributed to the steroid and not the bronchodilator. In the central airways, fluticasone/salmeterol treatment reversed extracellular matrix remodeling (of which collagen is a component) both within the lamina propria (decreased thickness) and within the smooth muscle layer.[146]

Treatment and Prognosis

ENVIRONMENTAL MANAGEMENT. Environmental management remains the single most important therapeutic and prophylactic intervention. RAO-prone and RAO-affected horses should be kept outside at all times, blanketed during inclement weather as needed, and provided access to a well-ventilated, two- or three-sided shelter free of manure and urine (ammonia) fumes. When pasture is limited, the diet is supplemented with complete pelleted feed or hay cubes. Some horses will tolerate hay that has been soaked in water, but this practice is often forsaken when the weather becomes cold. Steaming hay can prevent exacerbations of RAO in susceptible horses,[147] as this reduces bacterial and mold counts of the hay.[148] In affected horses that have been turned out to pasture, clinical remission and normalization of pulmonary function test results usually take 4 to 8 weeks depending on weather conditions.[149] Reductions in peripheral airway smooth muscle mass take 12 months.[145] Acute exacerbations of RAO occur in pastured, susceptible horses during periods of hot, humid weather.[86,150] Owners should provide an alternative clean, cool environment during these periods to reduce the risk of pulmonary crises in susceptible horses.

In addition to alterations in forage, horses that are stabled should be bedded on a material that has a low respirable dust particle count. Cardboard bedding has a significantly lower particulate concentration (dust, *A. fumigatus*, *F. rectivirgula*, and *T. vulgaris*) than do wood shavings, wheat, or flax straw, although cardboard may be difficult to obtain and store.[149,151] Auger and colleagues found optimal reductions in airborne respirable dust in barns when horses were bedded on shavings and fed steamed hay.[152] In affected horses that are bedded on shavings and fed pelleted rations, significant improvements in the PFT results occur within 3 days.[153] Complete resolution of clinical signs may take 30 days, although not all horses respond to only allergen reduction measures while stabled indoors.[154] When implementing changes for RAO-susceptible horses, attention should be given to making similar alterations to surrounding stalls within the common airspace.[122,155] At-risk horses should be removed from the barn when stalls or other areas are being cleaned. When environmental management changes are implemented, horses in remission can remain clinically normal for months and exhibit normalization of BAL fluid neutrophil percentages and other indices of airway inflammation such as exhaled ethane. Nevertheless, bronchial hyperreactivity and forced expiratory airflow in RAO-prone horses still remain abnormal.[119,156-158] Therefore these horses will always be more susceptible to disease development than healthy horses.

Environmental management considerations should also be implemented when horses are transported. Their heads should not be tied in close proximity to the hay net, as this practice places their breathing zone near a concentrated source of organic dusts and molds and restricts their head position so as to further decrease mucociliary clearance of respiratory secretions.[159]

BRONCHODILATORS. During acute exacerbations of RAO, bronchodilators improve lung mechanics and are useful in establishing the reversibility (and thus diagnosis) of RAO. The three main classes of bronchodilators that have been used in RAO-affected horses are the anticholinergics (muscarinic antagonists), the β_2-agonists, and the phosphodiesterase (PDE) inhibitors.

Muscarinic antagonists such as atropine, ipratropium, and N-butyl-scopolammonium bromide block the smooth muscle–constricting effects of acetylcholine. These actions exert the greatest effects in the central as opposed to the peripheral airways. IV administration of 0.01 to 0.02 mg/kg of atropine sulfate improves clinical signs and pulmonary function parameters (ΔP_{plmax}, respiratory rate, R_L, E_L) within 10 minutes of administration.[160-162] Atropine's short duration of action (2 hours) and undesirable side effects (mydriasis, ileus, tachycardia, dry airway secretions) preclude its routine use in the treatment of RAO. In contrast, ipratropium bromide is poorly absorbed from either the respiratory or the GI tract, minimizing the development of systemic effects. The powder form is nebulized (2 to 3 µg/kg) and exhibits an onset of action within 30 minutes; effects last from 4 to 6 hours.[163] In resting horses it reduces R_L and ΔP_{plmax} and increases C_{dyn} but produces no further improvement if horses are exercised.[164] N-butyl-scopolammonium bromide, when administered at 0.3 mg/kg IV, improves clinical scores and pulmonary function tests of RAO-affected horses within 10 minutes of its administration; effects last for 30 to 60 minutes.[162,165] No clinically adverse effects were noted following its use in research trials.

The β_2-adrenergic agonists—clenbuterol, albuterol, levalbuterol, and salmeterol—produce relaxation of smooth muscle

by increasing the intracellular levels of cyclic adenosine monophosphate (cAMP). The bioavailability of clenbuterol is greater than 90%, and when administered orally at a dose of 1.6 µg/kg of body weight twice per day (bid), a significant improvement in the clinical signs of affected horses can occur.[166] The effective dosage of clenbuterol varies among horses. If clinical improvement is not observed within 3 days of initiating treatment, the dose is increased stepwise (e.g., 2.4 µg/kg for 3 days, 3.2 µg/kg for 3 days). Adverse side effects (anxiety, shivering, sweating, and tachycardia) occur at higher dosages but may be minimized if clenbuterol is increased in a stepwise manner. Reports of fatal overdoses of clenbuterol in horses estimated to have received 100 µg/kg orally of a compounded product have occurred.[167] In addition to its bronchodilatory effect, clenbuterol also exerts an antiinflammatory effect: IV administration (0.75 µg/kg bid) to RAO-susceptible horses prior to hay dust exposure attenuates BAL fluid neutrophilia and TNF-α and IL-1 gene transcription.[168] Prolonged administration of clenbuterol (0.8 µg/kg bid for 3 weeks) may result in tachyphylaxis[169] due to downregulation of β-adrenoceptors, but this phenomenon may be reversed with concurrent corticosteroid administration.[170]

Aerosolized β_2-agonists are used to treat RAO-affected horses and permit direct delivery of the drug to the respiratory tract, minimizing the total amount of drug needed and reducing the prevalence of unfavorable systemic effects. The metered dose inhaler containing the drug is attached to a delivery system such as the Equine Haler (Equine Health Care, Inc., Hørsholm, Denmark) or Aerohippus (Trudell Medical, Inc., London, Canada). Both devices exhibit similar efficacy in drug delivery and clinical improvement.[171] Albuterol sulfate and levalbuterol improve pulmonary function by 60% to 70% in RAO-affected horses for approximately 1 to 3 hours, necessitating frequent administration of the drugs.[172,173] They are poorly absorbed, so systemic effects are uncommon. These drugs are typically used in "rescue" protocols to treat horses in respiratory distress. The recommended dose of albuterol is 1 to 2 µg/kg q1-4h and of levalbuterol is 0.5 µg/kg q4h.[174] Salmeterol, a long-acting β_2-agonist, is administered at a dose of 0.5 µg/kg q6-8h. Clinical improvement develops within 2 hours of administration, and significant decreases in pulmonary resistance last for 6 hours.[175]

Aminophylline and pentoxifylline are examples of the PDE inhibitors that produce smooth muscle relaxation by inhibiting the breakdown of intracellular cAMP. PDE inhibitors also exert antiinflammatory properties.[176] Administration of 12 mg/kg IV of aminophylline (in 1 L of 5% dextrose) improved clinical signs and reduced ΔP_{plmax} in approximately 50% of RAO cases[161] but caused hyperexcitability, hyperesthesia. and trembling. Because of the narrow range between therapeutic efficacy (serum concentration of 10 µg/mL) and toxicity (serum concentration of 15 µg/mL), aminophylline is not routinely used for the treatment of RAO. Pentoxifylline is well absorbed after oral administration (32 mg/kg q12h), improves some indices of pulmonary function, but does not improve BAL fluid neutrophilia.[177]

ANTIINFLAMMATORY DRUGS. NSAIDs, in contrast to corticosteroids, are not beneficial in the treatment of RAO.[61] Of the glucocorticoids evaluated, oral prednisone is not used because of its poor bioavailability and lack of conversion to the active metabolite prednisolone.[178,179] Liquid and tablet forms of prednisolone are rapidly absorbed from the equine GI tract (bioavailability is approximately 50%), achieve peak concentrations 45 minutes post administration, and exert pharmacologic effects (based on changes in serum cortisol levels) for 8 hours.[179] Oral prednisolone (2 mg/kg PO once per day [sid] for 7 days) improved R_L, E_L, and ΔP_{plmax} within 3 days of its administration to RAO-affected horses stabled and continuously exposed to dusty hay. It was less efficacious than dexamethasone administered by intravenous (1 mg/kg q24h)[178] or oral (0.05 mg/kg q24h)[180] routes.

In RAO-affected horses receiving dexamethasone, within 2 hours of IV administration (0.1 mg/kg) there is a 37% decrease in ΔP_{plmax} that is further reduced by 4 hours post treatment.[181] Oral administration of the parenteral formulation of dexamethasone (0.164 mg/kg q24h to account for bioavailability) improves lung function parameters within 6 hours of treatment, with peak effects occurring 24 hours later. When horses are maintained in dusty environments, IV dexamethasone (0.1 mg/kg q24h) or dexamethasone isonicotinate (0.04 mg/kg IM every 3 days for three treatments) improves pulmonary function within 3 days of initiating therapy[178,181] and reduces airway inflammation (BAL fluid neutrophilia) within 10 days of treatment.[178,182] As might be predicted, a single dose of dexamethasone isonicotinate (0.06 mg/kg IM) administered to RAO-affected horses maintained in a dusty environment fails to provide discernible improvements in the clinical score, the PFT results, the BAL cytologic findings, or the activities of the transcription factors NF-κB or activator protein 1 (AP-1) evaluated 10 days post treatment.[183] In general, the rapid onset of action of IV dexamethasone makes it an antiinflammatory of choice in horses exhibiting respiratory distress caused by RAO.[184]

Long-acting corticosteroids have also been evaluated in RAO-affected horses maintained in a dusty environment. A single IM dose of triamcinolone acetonide (0.09 mg/kg) markedly improved lung mechanics for 4 weeks. Cytologic changes (evaluated 14 days post treatment) demonstrated a reduction in airway neutrophilia (from 62% to 32%), but this change was not statistically significant.[185] Adverse effects of triamcinolone administration were not reported. In another study, RAO-affected horses received isoflupredone acetate for 14 days (0.03 mg/kg IM q24h) while being maintained in a dusty environment. Significant improvements in pulmonary function indices occurred within 3 days of initiation of the treatment,[186] and beneficial effects continued 7 days beyond the cessation of drug therapy. The only adverse effect noted was the development of hypokalemia.

Inhaled corticosteroids such as beclomethasone and fluticasone have been used with success to treat RAO. In a 3-week study, fluticasone proprionate (2 mg q12h) was administered to RAO-affected horses while they were stabled and fed "good"-quality hay. By day 21, marked improvements in PFTs and normalization of BAL neutrophil counts occurred.[26] Robinson and colleagues compared the effects of inhaled fluticasone (6 mg bid) and IV dexamethasone (0.1 mg/kg q24h) on PFTs and BAL cytologies in RAO-affected horses.[184] They found that (1) no adverse effects, including laminitis, were associated with a 3-day course of fluticasone at 6 mg bid; (2) greater reductions in ΔP_{plmax} in RAO-affected horses were achieved with dexamethasone than with fluticasone treatment; and (3) prophylactic (3-day) and continual (4-day) administration of fluticasone (6 mg bid) to RAO-susceptible horses subjected to stabling and dusty hay exposure were more efficacious in preventing the disease than was dexamethasone. They recommended that dexamethasone should be used for "rescue" therapy and fluticasone used as a preventive agent. Fluticasone is approximately 18 times more potent than another inhaled corticosteroid, beclomethasone dipropionate. Nasal or oral administration of fluticasone has no effect on circulating glucocorticoid levels, suggesting that its bioavailability across nasal and intestinal epithelium is poor.[187] However, daily aerosolization of fluticasone (dose of 1.5, 3, or 6 mg bid) significantly reduces serum cortisol measured 72 hours after initiating therapy.[184,187] The effect of long-term fluticasone administration on immunologic parameters has also been investigated. Administration of fluticasone (2 mg bid for 11 months) to RAO-affected or susceptible horses had no significant

VetBooks.ir

effect on (1) peripheral blood leukocyte, neutrophil, or lymphocyte numbers; (2) percentages of lymphocyte phenotypes; (3) blood neutrophil chemokine (IL-8, TNF-α) and glucocorticoid receptor gene expression; (4) IgG vaccine titers induced by immunization against tetanus toxoid or an inactivated infectious bovine rhinotracheitis (IBR) vaccine; or (5) mitogen-induced lymphocyte proliferative responses.[188] These data suggest that fluticasone is a relatively safe drug for use in the treatment of RAO.

Another inhaled corticosteroid that has been widely investigated in RAO-affected horses is beclomethasone dipropionate. When administered at a dose of 1320 to 1500 μg bid for 7 to 10 days to diseased horses continuously stabled and fed dusty hay, investigators noted that by day 7 of treatment there was a significant improvement but not a complete normalization of pulmonary function test results and BAL fluid neutrophil percentages.[182,189]

Inhaled steroids are often used in conjunction with inhaled bronchodilators for maximal therapeutic effects. When separate formulations are used, it is recommended that the bronchodilator be administered first so as to improve subsequent glucocorticoid deposition in the peripheral airways.[190] As suggested earlier, when administering glucocorticoids, adrenal gland atrophy, immunosuppression, and precipitation of laminitis remain a concern. All of the previously discussed parenteral and inhaled glucocorticoids reduce endogenous serum cortisol levels, but despite prolonged treatment protocols with glucocorticoids, adrenal gland responsiveness to adrenocorticotropic hormone administration remains.[185,186,189,191] Despite the improvement in clinical signs and in PFTs achieved with glucocorticoid therapy, BAL neutrophilia remains evident until environmental management changes are implemented.

OTHER THERAPIES. In horses that develop respiratory distress because of the bronchospasm and airway inflammation, additional therapies are required. Administering nasal oxygen at flow rates as low as 5 L/min improves arterial oxygen tension by as much as 30 mm Hg in some severely affected horses.[192] Flow rates of 30 L/min (delivered by 2 nasal cannulae at 15 L/min) are associated with coughing and gagging in horses. Nasal oxygen supplementation does not reduce breathing frequency, suggesting that stimulation of vagally mediated afferents (perhaps responding to inflammatory mediators) is responsible for the tachypnea.

Furosemide (1 mg/kg IV or nebulized) provides beneficial effects to RAO-affected horses within 20 minutes of its administration, decreasing R_L and increasing C_{dyn} without affecting PaO_2.[193] The beneficial effects appear to be mediated by PGE2, derived from either the renal or the airway epithelium, which promotes smooth muscle relaxation. Prior treatment with the cyclooxygenase inhibitor flunixin meglumine prevents the furosemide-induced bronchodilation.[194] Furosemide may have a local effect on vagal sensory afferent discharge independent of reflex anticholinergic bronchodilation.[195]

Another therapeutic agent proposed for the treatment of RAO is tamoxifen. This is a selective estrogen receptor modulator that, when administered at 100 mg PO every other day for three treatments, reduced airway neutrophilia in RAO-affected horses.[196] Tamoxifen also enhances apoptosis of peripheral blood and BAL neutrophils. Long-term studies of its efficacy and safety remain to be conducted.

Finally, Barussi and colleagues reported that in a clinical trial with only four horses, intratracheal instillation of autologous bone marrow–derived mononuclear cells improved clinical scores and reduced BAL neutrophilia.[197] Larger studies need to be completed before this approach can be recommended.

Additional therapeutic approaches that have *not* been found to be efficacious in the treatment of RAO-affected horses include a single acupuncture treatment,[198] the oral administration of an herbal preparation containing thyme and primula,[199] the rapid IV administration of 30 L of isotonic saline,[200] treatment with a constant rate infusion of IV lidocaine,[201] and sound-wave physiotherapy.[202]

Prognosis RAO-prone horses are likely to develop acute exacerbations of the disease when husbandry practices lapse or when weather conditions become adverse. Horses do not "outgrow" the disorder, and in fact some clinicians believe that the inflammation becomes more difficult to manage as the horse ages. The basis for the lack of clinical response is unknown but may be the result of lung remodeling or potential downregulation of the glucocorticoid receptor.

If proper environmental management changes are implemented and if the appropriate therapy is initiated, clinical remission occurs in most cases. In a follow-up survey conducted by Naylor of RAO-affected horses that had been examined and treated at a referral center 2 to 4 years previously, it was found that 20% of the original cases (3 of 15) had been euthanized, 33% were still receiving bronchodilators on an as-needed basis, and athleticism had not decreased in 92% of the horses.[88] Similarly, in a follow-up survey conducted by Aviza and colleagues,[89] 13% of the horses that had been diagnosed with RAO 3 to 4 years earlier had been euthanized. However, in contrast to Naylor's findings, Aviza noted that more than 50% of the respondents in that survey stated that the athletic performance of the horse had been compromised by the disease. Perhaps this difference between the two surveys simply reflected a failure of the owners to comply with environmental management recommendations. When queried about the husbandry practices, 77% of the respondents still stabled the horse for part of the day, and 84% still fed the horse dry hay.[89]

Because the effects of repetitive episodes on the development of irreversible changes in lung structure have yet to be determined, clients should be encouraged to implement effective husbandry changes that minimize the recurrences of RAO and prevent pulmonary parenchymal damage.

Summer Pasture-Associated Obstructive Pulmonary Disease

Dorothy M. Ainsworth

Definition and Etiopathogenesis A condition clinically similar to RAO develops in mature horses in the southeastern United States that are kept outdoors on pasture. It is called *summer pasture–associated obstructive pulmonary disease* (SPAOPD), pasture asthma, or more recently severe equine asthma. As with RAO, this new term applies to horses that are exhibiting clinical exacerbations or are in remission. Clinical signs typically occur in June through September when the weather is warm and humid[1]; clinical signs resolve partially or completely when the horse is removed from the pasture. Winter manifestations of the disease are uncommon. Clinical signs parallel increases in environmental fungal spore (basidiospore, *Nigrospora*, and *Curvularia*) and grass (Bermuda grass and Johnson grass) pollen counts,[2] suggesting that aeroallergens (and potentially others) trigger the disease. SPAOPD has also been reported in horses in the United Kingdom, although some of those cases may represent horses with underlying RAO whose condition is exacerbated by hot weather and airborne particulates.[3-6]

As with RAO, the immunopathogenesis of SPAOPD is uncertain. In one study, neither the total nor the antigen-specific IgE and IgG titers to certain fungi (*Aspergillus* spp., *Cladosporium herbarum*, *Penicillium* spp.), to thermophilic actinomycetes species *(Faenia rectivirgula*, *Saccharomonospora viridis*, *Thermoactinomyces thalpophilus)*, or to the forage mite *Lepidoglyphus destructor* in the tracheal lavage fluid were

VetBooks.ir

increased in SPAOPD-affected horses relative to controls.[7] Cytokine mRNA profiles in BAL cells and in peripheral blood mononuclear cells (PBMCs) isolated from SPAOPD-affected and control horses fail to provide consistent support for a polarized response. Increased IL-4 and IFN-γ copy number in BAL cells and PBMCs isolated from affected horses relative to controls was reported in one study.[8] In another investigation by the same group,[9] the gene expression of IFN-γ and IL-13 (but not IL-4) in BAL cells and peripheral blood lymphocytes isolated from symptomatic horses exceeded that of controls.

In a gene expression study of peripheral lung tissue isolated from affected and control horses,[10] 18 genes of known function were differentially expressed and found to be involved with lung protection, defense, mediation of proinflammatory or antiinflammatory responses, promotion of or protection from oxidative stress, cell recovery and repair, and mitogenesis. Of the 18 genes, only secretoglobin was downregulated in diseased horses—similar to what occurs in RAO horses.[11-13] In addition to blocking phospholipase A2 activation, secretoglobin reduces IL-8–enhanced neutrophil chemotaxis. Venugopal also reported upregulation of eight genes that encode proteins associated with cell repair and proliferation[10] involved in lung repair and airway remodeling, supporting histopathologic changes previously described in affected horses.[14] Differential expression of immune cytokines (IL-4, IFN-γ, IL-17, TGF-β) was not reported in their transcriptome study of lung tissue.

Because of its role in the pathophysiology of human obstructive pulmonary disorders, investigators have also evaluated endothelin-1 (ET-1) concentrations in horses with SPAOPD. This 21–amino acid peptide induces bronchoconstriction; enhances mucus secretion; promotes DNA syntheses and cell proliferation in airway smooth muscle cells; and facilitates airway inflammation by upregulating IL-1, IL-4, IL-8, TNF-α, and IFN-γ expression.[15,16] Compared with control horses, SPAOPD-affected horses have increased ET-1 protein concentrations in the venous blood, BAL, and pulmonary epithelial lining fluid.[16] This finding, coupled with the observation that endothelin receptors A and B in the bronchial smooth muscle of affected horses are increased,[15] suggests that ET-1 is just one of many mediators involved in the pathophysiology of SPAOPD.

Clinical Signs and Differential Diagnoses The clinical signs of SPAOPD are seasonal, reversible, and vary in severity. As with RAO, initial signs can be subtle and include exercise intolerance, intermittent cough, intermittent nasal discharge (serous or mucoid), and tachypnea. Horses are afebrile. As the disease progresses, accentuated expiratory efforts (heave line), nostril flaring, frequent coughing, and even respiratory distress can occur.[1] Crackles, wheezes, and "silent areas," suggesting the absence of air movement, may be auscultated.[1,14] Differential diagnoses include bacterial, viral, or fungal respiratory infections (ruled out by evaluation of blood work and culture and examination of tracheal aspirates) and anhidrosis (ruled out by assessing sweat production in affected animals).

Diagnosis Historical and physical examination findings, along with the temporal development of clinical signs, support the diagnosis of SPAOPD. As with RAO, endoscopy of the lower respiratory tract reveals an accumulation of mucopurulent exudate within the tracheobronchial tree, evidence of bronchial epithelial hyperemia and dynamic collapse of intrathoracic airways during expiration. Cytologic analysis of BAL fluid demonstrates neutrophilia (>25%), the absence of intracellular bacteria, and excessive mucous production.[14] Microbial culture of pulmonary secretions is typically negative. Thoracic radiographic examination may reveal mild to moderate bronchointerstitial patterns with evidence of lung field hyperexpansion (flattened diaphragm). Ultrasonographic findings, although not specifically described in SPAOPD-affected horses, would be expected to be similar to those in horses with RAO. Postmortem examination of the lungs from affected horses reveals overinflation, the presence of rib impressions, and a failure to collapse. Histopathologic changes include accumulation of mucus and neutrophils in the small airways, peribronchiolar smooth muscle hypertrophy, peribronchiolar submucosal fibrosis, epithelial hyperplasia, goblet cell hyperplasia or metaplasia, and peribronchial neutrophilic and lymphocytic infiltrates, similar to RAO. There is usually minimal evidence of emphysema and fibrosis.[14,17] Collectively these changes represent airway remodeling similar to what occurs in RAO.

Treatment The most important management change to implement is to move the horse from the offending pasture either to another pasture or to a cool, dust-free stall that is bedded with shavings. Hay should be moistened or steamed and fed to the horse from the ground to reduce inhalation of organic dusts. When stalls and barn areas are being cleaned, the horse should be removed from these areas. Medical therapies include administration of glucocorticoids and bronchodilators, as described for horses with RAO (see the Treatment and Prognosis section for RAO).

Prognosis Recurrence of the condition is likely to develop when susceptible horses are exposed to environmental triggers. Longitudinal studies have not been performed to ascertain the risk of permanent (irreversible) lung remodeling in recurring cases. The heritability of SPAOPD has not been established.

Inflammatory Airway Disease in the Horse

Melissa Mazan

What Is Inflammatory Airway Disease?

Inflammatory airway disease (IAD), *small airway inflammatory disease*, *small airway disease*, and *allergic airway disease* are often used interchangeably, but the once-fluid definition of IAD is slowly taking form. Although low-grade inflammation of the small airways is recognized as a common cause of poor performance in young to middle-aged athletic horses, it is only recently that a clear distinction has been made between heaves, or recurrent airway obstruction (RAO), and IAD. Workers in the field continue to debate whether IAD is a discrete disease entity or whether it is merely part of the continuum of airway inflammation that, if left untreated, will progress inexorably to the better characterized syndrome of RAO.[1] The recent Revised Consensus Statement on IAD[1] suggests that the term *equine asthma* better covers the spectrum of diseases that are characterized by excessive mucus accumulation in the airways and extend from severe heaves to mild IAD. Horses with IAD are generally young, although middle-aged horses may also be affected; have impaired performance that may go unnoticed at rest or during light work[2-4]; have mild to moderate airway inflammation that may involve neutrophils, mast cells, eosinophils, or lymphocytes[2,4-7]; have variable clinical signs, including cough, nasal discharge, and abnormal lung sounds; may have endoscopic evidence of tracheobronchial mucus accumulation; and may have normal lung function at rest but show evidence of airway hyperresponsiveness on exposure to nonspecific agents such as histamine or evidence of low limitations on forced expiratory maneuvers.[3,8-12] In addition, these horses may have lung dysfunction, as evidenced by airway obstruction, airway hyperresponsiveness, or abnormal blood gas exchange. This definition specifically excludes horses that appear systemically sick or that have overt evidence of respiratory dysfunction, such as flaring nostrils or excessive thoracic or obvious abdominal breathing efforts.

VetBooks.ir

The prevalence of IAD is somewhat of a guessing game. One study involving 965 Standardbreds in active racing found that 22% had evidence of mucopus at the trachea or bronchial bifurcation when examined endoscopically, although these horses were diagnosed as having chronic obstructive pulmonary disease (COPD); undoubtedly they properly belong in the IAD group.[13] Similarly, 27% of actively racing Thoroughbreds in one study had IAD.[14] A remarkable 55% of 2-year-old Thoroughbreds in training could be classified as having lower airway disease on the basis of finding mucus in the trachea on endoscopy and inflammation on examination of tracheal aspirate fluid, and abattoir studies have shown that up to 37% of horses have histopathologic evidence of airway inflammation.[15,16] Because a standard definition of IAD has only recently been agreed on, the prevalence of IAD has varied according to the individual researcher's case definition. Nonseptic airway inflammation, regardless of whether it causes overt signs of respiratory disease, appears to be very common in performance horses. This discussion adheres to the definitions of IAD and RAO as developed by the International Workshop on Equine Chronic Airway Disease and the recent ACVIM consensus statement on IAD.[1,17] With RAO, horses have demonstrable lower airway obstruction, characterized by peak pleural pressures of at least 15 cm H_2O, induced by an environmental challenge of moldy hay, largely reversible by use of a bronchodilator or return to a nonchallenge environment, and accompanied by an increase in BAL fluid neutrophils during challenge. In contrast, IAD refers to a nonseptic airway disease in athletic horses that does not have a clearly defined allergic cause. The data from the many studies involving horses with what was traditionally known as COPD and is now more properly referred to as RAO, or heaves, did not conform with these guidelines, and many of the horses would more properly be characterized as having IAD.

Clinical Findings

Although most investigators agree that IAD is a disease of younger horses expected to do athletic work, and as such is distinct from the picture of the dyspneic horses with overt RAO, there remains a plethora of clinical signs and case definitions for IAD. One of the most common findings in IAD is exercise intolerance, with or without overt signs of respiratory disease. Of 25 horses referred either for routine physical examination or for poor performance, and without any clinical signs or history of respiratory disease, 76% had evidence of airway inflammation according to an inflammation scoring system based on endoscopy and tracheal wash findings.[18] Subclinical airway disease may result simply in mild abnormalities on auscultation and endoscopy, and occasionally in coughing.[19] Signs such as nostril flaring and excessive abdominal effort at rest, however mild, are usually associated with horses that have true RAO, as clinical signs that can be reliably detected using clinical scoring systems usually are accompanied by significant mechanical dysfunction of the respiratory system.[20] The prevalence of cough in horses with IAD is difficult to estimate, as many studies use the presence of cough as an inclusion criterion. Other studies have shown that cough may be seen less than 16% to 50% of the time.[21,22] On endoscopic examination, excessive airway mucus is often seen, ranging from multiple specks to streams of mucus.[23] Other clinical signs that are frequently noticed include prolonged respiratory recovery; respiratory embarrassment at exercise; worsening of signs during hot, humid weather; and inability to perform work during collection. Racehorses with IAD are typically described as fading during the last quarter of the race (Mazan, personal observation). It is interesting to note that horses with dorsal displacement of the soft palate (DDSP) have a higher prevalence of IAD than do control horses. This brings into play a chicken-or-egg argument, as it cannot be determined whether IAD is a risk factor for DDSP or DDSP is a risk factor for IAD.[24]

How does IAD affect performance? The answer depends on the use of the horse and the expectations of the owner. A practitioner with a primarily pleasure-horse practice or with show-hunter clientele might report a very low incidence of IAD in younger horses, primarily because the level of exercise in these horses is not likely to force a diagnosis through signs of exercise intolerance. A racetrack practitioner, on the other hand, would be far more likely to detect exercise intolerance resulting from lower airway disease in young horses because the level of expected athletic output is much higher and the horses have a greater likelihood of being examined endoscopically. Indeed, in a National Hunt racing population, excessive mucus was detected endoscopically in 68% of horses,[25] and IAD was one of the top two reasons cited for horses not running.[26] As might be expected, cough is more common in sport horses than in racehorses, as is an elevated respiratory rate, reflecting the generally earlier diagnosis in racehorses. Indeed, racehorses with excessive tracheal mucus performed at a lower level than those with no mucus found on endoscopic examination.[11,13]

Low-grade nonseptic airway inflammation was found to have a negative impact on ventilatory capacity, but this was more pronounced in racehorses. Moreover, using bronchiolar biopsy, this group also demonstrated that oxygen uptake and pulmonary ventilation correlated inversely with the morphologic grade of small airway disease and the height of the bronchiolar epithelium—the last finding suggesting that the extent of obstruction may determine the extent of exercise impairment.[27] Racehorses with IAD have impaired gas exchange during exercise.[3] However, other studies have found that horses with obvious evidence of airway inflammation do not necessarily have a history of exercise intolerance.[28] However, this may reflect the difficulty of diagnosing low-grade respiratory impairment and the trainer's failure to recognize poorer performance than nature intended, rather than the benign nature of the underlying disease.

Diagnosis

BRONCHOALVEOLAR LAVAGE. Varying levels of specificity are used when documenting the presence of airway inflammation. The least specific is the documentation of mucus in the trachea, although it is the method that best lends itself to large studies in the field. However, visualization of mucus in the trachea gives little information as to the nature and the exact origin of the inflammation. Many workers have used and continue to use tracheal aspirate cytology to describe the nature of inflammation in IAD. Although tracheal aspiration can be used to explore the presence of inflammation and has been used to document neutrophilia, mastocytosis, and eosinophilia in young performance horses, the question of the nature and exact origin again presents itself.[29] Studies have shown poor correlation between tracheal aspiration and BAL cytology in horses.[30,31] Whereas tracheal aspiration harvests primarily neutrophils and epithelial cells, BAL yields primarily alveolar macrophages and lymphocytes in normal horses. Moreover, there is no evidence of correlation between tracheal wash findings and performance. Consequently, to avoid the problem of neutrophil count sensitivity to the collection method, BAL is the best choice for sampling respiratory secretions in horses with IAD.

Different pictures of inflammation emerge from various BAL studies, leading to speculation that different genetic predispositions and environmental exposures are important to the inflammatory phenotype. In comparison with healthy horses, BAL cytology in horses with IAD has shown, variably, neutrophils, mast cells, eosinophils, or lymphocytes. In general, horses with IAD have airway inflammation that may involve increases in nucleated cells or may also involve lymphocytosis. This is distinguished from RAO by the relatively low percentage

VetBooks.ir

of abnormal cells in IAD; whereas horses with RAO may exhibit almost entirely neutrophils in the BAL fluid, horses with IAD seldom have more than 2% to 15% neutrophils.[1] It is problematic that all BALs are not created equal. Even when the infused fluid is within the usual recommendations of 250 to 500 mL, when larger volumes are instilled, the percentage of neutrophils decreases.[32] Thus it is important to note volume of fluid instilled when assessing any report of airway inflammation based on BAL cytology.

HISTOPATHOLOGY. A recent study has given us insight into the inflammation that exists in the lower airways even of horses that have not been identified to have respiratory disease.[33] Inflammatory cell infiltrates (primarily CD3+ T cells) and smooth muscle hyperplasia were identified in most of the horses, although epithelial changes were not noted. Bronchiolar biopsies of athletic young horses with lower airway inflammation have shown inflammatory mucosal cellular infiltrates and luminal exudates, bronchiolar hyperplasia, and goblet cell metaplasia.[8] It is interesting to note that 80% of supposedly normal horses had minimal evidence of peribronchiolitis; this raises the question of what constitutes normal. O'Callaghan, while directing his concern to exercise-induced pulmonary hemorrhage (EIPH), nevertheless found plentiful evidence of multifocal, small airway–centered disease on postmortem examination of young racehorses.[34] These findings included thickened walls caused by increased quantities of mucosal and peribronchiolar connective tissue, mononuclear bronchiolar cuffs, and extension of nonciliated bronchiolar epithelial cells into alveolar ducts.[34] Lakritz,[35] looking at lung tissue of clinically normal, young Thoroughbred horses in training, found evidence of increased collagen, disruption of the epithelial basement membrane, and duplication of the epithelial basement membrane, suggesting previous airway inflammation and epithelial injury, which correlate with an increased interstitial pattern on radiographs. An ultrastructural study of young horses with "mild COPD" in one study found a decreased number of typical Clara cell granules and goblet cell metaplasia before the bronchioles began to show signs of inflammation typical of RAO.[36] Although the authors state that there was good correlation between histopathology and the results of a battery of PFTs, auscultation, bronchoscopy, blood gas analysis, and BAL in these horses, it is a lasting disappointment that the results of the ancillary testing remain unpublished. These data, in sum, suggest that the histopathologic lesion of IAD is not only local bronchiolar inflammation but also remodeling and thickening of the bronchioles themselves, which lends itself to at least low-grade airway obstruction.

LUNG FUNCTION TESTING. The esophageal balloon and pneumotach method for measuring lung function tends not to detect airway obstruction even in horses with RAO in remission.[37] However, use of the forced oscillatory technique and forced expiratory maneuvers has shown the existence of low-grade obstruction of the small airways of some horses with IAD.[3,38] The mechanical behavior of the respiratory system has been shown to differ with sampling frequencies in asthmatic humans,[39] and a pattern of decreasing respiratory system resistance (RSR) with increasing frequency has been termed *negative frequency dependence of resistance* and has been interpreted as evidence of underlying small airway obstruction despite baseline measurements within the expected range. Similarly, horses with IAD as a group have significantly higher values for RSR at the lower frequencies (1 to 3 Hz) and mild frequency dependence of resistance compared with controls,[40,41] although the baseline measurement of RSR may still frequently fall within the normal range. A study finding that lower oxygen uptake capacity and tidal volume correlated to a reduced diameter of the bronchiolar lumen owing to epithelial hyperplasia is strongly supportive of the existence of airway obstruction in IAD.[27] Likewise, lung resistance decreases with increasing minute ventilation in control horses but not in horses with IAD.[42] Consequently, without dynamic, frequency-dependent tests of lung function, forced maneuvers, or bronchoprovocation, it seems that researchers are simply failing to document a common feature of small airway obstruction in horse with IAD because testing devices are not sufficiently sensitive to these changes.

AIRWAY RESPONSIVENESS. Horses with clinical signs compatible with IAD also exhibit signs of airway hyperresponsiveness (the threshold at which horses react) and hyperreactivity (the slope, which correlates to the magnitude, of the response) when they are exposed to nonspecific agents such as histamine aerosol. The basis for airway hyperresponsiveness remains hotly debated among pulmonary physiologists. It is likely a multifactorial phenomenon that has been associated with airway wall thickening undetectable by conventional lung function testing, airway inflammation, and autonomic nervous system dysfunction.[43] There is a paucity of information concerning the mediators of airway hyperresponsiveness in horses with IAD. In our laboratory, horses with a clinical history and signs compatible with IAD have significantly greater airway reactivity than controls, although some control horses display airway hyperresponsiveness (AWHR) as well. A study in Standardbred racehorses with unexplained poor performance or cough showed a discordance in some horses between positive BAL findings and positive airway hyperreactivity,[44] raising the idea that without testing for AWHR, some horses affected with IAD will be missed. This nonspecific airway hyperresponsiveness has been seen in humans and is associated with a greater risk of eventual development of asthma.[45] Although nonspecific airway hyperresponsiveness has been noted both in adult horses without signs of respiratory disease and in foals, the significance of this finding remains unclear.

Although radiography can be useful in helping exclude septic causes of lower respiratory tract disease, such as pneumonia, lung abscess, or pleuropneumonia, its sensitivity in IAD is too low for it to be useful for identification of this disease. Moreover, no correlation exists among thoracic radiographs, airway hyperresponsiveness, and BAL cytology.[46] However, the more frequent finding of a bronchial pattern on thoracic radiographs supports the existence of airway obstruction in these horses.

ENDOSCOPY. Tracheal endoscopy is convenient and easily performed, and lower airway scoring correlates with lower airway inflammation; moreover, particulate levels in the air have been correlated with endoscopically visible mucus in the trachea. Thickening of the septum has been shown to be useful in distinguishing horses with RAO from horses with IAD. The accumulation of mucus in the trachea has been shown to correlate with neutrophil percentages, but there was no such correlation with thickening of the septum.[47-49]

BIOMARKERS. Although there was no utility found in using the circulating acute phase proteins C-reactive protein, haptoglobin, or serum amyloid A (SAA) to distinguish IAD from other causes of unexplained poor performance in racehorses,[50] SAA was found to be useful in distinguishing horses with IAD from those with infectious airway diseases, thus demonstrating the use of SAA in ruling out subclinical infectious disease.[51]

■ ***Etiology*** No single cause of IAD has been identified, although there has been plentiful speculation about the role of environment, viral disease, infection, air pollution, and genetic predisposition. Although horses with IAD do not seem to experience bouts of overt airway obstruction on exposure to

VetBooks.ir

an allergenic environment, organic dust associated with stabling likely contributes to the initial inflammation. Sweeney noted that the racehorses in her study lived in conditions of poor ventilation, and she speculated that covert IAD may be instigated by the organic dusts, especially mold, in hay.[52] Others have noted that there is more mucopus in the tracheas of horses kept in poorly ventilated conditions, and in one study Thoroughbred racehorses in training, housed on straw, were found to be twice as likely to suffer from lower airway disease as those kept on shredded paper.[23] More recently, Holcombe and colleagues[53] showed that yearlings had a significantly higher number and percentage of neutrophils (polymorphonuclear neutrophils as high as 18%) in BAL fluid when they were stabled versus when they were at pasture. In support of this finding, endotoxin concentrations are, as expected, higher in stables than at pasture.[54,55] Although none of these horses had any clinical signs of respiratory disease or evidence of exercise intolerance, they were not in work, and subtle signs of performance impairment could easily have gone undetected. Dust levels in the horse's breathing zone can be as high as 25 mg/m^3 (a level that would be considered unacceptable in any human workplace), which can explain the development of airway neutrophilia as a nonspecific response to high levels of particulates.[56] It is also likely that increased levels of endotoxin in hay and grain dust contribute to the development of airway neutrophilia,[57-59] which is supported by the finding that hay eating is a risk factor for increased tracheal mucus in pleasure horses.[28] A recent study of Thoroughbred racehorses in training confirmed that feeding hay from a net resulted in a significantly higher concentration of particulates and respirable endotoxin in the horse's breathing zone as well as an increase in eosinophil numbers in the BAL fluid.[60] In addition, the horse's position in the stable may affect development of IAD. In one study there was a significant association between the presence of visible accumulation of mucus in the trachea and the stable, stall, and particulate concentration and numbers.[61] Moreover, even when unaffected horses are exposed to stable dust, the neutrophil chemoattractant, IL-8, increases in the BAL fluid.[62]

Previous viral disease is commonly invoked as a predisposing factor in the development of IAD, and the evidence needed to implicate virus is increasing. As in humans with asthma, viral respiratory disease has been shown to cause AWHR for a period of time after infection, perhaps because of denuding of the respiratory epithelium. In one study various equine herpesviruses were found with greater frequency in the tracheal aspirate of poorly performing horses with signs compatible with IAD,[63] and more recently both EHV-2 DNA and equine rhinitis B virus RNA were found in the tracheal fluid but not in the nasal fluid of young racehorses with cough.[64] Similarly, in a different laboratory, horses with IAD had higher titers to equine rhinitis A virus, and there was a significant association between nasal shedding of EHV-2 DNA and diagnosis of IAD.[65] Moreover, both alphaherpesviruses (EHV-1 and EHV-4) and gammaherpesvirus (EHV-2d) have been associated with more long-lasting airway inflammation.[66]

The role of bacterial infection in IAD, particularly in young racehorses, is unclear. In several studies there was a strong relationship between inflammation of the lower respiratory tract and the presence of streptococcal species; horses with greater evidence of airway inflammation on tracheal aspiration and endoscopy had higher mean bacterial counts in tracheal aspirate,[23] and horses with bacteria found in the tracheal aspirate had a greater tendency to cough.[15] Recently, it has been shown that the respiratory microbiota differs between horses with IAD and those without respiratory disease, with streptococcal species being increased in horses with IAD. Moreover, treatment with dexamethasone exacerbated this difference.[67] However, it is important to remember that association is not necessarily causation, and so increased numbers of bacteria may reflect impaired airway clearance rather than a causative role for bacteria. The role of bacterial and viral infection in IAD remains unclear at this time.

Because horses sample the ambient air on a continual basis, it seems logical that air pollution might contribute to the development of IAD. In one study, clinically normal horses exposed to ozone had significant increases in the glutathione redox ratio as well as total iron levels in the pulmonary epithelial lining fluid (both markers of exposure to oxidizing agents), and there was a strong correlation between airway inflammation score and the glutathione redox ratio in horses examined for poor performance but without overt airway disease.[68] In contrast, horses living in urban environments have been shown to have less airway reactivity, although greater levels of iron in the BAL fluid, than do horses living in rural environments.[69]

There are multiple other possible contributors to the development of IAD. Cold air exposure is an important risk factor for the development of asthma in human athletes, and cold air exposure has been shown to be a risk factor for development of tracheal mucus accumulation in some horses.[28] In support of this observation, exposure of equine airways to cold air resulted in altered immunologic responses for at least 48 hours. Exercise may also play a role in the development of IAD, in that neutrophils are increased in the BAL fluid for at least 48 hours after exercise, and there is a corresponding increased late-phase expression of IL-8 and TNF-α in the BAL fluid.[70,71]

There is no convincing evidence of an allergic response in horses with IAD. However, the presence of increased numbers of mast cells in the BAL fluid of horses with poor performance,[2] the association of BAL mastocytosis with AWHR,[72] and immunohistochemistry studies showing more IgA-containing cells and occasionally increased numbers of IgM- and IgG-containing cells are suggestive of a degree of allergic response and a heightened immune response. Anyone looking at recent studies of gene expression profiles in the BAL fluid of horses with IAD should take note of whether the horses were diagnosed as having IAD on the basis of a generalized increase in inflammatory cells or if the study group was parsed more thoroughly into horses with increased mast cells or horses with increased neutrophils. One study of horses with a generalized increase in inflammatory cells revealed an upregulation of IL-1β, IL-23, and TNF-α but no evidence of a polarized cytokine response.[73] On the other hand, when horses are stratified into mast cell versus neutrophil groups, mRNA for IL-4 correlated with mast cells but not neutrophils, whereas for all groups, similar to the previous study, TNF-α and IL-1β were increased.[74,75] It is most likely that multiple factors contribute to the development of IAD in individual horses; a critical level of risk factors or exposure is probably necessary for the disease to manifest itself. Recently, measurement of cytokine concentrations in BAL fluid suggested that neutrophilic IAD involved activation of the innate immune system and a Th1 polarized response; at the same time, the study supported other emerging findings that different cytologic profiles are likely associated with differing immunologic pathways.[76]

Differential Diagnoses

The diagnosis of IAD often requires the exclusion of other diseases that may have a similar clinical picture. Whereas horses with RAO (heaves) or summer pasture–associated RAO (SPARAO) in remission may be very difficult to distinguish from horses with IAD, horses with RAO or SPARAO have a history of episodes of obvious breathing difficulty associated with exposure to either moldy hay or summer pasture. Upper airway disease, such as sinus infection or guttural pouch infection, may cause cough and nasal discharge, and both static and dynamic upper airway obstructions may cause poor performance and poor recovery from exercise. These may be largely ruled out by endoscopy. Horses with

pneumonia, bronchopneumonia, or lung abscess commonly have abnormalities suggesting systemic disease, such as abnormal findings on CBC, recent history of fever, weight loss, or inappetence. In these cases tracheal wash can be very helpful in determining a septic cause of disease. Thoracic radiographs or ultrasound will also aid in the detection of these septic respiratory diseases. EIPH may be seen in conjunction with IAD, but the presence of epistaxis, blood on endoscopy of the trachea, or red cells or hemosiderophages on BAL confirm the diagnosis of EIPH. Overt viral respiratory disease is difficult to confuse with IAD, as it usually manifests with fever and malaise, but horses with viral respiratory disease may exhibit prolonged cough and AWHR for weeks to months after resolution of the primary disease.

Therapy There is remarkably little evidence-based support for any particular therapy in treating IAD. However, the mainstay of treatment has become a combination of environmental remediation, corticosteroid therapy, and bronchodilators.

ENVIRONMENTAL REMEDIATION. The barn environment is a hotbed of particulate matter, respirable endotoxins, molds, and volatile gases such as ammonia. The worst offenders appear to be hay and straw. A study looking at different management systems showed that when hay and straw bedding were replaced by pelleted feed and wood shavings, the respirable particulate levels were remarkably reduced.[55] Further improvements can be made by using cardboard bedding to reduce dust and mold levels.[77] Indoor arenas present another high-dust challenge to the horse, with respirable particulate levels 20 times the level recognized to cause respiratory dysfunction in humans.[61] Other fairly common-sense strategies can be used. We make the following recommendations to owners in addition to the suggestion to change to low-dust feeds and beddings:

- Sprinkle aisles with water before sweeping.
- Avoid storing hay overhead. If unavoidable, lay a tarp under the hay to avoid dust raining down on the horses.
- Use a humectant or hygroscopic agent to reduce dust in the indoor and outdoor arenas.
- Remove horses from the barn while cleaning stalls or moving hay.
- Do not use blowers to clean aisles.
- Wet hay before feeding or use Dengie or other baked hay products.
- Remove cobwebs and other dust collectors routinely.

A recent study demonstrated that environmental control was by far the most important means of treating airway inflammation and dysfunction in horses with heaves (RAO), a more severe disease than IAD, and feeding hay in a net was shown to be the most important factor in high breathing zone particulate levels.[60,78] It is logical therefore to suppose that environmental management is equally important in the treatment of IAD.

CORTICOSTEROID THERAPY. Either parenteral or inhaled corticosteroids form the mainstay of drug therapy for IAD. Although the utility of corticosteroids for preventing or ameliorating airway remodeling in human asthma is debated, corticosteroids have recently been demonstrated to prevent airway smooth muscle thickening in mice with experimental asthma.[79,80] The degree of efficacy in decreasing BAL neutrophilia is not completely known. Some studies show an obvious benefit of dexamethasone in improving clinical signs and lung function and reducing BAL neutrophilia,[81] whereas others show improvement primarily in lung function with little effect on BAL cytology for dexamethasone only or for both dexamethasone and fluticasone.[78,82] Corticosteroid treatment certainly causes adrenocortical dysfunction, but this is less pronounced with inhaled therapy versus systemic.[81] Although concerns about precipitating laminitis with corticosteroid therapy are frequently expressed, the actual risk of laminitis with corticosteroid therapy is completely unknown.[6] In our clinic we frequently treat with an initial course of parenteral corticosteroids, typically a 4-week decreasing course of prednisolone followed by inhaled corticosteroids. A recent study demonstrated that fluticasone propionate is detectable in blood and urine after delivery by inhalation.[83]

BRONCHODILATOR THERAPY. Bronchodilators, especially the inhaled form, appear to be efficacious in treating IAD in conjunction with corticosteroids. The most commonly used bronchodilators in IAD include aerosolized β-adrenergics, such as albuterol, and aerosolized parasympatholytics, such as ipratropium. β-Adrenergic drugs such as albuterol also increase mucociliary transport. The use of systemic β-adrenergics such as clenbuterol is not advised, as the extent of bronchoconstriction in IAD does not warrant risking the adverse effect of cardiovascular remodeling, which has been shown to occur in horses.[84] Moreover, a recent study demonstrated that when clenbuterol is given to horses with AWHR, tachyphylaxis associated with increased airway reactivity develops by 21 days of treatment,[7] whereas no such increase in AWRH was noted when horses were given aerosolized albuterol over a 10-day period.[85]

MAST CELL INHIBITORS. Sodium cromoglycate can be efficacious in treating known mast cell–mediated IAD[9] but will not be of use for treating the majority of horses with neutrophil-mediated disease. The use of sodium cromoglycate requires considerable owner compliance, as the maximum response to this drug occurs at 1 to 2 weeks after beginning treatment.

AEROSOLIZED THERAPY. Aerosolized therapy using a combination of inhaled corticosteroids and bronchodilators is well established clinically in the treatment of IAD; however, there are no clinical trials establishing the efficacy of these drugs. When using inhaled drugs, we use a spacer and mask in order to improve delivery of the drug. Regardless of the type of mask and spacer device used, actual delivery of particles to the lower airways is poor in horses, as indeed it is even in humans, and the least efficacious means of delivering aerosolized drugs is by nebulization.[86,87] Unfortunately, strategies that we know improve lung deposition of aerosolized drugs in humans, such as slow deep breathing and breath holding, are not practical in horses. Devices currently on the market include the Aerohippus (Trudell Medical, Inc., London, Canada), the Equine Haler (Equine Health Care, Inc., Horshølm, Denmark), and the Flexineb® (Nortev Ltd., Galway, Ireland). Individual horse and owner preference determines which device should be used. Inhaled corticosteroids commonly used in the treatment of IAD include beclomethasone and fluticasone.

Although there are no reported clinical trials using corticosteroids in horses with IAD, horses with RAO treated with 3750 μg of beclomethasone dipropionate twice daily showed improvement in both clinical signs and lung function.[88] Smaller doses (500 to 1500 μg twice daily) were shown to be efficacious in horses with heaves, and we commonly use small doses (500 to 1000 μg twice daily) with good clinical effect in horses with IAD.

Fluticasone is a more potent corticosteroid than beclomethasone and has been shown to be efficacious in treating horses with heaves when administered using a delivery device that is no longer on the market at a dose of 2000 μg twice daily.[89] Unlike with beclomethasone, fluticasone did not cause adrenocortical dysfunction.[89] We use a decreasing-dose regimen, starting at 1500 to 2000 μg twice daily, working down to 1000 μg once daily or every other day. The lowest dose is reached over a 3- to 4-week period. Although we previously

advised use of a short-acting bronchodilator, such as inhaled albuterol, 5 to 15 minutes before treatment with inhaled corticosteroid to increase deposition of the latter by fully opening the small airways, the accepted practice in human medicine currently is to avoid this practice. The logic behind this is that it is important to get the most useful and costly drug administered first before compliance decreases. It is important that the owner understand that even with the higher doses of inhaled corticosteroid, it may require 1 to 2 months for the best therapeutic effects to be achieved.

The most commonly used inhaled bronchodilator is albuterol, a β_2-specific adrenergic drug. The onset of effect with albuterol is quite rapid, with maximum bronchodilation being seen within 15 minutes. However, it is important to note that the maximum effect lasts for only an hour in some horses, and there are side effects (such as anxiety, nervousness, trembling, and tachycardia) with higher doses of the drug, even in the inhaled form. There is no evidence to suggest that the oral form of albuterol is even absorbed in the horse, and it is not suggested as appropriate therapy. Longer-acting β_2-adrenergic agonists, such as salmeterol and formoterol, can also be used, with bronchodilation lasting for 6 to 8 hours. Parasympatholytic drugs such as ipratropium have a slower onset of action but longer duration (at least 6 hours) than albuterol and lack the severe side effects of parenteral use of drugs such as atropine. It is important to remember that these bronchodilators are symptomatic drugs only; they do not treat the underlying inflammation and therefore are unsuitable for single-drug therapy.

Mast cell inhibitors that can be administered by metered dose inhaler include Intal (cromolyn) and Tilade (nedocromil sodium). They are discussed in earlier sections. Many putative ancillary treatments have been touted as efficacious in the treatment of airway inflammation in the horse. The only one with good evidence for efficacy is the use of omega-3 fatty acids in the feed.[90]

In summary, IAD is a disease characterized by nonseptic inflammation, visible on BAL cytology as excessive neutrophils, mast cells, or eosinophils, and involving low-grade airway obstruction and AWHR. Clinical signs include variable cough, nasal discharge, and poor performance. Excessive amounts of mucus may also be visualized in the trachea during endoscopic examination. The cause of IAD is unknown, but the disease is probably best avoided by achieving a low-dust and low-endotoxin environment. Treatment logically begins with environmental remediation and is supplemented by anti-inflammatory drug therapy using systemic or inhaled corticosteroids and inhaled bronchodilators. IAD that involves an excess of mast cells in the airways can be further treated with inhaled mast cell inhibitors.

Tuberculosis

Peggy S. Marsh

Tuberculosis refers to any infectious disease caused by *Mycobacterium* spp. and associated with the formation of focal granulomatous lesions. In humans many forms of the disease exist, with the primary site of infection most commonly being the lungs. *Mycobacterium tuberculosis* is the typical causative agent in humans, whereas *Mycobacterium avium* or *Mycobacterium bovis* is usually implicated in animal cases.[1] Tuberculosis is extremely rare in horses, especially in the United States. Most cases in horses have reported isolation of *M. avium*[2-5]; however, there are reports of infection with *M. bovis*[6-8] and *M. tuberculosis*.[9] In equine cases it appears that the organism is usually ingested, although primary respiratory infection may occur. Spread is hematogenous, and the organism frequently settles in lymph nodes and the spleen.

The most frequent presenting complaint is chronic weight loss with ensuing weakness and lethargy. Terminally ill horses with the pulmonary form are febrile and dyspneic and have a cough. Radiographic or sonographic evaluation of the thorax may be helpful in defining the pattern and distribution of lesions. Other clinical signs may be noted depending on the organ systems affected; these signs include intestinal tract abnormalities, hepatitis, and osteomyelitis of the cervical vertebrae.[1-9]

Diagnosis, usually made after the horse's death, is based on the presence of tubercles and isolation of the organism. The intradermal skin test is not reliable in the horse because a majority of clinically normal horses may have positive test results.[9] Cytologic or histologic evaluation of a wash or aspirate of a lesion may reveal acid-fast bacilli. Biopsy of the lesion(s) is necessary for a definitive diagnosis. When tuberculosis is suspected, culture of an appropriate sample, such as a tracheal aspirate with primary pulmonary involvement, is advisable. However, this is a very slow-growing organism, and isolation may take multiple weeks to months.[6] PCR technology has proven to be a useful tool, often in conjunction with culture.[6,7,9]

Due to public health concerns, treatment is not usually attempted. If treatment is undertaken, the horse should be isolated, with precautions taken to prevent the spread of disease and in consultation with the public health officials and/or the horse handler's physician. Tuberculosis is a reportable disease in other species. In one case a horse was treated with a prolonged course of antimicrobial medications (enrofloxacin and potassium iodide) while it took 4 months to identify *M. bovis* from biopsy samples from a lung mass. The horse went on to live at least another 8 years with no further problems related to the *M. bovis* infection.[6] Because treatment is usually not a viable option in horses, prognosis is very poor.

Bacillus Calmette-Guérin vaccine has been used in humans with potential exposure, but the benefit of its use in horses to provide increased resistance after exposure to a tuberculosis infection is unknown.

Pneumoconiosis (Silicosis)

Peggy S. Marsh

Pneumoconiosis refers to lower respiratory tract disease associated with deposition of small particles (dust) within the lungs. In human medicine the majority of cases are related to occupation and include coal worker's lung, silicosis, and asbestosis.[1,2] There are two related reports of silicosis in horses.[3,4] The majority of the horses originated from the Monterey-Carmel Peninsula in California. Silicosis is a disease caused by inhalation of crystalline silica. There are several clinical forms of silicosis in humans, including simple and complicated chronic forms as well as acute silicosis (silicoproteinosis). Silicosis has been associated with mycobacterial diseases, airway obstruction, and pulmonary neoplasia.[5] Freshly fractured silica is more toxic to alveolar macrophages than aged silica. Crushing silica leads to the formation of reactive radials.[6] The small (0.5 to 5 mm) particles are deposited in small airways and alveoli, then subsequently phagocytosed, initiating a cycle of granulomatous inflammation, oxidative stress, and apoptosis leading to chronic fibrotic interstitial disease.[1,5,6]

The clinical signs reported in horses are similar to those of severe equine asthma (heaves) and include weight loss, cough, exercise intolerance, and sometimes exercise-induced respiratory distress (sweating, nostril flaring, abducted elbows, reluctance to move, and shaking). Resting respiratory rates are often increased. Physical examination revealed a restrictive pattern of breathing with harsh breath sounds and exercise-induced wheezing on auscultation.

Diagnosis was based on the presence of birefringent crystalline inclusions within pulmonary macrophages from samples

obtained via tracheal aspiration, BAL, lung biopsy, or at necropsy.[4] In some cases repeated tracheal sampling was required. Radiographs of the thorax revealed a variety of findings, including most commonly an interstitial pattern (miliary, reticulonodular, and linear) most severe in the caudodorsal lung fields. Other radiographic abnormalities noted included lymphadenopathy, pleural effusion or thickening, hyperinflation, and pulmonary consolidation.[4]

Gross pathologic analysis revealed interstitial granulomatous pneumonia and fibrosis. Histologic examination with both light and electron microscopy revealed peribronchitis, perivasculitis, and cellular infiltrates of refractile inorganic dust particles within macrophages and giant cells.[3,4]

In general the horses reported to have silicosis had a poor prognosis. The original report presented postmortem findings of nine horses diagnosed with silicosis.[3] In a later, related paper, a total of 19 horses were identified.[4] Short-term (2 to 12 months) follow-up evaluation was available in eight of these individuals, with a progressive loss of respiratory function noted in four of the cases, leading to euthanasia. Treatment consisted of environmental change and glucocorticoid therapy. Novel forms of therapy, including inhibition of inflammatory mediators as well as inhibition of apoptosis, may be seen in the future[6]; however, silicosis remains with no cure.[2]

Recent work has revealed a systemic osteoporosis in a group of horses associated with fibrosing pulmonary silicosis.[7] Also, there are reports of pneumoconiosis in other domestic species that was caused by environmental contamination.[8] It may be prudent to keep environmental contamination in mind when investigating chronic noninfectious forms of lower respiratory tract disease in the horse.

Mycoplasma

Peggy S. Marsh

Mycoplasma spp. are a group of bacteria that differ from other bacteria because they lack a cell wall, are much smaller than most bacteria, and need cholesterol to survive. These organisms are proven to cause respiratory disease in humans, cattle, and pigs. *Mycoplasma felis* has been isolated as a pathogen causing pleuritis and pericarditis in the horse.[1-3] Experimental infection with *M. felis* in ponies induced pleuritis.[3] The relative importance of *Mycoplasma* spp. as a pathogen in acute respiratory disease of the horse has been debated. Several species of *Mycoplasma* can be isolated from the respiratory tract of healthy and diseased animals, both adults and foals. A report from Australia did not yield growth of *Mycoplasma* spp. in any of the samples from young racing horses with coughs.[4] However, a similar case control–type study from the United Kingdom showed an association between *M. felis* and inflammatory airway disease in young racehorses.[5] Also, a Canadian report demonstrated growth of *Mycoplasma equirhinis* and *M. felis*, along with other bacteria commonly thought of as respiratory pathogens, in horses with acute lung disease.[6] *M. felis* has been reported as a potential cause of an outbreak of acute respiratory disease in a stable of young racehorses, as well as of respiratory disease in foals.[7]

Clinical signs of pleuritis caused by mycoplasma infection, including fever, depression, and pleurodynia, mimic other bacterial pleural pneumonia cases. Auscultation of the thorax may reveal pleural friction rubs and dull lung sounds over the cranioventral thorax. Sonographic examination of the thorax reveals pleural effusion, often bilateral. Thoracocentesis should be performed for both diagnostic and, if necessary, therapeutic purposes. The fluid is most often an exudate, lacking any odor. Cytologic examination reveals large numbers of neutrophils within the pleural fluid.

Crucial to diagnosis of mycoplasma infection is the elimination of more common pathogens, such as streptococcal infections. Thus routine cultures for aerobic and anaerobic bacteria should be performed in any case of pleuritis. Culture for the presence of *Mycoplasma* bacteria is difficult to obtain, and *Mycoplasma*-specific media should be used. Seroconversion can also be an aid in diagnosis, with seroconversion occurring in a large number of the reported cases of *M. felis* infection.[1,2,7] Experimental infection revealed that once seroconversion has occurred, the organism can no longer be isolated from culture samples.[3] Seroprevalence in the United States is not known. Diagnosis may be aided by the use of RT-PCR methods for the detection of *M. felis*.[8]

Experimentally infected ponies recovered without treatment in one study, so the requirements of treatment specific for mycoplasma are unclear.[3] Where available, sensitivity testing should be performed on any *Mycoplasma* spp. isolate to help with antimicrobial selection. Macrolides and tetracyclines are generally effective for infections in other species. The role these organisms play in equine respiratory disease is still unclear, and investigation continues.

Glanders (Farcy)

Faisal Ghazi Habasha

Glanders is a serious zoonotic bacterial disease that primarily affects horses, mules, and donkeys. Some animals die acutely within a few weeks. Others become chronically infected and can spread the disease for years before succumbing. Without antibiotic treatment, the case fatality rate can be as high as 95%. Glanders also occurs in other mammalian species, particularly members of the cat family, dogs, sheep, goats, camels, and humans. Swine and cattle appear to be resistant.[1,2] The term *farcy* is limited to the visible appearance of external lesions, but in the latter case internal lesions always exist, although they may not be evident.[3]

Glanders is one of the oldest diseases of horses described. Absyrtus, a Greek veterinarian in the army of Constantine the Great (CE 300), described the disease with considerable accuracy and recognized that it was contagious.[4]

Etiology Glanders is caused by *Burkholderia mallei*, a nonmotile, nonsporulating, facultative intracellular gram-negative bacillus in the family Burkholderiaceae. The organism name comes from the Greek *melis* ("severe disease") and its Latin derivative *malleus* ("depicting a malignant disease"). The organism was first identified in Germany by Loeffler and Schutz in 1882 and confirmed as the cause of glanders in 1886.[3] The organism was formerly known as *Pseudomonas mallei* before being reclassified into the new genus *Burkholderia* in 1992. Traditionally the *Burkholderia* spp. are known as plant pathogens and soil bacteria, with two important exceptions, *B. mallei* and *Burkholderia pseudomallei*, the latter of which causes melioidosis. These two organisms differ in their survival in the environment. *B. mallei* is subject to inactivation in the environment, and it is not thought to persist outside equine hosts for long periods of time. Limited environmental survival, particularly in wet, humid, or dark conditions, may be possible for 3 to 5 weeks, and the organism can remain viable in 20° to 25° C (68° to 77° F) water for as long as a month.[4] It is inactivated by heat, direct sunlight, and commonly used disinfectants, including hypochlorites.[1-3]

GENOME STRUCTURE. The genome of *B. mallei* consists of two circular chromosomes. Chromosome 1 contains 3,510,148 base pairs (bp), and chromosome 2 contains 2,325,379 bp. A total of 5535 predicted protein-encoding open reading frames are identified in the genome.[5] The genome of this organism carries a large number of insertion sequences as compared with the related *B. pseudomallei*, with a large number

of simple sequence repeats that may function in antigenic variations of cell surface proteins (National Center for Biotechnology Information [NCBI] genome project).

GEOGRAPHIC DISTRIBUTION. Glanders was a concern during the 2016 Olympic Games in Brazil. It was also reported in western Europe in 2016.[6] Glanders is thought to be endemic in parts of the Middle East, Asia, Africa, Central America, and South America. Between 1998 and 2012, cases were reported in Brazil, Turkey, Russia, Eritrea, Ethiopia, Iran, Iraq,[7,8] United Arab Emirates, India, Pakistan, Afghanistan, and Mongolia, with suspected cases in other parts of Africa.[1] Glanders was reported active recently in Iran and the Philippines.[1] The disease was eliminated from horses in the United States during the 1940s, although one human case of glanders was reported in a laboratory worker in 2000.[9] This was the first human case reported in the United States since 1945.

Transmission

Glanders is mainly transmitted by contact with skin exudates and respiratory secretions from infected equids. Both latently infected and clinically ill animals can spread the disease.[1,2]

Horses, mules, and donkeys often become infected when they ingest *B. mallei*–contaminated food or water. The organism can also be spread in aerosols and via entry through skin abrasions and mucous membranes. Carnivores usually become infected when they eat contaminated meat. *B. mallei* is readily spread by fomites such as harnesses, grooming tools, and food and water troughs. Humans are infected by contact with sick animals, contaminated fomites, tissue, or bacterial cultures. Rare cases of person-to-person transmission have been reported in family members who nursed sick individuals. *B. mallei* has been weaponized and was used as a biological weapon against military horses and humans during World War I and World War II. Aerosols may be the major route of infection in bioterrorist attacks.[10]

INCUBATION PERIOD. The incubation period varies with the form of disease from a few days to several weeks. Septicemia or localized disease usually becomes apparent after 1 to 5 days, whereas the pulmonary form typically becomes clinically apparent after 10 to 14 days.[1,2]

Clinical Signs and Differential Diagnosis

In equids, glanders is traditionally categorized into nasal, pulmonary, and cutaneous forms (farcy).[1,2] In the nasal form, deep ulcers and nodules occur inside the nasal passages, resulting in a thick, purulent, yellowish discharge. This discharge may be unilateral or bilateral and can become bloody. Nasal perforation is possible. The regional (submaxillary) lymph nodes become enlarged and indurated and may suppurate and drain. Healed ulcers become star-shaped scars. In the pulmonary form, nodules and abscesses develop in the lungs. Some infections are inapparent, whereas others vary from mild dyspnea to severe respiratory disease. In more severe cases, the clinical signs include coughing, dyspnea, febrile episodes, and progressive debilitation. Diarrhea and polyuria may also be seen. Discharges from pulmonary abscesses can spread the infection to the upper respiratory tract.

In the cutaneous form, the skin contains nodules that rupture and ulcerate, discharging an oily, purulent yellow exudate (Fig. 31.38). The regional lymphatics and lymph nodes become chronically enlarged and are filled with purulent exudates. There may also be swelling of the joints and painful edema of the legs. Orchitis is a common symptom in males. Clinical cases are usually a combination of these forms and can occur as acute, chronic, or latent disease. Donkeys and mules, as a general rule, manifest the acute symptoms, which progress rapidly, whereas horses usually have the chronic or latent disease.

FIG. 31.38 Typical cutaneous form of glanders (known as farcy) showing skin nodules.

Nasal and pulmonary signs are usually seen in the acute form. The symptoms include a high fever, decreased appetite, coughing, progressive dyspnea, nasal discharge, and ulcers and nodules on the nasal mucosa. Bloody crusting may be seen on the nostrils, and there may be a purulent ocular discharge. The submaxillary lymph nodes are usually swollen and painful. Central nervous system signs have been reported in experimentally infected horses, possibly as the result of secondary bacterial infection from a compromised blood-brain barrier.[11] Animals with the acute form of glanders usually die in a few days to a few weeks.

The chronic form develops insidiously and results in progressive debilitation. The symptoms may include coughing, dyspnea, intermittent fever, enlargement of the lymph nodes, a chronic nasal discharge, and ulcers, nodules, and stellate scars on the nasal mucosa. The skin and lymphatics may also be involved. The chronic form is often fatal, but affected animals may live for years before succumbing to the disease.

In the latent form, there may be few symptoms other than a nasal discharge and occasional labored breathing. Lesions may be found only in the lungs.

The differential diagnoses for glanders include strangles caused by *Streptococcus equi;* epizootic lymphangitis, which is a chronic granulomatous and suppurative fungal infection caused by *Histoplasma farciminosum;* sporotrichosis, a chronic subcutaneous lymphatic mycosis caused by a gram-positive fungus *Sporotrichum schenckii;* ulcerative lymphangitis, a bacterial disease caused by *Corynebacterium pseudotuberculosis;* and melioidosis (Whitmore's disease), which is caused by *B. pseudomallei.* Melioidosis is particularly difficult to differentiate because *B. pseudomallei* and *B. mallei* cross-react in many serologic and hypersensitivity tests.[1,2]

Diagnosis

A diagnosis of glanders based on clinical signs can be made when *B. mallei* is isolated from samples or an immunologic reaction to the organism is detected serologically or on the basis of hypersensitivity test results. Isolation and identification of *B. mallei* in cultures of samples from lesions or various exudates, including respiratory secretions, is regarded as a gold standard for the diagnosis of glanders. *B. mallei* can be stained with methylene blue, Wright's stain, or Gram stain, but the staining can be weak or irregular, and bipolar staining of the gram-negative organism may be observed. They can be pleomorphic in older cultures, but in clinical samples and young cultures they typically form straight or slightly curved rods that are 0.3 to 0.8 μm in width and 2 to 5 μm in length. Some authors report that, in tissues, the organism is identified best with Giemsa stain.[12]

VetBooks.ir

B. mallei can be grown on routine culture media, including nutrient, blood, and MacConkey agars; growth is slow, but colonies are usually visible within 48 hours. Optimal growth occurs at 37° C (98.6° F).

Automated bacterial identification systems do not always correctly identify this organism. All isolations must be performed in biosafety level 3 laboratories. Inoculation into laboratory animals, particularly guinea pigs (the Strauss reaction) or hamsters, was used for identification of *B. mallei* in the past, but this technique is now rarely practiced.

A cell-mediated hypersensitivity reaction test (mallein intradermal skin test) was used extensively to screen horses for glanders. This test is still used to certify horses as negative for glanders during importation to some countries. It may also be used in the diagnosis of clinical cases. The mallein test is based on hypersensitivity reaction to mallein, a commercially available, purified protein derivative of *B. mallei.* The test is performed most often by intradermal palpebral injection. Reactors are identified by marked eyelid swelling that develops within 24 to 48 hours, accompanied by fever and occasionally by purulent ocular discharge. No reaction or minimal swelling of the eyelid develops in unsensitized animals. False-positive reactions can occur in animals that are sensitized to other closely related *Burkholderia* spp., including *B. pseudomallei*, and cross-reactions with *S. equi* have been described.

Serologic tests are sometimes used to screen horses for importation to glanders-free countries or to identify clinically affected animals. Measurable titers of serum antibody against *B. mallei* develop approximately 1 week after infection. Complement fixation was the preferred serologic test in past eradication programs because of its ability to detect subclinically or chronically infected animals. This test was most useful when the prevalence of disease was high. Complement fixation is still used by some countries to assess imported equids for glanders. Enzyme-linked immunosorbent assay tests are also used to screen animals for international trade. Other serologic tests include indirect hemagglutination,[13] counterimmunoelectrophoresis, immunoblotting, and indirect fluorescent testing, but these tests are not approved by the World Organisation for Animal Health (OIE) for use in international trade.[1,2] Rapid DNA tests, such as PCR assays, are now also used.

Treatment

Treatment of glanders is often not advised because infected animals may remain subclinically infected and shed *B. mallei*.[1,2] The risk of zoonotic transmission also discourages treatment. Systemic treatment with antibiotics, including penicillin and streptomycin, is usually ineffective in controlling the disease. Some evidence has accumulated that enrofloxacin, erythromycin, ampicillin, sulfonamide, gentamicin, and tetracycline might be effective against *B. mallei.* This evidence has emerged from in vitro antibiotic sensitivity testing and from treatment studies in experimentally infected guinea pigs. Experimentally, in lab animals effective treatments also include doxycycline, ceftazidime, gentamicin, and trimethoprim sulfas.[1]

Prevention and Control

Cases of glanders in animals must be reported to the OIE.[1] The occurrence of this disease in any country can result in restrictions on international trade in horses and other affected animals. The mallein test and complement fixation test are approved assays recommended by the OIE for international trade purposes.[1]

If glanders is detected, control measures include strict quarantine of all infected and exposed animals, diagnostic testing of animals with clinical signs indicative of glanders, and assessment of apparently normal equids with the elimination of those that react positively in screening tests. Ill animals and those with positive results of mallein tests are euthanized. Horses exposed to *B. mallei* that yield negative results in mallein tests are isolated and retested 2 to 3 weeks later. Carcasses and contaminated bedding and feed should be burned or buried. Equipment or other items in contact with infected animals should be disinfected.

People who handle tissues from infected animals, bacterial cultures, or contaminated fomites should implement strict precautions to prevent infection. Protective clothing, including masks, gloves, face shields, and gowns, should be worn. In clinical and research laboratories, *B. mallei* requires biosafety containment level 3 accommodation. Precautions are indicated for activities that are likely to produce aerosols, droplets, or concentrations of bacteria. Currently there is no commercial vaccine against glanders for use in humans or any other animal species.

Exercise-Induced Pulmonary Hemorrhage

Kenneth W. Hinchcliff

Exercise-induced pulmonary hemorrhage (EIPH) is a pervasive disorder of horses that perform strenuous exercise, well recognized in Thoroughbred and Standardbred racehorses and occurring in other breeds and uses of horses.[1-6] The disorder is associated with reduced performance of Thoroughbred racehorses and other breeds and costs the Thoroughbred and Standardbred racing industries in the United States and Canada between $100 million and $225 million (U.S. dollars [USD], year 1995 value) annually.

Management of EIPH in racehorses is the subject of much debate, especially within North America where the administration of furosemide is permitted on the day of racing.[7,8] The debate is fueled by concerns about the welfare of racehorses, the integrity of racing and use of medications on race day, and uncertainty about the etiology, pathophysiology, and optimal treatment of EIPH.[9] There are a number of recent reviews of EIPH.[10-12]

Definition and Etiology

EIPH is a disease that occurs only in horses during strenuous exercise.[10] It manifests as the presence of blood in the airways of horses after strenuous exercise. Definitions of EIPH vary from detection of blood using microscopic examination of BAL fluid or tracheal aspirates to observation of blood in the airways during tracheobronchoscopic examination.

The etiology of EIPH remains unclear, although the pathogenesis is now reasonably well described (see below).

Epistaxis and hemorrhage into airways can occur as a result of a number of diseases, including disorders of the upper airways and lungs (Table 31.12). Hemorrhage into the trachea or bronchi can be a result of EIPH, pulmonary abscess, fungal granuloma, trauma, pneumonia, pulmonary foreign body, or hemangiosarcoma or other pulmonary neoplasia. Epistaxis can be associated with all of these causes of hemorrhage into the lower airway and with diseases of the upper airway, including guttural pouch mycosis, ethmoidal hematoma, trauma, and neoplasia of the upper airways and associated structures. Thrombocytopenia can cause epistaxis.

There is evidence of a heritable component to exercise-associated epistaxis in Thoroughbred racehorses ($h^2 = 0.27$ for lifetime risk of epistaxis and 0.5 for risk of a repeated episode during an individual race,[13] and $h^2 = 0.23$ for an individual and 0.40 for a sire).[14] While there is evidence of heritability of epistaxis, there are no reports of the specific genetic factors contributing to EIPH (of which epistaxis is one manifestation; see below), such as could be identified by genome-wide association studies or other techniques.[15]

Clinical Signs and Differential Diagnosis

Poor athletic performance and epistaxis are the most common

TABLE 31-12

Causes of Epistaxis in Horses. (Reproduced With Modifications by Permission.[91])

Disease	Epidemiology	Clinical Signs and Diagnosis	Treatment and Control
Hemorrhage Into Trachea or Bronchi, Sometimes With Epistaxis			
Exercise-induced pulmonary hemorrhage (EIPH)	Horses after strenuous exercise Most common in Thoroughbred and Standardbred racehorses	Epistaxis is a rare but very specific sign of EIP; only occurs after exercise Endoscopic examination of the airways is diagnostic	Efficacy of various drugs used for treatment and control is debated Furosemide is used extensively before racing
Trauma	Sporadic; associated with trauma to head, neck, or chest	Physical examination reveals site and nature of the trauma; can require endoscopic examination of upper airways	Symptomatic treatment
Pneumonia	Recent transport or respiratory disease; can occur as outbreaks though usually individual animals	Fever, tachypnea, abnormal lung sounds, leukocytosis, radiography demonstrates lung lesions; cytological and microbiological examination of tracheal aspirate	Antimicrobials, NSAIDs, oxygen Control by vaccination and prevention of respiratory disease
Lung abscess	Sporadic; hemorrhage can occur after exercise	Sometimes no premonitory signs fever, depression, anorexia, cough hemogram demonstrates leukocytosis Hyperfibrinogenemia ultrasonography or radiography demonstrates lesion Tracheal aspirates	Antibiotics
Intrabronchial foreign body	Sporadic	Cough, hemoptysis, fever; endoscopy or radiography reveals foreign body	Removal of foreign body—often not readily achieved
Pulmonary neoplasia	Sporadic; often older horse, but not always hemangiosarcoma	Cough, hemoptysis demonstrate mass on ultrasonographic or radiographic examination	None
Epistaxis (in Addition to the Above Diseases)			
Guttural pouch mycosis	Sporadic; acute onset epistaxis	Severe, life-threatening epistaxis; tachycardia, anemia, hemorrhagic shock	Surgical ligation or occlusion of arteries in the guttural pouch
Ethmoidal hematoma	Sporadic	Epistaxis not associated with exercise Usually unilateral	Surgery or injection of mass with formaldehyde
Thrombocytopenia	Sporadic	Epistaxis, mild, intermittent Petechiation and ecchymotic hemorrhages Thrombocytopenia	Glucocorticoids
Coagulopathy	Sporadic, congenital or associated with ingestion of rodenticides	Epistaxis, increased bleeding from minor wounds, hemarthrosis,	Identify and correct underlying cause Vitamin K administration
Neoplasia	Sporadic	Neoplasia of upper airways	None
Trauma	Sporadic	Injury to head or pharynx	Symptomatic
Sinusitis	Sporadic	Endoscopic or radiographic examination of sinus	Drainage, antimicrobials

presenting complaints for horses with EIPH. Although poor performance might be attributable to any of a large number of causes, epistaxis associated with exercise is almost always secondary to EIPH.

Epistaxis due to EIPH occurs during or shortly after exercise and is usually first noticed at the end of a race, particularly when the horse is returned to the paddock or winner's circle and is allowed to lower its head. It is usually bilateral and resolves within hours of the end of the race. Epistaxis might occur on more than one occasion, especially when horses are raced or exercised at high speed soon after an initial episode. It is important to recognize that epistaxis is an uncommon manifestation of EIPH, occurring in as few as 4% of horses with EIPH.[16]

EXERCISE-INDUCED PULMONARY HEMORRHAGE AND PERFORMANCE. Failure of racehorses to perform to the expected standard (poor performance) is often, accurately or not, attributed to EIPH.[17] Many horses with poor performance have cytologic evidence of EIPH on microscopic examination of tracheobronchial aspirates or BAL fluid or have blood evident on endoscopic examination of the tracheobronchial tree performed 30 to 90 minutes after strenuous exercise or racing. However, it is important to recognize that EIPH is very common in racehorses, and it should be considered the cause of poor performance only after other causes have been eliminated. Severe EIPH undoubtedly results in poor performance and, on rare occasions, death of Thoroughbred racehorses.[10,17,18] Thoroughbred horses with EIPH have impaired performance

compared to unaffected horses.[17,19,20] The severity of EIPH is negatively correlated to race performance, with more severely affected horses having a lower likelihood of finishing in the first three places; they are less likely to be elite money earners and finish further behind the winner than do unaffected horses.[17,19,20]

Results of studies in Standardbred racehorses indicate either a lack of effect of EIPH on performance or an association between EIPH and superior performance. There was no relationship between presence of EIPH and finishing position in 29 Standardbred racehorses with intermittent EIPH, each examined on at least two occasions, or in 92 Standardbred racehorses examined on one occasion. However, of 965 Standardbred racehorses examined after racing, those finishing first or second were 1.4 times more likely (95% confidence interval 0.9 to 2.2) to have evidence of EIPH on tracheobronchoscopic examination than were horses that finished in seventh or eighth position.

There is no clear association between EIPH and performance (time) in barrel racing Quarter Horses.[21]

Diagnostic Approach

PHYSICAL EXAMINATION. Apart from epistaxis in a small proportion of affected horse, there are few abnormalities detectable on routine physical examination of horses with EIPH. Rectal temperature and heart and breathing rates might be elevated as a consequence of exercise in horses examined soon after exercise, but values of these variables in horses with EIPH at rest are not noticeably different from horses with no evidence of EIPH. Affected horses might swallow more frequently during recovery from exercise than do unaffected horses, probably as a result of blood in the larynx and pharynx. Coughing is common in horses recovering from strenuous exercise and after recovery from exercise; horses with EIPH are no more likely to cough than are unaffected horses.[10] Other clinical signs related to respiratory abnormalities are uncommon in horses with EIPH. Respiratory distress is rare in horses with EIPH and when present indicates severe hemorrhage or other serious lung disease such as pneumonia, pneumothorax, or rupture of a pulmonary abscess. Lung sounds are abnormal in a small number of EIPH-affected horses and, when present, are characterized by increased intensity of normal breath sounds during rebreathing examination. Crackles may be auscultated over the trachea in horses with EIPH but are also heard in unaffected horses.

TRACHEOBRONCHOSCOPY. Observation of blood in the trachea or large bronchi of horses 30 to 120 minutes after racing or strenuous exercise provides a definitive diagnosis of EIPH. The amount of blood in the large airways varies from a few small specks on the airway walls to a stream of blood occupying the ventral one third of the trachea. Blood might also be present in the larynx and nasopharynx. If there is a strong suspicion of EIPH and blood is not present on a single examination conducted soon after exercise, the examination should be repeated in 60 to 90 minutes. Some horses with EIPH do not have blood present in the rostral airways immediately after exercise but do have blood when examined 1 to 2 hours later. Blood is detectable by tracheobronchoscopic examination for 1 to 3 days in most horses, with some horses having blood detectable for up to 7 days.

Bronchoscopic examination can be used to estimate the severity of EIPH through the use of a grading system. The interobserver repeatability of tracheobronchoscopic assessment of severity of EIPH using a 0 to 4 grading scale is excellent, and this scoring system has been widely adopted (Table 31.13).[16,17,20-23]

It is assumed that a higher score represents more severe hemorrhage, but while the repeatability of this scoring system has been established, the relationship between the amount of blood in the large airways and the actual amount of hemorrhage has not been established.

TABLE 31.13

Validated System for Grading the Severity of Exercise-Induced Pulmonary Hemorrhage Detected on Tracheobronchoscopic Examination of Thoroughbred Racehorses[92]

Grade 0	No blood detected in the pharynx, larynx, trachea, or main stem bronchi
Grade 1	Presence of one or more flecks of blood or ≤2 short (<quarter the length of the trachea), narrow (<10% of the tracheal surface area) streams of blood in the trachea or main stem bronchi visible from the tracheal bifurcation
Grade 2	One long stream of blood (>half the length of the trachea) or >2 short streams occupying less than one third of the tracheal circumference
Grade 3	Multiple, distinct streams of blood covering more than one third of the tracheal circumference. No blood pooling at the thoracic inlet
Grade 4	Multiple, coalescing streams of blood covering >90% of the tracheal surface, with pooling of blood at the thoracic inlet

RADIOGRAPHY. Thoracic radiography is of limited use in detecting horses with EIPH. Radiographs can demonstrate the presence of densities in the caudodorsal lung fields of some horses, but many affected horses have minimal to undetectable radiographic abnormalities.[10] Examination of thoracic radiographs of horses with EIPH can be useful in ruling out the presence of another disease process, such as a pulmonary abscess, contributing to the horse's pulmonary hemorrhage or poor athletic performance. The utility of thoracic ultrasound for detection of EIPH has not been extensively reported. One report of detecting EIPH in 81% of 157 horses in which EIPH was diagnosed by relatively liberal assessment of BAL fluid reported sensitivity of presence of comet-tail lesions for diagnosis of EIPH of 86% and specificity of 25%,[24] indicating that ultrasound examination of the thorax has limited utility in confirming the presence of EIPH.

Clinical Pathology

EXAMINATION OF AIRWAY SECRETIONS OR LAVAGE FLUID. The presence of red blood cells or macrophages containing either effete red blood cells or the breakdown products of hemoglobin (hemosiderophages) in tracheal or bronchoalveolar lavage fluid provides evidence of EIPH.[25] Detection of red blood cells or hemosiderophages in tracheal aspirates or BAL fluid is believed to be both sensitive and specific in the diagnosis of EIPH, although in the absence of a gold standard for diagnosis, this claim is yet to be validated. Examination of airway fluids from a variety of breeds and uses of horses, including barrel racing horses,[21] indicates the presence of EIPH in a greater proportion of horses than does tracheobronchoscopic examination after strenuous exercise or racing. The greater sensitivity of examination of airway fluid is probably attributable to the ability of this examination to detect the presence of small amounts of blood or its residual products and the longevity of these products in the airways. Although endoscopic examination can detect blood in occasional horses up to 7 days after an episode of EIPH, cellular evidence of pulmonary hemorrhage persists for weeks after a single episode.

VetBooks.ir

VetBooks.ir

Red blood cells and macrophages containing red blood cells are present in BAL fluid or tracheal aspirates for at least 1 week after strenuous exercise or instillation of autologous blood into airways, and hemosiderophages are present for at least 21 days and possibly longer.[26]

Recent studies have reported on the use of red blood cell numbers in BAL fluid as a quantitative indicator of EIPH.[21,25,27-29] The diagnostic cutoff has not been determined, although 1000 cells/μL was used in one study,[21] and there is only a weak correlation between EIPH score determined by tracheobronchoscopic examination and red blood cell count in BAL fluid ($r^2 = 0.15$).[21] However, this indicator of EIPH severity has not been validated nor demonstrated to be more reliable or repeatable than tracheobronchoscopic examination and visual scoring. Furthermore, considerable concern exists over the suitability of red blood cell counts in BAL fluid for assessment of severity of EIPH given that an unknown area, although presumably small, of the lung is examined by lavage and there is a risk that this area of lung might not be representative of the lung as a whole, similar to the situation of examination of BAL fluid of horses with pneumonia.[7] BAL of sections of both lungs, achieved using an endoscope, might obviate some of these concerns given that BAL results of each lung in a horse differ.[30]

Tracheal aspirates can be obtained any time after exercise by aspiration either during tracheobronchoscopic examination or through a percutaneous intratracheal needle. Aspirates obtained through an endoscope may not be sterile, depending on the collection technique. BAL fluid can be obtained through either an endoscope wedged in the distal airway or a cuffed tube inserted blindly into a distal airway. Collection of fluid through an endoscope has the advantage of permitting examination of the distal airways and selection of the area of lung to be lavaged. However, it does require the use of an endoscope that is longer (2 m) than those readily available in most equine practices. Use of a commercial BAL catheter does not require use of an endoscope, and this procedure can be readily performed in field situations.

Necropsy

EIPH is a rare cause of death of racehorses, but among racehorses that die during racing for reasons other than musculoskeletal injuries, EIPH is common.[18] Necropsy examination of horses is usually incidental to examination for another cause of death. Grossly, horses examined within hours of strenuous exercise, such as horses examined because of catastrophic musculoskeletal injuries incurred during racing, can have severe petechiation in the caudodorsal lung fields. Horses with chronic disease have blue/gray or blue/brown discoloration of the visceral pleural surfaces of the caudodorsal lung fields that is often sharply demarcated, especially on the diaphragmatic surface. The discoloration affects both lungs equally with 30% to 50% of the lung fields being discolored in severe cases. Affected areas do not collapse to the same extent as unaffected areas and in the deflated lung have a spleen-like consistency. On cut surface, the discolored areas of lung are predominantly contiguous with the dorsal pleural surface and extend ventrally into the lung parenchyma. Areas of affected lung can be separated by normal lung. There is proliferation of bronchial vessels, predominantly arteries and arterioles, in affected areas. Histologically, affected areas exhibit bronchiolitis, hemosiderophages in the alveolar lumen and interstitial spaces, and fibrosis of interlobular septa and pleura and around vessels and bronchioles.

Pathogenesis

The cause of EIPH is rupture of alveolar capillary membranes with subsequent extravasation of blood into interstitial and alveolar spaces. The source of blood in such instances is the pulmonary circulation. Bleeding from bronchial circulation during exercise has been suggested, based on histologic evidence of bronchial angiogenesis in horses that have experienced previous episodes of EIPH, but contribution of the bronchial circulation to EIPH has not been demonstrated. Regardless of the contribution of bronchial circulation to blood in the airways, the likely proximate lesion is in capillaries associated with the pulmonary circulation, with the causative lesion likely in the pulmonary veins. In other words, pulmonary capillaries rupture, allowing blood to escape into the alveoli (the proximate lesion) due to lesions in the pulmonary veins that increase pulmonary capillary pressure. There is increasing evidence that the primary lesion is arteriovenous remodeling of pulmonary veins and that this remodeling differs in severity among lung regions and with the intensity of training.[31-37] Remodeling of pulmonary veins results in loss of distensibility and partial occlusion to blood flow, with subsequent presumed increases in pulmonary alveolar capillary pressure.[31,38] Hemorrhage into the interstitial space and alveoli, with subsequent rostral movement of blood in the airways, results in blood in the trachea and bronchi.

Rupture of alveolar capillaries occurs secondary to an exercise-induced increase in transmural pressure (pressure difference between the inside of the capillary and the alveolar lumen), which, as noted above, can occur as a result of venous remodeling and loss of distensibility of pulmonary veins.[35] If the transmural stress exceeds the tensile strength of the capillary wall, the capillary ruptures. The proximate cause of alveolar capillary rupture is the high transmural pressure generated by positive intracapillary pressures, which are largely attributable to capillary blood pressure, and the lower intraalveolar pressure generated by the negative pleural pressures associated with inspiration.

During exercise, the absolute magnitudes of both pulmonary capillary pressure and alveolar pressure increase, with a consequent increase in transmural pressure. Strenuous exercise is associated with marked increases in pulmonary artery pressure in horses. Values for mean pulmonary arterial pressure at rest of 20 to 25 mm Hg increase to more than 90 mm Hg during intense exercise because of the large cardiac output achieved by exercising horses.[39] The increases in pulmonary artery pressure, combined with an increase in left atrial pressure during exercise, probably result in an increase in pulmonary capillary pressure. Combined with the increase in pulmonary capillary pressure is a marked decrease (more negative) in pleural, and therefore alveolar, pressure during exercise. The pleural pressure of normal horses during inspiration decreases from approximately –0.7 kPa (–5.3 mm Hg) at rest to as low as –8.5 kPa (64 mm Hg) during strenuous exercise. Together, the increase in pulmonary capillary pressure and decrease (more negative) in intrapleural (alveolar) pressure contribute to a marked increase in stress in the alveolar wall. Although the alveolar wall and pulmonary capillaries of horses are stronger than those of other species, rupture may occur because the wall stress in the alveolus exceeds the mechanical strength of the capillary.[40-42]

Other theories of the pathogenesis of EIPH include small airway disease, upper airway obstruction, hemostatic abnormalities, changes in blood viscosity and erythrocyte shape, intrathoracic sheer forces associated with gait, and bit-induced asphyxia.[43,44] It is likely that the pathogenesis of EIPH involves several processes, including pulmonary hypertension, lower alveolar pressure, and changes in lung structure, that summate to induce stress failure of pulmonary capillaries.

Obstruction of either the upper or the lower airway has been proposed as a cause of EIPH. Inspiratory airway obstruction results in more negative intrapleural, and therefore alveolar, pressures. This effect is exacerbated by exercise, with the result that alveolar transmural pressure is greater in horses with airway obstruction. The higher transmural pressure in such horses can increase the severity of EIPH, although this has not been demonstrated. Moreover, although inspiratory airway obstruction might predispose to EIPH, the prevalence of this condition

is much less than that of EIPH, indicating that it is not the sole factor inducing EIPH in most horses.

Horses with moderate to severe EIPH have histologic evidence of inflammation of the small airways, and there is a clear association between the presence of EIPH and inflammatory changes in bronchoalveolar or tracheal aspirate fluid. However, instillation of autologous blood into the airways does not induce a marked inflammatory response in normal horses, and it is therefore unclear whether inflammation alone induces or predisposes to EIPH.[45,46] Theoretically, small airway inflammation and bronchoconstriction have the potential to produce intrathoracic airway obstruction and therefore a more negative alveolar pressure. Given that small airway disease is common in horses, there is the potential for an important effect of factors, such as viral infections, air pollution, and allergic airway disease, to contribute to the initiation or propagation of EIPH.

The characteristic location of lesions of EIPH in the caudodorsal lung fields has led to the proposal that hemorrhage is a result of tissue damage occurring when waves of stress, generated by forelimb foot strike, are focused and amplified into the narrowing cross-sectional area of the caudal lung lobes.[47] According to the theory, the locomotor impact of the forelimbs results in transmission of forces through the scapula to the body wall, from where they pass into the lungs and caudally and dorsally. As the wave of pressure passes into the narrower caudodorsal regions of the lungs, it generates progressively greater shearing forces that disrupt tissue and cause EIPH. However, studies of intrapleural pressures have not demonstrated the presence of a systemic pressure wave passing through the lung and do not provide support for this hypothesis. Furthermore, track surface is not associated with incidence of EIPH in Thoroughbred racehorses.[22,48]

Horses with EIPH have been suspected of having defects in either hemostasis or fibrinolysis. However, although exercise induces substantial changes in blood coagulation and fibrinolysis,[49] these is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis.[50]

Regardless of the cause, rupture of pulmonary capillaries and subsequent hemorrhage into airways and interstitium cause inflammation of both airways and interstitium, with subsequent development of fibrosis and alteration of tissue compliance. Heterogeneity of compliance within the lungs, and particularly at the junction of normal and diseased tissue, results in the development of abnormal shear stress with subsequent tissue damage. These changes are exacerbated by inflammation and obstruction of small airways, with resulting uneven inflation of the lungs. The structural abnormalities, combined with pulmonary hypertension and the large intrathoracic forces associated with respiration during strenuous exercise, cause repetitive damage at the boundary of normal and diseased tissue with further hemorrhage and inflammation. The process, once started, is lifelong and continues for as long as the horse continues to perform strenuous exercise.[35]

Epidemiology

EIPH is primarily a disease of horses, although it also occurs in racing camels and Greyhounds.[51,52] EIPH occurs in horses worldwide, and there does not appear to be any geographic distribution. It is a disorder of horses that run at high speed, such as Thoroughbred, Standardbred, or Quarter Horse racehorses; Quarter Horses used for barrel racing; and polo ponies.[2,5,21,53-55] The disorder is uncommon in endurance horses and is rare in draft breeds.[11,56] There is increasing recognition of its importance in sport horses, including 3-day event and show jumping, but there are no reports of the disease in horses used for dressage, although it is thought to occur.[57,58]

EIPH is considered to be associated with death during racing or in the hours after completion of racing in Thoroughbred and Standardbred horses,[59,60] although there is minimal evidence of the relative risk of death during racing of horses with EIPH.[10] Estimates of the incidence of such "sudden" deaths associated with EIPH in two large studies were 38% (60 of 157) and 35% (50 of 143) of deaths not attributable to musculoskeletal injury in Thoroughbreds, Standardbreds, and Quarter Horses or in solely Thoroughbreds, respectively.[59,60] However, there is uncertainty among some pathologists in attributing the cause of death to EIPH, and the role of EIPH in causing death of horses during strenuous exercise is unclear. Recognizing the subjectivity of both the diagnosis and the attribution of cause of death, it is suggested that EIPH associated with death during racing should be classified as "exercise-associated fatal pulmonary hemorrhage."[59]

The prevalence of EIPH varies with the method used to detect it and the frequency with which horses are examined, as discussed later in this section. Epistaxis associated with exercise is almost always attributable to pulmonary hemorrhage and occurs only in a small proportion of racehorses. Epistaxis occurs in only 3% of horses that have blood detected in the trachea by endoscopic examination performed within 2 hours of racing. The prevalence of epistaxis in racehorses varies between 0.1% and 9.0%, with the frequency depending on the breed, age, and sex of horses selected for study; the type of racing; and the timing and frequency of observation of horses after racing. Epistaxis is more common in older horses. There are conflicting reports of a sex predisposition, although epistaxis might be more common in female Thoroughbreds.[61] Epistaxis is more common after races of less than 1600 m than in longer races, although not all sources agree on this point. However, horses in steeplechase races, which are typically longer than 2000 m, are at greater risk of epistaxis than are horses in flat races.[47,61-63] Incidence of epistaxis in steeplechase horses in the United Kingdom is 5.3 per 1000 starts and 3.6 per 1000 starts in hurdle racing.[1] Risk factors for horses in jumps races (steeplechase) include previous epistaxis (odds ratio [OR] 6.1 [4.4 to 8.3]), racing in a claiming race (OR 5.9 [1.4 to 25]), more than 9 starts in the previous 4 to 6 months (OR 10 [2 to 47]), and racing on firmer ground.[1] *In summary, epistaxis is relatively uncommon, and most horses with EIPH do not have epistaxis.*

There are a variety of other methods of detecting EIPH, including endoscopic examination of the airways and microscopic examination of tracheal aspirates or BAL fluid, and the incidence, or prevalence depending on the study design, is influenced by the method used to detect EIPH and the definition of the disease.[10]

Almost all Thoroughbred racehorses in active training, and a large proportion of other types of horses undergoing regular high-speed exercise, have hemosiderophages in BAL fluid, indicating that all have some degree of EIPH.[27,64-66] The prevalence of EIPH decreases when diagnosis is based on endoscopic examination of horses after exercise or racing.

EIPH is very common in Thoroughbred racehorses, with estimates of prevalence, based on a single endoscopic examination of the trachea and bronchi, of 43% to 75%.[16,17] The prevalence increases with the frequency of examination, with more than 80% of horses having evidence of EIPH on at least one occasion after examination after each of three consecutive races.[67] There can be considerable variability in severity of EIPH within an individual horse on repeated examination over a racing season, with this variability being greatest in horses that have EIPH of the greatest severity.[16] Horses with evidence of EIPH on one examination are likely to have EIPH detected on subsequent endoscopic examinations, most commonly at low grade (Grade 1 or Grade 2).[16] The prevalence of EIPH in Standardbred racehorses is assumed to be lower, with 26% to 34% of horses reported to have blood in the trachea after racing. However, these studies were based on a single examination, and one study only reported

VetBooks.ir

as positive those horses with blood covering more than one half the tracheobronchial tree. When examined after each of three races, 87% of Standardbred racehorses have evidence of EIPH on at least one occasion, suggesting that EIPH is as common in Standardbred racehorses as it is in Thoroughbred racehorses.[68]

EIPH occurs in approximately 62% of racing Quarter Horses and in 54% of Quarter Horses used for barrel racing when the diagnosis is based on tracheobronchoscopy and 66% when the diagnosis is based on a red blood cell count exceeding 1000 cells/μL.[21,55] Approximately 11% of polo ponies are affected with EIPH.[5,6] The disease does not appear to occur with any important frequency in draft horses but is not well documented.[56]

Age is considered a risk factor for EIPH, with the prevalence of the disorder being higher in older horses, but the risk factor is the amount of racing a horse has completed, not its age.[69,70] There is no consistent association of sex with prevalence of EIPH. Among Thoroughbred racehorses there is an unclear relationship between the speed of racing and the risk of EIPH.[22,69] Lesions of EIPH are not detected in young Thoroughbred racehorses that have trained at speeds of less than 7 m/s.[71]

The risk of EIPH increases with racing at lower ambient temperatures[22,69] and with the wearing of bar shoes during racing.[22] There is no association between risk of EIPH and track hardness.[22,69]

Treatment Prevention of EIPH is contentious, as it can involve the administration of medications on the day of racing.[8] The efficacy of various interventions and medications has recently been evaluated in two systematic reviews that concluded that there was moderately strong to strong evidence that administration of furosemide before racing reduces the frequency and severity of EIPH in Thoroughbred racehorses.[10,12] There is either weak evidence or no evidence of efficacy of other interventions. There is a recommendation for use of furosemide, but because of the regulatory issues related to its use, this is only a weak recommendation.[10] Were there not regulatory considerations, the recommendation for use of furosemide would likely be strong, based on evidence of efficacy. Clearly, the decision to permit administration of furosemide to horses on the day of racing is based not only on its clinical efficacy but also on considerations of the welfare of the horse, integrity of wagering, policies on medication use in racehorses, and opinions of owners, bettors, trainers, and the public.[9]

A comprehensive evaluation of the efficacy of medications putatively used to treat or prevent EIPH is available, including citations to research.[10] Common features of many studies of interventions to reduce the incidence or severity of EIPH are use of a small number of horses, use of horses with signalment that is not typical of those affected by EIPH, an exercise model other than that which causes EIPH (e.g., treadmill exercise instead of overground exercise or racing), and lack of adequate reporting of results.[10,72] A key shortcoming of small studies is that they might fail to detect a treatment effect when such an effect does exist – the so called Type 2 error rate of underpowered studies.[72]

Furosemide apparently reduces pulmonary capillary pressure in exercising horses and likely does so by reducing blood and plasma volume as a result of profound diuresis.[73-76] There appears to be a direct effect of furosemide on pulmonary vasculature in some species,[77] but prevention of diuresis by ligation of ureters abolishes the hemodynamic effect of furosemide in anesthetized horses, suggesting that this is not an important mechanism of its hemodynamic effect in horses.[78]

Furosemide administration as prophylaxis against EIPH is permitted in a number of racing jurisdictions worldwide, most notably in Canada, the United States, Mexico, and most of the South American countries.[73] Within the United States and Canada, almost all Thoroughbred, Standardbred, and Quarter Horse racing jurisdictions permit administration of furosemide before racing. The vast majority (>90%) of Thoroughbred horses racing in the United States receive furosemide before racing, at an estimated annual cost of between $6 million and $20 million (USD, 1995 value). Although accurate numbers are not available, it appears that a smaller proportion of Standardbred and Quarter Horse racehorses receive furosemide before racing.

Therapy of EIPH is usually a combination of attempts to reduce the severity of subsequent hemorrhage and efforts to minimize the effect of recent hemorrhage. Treatment of EIPH is problematic for a number of reasons. First, the pathogenesis of EIPH has not been determined, although the available evidence supports a role for stress failure of pulmonary capillaries secondary to exercise-induced pulmonary hypertension. Second, with the exception of furosemide, there is a lack of information using large numbers of horses under field conditions that demonstrates an effect of any medication or management practice on EIPH. There are numerous studies of small numbers of horses (<40) under experimental conditions, but these studies often lacked the statistical power to detect treatment effects, and furthermore, the relevance of studies conducted on a treadmill to horses racing competitively is questionable.[10] Treatments for EIPH are usually intended to address a specific aspect of the pathogenesis of the disease and will be discussed in that context, but they should be considered in the context of the amount and strength of evidence, which for most treatments is scant and weak.

PREVENTION OF STRESS FAILURE OF THE PULMONARY CAPILLARIES. There is interest in reducing the pressure difference across the pulmonary capillary membrane in an effort to reduce EIPH. Theoretically, this can be achieved by reducing the pressure within the capillary or increasing (making less negative) the pressure within the intrathoracic airways and alveolus.

REDUCING PULMONARY CAPILLARY PRESSURE. Furosemide administration as prophylaxis of EIPH is permitted in a number of racing jurisdictions worldwide, most notably in Canada, the United States, Mexico, and most South American countries. Within the United States and Canada, almost all Thoroughbred, Standardbred, and Quarter Horse racing jurisdictions permit administration of furosemide before racing.

The efficacy of furosemide in treatment of EIPH is now well documented.[12,67] The mechanism by which furosemide reduces the severity of EIPH is unknown, although it is speculated that furosemide, by attenuating the exercise-induced increase in pulmonary artery and pulmonary capillary pressure of horses, reduces the frequency or severity of pulmonary capillary rupture. Whether this occurs as a result of furosemide's direct effect on pulmonary vasculature or an indirect effect resulting from a reduction in blood volume is unknown.[78-82]

Furosemide is associated with superior performance in both Thoroughbred and Standardbred racehorses, which further complicates assessment of its efficacy in treating EIPH.[83]

An increase in pulmonary capillary pressure secondary to altered rheostatic properties of blood during exercise has been suggested as a possible contributing factor for EIPH.[84]

INCREASING ALVEOLAR INSPIRATORY PRESSURE. Airway obstruction, either intrathoracic or extrathoracic, increases airway resistance and results in a more negative intrathoracic (pleural) pressure during inspiration to maintain tidal volume and alveolar ventilation. Causes of extrathoracic airway obstruction include laryngeal hemiplegia and other abnormalities of the upper airway, whereas intrathoracic obstruction is usually a result of bronchoconstriction and inflammatory airway disease.

VetBooks.ir

Horses with partial extrathoracic inspiratory obstruction or bronchoconstriction and airway inflammation associated with recurrent airway obstructive disease (heaves) have pleural (and hence alveolar) pressures that are lower (more negative) than those in unaffected horses or in horses after effective treatment. Hypothetical relationships between the horse's bit, airway obstruction, and EIPH are not supported to date by empirical evidence.[43,44]

Partial inspiratory obstruction, such as produced by laryngeal hemiplegia, exacerbates the exercise-induced decrease in intrapleural pressures with a consequent increase in transmural capillary pressures. These changes can exacerbate the severity of EIPH, although an association between upper airway obstructive disease and EIPH has not been demonstrated. Surgical correction of airway obstruction is expected to resolve the more negative intrapleural pressure, but its effect on EIPH is unknown.

Recently, the role of the nares in contributing to upper airway resistance, and hence lowering inspiratory intrapleural pressure during intense exercise, has attracted the attention of some investigators. Application of nasal dilator bands (Flair strips) reduces nasal resistance by dilating the nasal valve and reduces the red blood cell count of BAL fluid collected from horses after intense exercise on a treadmill.[28] Furthermore, application of the nasal dilator strips to horses in simulated races reduces red blood cell count in BAL fluid of some but not all horses.

The role of small airway inflammation and bronchoconstriction in the pathogenesis of EIPH is unclear. However, horses with EIPH are often treated with drugs intended to decrease lower airway inflammation and relieve bronchoconstriction. Beta-adrenergic bronchodilatory drugs such as clenbuterol and albuterol (salbutamol) are effective in inducing bronchodilation in horses with bronchoconstriction, but their efficacy in preventing EIPH is either unknown or, in very small studies, not evident.[10] Corticosteroids, including dexamethasone, fluticasone, and beclomethasone administered by inhalation, parenterally, or enterally, reduce airway inflammation and obstruction but have no demonstrated efficacy in preventing EIPH. Cromolyn sodium (sodium cromoglycate) has no efficacy in preventing EIPH.[85]

Water vapor treatment (inhalation of water-saturated air) has been proposed as a treatment for EIPH because of its putative effect on small airway disease. However, water vapor treatment has no effect on EIPH.[86]

The use of bedding of low allergenic potential (shredded paper) to prevent EIPH has no apparent effect on prevalence of the condition.[87] While it is suggested that preventing or minimizing small airway disease might reduce the severity of EIPH, studies to demonstrate such an effect have not been reported. However, optimizing the air quality in barns and stables and preventing infectious respiratory disease appear to be sensible precautions.

INTERSTITIAL INFLAMMATION AND BRONCHIAL ANGIOGENESIS. Hemorrhage into interstitial tissues induces inflammation, with subsequent development of fibrosis and bronchial artery angiogenesis. The role of these changes in perpetuating EIPH in horses is unclear but is probably of some importance. Treatments to reduce inflammation and promote healing with minimal fibrosis have been proposed. Rest is an obvious recommendation, and many racing jurisdictions have rules regarding enforced rest for horses with epistaxis. While the recommendation for rest is intuitive, there is no information that rest reduces the severity or incidence of EIPH in horses with prior evidence of this disorder.

Similarly, corticosteroids are often administered, either by inhalation, enterally, or parenterally, in an attempt to reduce pulmonary inflammation and minimize fibrosis. Again, the efficacy of this intervention in preventing or minimizing severity of EIPH has not been documented.

COAGULOPATHY AND FIBRINOLYSIS. Exercise induces substantial changes in blood coagulation and fibrinolysis. However, there is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis. Regardless, aminocaproic acid, a potent inhibitor of fibrin degradation, has been administered to horses to prevent EIPH. The efficacy of aminocaproic acid in preventing EIPH has not been demonstrated.[10] Similarly, estrogens are given to horses with the expectation of improving hemostasis, although the effect of estrogens on coagulation in any species is unclear. There is no evidence that estrogens prevent EIPH in horses.

Vitamin K is administered to horses with EIPH, presumably in the expectation that it will decrease coagulation times. However, because EIPH is not associated with prolonged bleeding times, it is unlikely that this intervention will affect the prevalence or severity of EIPH.

PLATELET FUNCTION. Aspirin inhibits platelet aggregation in horses and increases bleeding time. Seemingly paradoxically, aspirin is sometimes administered to horses with EIPH because of concerns that increased platelet aggregation contributes to EIPH. There is no evidence that aspirin either exacerbates or prevents EIPH. There is evidence of considerable variability between horses in the effect of aspirin on platelet function.[88]

CAPILLARY INTEGRITY. Capillary fragility increases the risk of hemorrhage in many species. Various bioflavonoids have been suggested to increase capillary integrity and prevent bleeding. However, hesperidin and citrus bioflavonoids have no efficacy in prevention of EIPH in horses.[89] Similarly, vitamin C is administered to horses with EIPH without scientific evidence of any beneficial effect.

SUMMARY OF TREATMENT OPTIONS. Selection of therapy for horses with EIPH is problematic.[10] Given that most horses have some degree of pulmonary hemorrhage during most bouts of intense exercise, the decision must be made as to not only the type of treatment and its timing but also which horses to treat. Moreover, the apparently progressive nature of the disease with continued work highlights the importance of early and effective prophylaxis and emphasizes the need for studies of factors such as air quality, respiratory infections, individual differences in susceptibility, and frequency and duration of high-intensity exercise in inciting the disorder.[35]

The currently favored treatment for EIPH is administration of furosemide before intense exercise.[10] Its use is permitted in racehorses in a number of countries but is contentious in many. A frequent practice is to administer furosemide before high-speed training, and not on the day of racing, in jurisdictions that do not permit race-day administration of medications. There is increasing interest in the effect of furosemide administered 24 hours before racing on the incidence or severity of EIPH.[90] Its efficacy in this situation remains to be determined, although a recent study found that furosemide administered 24 hours before simulated racing did not reduce the incidence or severity of EIPH compared to a saline placebo treatment.[29] However, the study did not have sufficient statistical power to detect important differences in EIPH grade or red blood cell count in BAL fluid; there is a high risk of type 2 error (failure to detect a difference when one actually exists), as is the case with many studies of treatments for EIPH that include small numbers of horses (in this case, 15).[10] The association between furosemide administration and superior performance in Standardbred and Thoroughbred

racehorses should be considered when recommending use of this drug.

Prevention and Control There are no documented preventive strategies. Rest is an obvious recommendation for horses with EIPH, but the hemorrhage is likely to recur when the horse is next strenuously exercised. The duration of rest and the optimal exercise program to return horses to racing after EIPH is unknown, although some jurisdictions require exercise no more intense than trotting for 2 months. Firm recommendations cannot be made on duration of rest because of a lack of objective information.

Although a role for lower airway disease (either infectious or allergic) in the genesis of EIPH has not been demonstrated, control of infectious diseases and minimization of noninfectious lower airway inflammation appear prudent.

Concern about the role of impact waves in the genesis of EIPH has led to discussion of "low-stress" training protocols, but these have not been adequately evaluated.

Prognosis Horses that have experienced one episode of epistaxis are more likely to have a second episode. For this reason most racing jurisdictions do not permit horses with epistaxis to race for a period of weeks to months after the initial instance, with more prolonged enforced rest after a subsequent episode of epistaxis and retirement from racing after a third bout. The recurrence rate after one episode of epistaxis in Thoroughbred horses is 20% to 30%.[13,62] This high rate of recurrence suggests that the inciting pulmonary lesions have not healed.

Long-term examination of performance of horses with EIPH indicates that horses with Grade 4 EIPH have shorter racing careers, but it is not clear if this is a function of the biology of the disease or a management decision by owners and trainers.[70] There is no association between measures of long-term performance measured over 10 years and Grades 1, 2, or 3 of EIPH in Thoroughbred racehorses.[70] Racehorses in Hong Kong that are EIPH positive on one or more occasions do not have fewer starts than horses for which EIPH was not detected (18 versus 15, $P = 0.17$) on endoscopic examination.[16]

Equine Thoracic Neoplasia

Fabio Del Piero • Pamela A. Wilkins

Surveys of equine neoplasms indicate a low prevalence of thoracic neoplasia in the horse. In an abattoir survey in London of 1308 horses, only 2 horses had pulmonary tumors: one granular cell tumor and one bronchiolar adenoma.[1] Two other necropsy surveys of 155 and 687 equines reported no thoracic neoplasms.[2,3] A report on chronic pulmonary disease in the horse states that the practical importance of lung tumors in this species is negligible.[4] University of Pennsylvania researchers examined 5629 horses between 1968 and 1987. Thirty-five horses had neoplasia involving the thoracic cavity, corresponding to a prevalence of 0.62%.[5]

The prevalence of primary lung neoplasms of any type is reported to be less than 1% of all reported neoplasms in domestic animals.[6] The lungs are susceptible to tumor emboli because of the filter action of the capillary bed associated with small capillary diameter and, perhaps, specific adhesion factors. It can sometimes be difficult or even impossible to distinguish metastatic disease from primary pulmonary neoplasia; thus an important part of the diagnosis is exclusion of possible primary sites elsewhere in the body. Primary pulmonary tumors reported in the horse include granular cell tumor, bronchial myxoma, adenoma, adenocarcinoma, anaplastic bronchogenic carcinoma, and pulmonary carcinoma (Fig. 31.39). Other primary thoracic tumors reported in the horse include pulmonary chondrosarcoma, pleural mesothelioma, thymoma, and lymphosarcoma. The majority of these neoplasms generally occurs in the mature or aged horse. The exception is lymphosarcoma, which may also be observed in young animals.

Antemortem diagnosis of thoracic neoplasia depends first on recognition of thoracic disease. Most of the reported cases of thoracic neoplasia involve metastatic disease. The horses' clinical signs are generally related to the primary site of the neoplasm; therefore the clinician often has no reason to suspect thoracic involvement. When respiratory signs such as dyspnea, tachypnea, hemoptysis, cough, cyanosis, nasal discharge, and epistaxis are present, relevant diagnostic tests are more likely to be performed. Ultrasonography and bronchoscopy increase the frequency of antemortem diagnosis of thoracic neoplasia.

Granular cell tumors are the most frequently reported primary pulmonary neoplasm of the horse. They are usually confined to the lungs and are characterized by single to multiple well-defined, whitish, dense nodules associated with a major bronchus, often protruding into the bronchial lumen or more distally within the parenchyma. Most granular cell tumors have been diagnosed only at postmortem examination, often as incidental findings. These homogeneous growths of granular eosinophilic cells express S-100 and occasionally neuron-specific enolase.[7] The ultrastructural morphology of this tumor may suggest a neural origin as well. Primary pulmonary chondrosarcoma has been reported in the horse.[8] Cytologic examination of pleural fluid and antemortem needle aspirate of the pulmonary mass revealed neoplastic chondrocytes. Another report describes metastatic chondrosarcoma in the lungs of a horse with a primary tumor in a rib.[9] A primary bronchial myxoma, characterized by loose spindloid mesenchymal cells, was reported in a 25-year-old Arabian mare with a history of intermittent coughing, hyperpnea, and respiratory disease of 2 years' duration.[10]

Primary pleural tumors are also rare. The type reported in the horse is pleural mesothelioma. The tumor is frequently associated with a large volume of pleural effusion. Cytologic examination of the pleural effusion revealing numerous pleomorphic mesothelial cells may aid in the antemortem diagnosis.

Thymomas are neoplasms of thymic epithelial cells, regardless of the presence or absence of lymphocytes. They are infrequently reported in the horse.[11-13] Equine lymphosarcoma occurs in mediastinal, alimentary, multicentric, cutaneous, and generalized forms; combinations of one or more of these are not infrequent.[14,15] In a 1973 review of 54 cases of equine lymphosarcoma,[3] the lung was involved in 16.6% of the cases, whereas the thoracic lymph nodes were involved in 35.2%.[16] In the University of Pennsylvania survey, lymphosarcoma was the single most common neoplasia of the thorax and was present in 19 (54%) of the cases.[3] Pleural fluid cytologic evaluation was diagnostic in six (75%) of the eight horses. Diagnosis was made by biopsy of a peripheral lymph node in several cases. In a report from the University of Bristol, thoracic malignant lymphoma accounted for 74% of the cases of thoracic neoplasia.[16] Metastatic adenocarcinoma accounted for 20% of the cases in the University of Pennsylvania study[5] and 11% of the cases in the University of Bristol study.[16] The primary sites of the tumor were thought to be kidney, uterus, thyroid, and ovary.

Gastric squamous cell carcinomas commonly metastasize to the thoracic cavity. Cytology of pleural fluid with identification of neoplastic epithelial squamous cells has allowed for antemortem diagnosis of the carcinoma in several cases. Metastatic squamous cell carcinoma of the thorax was found in 14% and 5% of the cases in the University of Pennsylvania[5] and University of Bristol[16] surveys, respectively. Neoplastic epithelial cells may also be identified in biopsy specimens via indirect immunohistochemistry using antibodies recognizing cytokeratins of various molecular weights.

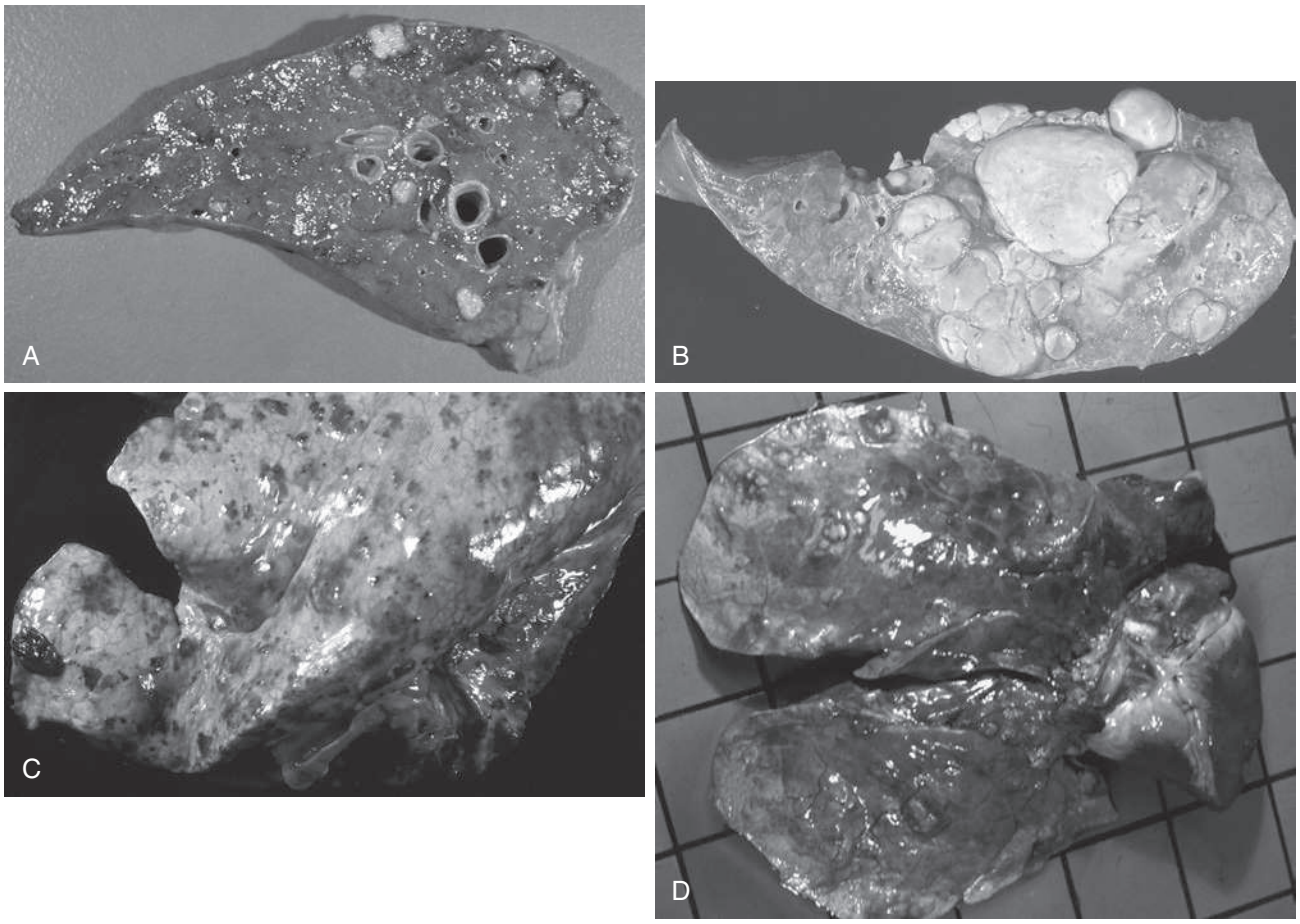

FIG. 31.39 **A,** Metastatic undifferentiated sarcoma. **B,** Granulosa cell tumor. **C,** Metastatic hemangiosarcoma. **D,** Metastatic squamous cell carcinoma.

Hemangiosarcoma with pulmonary involvement was found in 9% of the horses in the University of Pennsylvania survey.[5] Hemothorax, anemia, and dyspnea were commonly seen with this type of neoplasm. Tentative antemortem diagnosis of the hemangiosarcoma can be made by transcutaneous direct thoracoscopy and observation of hemorrhages over the visceral and parietal pleural surfaces as well as tissue biopsy of these sites. Identification of neoplastic endothelial cells demarcating irregular, sometimes blood-filled cavities allows diagnosis from the biopsy specimen.

Malignant melanoma in a 20-year-old gelding had widespread infiltration of many organs, including the lungs and pleura.[16] This pattern of distribution is not uncommon in malignant, less pigmented melanomas. Amelanotic melanomas are rare in the horse, and microscopic identification of melanin simplifies the diagnosis of these tumors. Equine melanocytes express S-100 and PNL2 proteins, and their detection can be used to diagnose melanocytic neoplasms.

Other pulmonary metastatic tumors reported are mammary carcinoma,[17] seminoma,[18] and malignant pheochromocytoma.[19] Pulmonary hamartomas are occasionally observed in the newborn foal. Although they are nonneoplastic growths, they appear as tumorlike masses that can compress the surrounding parenchyma and cause systemic passive congestion and hydrops of the amnion in the fetus. Their histologic characterization is that of bronchiolar-like structures lined by cuboidal epithelium with lack of alveolar development or by normal alveoli, bronchi, and blood vessels but with an alveolus/artery ratio greater than normal. Generally they are not compatible with a long period of extrauterine life.

An unusual progressive idiopathic multifocal granulomatous pneumonia of adult horses may resemble neoplasia behaviorally and morphologically during clinical examination.[20,21] Pulmonary biopsy may allow the identification of equine multinodular pulmonary fibrosis (EMPF), which has been associated with EHV-5 infection[21] (see Figs. 31.29 and 31.30).

Clinical signs of thoracic neoplasia are often inapparent or nonspecific—for example, depression, inappetence, weight loss, and pyrexia. More specific signs include cough, epistaxis, and dyspnea. Cytologic examination of tracheobronchial aspirate, BAL fluid, or pleural fluid and histologic examination of a thoracic mass tissue biopsy with ancillary histochemistry and indirect immunohistochemistry may allow for antemortem diagnosis of the neoplasm. Occasionally, electron microscopy may provide additional information. In equine patients with respiratory signs, all causes of infectious or allergic lung disease should be eliminated before neoplasia is considered in the differential diagnosis.

Diseases of Lymph Nodes, Vasculature, and Pharynx

Retropharyngeal Lymph Node Abscessation

John R. Pascoe

Definition and Etiology In horses, the retropharyngeal lymph nodes consist of medial and lateral lymphoid chains. The lateral chain (8 to 15 nodes) is located ventral to the atlas

and along the lateral sides of the guttural pouches. These lymph nodes are covered by the parotid gland and are not clearly distinguishable from the medial retropharyngeal lymph nodes (20 to 30 nodes). The medial retropharyngeal lymph nodes are located ventral to the lateral chain on the dorsolateral aspect of the pharynx and the caudoventral aspect of the guttural pouches.[1]

Retropharyngeal lymph node abscesses in horses are generally caused by *Streptococcus equi* subsp. *equi* infection (see the *Streptococcus equi* subsp. *equi* Infection [Strangles] section earlier) or are secondary to trauma.[2,3] Other bacterial isolates have included *S. equi* subsp. *zooepidemicus*, *Corynebacterium pseudotuberculosis*, *Actinomyces denticolens*, and *Actinobacillus* spp., including *Actinomyces denticolens*.[4,5] An unusual case of granulomatous infection of the guttural pouch caused by *Mycobacterium avium* complex was believed to have originated from the retropharyngeal lymph nodes.[6] Extension of guttural pouch infections into the retropharyngeal space has been suggested as another source of infection.[7] Lymphadenopathy of the retropharyngeal nodes may also occur during viral respiratory infections, including equine herpesvirus (EHV), influenza, and equine viral arteritis.[8] Retropharyngeal abscesses not associated with regional lymph nodes can result from perforation of the oropharynx or nasopharynx by ingested foreign bodies,[9] passage of a nasogastric tube,[10] or use of a balling gun.

In ruminants, the medial retropharyngeal lymph nodes are located on the dorsolateral aspect of the pharynx, one on each side of the midline. One to three lymph nodes may be present in cattle. The lateral retropharyngeal lymph nodes are located caudal to the medial retropharyngeal lymph nodes in the cranial neck region and are caudal to the retropharyngeal space.[11]

Abscessation of the medial retropharyngeal lymph nodes in cattle may result from pharyngeal actinobacillosis, foreign body penetration, or traumatic perforations by balling guns or dose syringes.[12-14] *Trueperella pyogenes* or *Actinobacillus* spp. are frequently isolated.[8] Cattle with abscessed pharyngeal lymph nodes often have a small ulcer in the mouth, most frequently at the junction of the base and shaft of the tongue. This is more likely to occur when cattle are eating dry scabrous roughage. In addition to traumatic perforations and foreign bodies, caseous lymphadenitis (CLA) caused by *C. pseudotuberculosis* frequently results in abscessation of the retropharyngeal lymph nodes in sheep and goats.

Clinical Signs and Differential Diagnosis

Clinical signs associated with retropharyngeal lymph node infection or abscessation in horses include dysphagia, odynophagia (painful swallowing), nasal or oral regurgitation, excess salivation, difficult and often noisy breathing, painful throatlatch swelling, mucoid to mucopurulent nasal discharge, extension of the head and neck, and weight loss. In 46 horses with retropharyngeal lymph node abscessation, common clinical signs were fever and increased heart and respiratory rates (80%), unilateral or bilateral throatlatch swelling (65%), respiratory stertor or distress (35%), purulent nasal discharge (20%), inappetence and signs of depression (15%), and dysphagia (9%).[3] Other signs observed endoscopically include decreased cross-sectional area or collapse of the pharyngeal lumen, asymmetry of the dorsal pharyngeal wall, and deviation of the laryngeal aperture away from the retropharyngeal mass.[2,3] Differential diagnosis for a retropharyngeal mass should include abscess, cellulitis, guttural pouch empyema or tympany, parotiditis, lymphadenopathy, neoplasia, and hematoma.

Clinical signs observed in cattle with infection or abscessation of the medial retropharyngeal lymph nodes include difficult breathing, excessive salivation, extension of the head and neck, anorexia, enlarged submandibular lymph nodes, nasal discharge, and swelling in the retropharyngeal space.[12] Other disease conditions that affect the oropharynx and surrounding lymph nodes should be considered in the differential diagnosis. These include actinobacillosis, lymphosarcoma, sialolithiasis, and necrotic laryngitis, laryngeal edema, or severe tracheitis caused by infectious bovine rhinotracheitis (IBR) virus.[8,12]

Affected sheep and goats may exhibit excessive salivation, increased respiratory rate, stertorous breathing, mucopurulent nasal discharge, regurgitation, gagging, depression, subcutaneous crepitation, weakness, and fetid breath. A false carotid aneurysm in the retropharyngeal space has been reported; on external examination it may be confused with abscessation of the medial retropharyngeal lymph nodes.[15] Enlarged retropharyngeal lymph nodes are usually easily palpated and identified in sheep and goats. CLA (see Chapter 37) is the most frequent cause of enlarged retropharyngeal lymph nodes in these species.

Clinical Pathology

Collection of purulent material from abscessed lymph nodes may assist in identification of the causal agent. Neutrophilic leukocytosis may be evident on the hemogram.

Laboratory Aids and Definitive Diagnostic Tests

Lateral radiographs of the pharynx, ultrasonography, and endoscopy facilitate the diagnosis of retropharyngeal infections or abscesses. In horses, radiography may reveal a large soft-tissue mass impinging on the guttural pouch from a caudoventral direction (Fig. 31.40, *A*), as well as thickening of the pharyngeal roof. The soft-tissue swelling may contain gas (Fig. 31.40, *B*). Compression of the larynx and trachea with ventral displacement may be evident (Fig. 31.40, *C*).[2] A gas-fluid interface on radiographs of the pharynx generally indicates abscessation, but care should be taken to distinguish a retropharyngeal abscess from guttural pouch empyema.[6] Foreign bodies associated with pharyngeal trauma are not typically radiopaque and thus not visible unless outlined by contrast medium. Exceptions include small wire foreign bodies likely ingested from baled hay that can perforate the tongue or oropharynx and cause cellulitis and dysphagia[9] and, in cattle, magnets that have been inadvertently placed retropharyngeally.

On endoscopy, asymmetry or collapse of the pharyngeal lumen, or both signs, suggests a retropharyngeal space-occupying mass. Recognition of drainage from the guttural pouch openings or examination of the guttural pouches may be necessary to differentiate between guttural pouch empyema and retropharyngeal lymphadenopathy or pharyngeal neoplasia. Occasionally the pharyngeal wall ruptures, allowing endoscopic observation of retropharyngeal drainage into the pharynx, usually near the esophageal entrance. Percutaneous needle aspiration of the mass may yield purulent material. Ultrasonography improves diagnostic precision by permitting more accurate identification of the abscess and highlighting its anatomic relationships to facilitate surgical drainage.[16]

Clinical examination, radiography, ultrasonography, endoscopy, and percutaneous centesis may all prove helpful in making a diagnosis of medial retropharyngeal lymph node infection or abscessation in ruminants. In cattle, localized swelling cranial to the larynx may be detected by digital palpation of the oropharynx.[12] Oropharyngeal examination must be performed carefully in animals with respiratory distress to prevent further airway compromise.

Pathophysiology

Upper respiratory tract disease, trauma, and foreign body penetration with resulting infection and drainage to local lymph nodes result in clinically apparent infection and abscessation of the retropharyngeal lymph nodes. In horses, the retropharyngeal space is occupied primarily by the guttural pouches. Because the vagus, glossopharyngeal, hypoglossal, spinal accessory, and sympathetic nerves traverse this area, their function can be affected by infectious or inflammatory processes involving the retropharyngeal space.[2] If such

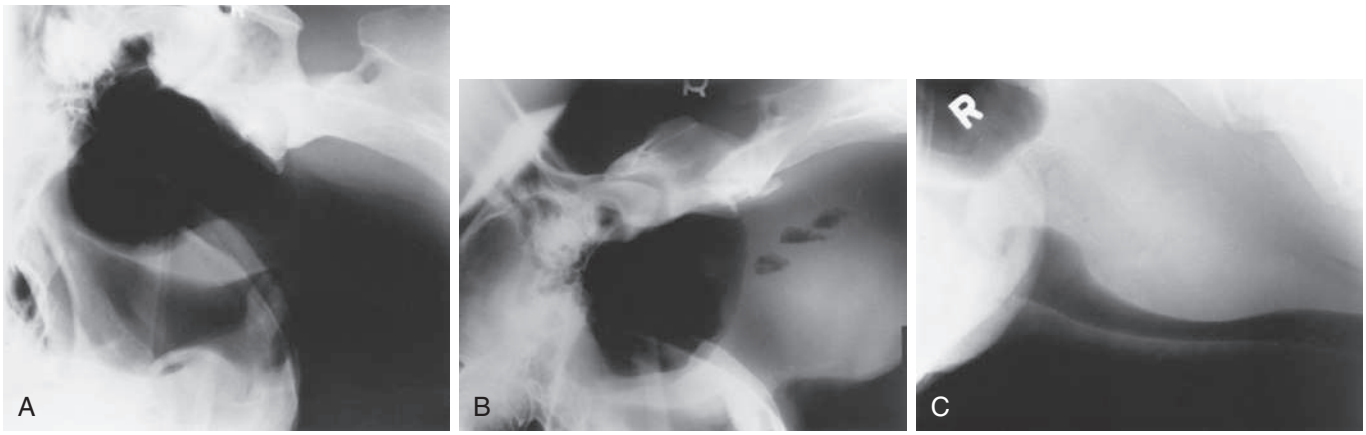

FIG. 31.40 **A,** Lateral radiograph. A soft-tissue density (retropharyngeal abscess) is distorting the floor of the guttural pouch. **B,** Lateral radiograph. There is increased soft-tissue density with gas shadows ventral to the cervical vertebrae. These changes are consistent with abscessation of the retropharyngeal lymph nodes. **C,** Lateral radiograph. There is increased soft-tissue density ventral to the cervical vertebrae, with compression of the dorsal border of the trachea. These changes were caused by cellulitis and abscessation of the retropharyngeal lymph nodes.

infections are contained within the lymph nodes or are confined within the fibrous capsule of the abscess, cranial nerve dysfunction is not usually evident.[2] Clinical evidence of dysphagia or odynophagia, such as the presence of feed and saliva at the external nares, may result from angina and from inflammation or injury of the glossopharyngeal nerve or pharyngeal branch of the vagus nerve, compression, or obstruction of the pharynx or esophagus. It has been suggested that retropharyngeal lymphadenitis may result in neuritis of the pharyngeal branch of the vagus nerve in young horses and contribute to the pathogenesis of dorsal displacement of the soft palate.[17]

Respiratory distress may occur when retropharyngeal lymph node enlargement compresses or obstructs the nasopharyngeal, laryngeal, or tracheal lumen, and the disease caused by *S. equi* subsp. *equi* in horses is appropriately called *strangles*.

The most common cause of pharyngeal inflammation and infection in cattle is pharyngeal trauma associated with balling guns, dose syringes, paste wormer guns, esophageal feeders, or nasogastric tubes. A careful history to determine whether any of these devices were used is important in determining the source of pharyngeal abscessation. Such infections usually involve mixed bacterial flora, because the trauma is directly related to the oropharynx.

Epidemiology

Infection with *S. equi* usually results from contact (inhalation or ingestion) with pasture, feed, or water contaminated with nasal discharge from infected horses or asymptomatic carriers.[18] The likely bacterial reservoir in carrier horses is the guttural pouch, particularly if chondroids are present[18-20] or if there are swollen or discharging lymph nodes in the floor of the medial compartment of the guttural pouch. Infection of the pharyngeal and nasal mucosa results in an acute pharyngitis and rhinitis, and drainage to regional lymph nodes results in lymphadenopathy and possible abscessation.[8]

CLA is spread through discharges from ruptured lymph nodes. The causal agent, *C. pseudotuberculosis*, may persist in the environment for long periods, and infection results from inhalation or from contact of shearing, docking, or castration wounds with contaminated soil, equipment, or freshly ruptured abscesses. Sheep dips have been reported as another source of infection.[8] Spread of infection from skin wounds often leads to involvement of local nodes and abscess formation.

Necropsy Findings

Fatalities are rare and typically occur from respiratory compromise or septicemia. Necropsy lesions include cellulitis with compression and ventral displacement of the larynx and cranial aspect of the cervical trachea. Abscesses are variable in size and may contain either caseous *(C. pseudotuberculosis)* or liquid *(S. equi* subsp. *equi)* material. A thick, fibrous capsule may occur in response to the infectious process and may account for the surrounding tissue compression. Occasionally, draining tracts may connect the abscess to the pharynx, guttural pouch, or skin.[10,21]

Treatment and Prognosis

Treatment goals are relief of respiratory distress and control of infection. Temporary tracheotomy may be needed for relief of respiratory distress and may be prudent, before percutaneous drainage is attempted. After surgical drainage, appropriate systemic antibiotics are administered, and supportive therapy to further reduce swelling may be beneficial.

Surgical approaches include percutaneous drainage, intraoral drainage, and marsupialization.[2,12] Percutaneous drainage is commonly used in horses because the long narrow oral cavity makes an intraoral approach very difficult. For abscesses visible through the mucosal lining of the guttural pouch, endoscopically assisted drainage into the pouch can be considered. Surgical access to the retropharyngeal space includes dorsal, ventral, and lateral approaches and access through Viborg's triangle.[3] A ventral surgical approach is recommended because of the relative lack of vital structures encountered and because excellent ventral drainage can be achieved. In standing sedated horses, less invasive drainage can be established by ultrasound-guided percutaneous needle placement into abscessed lymph nodes. Affected nodes can have a wall thickness of 1 to 2 cm and a diameter of 5 to 11 cm.[16] Aspiration of purulent matter and cavity lavage with antiseptic solutions and concurrent administration of parenteral antibiotics may be sufficient for resolution. If aspiration is not possible because the purulent material is too viscous, incision directly along the needle shaft, after careful consideration of regional anatomy, provides adequate exterior drainage and access for cavity lavage with antiseptic solutions or use of a seton or gauze packing. If the abscess is endoscopically visible beneath the guttural pouch mucosa, drainage into the guttural pouch and subsequent lavage of the purulent material can be accomplished. Before or at the time of abscess drainage or excision, the horse should be started on broad-spectrum antimicrobials, followed by the appropriate specific antimicrobial drug when results of microbial susceptibility testing are known.

Occasionally, medical management alone may resolve infection; however, this is less likely if abscessation has occurred.

VetBooks.ir

Because the most common bacterial isolate in horses is *S. equi*, parenteral antimicrobial therapy with procaine penicillin G (22,000 IU/kg IM twice daily) or potassium penicillin (22,000 IU/kg IV four times daily) is recommended. Systemic NSAIDs are useful to reduce inflammation and swelling, and fluid and electrolyte therapy may be necessary if there is odynophagia or dysphagia. Aspiration pneumonia can occur with dysphagia or if there is oral or nasal regurgitation associated with painful swallowing.

In cattle with pharyngeal trauma, an existing wound is often draining from the retropharyngeal area into the oropharynx, making surgical drainage unnecessary, and response to parenteral broad-spectrum antimicrobial therapy is typically favorable.[22] Parenteral antimicrobial therapy alone has been ineffective in treating retropharyngeal abscesses when there is no draining tract.[12] Intraoral or percutaneous drainage has been used successfully in conjunction with broad-spectrum, parenteral antimicrobial therapy. After drainage, the abscess cavity is flushed daily with an antiseptic or antibiotic solution[12] with the head lowered so that exudate or flush solution is not aspirated; inspection of the granulating abscess cavity is necessary if feed impaction is suspected.[2,12] Aspiration pneumonia may be a serious complication when dysphagia is present.

In sheep and goats, walled-off *C. pseudotuberculosis* abscesses can be safely drained by marsupialization before opening the capsule, which prevents contamination of other retropharyngeal structures and markedly reduces postsurgical cellulitis. Although *C. pseudotuberculosis* is susceptible in vitro to a number of antimicrobial agents, these abscesses are typically not well controlled by antimicrobial therapy. Walled-off *C. pseudotuberculosis* abscesses are difficult to eliminate solely with antimicrobial therapy, and drainage or removal of the entire lymph node gives optimal results.

Prevention and Control

Preventive measures to limit infection and abscessation of retropharyngeal lymph nodes include isolation of horses affected with viral or bacterial upper respiratory tract disease, vaccination against strangles, vigorous treatment in the early stages of streptococcal infection, and correct administration of therapeutic agents with balling guns and dose syringes. Reducing environmental sources of contamination and preventing contamination of shearing equipment, dipping vats, and feeders with *C. pseudotuberculosis* are important to limiting spread in sheep. Culling affected sheep and goats may also help reduce the incidence of CLA.

Pharyngitis

John R. Pascoe

Definition and Etiology

Pharyngitis is inflammation of the pharyngeal tissues. It is not generally considered to be a specific disease entity but rather a response to other diseases, particularly viral and bacterial respiratory disease, and to a lesser extent to local physical, chemical, or allergic causes. Acute and chronic forms are recognized.

Although physical and chemical causes of pharyngitis may be identified with certainty, the role and specificity of microbial pathogens as causative agents remain controversial. In horses, *Streptococcus* spp. and various viral respiratory diseases have been incriminated as specific causes of pharyngitis, but given the ubiquitous nature of some virus groups in horses, a direct causal association remains unsubstantiated.[1,2] In cattle, *Trueperella pyogenes*, *Actinobacillus* spp., and *Fusobacterium necrophorum* are frequently isolated.[3]

Synonyms for chronic pharyngitis in horses include pharyngeal lymphoid hyperplasia (PLH), chronic pharyngitis, chronic lymphoid follicular hyperplasia, follicular pharyngitis, and follikelkatarrh.[4-6]

Clinical Signs and Differential Diagnosis

In acute pharyngitis, signs are associated with pharyngeal pain (odynophagia, dysphagia), nasal discharge (serous, seromucous, mucopurulent, purulent, feed-contaminated), regional lymphadenopathy (submandibular, retropharyngeal nodes), ptyalism (especially in cattle), respiratory noise (often inspiratory), pharyngeal swelling, and cough. Mouth breathing may occur in cattle when there is increased resistance to breathing associated with excessive exudate, diphtherous membranes, and lymphadenopathy. Pharyngitis from local pharyngeal trauma or incarcerated foreign bodies may be associated with odor of nasal discharge or the breath. Cattle with necrotic laryngitis, pharyngitis, and stomatitis have a characteristic malodorous breath. Acute laryngeal inflammation and edema of unknown cause can occur in horses and ruminants and is characterized by marked inspiratory difficulty and stertor without malodorous breath. Treatment of acute edema with dexamethasone (0.05 mg/kg IM; avoid in pregnant heifers or cows) and broad-spectrum antimicrobials has produced rapid clinical improvement.

Signs observed on endoscopic or oropharyngeal examination in cattle include pharyngeal hyperemia and edema, lymphonodular swelling, and either a moist appearance of the pharyngeal surface or the presence of exudate or a diphtherous membrane adhering to the pharyngeal surface. Focal necrosis or ulceration of the mucous membrane and tonsillar tissue may occur; signs associated with rhinitis and laryngitis may be evident. Signs of chronic pharyngitis are similar. In horses, there may be endoscopic evidence of more marked hyperplasia of the lymphonodular follicles within the pharyngeal mucosa, and single or multiple lymphonodular masses may be within, or protrude from, the pharyngeal mucosa. Biopsy and cytologic evaluation are recommended to rule out neoplasia, particularly squamous cell carcinoma, lymphoma, and lymphosarcoma. Differential diagnostic possibilities include rhinitis and laryngitis, and in cattle, rabies should be strongly considered before oropharyngeal examination. If the predominant sign is dysphagia (see Chapter 7), other diagnostic rule-outs include foreign bodies in the tongue, fractures of the hyoid apparatus or jaws, and in the horse, diseases of the guttural pouches. If exercise intolerance is the primary complaint in a horse, pharyngitis should be considered only after other possible causes of impaired performance have been eliminated (see Chapter 5).[7-11] Pharyngitis is not a risk factor for poor racing performance in racing Thoroughbreds[12] or Standardbred trotters.[10] More severe PLH grades were found in poorly performing endurance horses (primarily Arabian horses); however, more definitive causes for poor performance were identified in these horses.[11]

Upper airway inspiratory pressures recorded during strenuous exercise in horses with grade IV PLH are not different from those of normal horses under the same exercise conditions.[8] Assuming that airflow in both groups of horses was comparable, severe PLH does not appear to cause functional upper airway obstruction. It is conceivable that pharyngeal pain associated with PLH may contribute to impaired performance; however, this effect remains unproven.

Clinical Pathology

Changes in the hemogram and serum biochemical profiles are likely to result from concurrent respiratory disease (increases or decreases in absolute or differential leukocyte counts, hyperfibrinogenemia, anemia) or to reflect abscess formation (neutrophilia, hyperfibrinogenemia) or dehydration and fasting associated with dysphagia. Electrolyte losses associated with drooling may alter serum electrolyte and acid-base status.

Laboratory Aids and Definitive Diagnostic Tests

Although a presumptive diagnosis can be made from clinical signs, definitive diagnosis requires observation of the pharynx

(Fig. 31.41) and, more important, exclusion of other conditions that have similar signs. Radiography of the pharynx can provide information on pharyngeal anatomy, radiodense foreign bodies, soft-tissue masses, fractures, and in horses, guttural pouch disorders. Ultrasonography of the pharyngeal region and, if indicated by the clinical examination, both radiographic and ultrasonographic examination of the thorax may help define the extent of concurrent pulmonary disease.

Microbial culture of pharyngeal secretions can be considered, but interpretation is difficult because (1) the pharynx normally has resident microflora with considerable individual variation, and (2) many of the microorganisms isolated are capable of opportunistic infection. In horses with grades III and IV PLH, the number of bacteria recovered per gram of pharyngeal secretion was almost 100-fold greater than in normal horses.[9] The pattern of microbial isolation was not consistent among horses, suggesting that these organisms were not the source of the pharyngitis but rather that other factors had made conditions for colonization more favorable.

Biopsy and cytologic examination are indicated in refractory cases and when abnormal masses are present to rule out neoplasia.

Pathophysiology Acute pharyngitis occurs as a sequela to inflammation of regional lymphoid tissue (see Kumar and colleagues[13] for a description of the morphologic and histochemical features of the normal equine nasopharyngeal tonsil).[14] In horses, the pharyngeal tonsil consists of discrete lymphoid follicles diffusely distributed in the dorsal and lateral walls of the pharynx. In ruminants, the pharyngeal tonsil is located caudal to the pharyngeal septum in the caudodorsal wall of the pharynx and is bounded by long ridges and grooves into which mucous glands open. In response to local or lymphogenous spread of infection, the tonsillar tissue becomes inflamed and the tonsillar crypts become filled with desquamated epithelium, leukocytes, and bacteria. Clinically this is seen as hyperemia and edema of the pharyngeal tonsil with diffuse white or yellow tips to the lymph nodules. The edematous appearance is associated with hyperplasia of the lymph nodules and sequestration of perinodular inflammatory fluid.

If extensive destruction of the lymphoid cells or subsequent invasion of the nodules or supporting soft tissue is evident, the result is focal or diffuse necrosis, which may be seen as pinpoint areas of follicular necrosis or diffuse necrosis with associated purulent or fibrinonecrotic exudate. With resolution, atrophy of some follicles and increased fibrosis are present. Follicular atrophy also occurs with aging.

FIG. 31.41 Endoscopic view showing the nodular appearance of pharyngeal lymphoid hyperplasia.

Epidemiology No specific epidemiologic data are available. When pharyngitis occurs as a sequela to respiratory tract infection, the population demographics should be similar to those known for the specific respiratory disease. For example, grade II PLH was identified in 60% of foals with distal respiratory tract infection and in only 13% of control foals.[15] Because physical and chemical injury to the pharynx occurs sporadically, no universal epidemiologic characteristics would be anticipated.

PLH is prevalent in horses younger than 5 or 6 years of age, and the severity of PLH grades[5] is inversely correlated with age.[4,12,16,17] In endoscopic surveys of primarily Thoroughbreds in race training, prevalence of PLH ranges from 29% to 34%, with grade II PLH observed in 45% to 63% of 2-year-olds and less than 12% to 20% of horses older than 5 years affected.[16] Similar results are reported from Japan in racing Thoroughbreds with a history of cough or abnormal respiratory noise[18] and in a mixed population of horses in Calgary, Canada.[17] Pharyngeal mucus scores are not correlated with PLH, transtracheal wash aspirate, or BAL fluid variables, suggesting that PLH is not directly a manifestation of lower airway inflammation or disease.[17,19]

Treatment and Prognosis Approach to treatment is largely symptomatic and directed at palliation of pharyngeal pain and maintenance of unobstructed breathing until the initiating disease process has abated. In many instances, the signs are sufficiently mild that treatment is unnecessary. When pharyngeal angina is causing inappetence or dysphagia, administration of NSAIDs should be considered. Dehydration should be corrected by either parenteral or enteral fluid administration. Enteral fluid therapy may be difficult because passage of a nasogastric tube may elicit too much pain. For inappetent animals, nutritional support may be necessary until pharyngeal pain subsides sufficiently for normal eating to resume. Soft feeds, especially green grass, should be offered when available to encourage animals with pharyngeal discomfort to eat.

Antimicrobial therapy is probably not indicated, but it is often given to limit development of secondary bacterial infection. Infections caused by foreign body injury should be treated with antibiotics that have a broad aerobic and anaerobic spectrum of activity. Daily lavage of any cavitary wounds, débridement, and removal of feed material may be necessary to prevent additional abscess formation and hasten healing.

Custom topical preparations, usually containing an antibiotic, an antiinflammatory drug, and a hygroscopic agent (glycerin) or DMSO, are often used for palliation of clinical signs, especially in horses with PLH. These preparations are usually administered two or three times daily and sprayed onto the pharyngeal surface through a transnasal catheter. Despite frequent use, the efficacy of this therapy is unknown, and response may reflect natural resolution of the predisposing cause.

Treatment of PLH is empirical and generally palliative. Rest from training for 4 to 8 weeks is commonly recommended, and although some horses have recurrence when training resumes, this enforced rest is beneficial as convalescence for any concurrent subclinical respiratory disease. Horses kept

in training are often initially treated empirically with sulfa compounds and topical throat preparations. With continued clinical signs, penicillin or broad-spectrum antibiotics are often administered. If PLH does not improve or resolve after therapy, pharyngeal cautery may be used. Techniques for pharyngeal cautery include topical application of trichloroacetic acid, electrocautery, freezing with liquid nitrogen or Freon, and photoablation by neodymium:yttrium aluminum garnet (Nd:YAG) laser with either a contact or a noncontact technique.[20] Although cauterization techniques have received considerable testimonial support, it is likely that cautery does not effect a cure but simply obliterates reactive tissue so that it is no longer clinically evident.

Routine immunization for known viral respiratory pathogens is also recommended for treatment and prevention of PLH.[21]

Prevention and Control Methods used to control and prevent most of the common viral and bacterial respiratory diseases (see Chapter 48 for vaccines) should limit herd problems with acute pharyngitis. Non–respiratory disease–related causes such as trauma from balling guns, nasogastric tubes and dose syringes, foreign objects, and chemical burns can be minimized by improved husbandry practices.

Prevention of PLH in horses by prophylactic immunization against common equine viral respiratory agents at regular intervals has been discussed at length, but there is no evidence to support this practice. Nevertheless, racetrack veterinarians maintain that frequent immunization (60-day intervals) against influenza and rhinopneumonitis markedly reduces the severity of PLH and improves exercise tolerance.[21] Considering the mobility of racing and show horse populations, this approach should at least be beneficial for limiting outbreaks of viral respiratory disease and consequently perhaps limiting chronic PLH. Until more is understood about the clinical appearance of the pharyngeal tonsil in horses, along with normal variations that occur with aging in exercised and nonexercised horses, and these findings can be correlated with immunopathologic events and indices of performance, it will remain difficult to treat, control, and prevent pharyngitis in a systematic manner.

Guttural Pouch Diseases

John R. Pascoe

Definition and Etiology The guttural pouches are paired, air-filled diverticula of the eustachian tubes that communicate between the middle ear and the pharynx. Located ventral to the atlas, dorsocaudal to the pharynx, and rostrodorsal to the retropharyngeal lymph nodes, they occupy a large part of the retropharyngeal space. Each pouch has a capacity of approximately 300 mL and is divided into medial and lateral compartments by a stylohyoid bone that courses through the caudolateral aspect of each pouch. The larger medial compartment accounts for approximately two thirds of the volume, and they appose each other on the midline, separated by a membranous septum. The medial compartment contains cranial nerves IX (glossopharyngeal), X (vagus), XI (spinal accessory), and XII (hypoglossal); the cranial cervical ganglion; and the cervical sympathetic trunk. The internal carotid artery lies deep to the caudolateral wall of the medial compartment. The pharyngeal branch of the vagus nerve and the cranial laryngeal nerve are immediately ventral to the floor of the medial compartment. In the lateral compartment, the facial nerve (VII) is located caudodorsally, and the external carotid artery and its branches, notably the maxillary artery, are associated with the roof of the lateral compartment.[1] The intimate relationship of these vessels and nerves with the mucous membrane lining the guttural pouches explains why epistaxis and nerve dysfunction frequently accompany guttural pouch disease. Communication with the pharynx occurs through a slit-like opening rostral and ventral to the pharyngeal recess. This funnel-shaped pharyngeal opening is wider rostrally than caudally. A mucous membrane fold within the pouch, the plica salpingopharyngea, contributes to the caudal narrowing of the opening and makes catheterization of the guttural pouch difficult. Redundancy of this tissue fold may contribute to guttural pouch tympany.[1]

Lined with pseudostratified ciliated epithelium containing goblet cells,[2] the guttural pouch is an extension of the pharynx and is not a sterile environment. In 30 normal horses, 59% of percutaneous guttural pouch lavage aspirates had bacterial growth, although only 7% had bacteria considered to be pathogenic; no fungi were isolated.[3] Aspirates were considered normal if they had less than 5% neutrophils; typical cell distribution was primarily ciliated columnar epithelial cells, a few nonciliated cuboidal epithelial cells, and less than 1% monocytes, lymphocytes, and macrophages.[3] Inflammatory cell counts and altered cell distribution were correlated with recovery of bacteria. Horses exercised strenuously on a regular basis had lower total cell counts, lower neutrophil counts, and fewer bacteria isolated.[3] Preventing horses from head lowering for 12 to 24 hours increases the frequency of bacterial isolation, especially at 24 hours, including an increase in neutrophil counts, likely indicating a reduced ability to clear guttural pouch secretions.[4] Interpretation of microbial isolates from guttural pouches requires correlation with cytologic characteristics of guttural pouch fluid and clinical signs.[5]

Three disease conditions commonly affect the guttural pouches: tympanitis, empyema, and mycosis. Less common conditions include neoplasia,[6] fractures of the hyoid bone, temporohyoid osteoarthropathy, foreign bodies,[1] and cystic structures.[7]

Guttural Pouch Tympany

Tympany of the guttural pouch occurs infrequently. It can be recognized in foals from birth to 1.5 years of age[8-10]; affected foals are usually identified within the first 2 weeks of life. Fillies are more commonly affected, with the ratio of females to males ranging from 2:1 to 4:1. Familial and complex inheritance of guttural pouch tympany occurs in Arabian horses and German Warmblood horses, and sex-specific quantitative trait loci have been identified.[11]

Tympany is characterized by unilateral or bilateral distention of the guttural pouch with air. The exact cause is unknown, but congenital redundancy of the plica salpingopharyngea has been suggested. This mucosal fold acts as a one-way valve apparently permitting airflow into but not out of the pouch. Upper airway infection or inflammation has been postulated to result in enlargement of the fold or neuromuscular dysfunction contributing to air trapping.

Clinical Signs and Differential Diagnosis Affected foals usually have a nonpainful, soft, fluctuant swelling in the retropharyngeal space (Fig. 31.42, *A*) with variable respiratory distress, extension of the head and neck, nasal discharge, signs of dysphagia, and possible development of aspiration pneumonia.[8,9] Guttural pouch fluid accumulation and empyema can occur. Mild tympany may not result in signs other than swelling of the throatlatch (retropharyngeal) region. Respiratory distress occurs when continued distention of the pouch compresses the pharyngeal area. The differential diagnosis for throatlatch regional swelling should include guttural pouch empyema and retropharyngeal abscesses or cellulitis.

Clinical Pathology Stress leukocytosis may occur if there is marked respiratory distress.

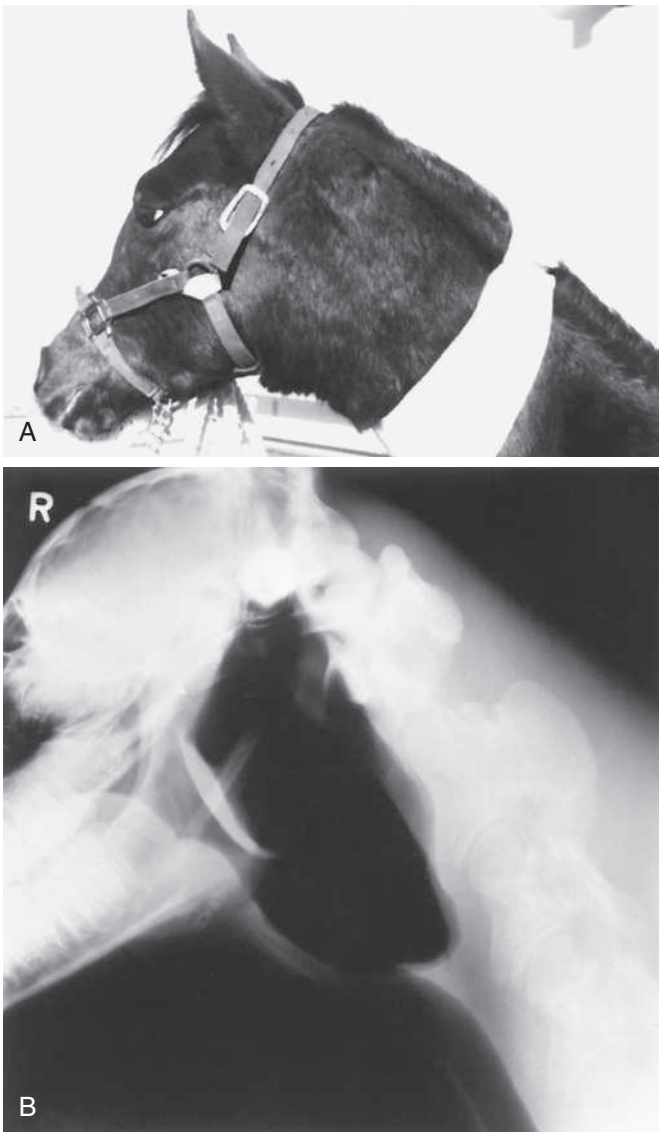

FIG. 31.42 *A*, Foal with guttural pouch tympany. Note the protrusion of the soft tissues over the lateral and ventral aspects of the throatlatch. **B,** Lateral radiograph of a foal with tympanitis of both guttural pouches.

Diagnostic Aids Diagnosis of guttural pouch tympany is based on recognition of characteristic swelling in the retropharyngeal space and confirmation by clinical examination. Although distention is most often unilateral, extreme distortion of a single pouch may give the impression of bilateral involvement. Differentiation between unilateral and bilateral involvement can be difficult and may require deflation of the affected guttural pouch by catheterization or percutaneous needle aspiration combined with external compression. Other adjunctive diagnostic procedures include radiographic demonstration of gas distention of one or both pouches (Fig. 31.42, *B*) and endoscopic observation of pouch distention and pharyngeal distortion.

Treatment and Prognosis Guttural pouch tympany and respiratory distress can be alleviated temporarily by aspiration of air from the affected pouch by percutaneous decompression at the point of greatest distention through Viborg's triangle or by introduction of a catheter through the pharyngeal opening of the guttural pouch. These measures are palliative, and the pouch rapidly refills after decompression. Treatment methods include surgical excision of the plica salpingopharyngea and part of the medial lamina of the eustachian tube; partial resection or photoablation of the plica; fenestration of the median septum between the two pouches by excision, electrosurgery, or photoablation; or creation of a salpingopharyngeal fistula by photoablation and temporary stenting of the fistula.[8-10,12-15] The latter technique is similar to an older, successful approach that involved incising the floor of the guttural pouch into the pharynx.[16] If the condition is bilateral, fenestration of the median septum alone is usually insufficient, and excision of one or both plica salpingopharyngea, in combination with septal fenestration or septal fenestration and salpingopharyngeal fistula formation, must be performed. After surgery the prognosis for resolution of guttural pouch tympany is generally favorable[10] unless complicating factors such as aspiration pneumonia exist.[9] Early recurrence after surgery can range from 15% to 30%, but further resection of the plica salpingopharyngea or refenestration of the median septum or enlargement of the fenestration typically results in resolution of signs.[9,10]

Guttural Pouch Empyema

Guttural pouch infections are introduced directly through the pharyngeal opening or by lymphatic spread. Accumulation of purulent material (empyema) is considered to be a secondary, chronic, localized manifestation of a more generalized ascending respiratory infection. Empyema is usually unilateral and often a sequela to respiratory disease, especially infection by *S. equi* subsp. *equi*.[17-19] Typically a horse with guttural pouch empyema has continued nasal discharge after recovery from streptococcal infection.[19] In a case control study of foals with lower respiratory tract infection, 21% had concurrent mucopurulent drainage from the pharyngeal openings of the guttural pouches.[20] *S. equi* subsp. *zooepidemicus* was isolated from respiratory secretions of most infected foals and from exudate collected from guttural pouches.[21] Rupture of retropharyngeal abscesses into the guttural pouch has also been associated with empyema, suggesting that strangles or other upper respiratory tract infections may have an important role in the development of guttural pouch infection in horses.[17]

Clinical Signs and Differential Diagnosis Clinical signs include intermittent nasal discharge that may worsen when the head is lowered, retropharyngeal swelling, cough, fever, parotid swelling and pain, dysphagia, difficult breathing, and pneumonia.[22] Nasal discharge can be unilateral or bilateral, even if only one pouch is affected, because the pharyngeal openings of the guttural pouches are located caudal to the nasal septum. Nasal discharge is generally nonodorous, white, and opaque. Altered breathing may result from gradual collapse of the pharynx as the guttural pouch distends. Signs of dysphagia may occur from pharyngeal compression or paresis. Inspissation of the purulent material results in chondroids (hard concretions of inspissated pus). Differential diagnosis of guttural pouch empyema should include diseases with chronic mucopurulent nasal discharge such as pneumonia, sinusitis, upper respiratory tract infections, and guttural pouch tympany.

Clinical Pathology Leukocytosis is often present. Plasma fibrinogen concentration is often increased[22]; changes occur in parallel with development of leukocytosis, pyrexia, and clinical signs of strangles or primary guttural pouch empyema. Analysis of fluid from the guttural pouch often yields a β-hemolytic *Streptococcus* spp.,[17] although other bacteria have been isolated.[22-24]

Diagnostic Aids Guttural pouch empyema should be considered when there is a chronic, nonresponsive nasal discharge. Diagnostic aids include endoscopy, radiography, percutaneous centesis, and aspiration of material from the pouch through the pharyngeal opening. Recognition of fluid

VetBooks.ir

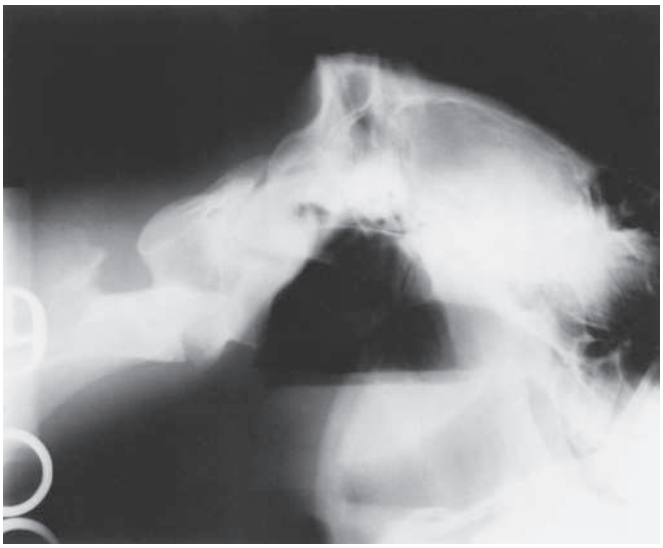

FIG. 31.43 Lateral radiograph demonstrating distinct fluid lines in both guttural pouches.

(Fig. 31.43) or radiodense masses (chondroids) within the pouch on standing lateral radiographs supports a diagnosis of empyema. Physical and endoscopic examination or oblique radiographic projections may be needed to identify which pouch is involved. Endoscopic examination permits identification of the affected pouch and evaluation of the character of the fluid. Endoscopic examination of the lateral compartment is important to avoid missing sequestered fluid or chondroids.[23] Absence of fluid at the pharyngeal ostium does not preclude the possibility of guttural pouch empyema, as the fluid may be inspissated or the ostium may be sealed.[24] Fluid identified on radiographs should be characterized by endoscopic examination of the pouches or aspiration of the fluid with cytologic and microbial analysis. Fluid samples can be aspirated through the pharyngeal ostium using a sterile artificial insemination pipette, Chambers catheter, or tubing advanced through the biopsy channel of an endoscope. Alternately, fluid can be aspirated percutaneously but should be performed cautiously to minimize the likelihood of bacterial contamination along the needle tract and development of cellulitis.

Pathophysiology Guttural pouch empyema may result from extension of the upper respiratory tract infection with *S. equi* subsp. *equi* (strangles) to the guttural pouches or from rupture of retropharyngeal lymph node abscesses into the guttural pouch.[17] Commonly isolated bacteria from guttural pouch empyema include *S. equi* subsp. *equi*, *S. equi* subsp. *zooepidemicus*, *E. coli*, and *Klebsiella* spp.[22] Not all horses with empyema have a history of strangles or previous respiratory infection, and empyema seemingly can occur by many of the same mechanisms as middle ear infection; that is, fluid accumulates in the area, and uncontrolled growth of bacteria normally present results in inflammation and exudation.

Treatment and Prognosis Treatment of guttural pouch empyema is complicated by poor drainage from the affected pouch. The pharyngeal opening of the guttural pouch is located rostrodorsal to the floor of the guttural pouch, and drainage can be achieved only by lowering the horse's head; however, adequate drainage may not occur if there is ventral distortion of the pouch. Inflammation of the lining mucosa may result in swelling of the tissue surrounding the pharyngeal opening, further compromising normal drainage.

Treatment approach depends on the duration and nature of the empyema and the presence of chondroids. Parenteral antimicrobial therapy may reduce the quantity of the nasal discharge, but relapse often occurs after treatment stops.[22] The early stages of empyema may respond to daily lavage of the affected guttural pouch. Because of the thin nature of the mucosal lining and the proximity of cranial nerves VII and IX to XII and the cranial sympathetic trunk, it is important to use nonirritating solutions (e.g., physiologic or saline antibiotic solutions) to avoid neural inflammation or neuritis. Large volumes have caused guttural pouch rupture. Typically, 500 mL should be flushed into the pouch under moderate pressure to create contact with as much of the interior of the guttural pouch as possible. During lavage the head should be lowered to prevent aspiration of fluid and facilitate drainage. Purulent fluid from the affected guttural pouch should be aspirated on initial catheterization and submitted for microbial culture and antimicrobial susceptibility testing. Fluid collection can be accomplished with most flexible uterine culturettes under direct endoscopic observation. Parenteral antimicrobial drugs should be administered on the basis of susceptibility testing results. Streptococcal isolates may be resistant to potentiated sulfonamides and sulfadimethoxine.[22] Although medication may be of benefit in treating empyema, adequate drainage and local therapy are of primary therapeutic importance.

Indwelling catheters in normal guttural pouches cause increasing purulent discharge over time, which diminishes after catheter removal and is typically resolved within 3 days. Although indwelling catheters are convenient, daily catheterization and irrigation using an artificial insemination pipette or Chambers catheter should be considered when treating an already inflamed guttural pouch to diminish the inflammatory response associated with indwelling catheters. However, daily catheterization must be weighed against the stress, possible tissue trauma, and time requirements for intermittent catheterization.

Treatment with parenteral antimicrobials and local lavage is successful and requires a patent opening for adequate drainage, but the course of treatment may be protracted. Povidone-iodine (1% available iodine) diluted to a 10% solution (0.1% available iodine) for lavage of the guttural pouch caused considerable reaction, including inflammatory infiltrates, hemorrhage, necrosis, and lymphoid reaction.[25] Likewise, antimicrobial concentrations of chlorhexidine gluconate are not recommended.[26] Although acetylcysteine, a mucolytic, has been used to resolve inspissated empyema,[27] subsequent reports have shown lack of efficacy and concern for added mucosal inflammation.[28] If response to lavage is poor or if secretions reaccumulate and empyema returns, surgical drainage of the guttural pouch should be considered.

Surgery is generally indicated when purulent material becomes inspissated or chondroids have formed,[29] although resolution was reported in one horse after prolonged lavage (14 days) through an indwelling catheter.[30] Surgical approaches include percutaneous drainage through standard approaches to the guttural pouches in anesthetized recumbent or standing sedated horses and creation of a nasopharyngeal fistula by use of an Nd:YAG laser.[31] Other approaches when chondroids are present include removal by retrieval devices passed endoscopically, standing removal through a modified Whitehouse approach,[32] and removal from the contralateral pouch after fenestration of the median septum when the ipsilateral ostium is closed.[24]

The prognosis for guttural pouch empyema is generally favorable if it is recognized promptly and treated appropriately.[22] Likewise, removal of chondroids typically has a good prognosis.[22]

Guttural Pouch Mycosis

Guttural pouch mycosis is a fungal disease of the guttural pouch that typically affects the dorsocaudal region of the medial compartment, although lesions affecting larger areas, including

VetBooks.ir

the lateral compartment, occur.[33-35] Fungal invasion of neurovascular structures coursing through the walls of the guttural pouches results in clinically apparent disease. The exact cause is unknown, although a number of fungi, especially *Aspergillus (Emericella) nidulans* and *Aspergillus fumigatus*, have been isolated from lesions.[35-39]

Clinical Signs and Differential Diagnosis Lesions are usually unilateral but can occur bilaterally. The wide spectrum of clinical signs that can occur with guttural pouch mycosis reflects the degree of fungal invasion and subsequent inflammation of vascular structures or nerves beneath the mucous membrane lining the guttural pouch; however, the size of the lesion is not correlated with the severity of clinical signs. Intermittent spontaneous epistaxis and dysphagia are the common clinical signs that stimulate owners to seek veterinary care; however, the earliest clinical sign in most affected horses is nasal discharge (serous to mucopurulent).[40] Epistaxis generally results from fungal erosion of the wall of the internal carotid artery in the roof of the medial compartment and less commonly from erosion of the external carotid artery (or its branches; e.g., caudal auricular artery) and maxillary artery in the lateral compartment. Epistaxis is usually unilateral from the ipsilateral nostril, but it can be bilateral because the pharyngeal openings of the guttural pouches are located caudal to the caudal border of the nasal septum.[34] Episodes of epistaxis typically occur at rest and vary from mild to severe, with several premonitory bleeds that generally culminate in a fatal episode of epistaxis.[34,35] Occasionally a horse dies from a single episode of epistaxis without previous clinical signs. Epistaxis may recur at intervals varying from 24 hours to 3 weeks.[34]

Dysphagia, the second most common clinical sign, likely results from damage to the pharyngeal branches of the vagus and glossopharyngeal nerves and generally occurs later than epistaxis in the course of the disease.[34] Horses with dysphagia cough during attempts to eat solid food, and in addition to food material in the nasal discharge, a considerable quantity of food is coughed from the mouth. Recovery from dysphagia may occur,[34] but in general the prognosis for full recovery is poor.

Other clinical signs include parotid pain, abnormal head posture, unilateral or bilateral nasal discharge, head shyness, abnormal respiratory noise from pharyngeal paralysis or laryngeal hemiplegia, sweating and shivering, Horner's syndrome, visual disturbances, colic, and facial paralysis.[34,35] These signs are the result of angina and dysfunction of cranial nerves and the sympathetic nerves.

The differential diagnosis for a horse with epistaxis should include EIPH, ethmoid hematoma, guttural pouch or pharyngeal neoplasia, tracheobronchial foreign bodies, and guttural pouch mycosis.[34] Differentiation of these diseases is aided by a thorough history and endoscopic examination. Differential diagnosis for dysphagia should include fractures of the hyoid apparatus; pharyngeal and guttural pouch fistula; cleft palate; esophagitis; pharyngeal paralysis; foreign body entrapment in the mouth or esophagus; pharyngeal neoplasia; lead poisoning; bacterial, viral, and mycotic central nervous system infections; and guttural pouch mycosis.[34]

Clinical Pathology If epistaxis is the presenting complaint, moderate to severe anemia with accompanying hypoproteinemia may also be present. Differential white cell distributions may be normal or may indicate a stress response. If dysphagia becomes a dominant clinical sign, other hematologic changes indicative of infection secondary to aspiration pneumonia may be evident.

Diagnostic Aids Clinical signs of epistaxis or cranial nerve dysfunction are suggestive of a diagnosis of guttural pouch mycosis. A thorough physical examination may reveal abnormal sensitivity on digital palpation of the parotid area on the affected side.[33] A definitive diagnosis of guttural pouch mycosis requires endoscopic observation of the characteristic diphtheritic lesion in the dorsocaudal aspect of the medial compartment, typically covering over the temporohyoid joint and internal carotid artery, or elsewhere within the guttural pouch.[34] Aneurysm of the internal carotid artery is rarely present. A healed lesion may be identified by presence of scar tissue within the mucous membrane.[34] Lesions vary in color (brown, yellow, black, or white) and size (from discrete nodules to diffuse irregular patches covering the roof of both the medial and the lateral compartments)[35]; erosion with fistula formation can occur into the opposite guttural pouch or pharynx. Occasionally the characteristic lesion is obscured by clotted blood, so that the diagnosis is based on the clinical signs of epistaxis correlated with blood present in the guttural pouch. Because hemorrhage may originate from the internal carotid, external carotid, or maxillary arteries, it is important to identify the source of bleeding before therapy, particularly if surgical intervention is being considered. Care should be taken not to dislodge a thrombus and produce further hemorrhage. If dysphagia is apparent, food and saliva may be identified during endoscopy of the pharynx and nasal passages.

In guttural pouch mycotic infections, radiographs are of limited value because only minimum suppuration is associated with mycotic infections; however, a lateral projection may allow assessment of the degree of fibrous reaction and loss of normal air space. Radiography may also aid in diagnosing some of the long-term sequelae, such as fibrous deposits in the pouch and associated bony changes.

Serum titers to *A. fumigatus* are not diagnostic; however, reactivity to 22-kd and 26-kd serum antigens measured by immunoblot analysis may be diagnostic for guttural pouch mycosis.[37]

Pathophysiology The pathogenesis and predisposing factors leading to guttural pouch mycosis and arterial erosion are unknown, but it is believed that the disease is initiated by some stress (inflammation, trauma, vascular insult) to the soft tissues where the mycotic plaques are generally found.[35] Aneurysm formation is not well correlated with the severity of the plaque formation. Although the nature of the initiating lesion remains unclear, it is generally agreed that the later stages are associated with deep fungal infections.[37] Fungal plaques have been induced experimentally after systemic and topical (guttural pouch) corticosteroid administration within 2 days of pouch inoculation with *A. fumigatus;* however, lesions resolved spontaneously within 15 to 28 days without apparent vascular or nerve involvement or induction of clinical signs.[38] *A. nidulans* and other *Aspergillus* spp. have been isolated and may be the causative agents[35-41]; *A. nidulans* is rarely pathogenic but may grow as an opportunist in the warm, humid environment of the guttural pouch.[35] The mycotic lesions show no predilection for either the right or the left guttural pouch.[34] Fungal infection of the pouch, erosion of major blood vessels, and involvement of nerves (IX, X, XI, XII, cranial cervical ganglion, and postganglionic sympathetic fibers) that traverse the area account for the epistaxis, local pain, and neurologic signs associated with guttural pouch mycosis.[34,35]

Epidemiology No apparent age, sex, breed, or geographic predispositions have been observed. Guttural pouch mycosis is a sporadic disease that tends to arise during the warmer months of the year and rarely affects more than one horse in a particular stable.[34] Affected horses are afebrile; infection is diagnosed when clinical signs such as epistaxis and dysphagia occur, although nasal discharge is often the earliest reported sign.[34]

Necropsy Findings Lesions are confined to the pharyngeal muscles, guttural pouch, and bones of the skull.[33] Gross

findings may include large blood clots in the nasal passages and at the pharyngeal opening of the guttural pouch. Unilateral denervation atrophy of the ipsilateral pharyngeal or laryngeal muscles may occur if there is involvement of the pharyngeal and recurrent laryngeal branches of the vagus nerve.[33] Examination of the guttural pouch generally reveals clotted blood and a diphtheritic plaque in the dorsocaudal aspect of the medial compartment that is firmly adherent to the underlying tissue and is clearly demarcated from surrounding tissue.[35] The lesion may be localized or may affect the entire roof of the pouch. If hemorrhage has occurred, the lesion may be obscured by clotted blood, pus, or mucus.[35] An intense inflammatory reaction may be evident in response to acute fungal infection, whereas the inflammation may subside with chronic healing lesions so that scar tissue is evident.[35] Active inflammation may also predispose to osseous lesions of the petrous temporal and stylohyoid bones.[33,35] Some cases of guttural pouch mycosis may not have associated clinical signs and may be diagnosed only on necropsy.[34]

Treatment and Prognosis Without treatment a poor prognosis is warranted because affected horses are at risk for a fatal episode of epistaxis. Both medical and surgical treatments have been recommended, with variable results; however, surgical treatment by an intraarterial occlusion technique is generally considered to yield the best prognosis.[42-44] Although apparently uncommon, spontaneous regression of guttural pouch mycosis can occur and must be considered when the various medical or surgical treatments are being evaluated.[34]

Medical treatment is topical therapy of the mycotic lesion through the pharyngeal opening of the guttural pouch by means of a catheter. Bathing the lesion in medication may be facilitated by anesthetizing the horse and positioning it in dorsal recumbency. Instilling fungicidal and fungistatic drugs, topical enzymes, and organic iodine compounds into the guttural pouch has been attempted with variable success.[45,46] The necessity and efficacy of these treatments are unknown, and systematic treatment is hampered by a lack of knowledge of the pathogenesis of guttural pouch mycosis.[47] Parenteral administration of antibiotics, corticosteroids, thiabendazole, ketoconazole, and iodine compounds also has questionable efficacy.[47] The response of guttural pouch mycosis to local and parenteral treatment is protracted; thus the risk of fatal hemorrhage exists long after initiating treatment.[48,49]

Surgical treatment of guttural pouch mycosis appears to offer the best prognosis for eventual cure. The internal carotid artery is not an end-artery, and blood can enter this vessel from the bifurcation of the common carotid or return from the cerebral arterial circle. Various surgical techniques have been described,[50] and use of a balloon-tipped catheter inserted into the distal internal carotid artery combined with proximal ligation of the internal carotid artery,[48-51] transarterial coil embolization,[43,52,53] or transarterial nitinol vascular plugs[54] induces thrombus formation and prevents hemorrhage from normal and retrograde blood flow. Thrombosis sufficient to prevent hemorrhage may develop in the distal internal carotid artery within 10 days of catheter placement.[51] Mucosal healing and complete regression of the fungal plaque have been reported to occur as early as 5 weeks after arterial catheterization[49] and as early as 15 days after coil embolization.[43] Insertion of a balloon-tipped catheter successfully prevented fatal epistaxis in 13 horses.[48] Topical or systemic treatment of the mycotic plaque is considered unnecessary after arterial catheterization.[48] Intraarterial insertion of latex balloons, embolization coils, or nitinol vascular plugs also results in lesion resolution,[54-57] although progression of a mycotic plaque after coil embolization and subsequent development of neurologic signs have been reported.[58] Complications associated with each of these arterial occlusion techniques have been reported.[59]

Diseases of the Paranasal Sinuses

Sinusitis

John R. Pascoe

Definition and Etiology Sinusitis, inflammation of the paranasal sinuses, results from primary microbial infection or from secondary bacterial infection associated with dental or other sinus disease. Lined by respiratory mucosa, the paranasal sinuses are at risk for developing diseases affecting the respiratory tract. Sinus empyema, accumulation of pus within a sinus cavity, may result from bacterial or viral infection.

Incidence of sinusitis is relatively low, likely less than 0.5% of disease in equine practice.[1] In two longitudinal retrospective studies, covering 25 years, of 477 horses referred with sinonasal disease, the distribution of causes was primary sinusitis (subacute or chronic; 33%), dental-associated sinusitis (21%), sinus cysts (13%), sinonasal neoplasia (7%), ethmoid hematoma (6%), sinonasal trauma (6%), mycotic lesions (4%), dental-related oromaxillary fistula (3%), and miscellaneous causes (6%).[2,3] The caudal maxillary, rostral maxillary, ventral conchal, and conchofrontal sinuses are more commonly involved, and the sphenopalatine sinus is affected less often.[4] The median age of horses affected with sinonasal disease is 7 to 11 years.[2]

Acute or chronic upper respiratory tract infections of viral or bacterial origin can result in primary sinusitis; *Streptococcus* spp. infection is the most common. Maxillary sinusitis caused by disease of the third (caudal roots) through sixth cheek teeth (modified Triadian numbers 109 to 111, 209 to 211) often results from alveolar periostitis, patent infundibula, fractured or split teeth, or deep diastemata between caudal maxillary teeth. Dental defects can permit access of food material or bacteria to the tooth root and sinus cavity, with extension to the frontal sinus likely through the frontomaxillary opening. Reported neoplasms include osteoma, osteosarcoma, adenocarcinoma, lymphosarcoma, squamous cell carcinoma, neuroendocrine tumors or neuroblastoma, fibroma, and chondrosarcoma.[5-7]

Clinical Signs and Differential Diagnosis Signs vary depending on cause, location, and extent of sinus involvement, with unilateral nasal discharge (serous, mucoid, mucopurulent, purulent) being the most frequent sign.[2,3] Physical examination of a horse with sinusitis should include observation for epiphora, facial asymmetry, altered nasal airflow, abnormal breath odor, mandibular lymphadenopathy, and sinocutaneous fistula.

Nasal discharge is typically unilateral because the nasomaxillary opening is located rostral to the caudal edge of the nasal septum. Intermittent or continuous nasal discharge need not be related to a previous upper respiratory tract infection. Although malodorous discharge is commonly associated with dental sinusitis and sinonasal mycosis, it has been reported to occur in 14% to 27% of primary sinusitis cases.[2,3] Mucopurulent discharge is more commonly associated with sinus cysts.[2] Sanguineous discharge is common with ethmoid hematoma and sinonasal trauma; however, guttural pouch mycosis, pulmonary hemorrhage, nasal turbinate necrosis, and neoplastic or granulomatous lesions should also be considered. Other differential diagnoses of nasal discharge should include guttural pouch empyema or mycosis, acute pharyngitis (strangles, rhinopneumonitis, influenza, trauma), neoplasia or necrosis of the turbinates, ethmoid hematoma, and pulmonary disease.

After nasal discharge, submandibular lymphadenopathy is the most common sign, particularly when microbial infection is a component of sinusitis.[3] Facial swelling occurs with frequency similar to that of lymphadenopathy, typically when sinus drainage is obstructed, there is an expansile mass within the sinus, or as an acute sign after facial trauma. Occasionally exophthalmos can occur with marked sinus distortion.

VetBooks.ir

VetBooks.ir

Patency of the nasomaxillary opening generally precludes facial distortion. Loss of patency occurs when inspissated exudate accumulates or mucosal lining tissue reaction obstructs the opening. Expansion of the sinus may result in reduced ipsilateral nasal airflow caused by distortion of the architecture of the nasal passages. In these cases abnormal respiratory noise rather than nasal discharge may be the primary presenting sign.

Epiphora occurs if there is nasolacrimal duct involvement from trauma, compression, or destruction of the duct associated with sinus disease. Approximately 20% to 50% of horses with dental sinusitis, sinus cyst, or sinonasal trauma have epiphora as a presenting sign.[2,3]

Percussion of the affected sinus may reveal dullness or pain, although normal resonance does not preclude the possibility of sinusitis. If there is bone thinning over gas above a fluid line (as can occur with some maxillary sinus cysts), percussion may elicit increased resonance.

Careful examination of the oral cavity for signs of dental or periodontal disease should be performed when any of these signs are present. Particular attention should be paid to examination of the occlusal surface of the teeth with a very fine dental pick (e.g., 22-gauge needle); however, it should be recognized that periapical abscess formation can occur without defects in the occlusal surface. Accuracy of diagnosis of dental disease is substantially enhanced by use of intraoral endoscopy and computed tomography (CT).

Clinical Pathology The hemogram generally remains within the normal range, although acute sinusitis of infectious origin may be associated with neutrophilia with or without hyperfibrinogenemia. With chronic sinusitis, there may be concurrent hyperfibrinogenemia and hyperglobulinemia. Sinus fluid obtained by percutaneous centesis should be examined cytologically (including a Gram stain) and submitted for microbial culture and susceptibility testing to differentiate among bacterial, fungal, and neoplastic disease. Flecks of feed material indicate sinusitis secondary to dental abnormalities.

Laboratory Aids and Definitive Diagnostic Tests A presumptive diagnosis of sinusitis can be made from the physical examination and associated clinical signs.[2,3,8] Procedures most helpful in establishing a diagnosis are sinonasal endoscopy, oral cavity examination, imaging (radiography, CT, scintigraphy, magnetic resonance imaging [MRI]), sinus centesis, and sinoscopy.[4,8,9]

Nasal cavity endoscopy may permit identification of exudate draining from the nasomaxillary opening or, in advanced cases, may reveal distortion of the nasal cavity secondary to sinus enlargement. Middle meatus examination is an important component of endoscopic examination. Diagnosis beyond recognition of the potential source of the nasal discharge is limited unless an obvious mass or abnormal tissue is observed. Sinoscopy can be accomplished by using an arthroscope[10] or flexible endoscope[11] inserted through small trephine holes in either the maxillary or the frontal sinus.[9] Examination of the rostral compartment of the maxillary sinus requires a separate portal unless the bony septum between the rostral and caudal compartments has been destroyed. Observation may be limited by fluid or tissue, especially in the rostral compartment of the maxillary sinus, but can potentially be enhanced after sinus lavage and aspiration. Alternately, fenestration of the ventral conchal bulla can be used to facilitate endoscopy of the rostral compartment of the maxillary sinus.[4]

Standard radiographic projections include standing lateral, dorsoventral, and right and left oblique views.[12,13] Radiographic findings include fluid lines within the sinus, space-occupying soft-tissue densities, areas of decreased bone density, fractures, or dental abnormalities. Dental root disease is identified radiographically by a loss of continuity of the lamina dura and lysis of the tooth root or surrounding bone, combined with new bone formation and cement deposition.[12] Anatomy of normal equine skulls as demonstrated by CT and MRI has been described.[14-18] Diagnostic accuracy, especially determination of the extent of involvement of structures within the skull, can be enhanced by CT.[19,20] MRI may be useful in some sinonasal disorders.[21,22]

Findings associated with dental caries include hypoattenuation of cementum, destruction of enamel, and filling of the infundibular cavity with gas, whereas with dental decay there is gas accumulation in the root area or fragmentation of the root and sinus mucosal thickening. Additional changes with sinusitis typically involve the maxilla with endosteal sclerosis, thickening, periosteal reaction, and deformation, especially involving the facial crest.[20] Scintigraphic examination may improve specificity in identifying dental involvement in sinusitis.[23,24]

Percutaneous sinus centesis may provide a definitive diagnosis and allow an avenue for subsequent therapy. Cytologic evaluation, with concurrent microbial culture and antibiotic susceptibility testing, may elucidate the cause of the sinusitis. Isolation of a single organism such as *Streptococcus* spp. generally indicates a primary sinusitis, whereas polymicrobial infection is more compatible with sinusitis of dental origin. Visual examination of the oral cavity, especially intraoral endoscopy, and careful probing of the occlusal surfaces with a dental pick may help identify dental abnormalities.

Necropsy Findings Affected sinuses contain fluid or tissue of variable color and consistency. Fluid character ranges from clear and odorless with cystic sinus disease to white, yellow, or green purulent fluid with a variable but often putrid odor in sinusitis resulting from other causes. Sinusitis of dental origin has a characteristically pungent and unpleasant odor. Granulomatous lesions often appear as large, lobular, gelatinous masses filling the sinus cavity. The gross appearance of neoplastic lesions within the sinus cavity depends on the type of neoplasm. Neoplasia may cause surrounding soft-tissue and bony destruction, whereas large, benign space-occupying lesions may result in distortion of the nasal turbinates and nasal septum, as well as visible facial bone distortion.

Treatment and Prognosis Not infrequently, horses with a chronic mucopurulent nasal discharge from sinusitis have a history of response to antimicrobial therapy, followed by recurrence of the discharge after antibiotic therapy ceases. Definitive diagnosis of sinusitis can be accomplished using the techniques described earlier. Sinoscopy permits examination of the paranasal sinuses and in some instances facilitates treatment.[25,26]

Suggested treatment for primary sinusitis or empyema involves daily lavage of the sinus through a percutaneous centesis site with 1 L of saline, to which a broad-spectrum antibiotic or antiseptic has been added. Once the results of microbial culture and susceptibility testing are available, the appropriate antibiotic should be administered locally in the flush solution, as well as systemically, for 14 days. Resolution or reduction in the volume of nasal discharge is an indication of successful therapy. Sinus lavage often fails to remove inspissated material, which is often the nidus for continuing sinusitis and must be removed for resolution.[8] If little progress is made after 10 to 14 days of lavage or if drainage recurs, sinusotomy (trephination or bone flap technique, standing or recumbent anesthetized) is recommended to remove inspissated material[22] or identify other causes. The prognosis is generally favorable if primary sinusitis is not chronic and if the mucous membrane is not markedly thickened.[26,27] Chronic sinus disease (longer than 6 months) carries a poor prognosis, and for resolution to occur, surgical removal of the thickened, infected mucous membrane is required; creation of sinonasal drainage by sinus fenestration is also recommended.

VetBooks.ir

Sinusitis that results from secondary factors is generally not responsive to medical management. Such conditions include diseased teeth, granulomas, or neoplasia; surgical removal of the inciting cause is required, and adjunctive treatment may be required. The prognosis for sinusitis associated with dental abnormalities is usually favorable once the diseased tooth has been removed.[26,27] Complications are lower with oral extraction than with repulsion of diseased teeth.[27] Generally, failure of oral extraction and subsequent tooth or tooth fragment repulsion results in lower morbidity than initial repulsion.[27] If the periodontal ligament is intact, endodontic therapy can be used to save the tooth. This is accomplished by surgical apicoectomy and retrograde occlusion of the root canal after débridement of the pulp. In geriatric horses with dental-associated sinusitis, when economic constraints limit surgical options, sinusotomy and periodic sinus lavage and antibiotic therapy have been used successfully to manage nasal discharge.

The prognosis for resolution of granulomatous lesions is generally guarded and depends on surgical access and extent of the lesion. Neoplastic lesions are often well established and have metastasized, either locally or regionally, by the time they become clinically apparent; the prognosis for resolution is generally guarded to poor.[4]

Prevention and Control

Prevention of sinusitis in horses is difficult because of the variety of causes. Isolation of horses from those with upper respiratory bacterial or viral diseases may be of benefit in preventing primary sinusitis. Regular dental care and a proper diet may help circumvent sinusitis caused by dental abnormalities, although many cases most likely result from a variety of causes not yet defined or over which the owner or veterinarian has no control.

Ethmoid Hematoma

John R. Pascoe

Definition and Etiology

Ethmoid hematomas (progressive ethmoidal hematoma[1]; hemorrhagic nasal polyps[2]) are slowly expanding angiomatous masses (median dimensions: 3.8 × 9 × 13 cm)[3] originating principally from the mucosal lining of the ethmoid conchae. Smaller hemangiomas arising from the mucosal lining of the frontal, maxillary, and sphenopalatine sinuses have been recognized, but the relationship between these benign endothelial tumors and ethmoid hematoma remains uncertain. Ethmoid hematoma is a relatively uncommon condition of unknown cause. Distinctly different histologic features characterize ethmoid hematoma and paranasal sinus cysts,[4] which makes it unlikely that these lesions are variants of each other with a common cause.[5] Although ethmoid hematomas have been reported in a 4-week-old foal and in 3-year-old horses, most affected horses are older than 8 years and are generally Thoroughbred, Arabian, or warmblood horses[6,7]; males (geldings) seem to be more commonly affected.[3]

Clinical Signs

A blood-tinged nasal discharge with intermittent epistaxis from one or both nostrils is the most common clinical sign. Unilateral or bilateral epistaxis varies from blood-tinged, mucoid, or mucopurulent discharge to blood spots or a trickle of blood. Fulminant or fatal epistaxis is uncommon. If the hematoma occupies the choanae or nasal cavity, a mucopurulent, occasionally malodorous nasal discharge with some blood discoloration is more commonly seen. Typically there is a history of abnormal respiratory noise, both inspiratory and expiratory, especially during exercise. With nasal cavity involvement, airflow may be reduced or absent on the affected side. Facial distortion or asymmetry is uncommon and more likely to occur with involvement of the frontal and maxillary sinuses. Secondary mycotic infections and empyema may be associated with intraparanasal sinus ethmoid hematoma.[8] Less commonly there may be an associated history of coughing, choking, ptyalism, increased respiratory effort during resting breathing, and either head shyness or headshaking.[1] If the hematoma has expanded into the paranasal sinuses, percussion yields a dull sound.

Laboratory Aids and Definitive Diagnostic Tests

Confirmation requires endoscopy of the ethmoid conchae and diagnostic imaging (Fig. 31.44). Although survey radiography is useful to identify the mass, its origin and extent are delineated more accurately with CT, which is also more reliable

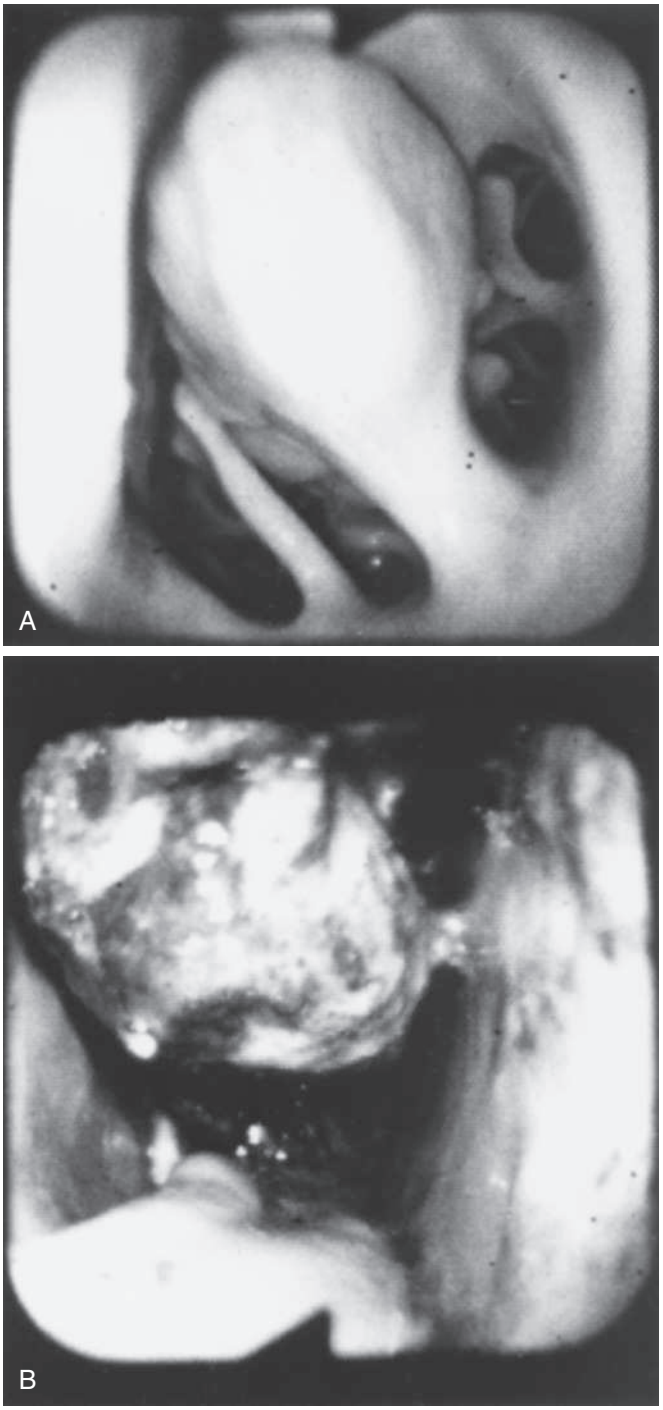

FIG. 31.44 Endoscopic view of left ethmoturbinate. **A,** Normal appearance. **B,** Ethmoturbinate obscured by an ethmoid hematoma.

VetBooks.ir

than a combination of clinical examination, endoscopy, and conventional radiography.[3] Limited information is available to assess the value of MRI for diagnosis of ethmoid hematoma.[9,10] In the absence of CT, sinoscopy may be of diagnostic value when the ethmoid hematoma involves the paranasal sinuses without nasal cavity protrusion. Rarely, ethmoid hematoma infiltrates the nasal conchae; these lesions, identifiable by CT, may be missed on sinoscopy. Definitive localization of ethmoid hematoma involving the sphenopalatine sinus is unlikely by radiography or sinoscopy.[3]

Ethmoid hematomas are bilateral in 30% to 50% of affected horses, so it is prudent to examine both ethmoidal conchae. The ethmoidal labyrinth is visible approximately 25 cm from the nares, with the endoscope positioned in the ventral nasal meatus and the viewing tip deflected dorsally. The rostral surface of the ethmoidal concha does not protrude beyond the caudal aspect of the nasal cavity; it has a bulbous shape and a moist pink to pale red mucosal covering. Distal to the rostral surface are numerous pillars that form the ethmoidal conchae and separate the ethmoidal spaces (cellulae ethmoidales). Ethmoid hematomas that project into the ventral meatus or through the choana into the nasopharynx often obscure the ethmoidal concha. Unilateral ethmoid hematomas that expand into the nasopharynx may extend into the contralateral ventral meatus and obscure that ethmoidal labyrinth.

The origin of hematomas that expand dorsally into the frontal sinus may not be visible on endoscopy, but hemorrhage that originates deep to the visible portion of the ethmoidal conchae may be evident or noticed from the region of the nasomaxillary opening in the middle meatus. Visible ethmoid hematomas vary in color from deep red to red-purple or may have a yellow-brown or yellow-green-brown to bronze color. The surface is irregularly rounded, with small punctate hemorrhages or erosions, and may be partially covered in yellow-white mucopurulent material that may be admixed with blood. Often the floor of the ventral meatus and regions of contact with the nasal cavity have pooled exudate (blood and mucopurulent matter). Manipulation of the hematoma surface with the endoscope may cause bleeding or oozing.

Radiographic recognition of a discrete, often smooth-surfaced homogeneous radiodensity originating from the ethmoidal conchae and extending into the frontal, maxillary, or sphenopalatine sinuses, or into the pharynx or nasal cavity, is suggestive of ethmoid hematoma. Precise definition of the hematoma origin is difficult to determine from radiographic projections, and small hematomas contained within the ethmoid labyrinth may not be visible.

CT examination allows more accurate assessment of the origin of the ethmoid hematoma,[3] allows determination of the extent of involvement of the paranasal sinuses (especially the sphenopalatine sinus) and conchae, and facilitates surgical planning. On CT scans, masses are often associated with bone destruction, especially of the ethmoturbinates and infraorbital canal, and typically abut the cribriform plate in 50% of cases. Masses commonly have mild to moderate signal heterogeneity and a hyperdense swirling appearance consistent with recent hemorrhage or mineralization, which are also common morphologic features.[3]

Necropsy Findings

Morphologic features have been described from surgical specimens, but few skulls with intact ethmoid hematomas have been examined.[2,3] Except in regions with necrosis or secondary infection associated with contact with the sinus or nasal cavity walls, the hematoma is a smooth-surfaced saclike structure containing blood in various stages of organization. The sac lining is generally healthy respiratory mucosa originating from a pedunculated region of the mucosal covering of the ethmoturbinate or sinus wall. On section, contents are amorphous red-black to chocolate brown, and in larger masses some evidence of irregular compartmentalization by fibrous tissue exists, especially on the inner surface of the sac.

Morphologic features include an outer covering of respiratory epithelium (flattened columnar or cuboidal ciliated epithelium-containing glands, and occasionally stratified squamous epithelium[4]) overlying an irregular zone of submucosal fibrous tissue, containing hemosiderophages, occasional plasma cells, and lymphocytes, less commonly neutrophils, that forms a pseudocapsule around hemorrhage in varying states of organization. There is variable organization of the fibrous tissue components. Endothelial cells do not show evidence of neoplasia. Thin endothelium-lined sinuses are often present within the myxomatous stroma. The respiratory epithelium is sometimes focally ulcerated and infiltrated with neutrophils, and occasionally there are squamous metaplastic changes. Ethmoid adenocarcinoma with a similar gross appearance to ethmoid hematoma has been reported.[3,11]

Treatment and Prognosis

Ethmoid hematomas slowly and progressively increase in size and can cause skull distortion if there is paranasal sinus involvement, so removal is recommended. Treatment method depends on location and size. Surgical ablation has been the preferred method; however, destruction of the hematoma by intralesional injection of formaldehyde solution is associated with less morbidity, although recurrence rates are similar to those achieved by other methods.[6-8,12,13] Surgical access is achieved by sinusotomy and then hematoma ablation by curettage, cryosurgery, or use of an Nd:YAG laser[13]; photoablation can be achieved through the biopsy channel of an endoscope. If sinusotomy is necessary, the pedunculated origin of the hematoma is identified by digital palpation and then dissected, frozen, or photoablated, and the hematoma is removed. If the hematoma is friable, intact removal may not be possible, and hemorrhage may make observation of the origin of the mass difficult. After removal, the paranasal sinuses and nasal cavity are packed with gauze to control postoperative hemorrhage.

Surgical curettage can be associated with marked intraoperative blood loss typically from the turbinates or sinus mucosa rather than the hematoma. Temporary occlusion of both carotid arteries[14] can reduce blood loss until the sinus cavity is packed with gauze. Blood loss is minimized with cryosurgical extirpation and photoablation techniques, but these approaches are not always practical with large hematomas. Although blood loss is minimal with transnasal photoablation, this technique requires multiple procedures to destroy large masses but can be performed in the standing sedated horse. Photoablation (Nd:YAG laser, 100 W in noncontact technique) is effective in controlling remnants after surgical extirpation or subsequent regrowth.[13] A complication of severe epistaxis, subarachnoid hemorrhage and peracute, severe neurologic signs that occurred during laser photoablation of an ethmoid hematoma in the right nasal cavity have been reported in one horse.[16]

Destruction of ethmoid hematomas by endoscopically guided intralesional injection of formalin in standing sedated horses may reduce the need for surgical ablation.[12,17] A catheter passed through the endoscope biopsy channel is advanced through the rostral surface of the mass toward its origin, then 10% formalin (4% formaldehyde solution) is injected intralesionally. Commercially available catheters with a beveled needle tip are available, but relatively stiff plastic tubing that slides through the biopsy channel will penetrate the hematoma capsule. Sufficient volume (10 to 100 mL) is injected until fluid leaks back alongside the catheter or from the mass. For visibly pedunculated masses, formalin should be injected at the origin or neck of the mass. Tissue necrosis and slough occur within 5 to 10 days and may be associated with nasal discharge. Repeat injections, typically at no longer than 10- to 14-day intervals, may be needed to destroy the mass. Removal of necrotic tissue can be facilitated by use of

long, grasping forceps and hydropulsion. Mycotic plaques may cover the treated site during healing but typically resolve without treatment; endoscopically delivered topical natamycin has been used if mycotic plaque is extensive and associated with malodorous, purulent discharge.[18] If the hematoma has a paranasal sinus extension, necrosis of that tissue within the sinus, after destruction of the ethmoturbinate origin of the hematoma, may result in sinus empyema, mycotic infection, or both,[8] requiring ancillary treatment.

Occasionally progression of the ethmoid hematoma may result in weakening or loss of the cribriform plate or roof of the sphenopalatine sinus.[18] During mass removal, loss of this protective bony covering may result in intraoperative or postoperative neurologic complications. Recognition of loss of the integrity of these bony plates may not occur until sinus lavage. In a rare complication, death occurred after intralesional formalin injection in a horse where the cribriform plate had been eroded by the ethmoid hematoma.[19] Erosion of calvarial bone is rare, but careful CT evaluation of these regions in horses with extensive hematoma formation involving the frontal or sphenopalatine sinuses is warranted.[3]

Irrespective of treatment method, recurrence of the hematoma occurs in 17% to 50% of cases from several months to years after the initial surgery.[2,3,6-8,12,13,18] Increased use of CT to guide surgical planning and for postoperative evaluation is likely to contribute to a reduction in recurrence rates.

Disorders of the Equine Soft Palate

Safia Z. Barakzai • Padraic Martin Dixon

Anatomy and Physiology of the Soft Palate The equine soft palate extends caudally from the hard palate and completely divides the pharynx into nasal and oral compartments. Because the horse is an obligate nasal breather, the caudal border of the soft palate normally fits snugly around the base of the epiglottis, and the soft palate remains in this subepiglottic position at all times except during deglutition. The soft palate consists of the oral mucous membrane, palatine glands, palatine aponeurosis, palatal muscles, and nasopharyngeal mucosa. The soft palate is relatively thick (>2 cm) rostrally and tapers caudally as the amount of glandular tissue within it reduces considerably.[1] The paired muscles that control palatal position include the *palatinus* muscles (running rostrocaudally on either side of midline), the *palatopharyngeus* muscles (running from the palatine aponeurosis and lateral aspect of the *palatinus*, sweeping laterally up the walls of the nasopharynx), the *tensor veli palatini* muscles that tense the rostral aspect of the soft palate, and the *levator veli palatini* muscles that elevate the soft palate during deglutition.

The dorsal aspect of the soft palate forms the floor of the nasopharynx and has longitudinal ridges that become more apparent endoscopically when the palate is flaccid. Horses that resent endoscopic examination of the upper respiratory tract often tense their soft palate, giving its rostral aspect a dorsally "domed" appearance.

Dysfunction of the soft palate presenting as dorsal displacement of the soft palate (DDSP) or palatal instability (PI) at fast exercise is by far the most frequent palatal abnormality that clinicians are presented with in equine practice. Other palatal disorders are relatively uncommon.

Dorsal Displacement of the Soft Palate and Palatal Instability

Palatal dysfunction, which includes the two syndromes of DDSP and PI, is the most commonly diagnosed cause of upper airway obstruction in racehorses, with a reported prevalence of around 10% to 20%.[2,3] It also affects other types of horses, particularly those that are exercised with their head and neck in a flexed position, such as dressage horses, showjumpers, and Saddlebreds.[4,5] Intermittent DDSP is a disorder that characteristically occurs in horses toward the end of fast work, when the caudal border of the soft palate becomes displaced dorsal to the epiglottis (Fig. 31.45). A definitive diagnosis of intermittent DDSP or PI can only be made using exercising endoscopy on a treadmill or using overground endoscopy. Palatal instability is seen as wavelike dorsal billowing of the rostral and caudal aspects of the soft palate but without actual displacement of the caudal border of the soft palate dorsal to the epiglottis. Palatal instability commonly precedes DDSP.[6-9] Swallowing may temporarily halt PI, but instability usually recurs within a few seconds and may then progress to true DDSP. As the soft palate "billows" dorsally, it may lift the epiglottis, changing the epiglottic conformation and causing the aryepiglottic folds to deviate medially.[9,10] It is unclear what degree of soft palate instability is "normal" and what percentage of horses diagnosed with PI would experience DDSP under different conditions, such as training versus racing. When PI is observed in isolation, it has been described as equivalent to a "presumptive" diagnosis of DDSP[11] and has also been suggested as a "prodromal" sign of impending DDSP.[9,12]

"Rostral palatal instability" is another form of palatal instability that has been reported in horses and ponies, associated with neck flexion during exercise.[13,14] As the name suggests, the condition is characterized by dorsoventral billowing confined to the rostral aspect of the soft palate. Rostral palatal instability causes inspiratory nasopharyngeal obstruction and respiratory noise. Experimentally this condition has been produced by bilateral *tensor veli palatini* tenectomy.[15]

Pathophysiology Horses that have other abnormalities of the palate or larynx, such as epiglottal entrapment, pharyngeal paralysis, and palatal cysts, are predisposed to DDSP. If no such abnormalities are present, the etiology of the disorder is currently unknown despite research efforts to improve understanding of the condition, with the ultimate goal of developing more effective treatments.[15-20] Current theories include neuromuscular dysfunction of the intrinsic soft palate muscles,[20-22] variations in the anatomic positioning of the laryngohyoid apparatus and the role of the thyrohyoid muscles in laryngeal "elevation,"[19,23,24] and the role of the distal hypoglossal nerve in maintaining nasopharyngeal stability.[25] Epiglottic hypoplasia

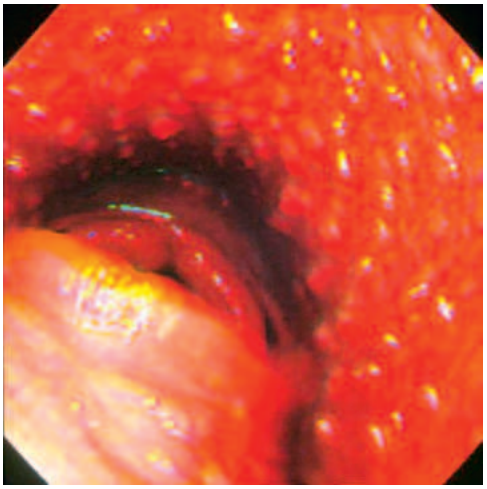

FIG. 31.45 Dorsal displacement of the soft palate seen in a horse undergoing exercising endoscopy. The epiglottis can no longer be visualized.

VetBooks.ir

or flaccidity was previously thought to be associated with intermittent DDSP. However, clinical and experimental data show that the epiglottis is not required to maintain the palate in a normal position and that the majority of horses that experience DDSP during treadmill endoscopy have an epiglottic length that is within normal limits.

Clinical Signs Most horses with DDSP make a rough "snoring" or "gurgling" noise at exercise and may either pull up abruptly or slow down significantly after the palate has displaced. DDSP results in a flow-limiting expiratory obstruction, leading to decreased airflow, increased tracheal expiratory pressure and impedance, reduced minute ventilation and subsequent hypoxia, hypercapnia, and impaired athletic performance.[17,26,27] Conversely, once the soft palate has displaced, minimal obstruction is observed during inspiration as the upper airway inspiratory pressure maintains the soft palate in close apposition to the dorsal aspect of the epiglottis. During expiration, because a proportion of the exhaled air is directed ventral to the displaced palate and into the oral cavity, some horses are reported to exhibit "fluttering" of the cheeks during exhalation. Palatal instability has also been shown to have a negative effect on ventilatory parameters if moderate to severe.[28] Low-frequency fluttering of the caudal border of the palate is believed to be the source of the loud expiratory and inspiratory "gurgle" or "snore" reported in 70% to 80% of affected horses[29]; however, up to 30% of horses can experience DDSP yet make no audible abnormal respiratory noise ("silent displacers").[30-32]

Diagnosis An accurate history that includes details of reduced exercise performance and of abnormal noise production, including the type of noise made and the stage of exercise when it occurred, can be very helpful. A thorough resting endoscopic examination of the nasopharynx should be performed to rule out other causes of palatal dysfunction such as pharyngeal or palatal cysts, epiglottic entrapment, or pharyngeal paralysis. The lower portion of the respiratory tract should also be examined for evidence of lower airway disease. DDSP and PI are dynamic conditions, and findings of resting endoscopy have been shown to correlate poorly with dynamic endoscopic findings.[12,31,32] Horses that displace their soft palates at rest are often normal during exercising endoscopy, and conversely many horses that are normal during resting endoscopic examination can develop DDSP at exercise.[12,32] One study reported that use of a characteristic history of gurgling and poor racing performance plus findings of resting endoscopy alone resulted in a 35% misdiagnosis rate of palatal dysfunction, as compared to findings of treadmill endoscopy.[32]

Exercising endoscopic examination, either on a high-speed treadmill with a standard videoendoscope or during ridden or driven exercise using a portable telemetric endoscopic system, is the gold standard for diagnosis of DDSP and PI.[3,6-8,12,31-34] Clinically normal horses may transiently displace their soft palates during exercise and particularly when pulling up. However, a normal horse typically swallows and replaces the palate to its normal subepiglottic position within a few strides, whereas DDSP is typically diagnosed if the palate remains dorsal to the epiglottis for a longer period of time (several seconds) or if DDSP occurs repeatedly.

Sound analysis has also been used as a research tool for diagnosis of DDSP,[30] but it has not been reported in significant numbers of clinical cases and its accuracy is therefore unknown. A significant relationship has been reported between the depth of the basihyoid bone measured using percutaneous ultrasonography at the caudal aspect of the lingual process at rest and the occurrence of DDSP at exercise.[35] A more ventrally located basihyoid at rest was associated with an increased probability of DDSP occurring during treadmill endoscopy. This test had a high negative predictive value (89%) but a low positive predictive value (36%),[35] meaning that DDSP could be ruled out with reasonable certainty but that care should be taken when making a positive diagnosis of DDSP using this method.

Treatment Many treatments are available for horses with DDSP, and this probably reflects both the unknown etiology of the disorder and the fact that most treatments have a similar success rate. Concurrent respiratory disorders, including upper or lower airway inflammation or infections, should be addressed fully, prior to resorting to surgical remedies, and if the horse has only just been brought into work, improving its fitness can resolve palatal issues. The use of systemic corticosteroids, NSAIDs, and topical antiinflammatory nasopharyngeal ("throat") sprays has been advocated to try to reduce upper airway inflammation.[2,31] One study showed that in young 2- and 3-year-old Thoroughbred racehorses, 56% of horses with DDSP were reported to show spontaneous resolution of the disorder within 3 months of their initial exercising endoscopic diagnosis, without receiving any specific treatment.[35] Spontaneous resolution was less common in older racehorses, with only 12% no longer experiencing DDSP on repeat overground endoscopic exam.[36] Tack changes, including use of a tongue tie,[36,37] dropped or crossed noseband,[36-39] and "W" or "Serena Song" bits, have also been reported anecdotally to be of benefit in affected racehorses. The laryngohyoid support device ("Cornell collar") has been advocated as a nonsurgical "tie-forward" procedure for horses with DDSP and was effective in 100% (7 of 7) of horses with experimentally induced DDSP.[40] In horses with naturally occurring DDSP, the Cornell collar was reported to be effective in around 60% of horses by one study.[36]

Surgical treatments for DDSP are numerous and include insertion of a thyrohyoid prosthesis (the laryngeal "tie-forward" procedure), staphylectomy, myectomy of the sternothyrohyoideus muscles, epiglottic augmentation with Teflon™, tension palatoplasty, thermocautery of the oral surface of the palate, laser cautery of the nasopharyngeal surface of the palate, in addition to multiple combinations of these procedures. A systematic review of treatments for palatal dysfunction in the horse[41] concluded that "the low level of evidence makes it difficult to draw firm conclusions as to the efficacy of procedures used to treat DDSP." The use of combinations of surgeries usually represents a "belt and braces" approach but arguably may provide a multimodal approach to a disorder with a multifactorial etiology. However, the use of multiple treatments in scientific studies also means that we are often left unsure as to which of the reported treatments, if any, may have had a beneficial effect.[41]

Failure of surgical remedies for DDSP is not uncommon. As a surgical principle, it is unwise to repeat a surgical procedure that the animal did not respond to the first time, unless the surgical procedure can be documented to have been performed suboptimally or has technically failed (i.e., broken or loose tie-forward suture).[42] Furthermore, the morbidity associated with certain procedures such as staphylectomy makes their repetition risky.[42] Few studies have analyzed the effects of surgery for DDSP using the "gold standard" of postoperative exercising endoscopy. A study that performed overground exercising endoscopy on 20 racehorses after laryngeal tie-forward showed that the surgery eliminated DDSP in 65% of horses but that 70% still exhibited a degree of palatal instability.[43] However, this study population was biased toward horses that had a suspected problem after the tie-forward (60% of cases presented had trainer-reported ongoing respiratory noise and/or poor performance).[43] Causes of failure of laryngeal tie-forward include not having a definitive diagnosis of the palatal issue preoperatively, migration of the larynx caudally after surgery, and suture pull-through or failure.

Persistent Dorsal Displacement of the Soft Palate

Persistent DDSP, where the soft palate is permanently positioned dorsal to the epiglottic cartilage, is rare compared to intermittent DDSP. It is observed in the resting horse and is often secondary to underlying structural abnormalities such as subepiglottic cysts, epiglottitis, epiglottic entrapment, intrapalatal cysts, pharyngeal paralysis, pharyngeal neoplasia, or pharyngeal foreign bodies,[13,41] but it can also be idiopathic. Persistent DDSP is seen most commonly after surgery to release epiglottal entrapment[44-46] if a large fold of the subepiglottic mucosa is resected but has also been reported after many other types of laryngeal surgery, including laryngoplasty and ventriculocordectomy.[47] Horses affected with persistent DDSP make a loud gurgling noise at exercise, have poor exercise tolerance, and can be dysphagic, often coughing when eating.[44,47]

Diagnosis Diagnosis is easily made by endoscopic examination of the nasopharynx in the resting horse where the epiglottis is never visible because the soft palate lies dorsal to it. Horses should be prompted to swallow several times during the examination to see if any transient relocation of the palate occurs. Ulceration of the caudal border of the soft palate can sometimes be observed. Observation of persistent DDSP with the endoscope passed per nasum, is an indication to perform endoscopy of the oropharynx (with a full dental speculum in place) to examine the epiglottis and associated structures for abnormalities. If 60-cm broncho-oesophageal forceps are available, the larynx and caudal soft palate can be desensitized by application of topical local anesthetic and the forceps then used to manipulate the palate to a subepiglottic position and to elevate the epiglottis to examine its ventral aspect (Fig. 31.46).

Treatment In most cases, persistent DDSP is secondary to some other disorder, and treatment should therefore be directed at the initiating cause. If no primary disorder is found, the tie-forward procedure (laryngohyoid prosthesis) has been reported to be effective in alleviating idiopathic persistent DDSP in 7 of 15 affected horses.[44] In the same case series, the remaining 8 of 15 horses additionally required laser staphylectomy after the tie-forward procedure to resolve persistent DDSP.[44] A subepiglottic "releasing" incision, which may include a hyoepiglottic myotomy, has also been described for treatment of cases where it was felt that the epiglottis could not be manually repositioned dorsal to the palate due to subepiglottic adhesions.[47]

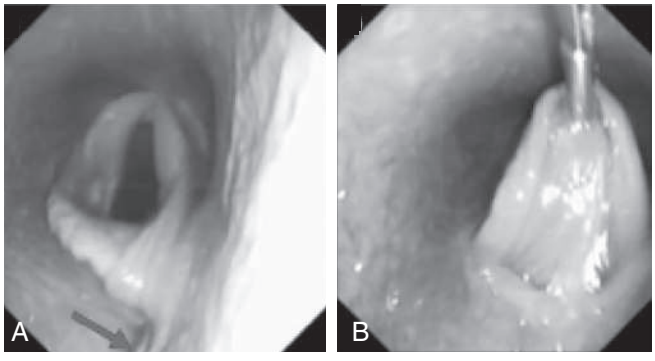

FIG. 31.46 Case of persistent dorsal displacement of the soft palate (at rest). **A,** A 60-cm broncho-oesophageal forceps *(arrow)* is used to manipulate the soft palate ventral to the epiglottis (topical local anesthetic has been applied). **B,** The forceps is then used to elevate the epiglottis and view the ventral surface.

Congenital Palatal Defects

Congenital defects of the palate (cleft palate or palatal hypoplasia) are rare in horses, having a reported prevalence of 0.01% to 0.02%.[2] True cleft palates arise from incomplete embryologic closure of the palatal folds, but often there is a tissue deficit that should correctly be called palatal hypoplasia. Tissue defects or clefts may involve only the caudal aspect of the soft palate (Fig. 31.47) or both the hard and the soft palates. Affected foals should be examined carefully for other congenital defects such as cardiac, GI, and nasal septum abnormalities.

Clinical Signs and Differential Diagnosis Clinical signs of cleft palate include nasal regurgitation of milk (in foals) or other feed material in older horses, coughing, poor growth, and signs indicative of aspiration pneumonia such as cough during eating and persistent nasal discharge.[48-52] If the defect is small, abnormal respiratory noise due to PI or DDSP may be the only presenting sign, or the foal or horse may be asymptomatic. Endoscopic examination of the nasopharynx (using a small-diameter endoscope) reveals an abnormal outline to the caudal soft palate and food material within the nasopharynx, larynx, and trachea. The defect can be characterized by a midline cleft where there is an almost normal amount of tissue but failure of fusion of the left and right sides, a unilateral (Fig. 31.48) or bilateral soft palate hypoplasia. Defects of both the hard and the soft palates are less common (7% to 18%[48,52]), and these animals are usually presented as foals,[48] probably due to the increased severity of clinical signs. Differential diagnoses for dysphagia with aspiration of food material in foals includes subepiglottic cysts, pharyngeal paralysis or dysfunction (which can be transient in neonatal foals,[53] particularly if premature or dysmature), and in older horses, oesophageal obstruction (choke), guttural pouch mycosis, severe arytenoid chondritis, complications of laryngeal surgery (e.g., laryngoplasty or arytenoidectomy), and large pharyngeal cysts or pharyngeal or laryngeal foreign bodies or neoplasms.

Treatment If signs associated with the palatal defect are confined to noise during exercise, occasional coughing after eating and/or nasal discharge (i.e., there are no or minimal systemic signs), affected foals can survive to adulthood and may be capable of ridden work if left untreated or treated symptomatically.[48,51,52] Surgical repair is possible for foals with less than 20% to 30% of the palatal tissue missing, but this is generally a salvage procedure only, and only a few go on to

FIG. 31.47 Congenital midline defect ("cleft") of the soft palate.

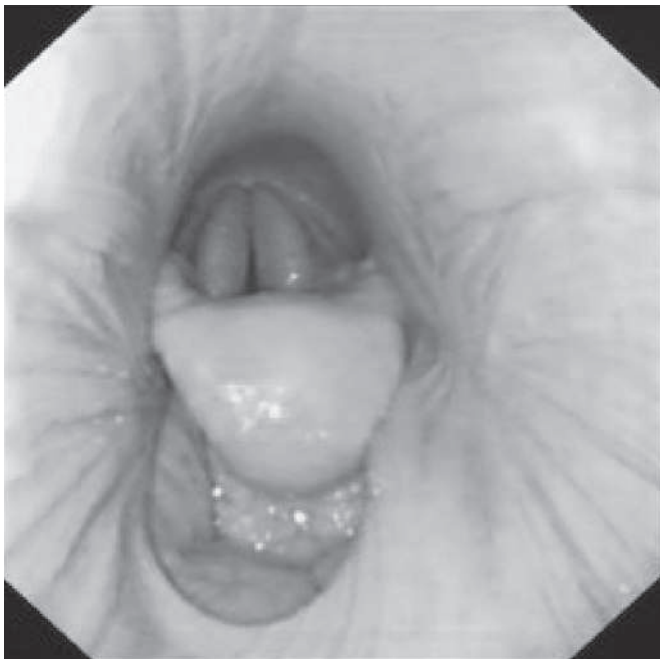

FIG. 31.48 Unilateral right-sided hypoplasia of the caudal soft palate.

perform athletically to a high level when older, even if surgery is successful.[2,52] Surgical repair of soft palate defects is extremely challenging and has a high prevalence of complications and failure. Therefore if signs of severe aspiration pneumonia or a large palatal defect are present, euthanasia of affected foals should be considered as an alternative. Surgical approaches to the soft palate include transoral, pharyngotomy, laryngotomy, and mandibular syphysiotomy, and laryngeal tie-forward has been described to close small palatal defects.[49,50-52]

Palatal Cysts

These rare lesions usually occur in young horses and may be a cause of abnormal respiratory noise and airway obstruction if they become large or if they disrupt the normal palate-epiglottic relationship. Palatal cysts probably form as the result of the obstruction of mucus-secreting glands within the soft palate, or they may have a traumatic aetiology.[54] The presence of palatal cysts predisposes horses to DDSP.

Clinical Signs and Diagnosis Clinical signs include respiratory noise (at rest or during exercise), coughing, exercise intolerance, nasal discharge, dysphagia, and signs of aspiration pneumonia. Diagnosis is made by endoscopic examination of the nasopharynx where a raised intrapalatal mass can be seen. Oral endoscopy (as described above) may also be of value. Obtaining an "open-mouthed" straight lateral radiograph (with the incisors held apart with a gag) will cause the soft palate to move dorsally away from the tongue and allows focal thickening of the palate to be visualized more easily than on a standard closed-mouth lateral view. Differential diagnoses include palatal neoplasia and intrapalatal abscesses, the latter being usually associated with intrapalatal foreign bodies or strangles infection. Transendoscopically guided aspiration of the cyst should yield clear, viscous fluid.

Treatment Treatment involves surgical excision or laser ablation of the cystic structure, if it is large enough to cause abnormal respiratory noise or airway obstruction. If the cyst is simply drained and some of the lining is left in situ, it is likely to recur.

Neoplasia

Neoplasms of the soft palate are rare. Lymphosarcoma and squamous cell carcinoma occur most frequently, and lesions may vary markedly in appearance. Surgical excision of pharyngeal neoplasms is rarely successful because total excision with wide margins is almost impossible to achieve. Radiotherapy may provide an alternative for treatment of pharyngeal neoplasms but is not widely available for horses.

Disorders of the Trachea

Safia Z. Barakzai • Padraic Martin Dixon

Anatomy of the Trachea

The equine trachea extends from the caudal larynx to the carina where it divides into the two mainstem bronchi at the level of the fifth to sixth intercostal spaces and is about 75 to 80 cm long in a 500-kg horse.[55] The trachea occupies a midline position in the neck and also in the rostral thorax, where it lies in a fold of mediastinum, but at its termination it becomes slightly displaced to the right by the adjacent aortic arch.[56] It is composed of 48 to 60 individual tracheal rings of hyaline cartilage, which are incomplete dorsally.[55] In the cervical trachea, the free ends of the tracheal rings usually overlap, but in the thoracic trachea, the free ends rarely meet.[56] Each individual tracheal ring is 10 to 12 mm wide, being 2 to 3 mm thick dorsally and 5 to 7 mm thick ventrally. The dorsal tracheal ligament completes the dorsal aspect of the tracheal lumen, attaching to the inner surface of the tracheal rings. The cartilage rings vary a little in shape in the normal horse; the first few rings are slightly dorsoventrally flattened but more distally the rings become more circular in shape. Finally, at the level of the aortic arch, the rings can become slightly laterally flattened, particularly on the left side.[55] The tracheal ligament contains the transversely oriented trachealis muscle, and this elastic structure allows the trachea to expand slightly during times of increased respiratory effort.

Each tracheal ring is covered by and connected to adjacent rings by an intimately attached fibroelastic ligament called the annular ligament. This arrangement of semirigid cartilaginous rings and elastic annular ligaments, along with the loose attachment of the tracheal adventitia to other tissues, allows much flexibility of the trachea during head and neck movement while retaining its rigid cross-sectional shape. The cricotracheal ligament, which attaches the first tracheal ring to the cricoid cartilage, is of similar structure to the annular ligaments but is wider (craniocaudally) and under less tension.

Running bilaterally along the dorsolateral aspects of the trachea are many vital structures, including the carotid artery, vagus and recurrent laryngeal nerves, sympathetic truck, tracheal lymph ducts, and cervical lymph nodes. The trachea is lined by a pale mucosa, containing numerous mucus and serous glands, and may contain fine longitudinal folds. Ciliated epithelial cells are the predominant cell type,[57] with each cell containing about 200 cilia that beat 15 to 20 times per second. These cilia transport mucus from the lungs proximally to the nasopharynx. In the equine trachea, mucus is transported at a velocity of 13 to 20 mm/min.[57] The "sump-like" depression in the rostral thoracic trachea is a common place for excessive respiratory secretions to accumulate in horses.[58]

Primary tracheal disorders are relatively uncommon in horses, but abnormal pooling of respiratory secretions in the "sump" of the trachea is often seen as a consequence of lower airway inflammation or exercise-induced pulmonary haemorrhage.[59] Primary lung disorders are not discussed further in this section.

Cricotracheal Ligament Prolapse

A limited number of clinical reports describe this disorder in Thoroughbred racehorses during fast exercise.[60-63] The cricotracheal membrane is normally longer (rostrocaudally) and under less tension than the tracheal annular ligaments. It is suggested that an abnormally long and/or slack cricotracheal ligament may prolapse dorsally, ventrally, or circumferentially into the airway lumen as a result of the very negative inspiratory airway pressures that are generated during fast exercise. One case series reported that cricotracheal ligament collapse can reduce the cross-sectional area of the tracheal lumen by 36% to 52%.[63] Concurrent upper and lower airway disorders may increase the severity of cricotracheal ligament prolapse by further increasing the negative pressure generated within the upper respiratory tract.

Clinical Signs and Diagnoses

Clinical signs include abnormal respiratory noise during exercise and reduced exercise performance[61-63] due to the dorsally displaced ligament causing turbulent and restricted airflow. Differential diagnoses must include all forms of dynamic upper airway collapse, in particular those that are associated with inspiratory noise, including recurrent laryngeal neuropathy, medial deviation of the aryepiglottic folds, vocal fold collapse, ventromedial luxation of the apex of the corniculate cartilages, epiglottic retroversion, and nasopharyngeal collapse. Diagnosis requires exercising endoscopy, either overground[63] or on a high-speed treadmill, with a specific effort made to examine the caudal laryngeal area by having the endoscope tip positioned caudally and a good light source. In most reports of this disorder, multiple concurrent dynamic upper airway abnormalities are present.[62-63] Presumably, cricotracheal collapse is exacerbated with head and neck flexion, as this position will reduce tension on the cricotracheal ligament; however, this has not been discussed in any of the case reports to date. Palpation of the ventral aspect of the cricotracheal ligament in the resting horse can subjectively reveal flaccidity, and much of the overlying tracheal lumen can be occluded with digital pressure. Ultrasonography of the ventral aspect of the cricotracheal ligament with the horse's head extended may be useful to measure the length and thickness of the ligament, but the range of these ultrasonographic measurements in normal horses has not yet been reported.

Treatment

Conservative management of cricotracheal ligament collapse (7 days of oral phenylbutazone therapy) is reported to be successful in young (~2 years old) Thoroughbred racehorses that had other concurrent dynamic abnormalities noted on exercising endoscopy at the time of diagnosis.[63] Horses in which cricotracheal ligament collapse spontaneously resolved had evidence of nasopharyngeal inflammation (grade 3 pharyngeal lymphoid hyperplasia) at the time of initial diagnosis. This inflammation decreased or resolved at the time of follow-up exercising endoscopy, when the cricotracheal ligament collapse was noted to have resolved.[63]

For persistent cases, treatment is via imbrication of the ventral aspect of this ligament after closing the space between the cricoid cartilage and the first tracheal ring.[61,63] The dorsal half of the ligament cannot be accessed without risk of damaging the recurrent laryngeal nerves; however, Pollock and colleagues[63] report that imbrication of the ventral aspect only appeared to prevent prolapse in two mature horses.

Tracheal Collapse

Tracheal collapse is commonly recorded in many breeds of toy dogs[64-66] and can also occur in goats,[67] sheep, and cattle (P.M. Dixon, personal observations). In Equidae, this developmental disorder is often reported in small ponies and miniature horses[68-73] but also occurs in larger breeds of ponies[74] and donkeys.[71,75] In many small ponies, the disorder remains undiagnosed due to their low workload. There is a high prevalence of tracheal deformities in donkeys; in one postmortem study, 68.8% of tracheal rings did not have an oval or circular shape. Affected donkeys are usually asymptomatic unless severe tracheal deformity or intercurrent pulmonary disorders, such as advanced pulmonary fibrosis, are present.[75]

Pathophysiology

Tracheal collapse is usually caused by a cartilage ring deformity, including where the normal rounded or oval tracheal ring is replaced classically by a flatter tracheal ring with a greatly reduced dorsoventral diameter (Fig. 31.49). In some cases, a slack and enlongated dorsal tracheal ligament can exacerbate the dynamic tracheal collapse.[68,69,74] A more recent study also showed that most cases of tracheal collapse in donkeys were caused by grossly misshapen tracheal cartilages,[75] and perhaps a term other than *tracheal collapse* should now be used.

Many ponies and donkeys with tracheal collapse will have some dorsoventrally flattened tracheal rings (especially in their lower cervical trachea) but will also have other types of ring deformities (Fig. 31.50) at more caudal thoracic sites.[71,75] In other cases with relatively normal-shaped tracheal rings, there appears to be separation of the dorsal ligament from the dorsal aspect of the tracheal rings (Fig. 31.51). This defect usually involves the mid and distal cervical as well the intrathoracic trachea and may occasionally involve the mainstem bronchi. Some affected equids may also have a degree of tracheal rotation,

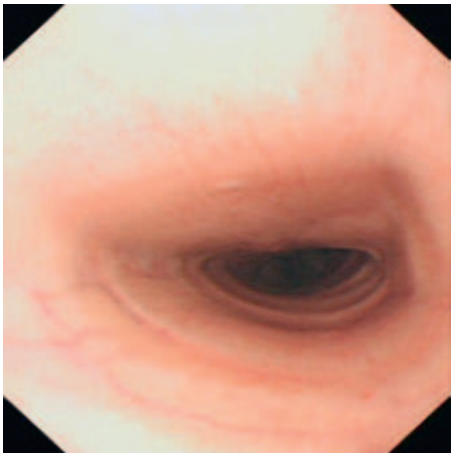

FIG. 31.49 Endoscopic view of a dorsoventrally collapsed trachea.

FIG. 31.50 Severe structural abnormality of an equid trachea.

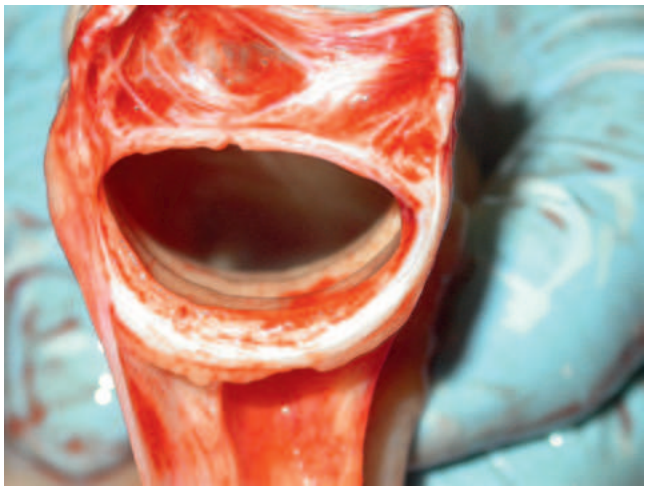

FIG. 31.51 This tracheal ring is a normal C shape, but the dorsal tracheal ligament has separated from the dorsomedial aspect of the tracheal rings.

with the dorsal aspect of trachea facing dorsolaterally (authors' personal observations).

Most ponies and miniature horses develop clinical signs of tracheal collapse in middle age,[73,75] thus indicating that some degenerative process of the tracheal cartilage or connective tissue also plays a role in the pathogenesis of this disorder. In one case series of 13 American Miniature Horses, all 4 horses that had tracheal histopathology performed on them had chondromalacia, which varied from mild multifocal hyalinization of the extracellular matrix to marked multifocal coalescing areas of chondromalacia characterized by complete degradation of the cartilaginous matrix and loss of chondrocytes.[73] The presence of chronic respiratory disease that may cause tracheal mucosal thickening and also increase intrapleural pressure swings, and neuromuscular problems causing loss of tone of the trachealis muscle have also been implicated in the pathogenesis of this disorder in donkeys.[75]

Temporary Tracheal Collapse

Horses with severe expiratory dyspnea due to pulmonary disease have increased positive intrathoracic pressure during expiration, which can cause a temporary collapse of the intrathoracic trachea, particularly of its dorsal ligament. Such temporary and often near-total tracheal collapse can also be observed transiently in all horses if they cough during bronchoscopy.

Clinical Signs The typical clinical signs in affected equids are dyspnea and stridor, which commonly occur in hot or humid weather and may regress in autumn. Aleman and colleagues[73] report that clinical signs were initially intermittent and often associated with stressful events, exercise, dusty environment, and eating, but that all owners reported increasing severity of clinical signs with age. Stridor may be very loud, with Delahanty and Georgi[68] reporting a pony that made sounds like a truck horn that could be heard more than 800 m away. The stridor is loudest when auscultated directly over areas of tracheal obstruction. Severe dyspnea may occur even at rest because hyperventilation will exacerbate the partial tracheal obstruction in a self-perpetuating cycle. Affected horses can also exhibit tachycardia (60 to 130 bpm) and hyperthermia (38.2° to 40.0° C).[73]

Exercise-induced pulmonary hemorrhage may occur in severe cases, presumably because of increasingly negative intrathoracic pressures. Coughing may also occur, and it is unclear if this is due to tracheal inflammation caused by abnormal contact of dorsal and ventral tracheal mucosa or due to underlying pulmonary disease that may have precipitated the clinical tracheal problem.

Diagnosis Palpation of a collapsed cervical trachea may reveal sharp lateral protrusion of the deformed cartilage rings. However, palpation of the lateral edges of the flattened trachea can be difficult, as the deeper, distal cervical trachea is most commonly affected. In addition, some small ponies such as Shetlands have very thick skin and much subcutaneous fat, which makes tracheal palpation difficult.[54]

Endoscopy of affected cases will show the normal circular or oval appearance of the tracheal lumen to be replaced by a wider, flatter, or otherwise restricted lumen. In addition, excessive dynamic movement of the dorsal tracheal wall and even airway occlusion may be observed during deep breathing, with inspiratory narrowing of the cervical tracheal lumen and expiratory narrowing of the intrathoracic tracheal lumen. The mucosa may be red and inflamed.

Lateral radiographs of the distal cervical and thoracic trachea may be diagnostic, demonstrating the flattened appearance of the trachea,[69,73] but must be taken during inspiration for the cervical trachea and during expiration for the intrathoracic trachea. Radiography can be misleading in cases where tracheal rotation is present along with collapse, where the affected trachea may actually appear wider than normal on lateral radiographs.

Treatment and Prognosis Treatment of such cases should initially be conservative, by restricting exercise, keeping affected cases indoors in cool boxes with an adequate water supply in hot weather, and treating any concurrent pulmonary disease. Acutely affected horses will benefit from intranasal oxygen therapy that reduces hyperventilation and thus decreases the degree of tracheal collapse. Tracheostomy usually does not provide relief because it does not bypass the affected region (usually distal cervical and intrathoracic trachea). Therefore insertion of an endotracheal tube via the tracheotomy to keep the collapsed trachea patent is usually necessary to provide a temporary functional airway in severely affected animals. Hyperthermia, if present, increases the metabolic rate and thus increases the respiratory demand further, causing a vicious cycle of events. Cooling down such ponies with a cold-water hose can be beneficial. Parenteral corticosteroids are also indicated in severely affected cases to reduce the secondary tracheal mucosal inflammation or edema that is likely to be present. The long-term prognosis for severely affected miniature horses appears to be poor, with 10 of 13 horses in the largest case series to date either dying of this disorder or requiring euthanasia.[73]

Surgical correction of affected cartilaginous cervical tracheal rings (as is commonly performed in miniature dogs), such as placing external stents over deformed tracheal rings[70,76,77] or inserting stainless steel sutures into every third tracheal ring along with imbrication of the slack dorsal membrane,[68] has been performed in horses and ponies with varying success. The use of a metallic intraluminal stent has also been reported to have been successful in one miniature horse, but intratracheal granulation tissue formation and lower airway infection was associated with the stented area.[72] In some ponies, surgically altering the shape of the tracheal rings may not be successful because separation of the dorsal ligaments from the cartilage rings is the primary problem. In addition, careful evaluation will usually reveal involvement of the intrathoracic trachea, and because only 3 to 4 intrathoracic rings can be exteriorized cranially to the distal cervical area for surgical correction, this type of surgery may be of limited benefit to the horse. Although intrathoracic surgery to correct more caudal tracheal deformities is technically feasible, it is not practical.

VetBooks.ir

Other Congenital Defects of the Trachea

Congenital defects of the trachea, other than tracheal collapse, are rare in horses, with only a few other types of deformities recorded, including a few reports of accessory or ectopic pulmonary tissue, including by Davis and colleagues,[78] who recorded an accessory cervical tracheal bronchus in a 3-day-old foal. The foal presented with a large, air-filled sac in its cervical region caused by rudimentary accessory lung that contained cartilaginous tissue and ciliated epithelium. Peek and colleagues[79] reported a combined tracheal and esophageal duplication cyst in a 4-month-old Arabian foal with a slowly developing cervical swelling that was successfully resected.

EXTERNAL TRACHEAL TRAUMA. Tracheal trauma is usually caused by blunt trauma, such as kicks to the neck region that can cause severe tracheal damage, particularly if the trachea is compressed between a hoof and the overlying cervical vertebral body. Tracheal trauma can cause tearing of the mucosa (Fig. 31.52) and of the overlying annular ligaments, and fracture of tracheal rings. Penetrating tracheal injuries occur less commonly.

FIG. 31.52 Tracheal trauma: oval-shaped tear in the tracheal mucosa showing separation of the underlying tissues.

Clinical Signs and Diagnosis

A common presenting sign in horses with tracheal rupture is extensive subcutaneous emphysema and swelling over the cranioventral aspect of the neck.[80-82] External skin wounds are not always present. The emphysema may later spread to involve the head, trunk, mediastinum, and even limbs. Horses will later become stiff and possibly febrile from secondary infection, and epistaxis and coughing may occur.[81] In addition to possibly having a ruptured trachea, horses with emphysematous cervical swellings should always be suspected of suffering from a ruptured esophagus[83] (authors' personal observations). Because the esophagus may lie lateral to the trachea at around the level of the sixth cervical vertebra in some horses, it is prone to trauma at this site.[54]

Cervical radiography of horses with tracheal or esophageal rupture will show extensive gas infiltration along the fascial planes of the neck, in addition to variable soft tissue or fluid-filled swellings of the cranial and ventral neck regions. Thoracic radiography may also reveal pneumomediastinum and possibly pneumothorax. Endoscopy (tracheoscopy) will confirm if tracheal trauma has occurred, by evidence of mucosal tears, prolapse of submucosal tissue into tracheal lumen, distortion or partial occlusion of the lumen due to cartilage ring fractures, and/or local inflammation.[81,82] Esophageal endoscopy to examine the integrity of the esophagus should also be performed with the greatest of care in horses with neck swelling and emphysema.

Treatment and Prognosis

If the esophagus is ruptured, the prognosis is poor, as compared to tracheal rupture, where the prognosis is usually good. Small tears of the tracheal mucosa will usually heal spontaneously. In addition to tetanus prophylaxis, NSAIDs should be administered to such cases to decrease the traumatic inflammation, along with broad-spectrum antibiotics to reduce the potential spread of pathogenic bacteria with entrapped air along the fascial planes of the neck and into the mediastinum. The emphysema present in such cases will usually resolve in 1 to 2 weeks but may remain for up to a month in some horses.[81] Large rents in the tracheal mucosa with extensive herniation of soft tissue into the tracheal lumen can be sutured as described by Fubini and colleagues.[82] Structural damage to the tracheal rings has been corrected using an extraluminal titanium mesh.[76]

Fractures of the cartilaginous tracheal rings with gross distortion of the trachea may also occur, and it may be difficult to evaluate the degree of cartilage ring damage in the presence of severe local inflammation and emphysema. If available, CT or MRI of such lesions is the optimal method of assessing cartilage damage. If life-threatening tracheal obstruction occurs, a temporary tracheostomy may be performed with insertion of an uncuffed endotracheal tube through the tracheostomy to open up the collapsed section of trachea if the obstruction is distal to the mid-cervical region.

Intraluminal granulation tissue and subsequent development of circumferential fibrotic bands of tissue can be long-term sequelae of tracheal trauma. Occasionally such rings of tissue may eventually (months later) reduce the tracheal lumen to a significant extent, leading to respiratory obstruction with stridor. Transendoscopic laser resection of the protruding stricture can be attempted, but the site should be monitored postoperatively for recurrence of the lesion. The use of topical corticosteroid after laser surgery may be of use in preventing recurrence of strictures. Complete resection of the affected cervical tracheal rings (up to four rings maximum) with end-to-end tracheal anastomosis can also be attempted,[84] but such procedures can be very challenging. If the stricture is in the cranial cervical trachea, a permanent tracheostomy can be placed at a more distal site for horses that are not required for competition.

Intraluminal Tracheal Trauma

There have been several reports of intraluminal tracheal damage associated with the use of endotracheal tubes for maintaining general anesthesia, including inflammation,[85] focal perforation,[86] and severe ischemia of the tracheal mucosa if excessive cuff pressure is applied.[87] An experimental study showed that histologic evidence of tissue damage was present in all horses at the site of cuff contact with the trachea, at pressures that are commonly used in clinical practice (up to 120 cm H_2O).[87] The use of ethylene oxide for sterilizing endotracheal tubes between patients may also pose a risk, as this chemical can be retained in rubber and plastic and can result in tissue necrosis if tissue comes into contact with the sterilized item.[88]

Recommendations for tracheal intubation in horses include flushing the horse's mouth before anesthesia, using a clean endotracheal tube, gentle intubation technique, minimal head and neck movement after the tube cuff is inflated, and disconnection of the endotracheal tube from the anesthesia machine while moving the horse.[88] Measurement of cuff pressure should also be performed to identify excessive inflation.[88]

Focal Intraluminal Tracheal Lesions Including Neoplasia

Apart from granuloma formation post tracheostomy (Fig. 31.53) or after tracheal trauma, focal intraluminal tracheal lesions are

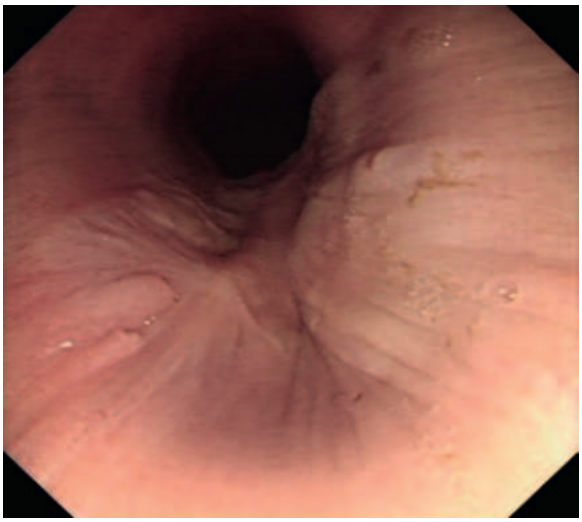

FIG. 31.53 Intraluminal scar tissue formation and cartilage deformity after tracheostomy tube removal.

rare in horses (although many horses and especially ponies have multiple small cartilaginous nodules that are of no clinical significance). Charlton and Tulleners[89] reported infected or necrotic mid-cervical tracheal proliferative lesions in two adult horses following intratracheal antibiotic administration in one and following a transtracheal aspiration in the other. The masses were resected using a transendoscopic laser in one horse and a combination of transendoscopic laser and conventional surgery in the other.

Malignant tracheal tumours are rare in horses, but squamous cell carcinomas have been reported in the trachea of aged horses.[90] Benign lesions including papillomas, fibromas, eosinophilic polyps, chondromas, and adenomas are more common[91,92] and often can be successfully resected using a distal cervical tracheostomy and/or a transendoscopic laser excision. Transnasal retrieval of excised masses is usually possible using a transendoscopic grasping or "basket"-type forceps.

Extramural Tracheal Compression

Occasionally, enlarged lymph nodes compress the trachea, causing stridor. Severe lymphadenopathy is usually associated with *S. equi* subsp. *equi* ("strangles") infection[93] and may involve the upper cervical chain, compressing the proximal cervical trachea. They can also involve the distal cervical chain that compresses the trachea at the thoracic inlet.[54,93-95] Diagnosis usually can be made from the history and clinical signs, which are indicative of strangles, and confirmation can be made by needle aspiration and/or ultrasonography of cervical swellings. Treatment of strangles is reviewed in the *Streptococcus equi* subsp. *equi* Infection (Strangles) section earlier in this chapter.

Mediastinal tumours, mainly lymphosarcomas; other cranial thoracic tumours, including primary lung tumours; or grossly abscessed mediastinal lymph nodes can cause compression of the intrathoracic trachea or of one or both mainstem bronchi, leading to stridor and dyspnea. Such an endoscopic finding should lead to a careful thoracic examination, including radiography and ultrasonography. Thoracic tumours are usually untreatable in the horse.

Tracheobronchial Foreign Bodies

Inhaled foreign bodies are common in man and dogs but less common in horses, possibly due to their height. O'Connor[96] described a range of laryngeal and tracheal foreign bodies in horses and stated that a fatal bronchopneumonia could develop if the foreign body was not expelled by coughing. Inhaled foreign bodies seldom bypass the larynx, but if they do, they will usually become entrapped at the carina or in the mainstem bronchi,[97-100] predominantly in the right mainstem bronchus.[76]

A history of sudden onset of persistent coughing is a very prominent finding in these cases, and malodorous breath will often be present. Other signs of pulmonary disease, such as increased respiratory rate or the presence of abnormal lung sounds, are usually absent, at least initially, unless secondary lung infection occurs. If significant pulmonary infection develops, abnormal lung sounds and possibly purulent or blood-tinged nasal discharge may occur. No or only a temporary response (decreased coughing and nasal discharge) may occur following antibiotic therapy. Radiography may show a localized interstitial pattern caudal to the vena cava.[99]

Endoscopically, local airway inflammation and purulent respiratory secretions may obscure a foreign body. Even small foreign bodies may significantly obstruct airflow if they become lodged in a bronchus, and the induced local bronchial inflammation may also obstruct normal drainage of respiratory secretions from the affected bronchus, inducing severe, focal pulmonary infection. Transendoscopic lavage of the area may help determine if a bronchial foreign body or tumour is present. When identified, bronchial foreign bodies may be removed using transendoscopic grasping or basket forceps. Cranially facing leaves, branches, or thorns will make the recovery of such vegetation difficult, but with persistence, most bronchial foreign bodies will eventually become loose and retrievable. If this is unsuccessful, a distal cervical tracheostomy can be performed, and long, rigid, grasping instrumentation (such as broncho-oesophageal grasping forceps) can be used under endoscopic guidance to grasp and retrieve the foreign body.[98,99]

Epiglottic Entrapment

Santiago D. Gutierrez-Nibeyro

Definition and Etiology Epiglottic entrapment, persistent or intermittent, refers to the dorsal displacement of the aryepiglottic folds and subepiglottic mucosa over the epiglottis. The aryepiglottic folds attach to the free margins of the epiglottis and blend with both the dorsal epiglottic and the subepiglottic mucosa. Normally the subepiglottic mucosa is loosely attached to the epiglottis to allow movement of the cartilage during swallowing. The etiology of the disease is unknown, but inflammation of the subepiglottic mucosa and submucosa, redundant subepiglottic mucosa, and epiglottic hypoplasia or flaccidity have been reported as predisposing factors.[1-4] Epiglottic entrapment has a reported prevalence of 8% to 27% in Thoroughbred and Standardbred racehorses,[5-8] although it has been reported in nonracing Thoroughbreds and other breeds.[9] Epiglottic entrapment is often an incidental finding in weanlings and yearlings.[10]

Clinical Signs and Differential Diagnoses Clinical signs are variable and depend on the severity of the entrapment and the presence of other diseases of the upper respiratory tract. Some racehorses can be asymptomatic and compete successfully with an entrapped epiglottis.[8,11] However, affected horses most commonly have a variable degree of abnormal respiratory noise and/or exercise intolerance due to partial airflow obstruction.[1,2,12] Clinical signs may also include coughing and nasal discharge.[9,13] Severe inflammation and ulceration of the entrapping tissue can exacerbate airway obstruction and noise production; rarely it may also cause dysphagia.[1,12] Potential endoscopic differential diagnoses include subepiglottic cysts, epiglottitis, epiglottic granulomas, and dorsal displacement of the soft palate.[5,13,14]

VetBooks.ir

Definitive Diagnostic Tests

Endoscopic examination of the nasopharynx with the horse at rest is frequently diagnostic. Typically the scalloped edge of the epiglottis and the vessels on its surface are not evident on endoscopy because they are obscured by the entrapping aryepiglottic fold (Fig. 31.54). Most epiglottic entrapments are persistent and thick, and approximately half of them are ulcerated.[2,12] If the epiglottis is not entrapped during the initial endoscopic evaluation but intermittent entrapment is suspected, overground endoscopy or endoscopy during a high-speed treadmill test is necessary for definitive diagnosis.[5,8]

Although radiography is not used to diagnose the disease, an epiglottic entrapment can be detected using this diagnostic technique.[4] Epiglottic hypoplasia can be determined with both subjective endoscopic evaluation and radiographic measurement of the epiglottic length (determined by thyroepiglottic length).[4,15]

Treatment and Prognosis

Intermittent epiglottic entrapment may be treated conservatively with topical and systemic anti-inflammatory therapy and exercise restriction. Persistent epiglottic entrapment is typically treated surgically.[2,12] Surgical techniques to correct epiglottic entrapment include transendoscopic axial division using a Nd:YAG or diode laser,[2] transnasal or transoral axial division using a curved bistoury,[1,12,16-18] transnasal axial division using a shielded curved bistoury,[19] transendoscopic axial division using monopolar electrocautery,[20] transoral wire-snare resection of redundant subepiglottic mucosa,[21] and surgical excision via a laryngotomy.[3] Currently axial division of the entrapping aryepiglottic folds and subepiglottic mucosa is the preferred technique because the tissues are simply transected avoiding "debulking" of the epiglottis and excessive scarring postoperatively, which can cause dorsal displacement of the soft palate.[22] Resection of the entrapping tissues through a ventral laryngotomy is typically reserved for excessively thickened, ulcerated, or fibrotic-appearing entrapping membrane.[3] Postoperative care consists of topical and systemic antiinflammatory therapy and exercise restriction.

The prognosis is generally good; however, postoperative complications include recurrence of the entrapment, intermittent or persistent dorsal displacement of the soft palate, and epiglottis deformity.[2,12,17,23] The recurrence rate after surgical correction of an entrapped epiglottis using laser axial division is 5%[2]; it is between 0% and 15% using a curved bistoury[12,16,18,19] and as high as 40% using electrosurgical division.[20]

Pharyngeal Cysts in Horses

Santiago D. Gutierrez-Nibeyro

Definition and Etiology

Pharyngeal cysts are uncommon in the horse[1-3]; however, they are occasionally diagnosed in young Thoroughbreds, Standardbreds, and Quarter Horses.[4-8] Pharyngeal cysts occur most commonly in the subepiglottic region (Fig. 31.55) and occasionally in the soft palate (see the Congenital Palatal Defects section earlier in this chapter) or dorsal wall of the nasopharynx (Fig. 31.56).[4,6,8] Some authors believe that subepiglottic cysts are embryonic remnants of the thyroglossal duct (precursor of the thyroid gland), but others believe that these cysts are secondary to inflammation and obstruction of the mucus-secreting glands that line the pharynx.[5] Cysts formed within the dorsal nasopharyngeal wall are thought to be embryonic remnants of the craniopharyngeal duct (precursor of the adenohypophysis).[4] The origin of soft palate cysts has not been elucidated; however, histopathologic examination of these cysts is consistent with a mucocele.[6]

Clinical Signs

In foals subepiglottic cysts are frequently asymptomatic,[3] but many cause increased respiratory noise, cough, nasal discharge, persistent dorsal displacement of the soft palate, dysphagia, and aspiration pneumonia.[5,6] The most common presentation in the adult performance horse is partial obstruction of the upper respiratory tract, abnormal respiratory

FIG. 31.54 Endoscopic image of the nasopharynx of a 3-year-old Standardbred racehorse with a history of increased respiratory noise and chronic epiglottic entrapment. The entrapping membrane was thick, wide, and mildly ulcerated, and the epiglottis had moderate hypoplasia once the entrapment was corrected surgically. As in this case, most epiglottic entrapments are persistent and thick, and approximately half are ulcerated.

FIG. 31.55 Endoscopic image of the nasopharynx of a 2-year-old Standardbred horse with a small, smooth, and rounded subepiglottic cyst. The horse had a history of abnormal respiratory noise during training.

FIG. 31.56 Endoscopic image of the nasopharynx from a 1-week-old foal with a large cyst attached to the dorsal wall of the pharynx and a nasogastric tube in place. The cyst was resected with a cyst snare under endoscopic control.

noise, exercise intolerance, coughing, dysphagia, and in rare cases, complete obstruction of the upper respiratory tract.[4,7-9]

Clinical Pathology CBC and biochemistry profiles are typically within normal limits unless concurrent inflammatory airway disease, pneumonia, or acute upper respiratory tract obstruction exists.

Definitive Diagnostic Tests Endoscopic examination of the nasopharynx confirms the diagnosis and may also detect concomitant pathology such as epiglottic entrapment.[4,5,8] Occasionally a lateral radiographic view of the pharynx or transoral endoscopic examination of the oropharynx with the patient anesthetized is needed if the cyst is within the soft palate or beneath the epiglottis protruding into the oropharynx. Although contrast pharyngography has been described to help delineate cysts in the oropharynx,[6] in the authors' opinion the use of contrast is unnecessary if digital radiography is available. The use of ultrasound has been described to delineate the cyst from the adjacent structures before surgery, if necessary.[10]

Treatment and Prognosis Pharyngeal cysts can be surgically removed, ensuring complete removal of the secretory lining without excessive excision of surrounding pharyngeal mucosa in the case of a subepiglottic cyst, which may lead to cicatrization and epiglottic dysfunction.[8] Subepiglottic cysts can be removed by a ventral laryngotomy,[4] via an oral or transnasal approach using an endoscopically guided laser, electrocautery snare, or cyst snare constructed with obstetric wire loop threaded through a Chambers catheter.[8,9] More recently, intralesional administration of 10% formalin has been reported, which provides an economically suitable alternative to surgical treatment[11]; however, multiple treatments may be required for complete resolution of the cyst.[11] Postoperative care consists of topical and systemic antiinflammatory therapy and exercise restriction. The prognosis following removal of subepiglottic cysts is good, and most horses return to full athletic function.[4,8] Less information is available regarding the prognosis after removal of other pharyngeal cysts.

Nasopharyngeal Cicatrix Syndrome

Ben Buchanan

The nasopharyngeal cicatrix syndrome is an inflammatory condition that was first described in 1987 in horses from south Texas[1] and continues to be a common finding of horses grazing pastures in certain areas of Texas. It is also sporadically reported in other U.S. Gulf Coast states. The syndrome is a combination of inflammation and scarring of the nasal passage, pharynx, larynx, arytenoid cartilages, and proximal trachea. Severity ranges from incidental findings during endoscopy to airway obstruction that requires permanent tracheostomy.[2,3]

Clinical Signs Clinical signs include abnormal respiratory noise, nasal discharge, exercise intolerance, coughing, respiratory distress, and abnormal vocalization.[4] The character of the nasal discharge is frequently clear and mild. When compared with a case-controlled population in a retrospective study, affected horses made up 118 of 1236 horses examined endoscopically for any reason.[4] Of these affected horses, 97% had some degree of pharyngeal inflammation or scarring, of which 50% had a circumferential scar. In addition, 91% of affected horses had some inflammation or scarring of the larynx, and 39% had an airway obstruction, with the majority being at the level of the larynx. In this same study, horses with endoscopic evidence of acute nasopharyngeal cicatrix syndrome were more likely to have nasal discharge and respiratory distress, whereas horses with endoscopic evidence of chronic nasopharyngeal cicatrix syndrome were more likely to make respiratory noise or suffer from respiratory distress.

Endoscopic Signs A scoring system used by the author is presented in Fig. 31.57 and builds on a system previously proposed by Rakestraw.[5] This system was developed to provide practitioners with a concise, simple, and complete system to document any abnormality of the upper respiratory tract seen on standing endoscopy.

NASAL PASSAGE. Both nasal passages should be examined. Lesions in the nasal passage appear as ulcerations and occur in less than 10% of cases.[4]

PHARYNGEAL SCAR. Schumacher and Hanselka first proposed a scoring system for this syndrome that focused on the pharyngeal scar.[1] This system has been adapted into a 7-point scale, with 0 indicating no visible scarring. A score of 1 indicates a scar just forming on the ventral floor. A score of 2 indicates a consistent ventral scar. A score of 3 indicates a prominent ventral ridge with scarring just evident on the lateral walls of the pharynx. A score of 4 indicates a ventral scar with evidence of a dorsal scar just forming. A score of 5 indicates a complete ring with less than 25% reduction in the size of the airway. A score of 7 indicates a severe case with a complete ring that has reduced the airway more than 75% (Fig. 31.58).

GUTTURAL POUCH PLICA. Occasionally, scarring of the external guttural pouch plica is observed as a deformity to the guttural pouch openings.

PHARYNGEAL INFLAMMATION. The overall appearance of the pharyngeal walls should be graded with attention to degree of redness, edema, and chronic scarring. Acute/active is indicated by erythematous edematous tissue with or without discharge and no areas of scarring noted (Fig. 31.59). The level of inflammation should be graded as mild, moderate, or severe. Chronic/active is similar, with areas of active inflammation mixed with areas of previous scarring (Fig. 31.60). The degree of inflammation should be graded as mild, moderate, or acute.

VetBooks.ir

Pharyngeal/Laryngeal Evaluation

PICTURES ON FILE
REPEAT EXAM

Name: Date:

Nasal Passage – Are lesions present?
Left nasal passage ☐ YES ☐ NO **Right** nasal passage ☐ YES ☐ NO

Pharyngeal Scar – Describe pharyngeal scar / cicatrix according to the scale below.
0. No scarring visible
1. Scarring just visible on floor of pharynx
2. Scarring on floor of pharynx w/ prominent ventral ridge
3. Prominent ventral ridge with scarring evident on lateral walls of pharynx
4. Prominent ventral ridge with scarring evident on walls and forming dorsally
5. Complete circular scar with prominent ventral ridge and just starting to constrict <25% of airway
6. Complete circular scar constricting 25-50% of airway
7. Complete circular scar constricting >50% of airway

Guttural Pouch Plica – Are alterations to plica of guttural pouch opening present?
Left plica ☐ YES ☐ NO **Right** plica ☐ YES ☐ NO

Pharyngeal Inflammation – Describe the overall inflammation of the pharynx.
None
Acute/Active – Tissue inflamed with no areas of chronic scarring noted. Score changes as mild, moderate, or severe.
Mild – Diffuse reddening with or without some yellow discharge and minimal edema
Moderate – Edema present in mucosal tissue with diffuse reddening and/or yellow discharge and plaques
Severe – Significant edema present in mucosal tissue
Chronic/Active – Areas of previous scarring visible with new areas of acute inflammation. Score changes as mild, moderate, or severe.
Mild – Diffuse reddening with or without some yellow discharge and minimal edema
Moderate – Edema present in mucosal tissue with diffuse reddening and/or yellow discharge and plaques
Severe – Significant edema present in mucosal tissue
Chronic – No edema, reddening, or yellow discharge present. Areas of scarring may be visible.
Is there lymphoid hyperplasia? ☐ YES ☐ NO

Dorsal Pharyngeal Recess – Describe the inflammation / scarring of the dorsal pharyngeal recess.
Normal
Mild – Minimal edema of tissue
Moderate – Significant edema of tissue
C
Severe – Severe edema of tissue obliterating the recess
Chronic Scarring – No inflammation but obvious scarring present

Epiglottis – Describe changes to epiglottis. Score changes as mild, moderate, or severe.
Normal
Mild – Inflamed w/ diffuse swelling +/– curling of margins
Moderate – Scarring of epiglottis not occluding airway
Severe – Scarring of epiglottis occluding airway
Is there dorsal displacement of soft palate (DDSP)? ☐ YES ☐ NO Is there an epiglottic cyst? ☐ YES ☐ NO

Aryepiglottic Fold – Describe changes to aryepiglottic fold. Score changes as mild, moderate, or severe.
Normal
Mild – Minimal edema of fold just making it visible
Moderate – Significant edema of fold making it prominent
Severe – Severe edema of fold causing overlapping of the arytenoid cartilages
Is there an epiglottic entrapment? ☐ YES ☐ NO

Arytenoid – Describe changes to left and right arytenoid cartilages. Score changes as mild, moderate, or severe.

Left	**Right**
Normal	**Normal**
Mild – Minimal edema/inflammation with or without reddening. Maintains complete abduction	**Mild** – Minimal edema/inflammation with or without reddening. Maintains complete abduction
Moderate – Significant edema/inflammation with or without scarring. Altered but not complete abduction	**Moderate** – Significant edema/inflammation with or without scarring. Altered but not complete abduction
Severe – Obvious scarring of cartilage that cannot be abducted from midline	**Severe** – Obvious scarring of cartilage that cannot be abducted from midline
Is there laryngeal hemiplegia? ☐ YES ☐ NO *I, II, III, IV, V*	*Is there laryngeal hemiplegia?* ☐ YES ☐ NO *I, II, III, IV, V*

Vocal Folds – Are alterations to vocal folds present?
Left ☐ YES ☐ NO **Right** ☐ YES ☐ NO

Palatopharyngeal Arch – Describe changes to the palatopharyngeal arch. Score changes as mild, moderate, or severe.
Normal
Mild – Mild rostral displacement of palatopharyngeal arch
Moderate – Prominent displacement and inflammation of palatopharyngeal arch
Severe – Prominent displacement and inflammation of palatopharyngeal arch overlapping arytenoid cartilages

Trachea – Describe changes to the proximal trachea. Score changes as mild, moderate, or severe.
Normal
Mild – Focal to multi-focal areas of edema/inflammation
Moderate – Multi-focal coalescing areas of inflammation constricting airway <25%
Severe – Areas of inflammation/cicatrix constricting airway >25%

FIG. 31.57 Pharyngeal/laryngeal scoring system.

VetBooks.ir

FIG. 31.58 Endoscopic image of nasopharyngeal cicatrix. This is an example of a grade 7 cicatrix.

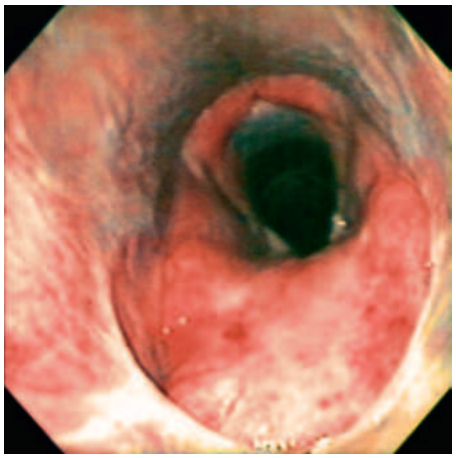

FIG. 31.60 Endoscopic image of chronic/active nasopharyngeal syndrome. There is both inflammation and swelling with a grade 3 cicatrix.

FIG. 31.59 Endoscopic image of acute pharyngeal inflammation and swelling consistent with nasopharyngeal cicatrix syndrome.

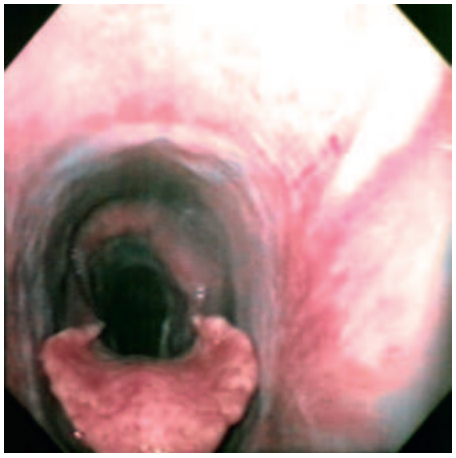

FIG. 31.61 Endoscopic image of chronic nasopharyngeal syndrome. There is scarring of the epiglottis and left arytenoid cartilage and a grade 3 cicatrix.

A chronic description is indicated when there are areas of scarring with no active inflammation (Fig. 31.61). Any level of pharyngeal lymphoid hyperplasia should be noted.

DORSAL PHARYNGEAL RECESS. The dorsal pharyngeal recess should be examined for inflammation and areas of previous scarring. Occasionally this area is the only area of inflammation noted in the pharynx. The recess should be graded as mild, moderate, severe, or chronic.

EPIGLOTTIS. The epiglottis should be examined for swelling, scarring, displacement, occlusion of the airway, and cysts. Mild changes of the epiglottis include diffuse swelling with some curling of the margins. Moderate changes, although more severe, do not occlude the airway. Severe changes are noted as scarring of the epiglottis with occlusion of the airway. Any displacement of the soft palate or epiglottic cysts should be recorded.

ARYEPIGLOTTIC FOLD. The aryepiglottic fold should be examined for edema and entrapment of the epiglottis. The abnormalities should be described as mild, moderate, or severe. Mild abnormalities are noted as minimal edema just making the fold visible. Severe changes are noted as significant edema causing the fold to overlap the arytenoid cartilages.

ARYTENOIDS. The left and right arytenoid cartilages should be evaluated for swelling, reddening, scarring, and abnormalities of abduction. Each cartilage is graded separately as having mild, moderate, or severe changes. Mild changes are noted as minimal edema or inflammation with or without reddening of the cartilage, with complete abduction. Moderate changes are noted as significant edema or inflammation with or without scarring, causing altered abduction of the cartilages. Severe changes are noted as obvious scarring of the cartilage that cannot be abducted from midline. Any laryngeal hemiplegia should be recorded.

VOCAL FOLDS. The vocal folds should be evaluated for edema and scarring. Changes in this area are common and should be recorded as present or absent.

PALATOPHARYNGEAL ARCH. The palatopharyngeal arch should be examined for edema and rostral displacement. The abnormalities should be described as mild, moderate, or severe. Mild abnormalities are noted as minimal edema causing minimal displacement. Moderate changes are noted as significant edema causing a prominent rostral displacement. Severe changes are noted as significant edema causing overlap of the palatopharyngeal arch over the apex of the arytenoids. Rostral displacement of the palatopharyngeal arch was noted in 36% of cases.[4]

TRACHEA. The proximal trachea should be evaluated for areas of edema, inflammation, and scarring, as lesions in the

VetBooks.ir

proximal 6 to 10 rings of the trachea are common. Changes in this area should be graded as mild, moderate, or severe. A mild change involves multifocal areas of inflammation not reducing the size of the airway. A moderate change involves areas of inflammation causing a reduction in the airway of less than 25%. A severe change causes airway reduction greater than 25%. Abnormalities in the trachea have been reported in 75% of cases.[4]

Progression This syndrome is rarely seen in horses younger than 4 years of age, and the length of time for an acute case to develop respiratory distress is unknown. In the author's experience the most severe cases occur in older horses.

Pathogenesis To date no specific etiology has been identified, although some risk factor analysis has been completed. A retrospective case-control study of 121 horses[2] with nasopharyngeal cicatrix syndrome found a high association with housing on pasture or part time on pasture and with increased age. Cases of nasopharyngeal cicatrix syndrome were more likely to be presented in the summer months, with acute cases also being seen in the spring and fall. No breed or sex risk factor was noted. Cases seem to be more prevalent in years with higher rainfalls, although a few new cases may be seen during times of drought.

Inhalation of larger sized particulate matter (>5 microns) is suspected to be the inciting cause, as these particulates are deposited in the nasal mucosa, pharynx, larynx, and proximal trachea. This corresponds to the anatomic areas where the inflammation and subsequent scarring are noted. Whether these particulates include bacteria, fungus, allergen, or some other irritant is not known. There is some discussion of the oomycete *Pythium insidiosum* as a possible cause, although in the author's experience this is not likely a primary pathogen in these cases.

Treatment Because the agent or combination of agents causing this syndrome has not been identified, a single effective therapy has not been found. In addition, identification of effective treatments is complicated by the chronicity of the syndrome when it is typically first identified, the cyclical or seasonal nature of the clinical signs, and the response to changes in environmental factors. Current therapy consists of reducing exposure to pasture and reducing inflammation. No treatment has been effective if the horse remains on pasture. Surgical resection of affected areas frequently leads to excessive granulation tissue, especially after arytenoidectomy. If the airway is compromised, a permanent tracheostomy is the therapy of choice. If surgical reduction of the affected tissue is elected and the horse is not moved to a new environment, the lesions will recur.

Outcome In acute cases, simply removing the horse from pasture and feeding in a dry lot or stall resolves most of the condition. It is believed that repeat or continual exposure of acute cases leads to the chronic scarring. Once the chronic scarring has developed, it will not resolve.

Equine Influenza in Australia*

Brett Tennent-Brown • Andrew W. Van Eps

Until 2007, Australia was one of a small number of countries that had never experienced an outbreak of equine influenza (EI). EI has never been reported in New Zealand. However, in August 2007 a consignment of horses, all of which had been vaccinated in accordance with Australian quarantine requirements, was admitted into the quarantine station in Sydney. At least one of these horses was subclinically infected with EI, and the virus subsequently spread among horses within the quarantine station. Following a break in biosecurity, EI virus escaped and spread rapidly through the naive horse population, affecting more than 76,000 animals on 10,600 premises in New South Wales and Queensland. Control of the outbreak and eradication of the virus from Australia cost an estimated US$1 billion.

As soon as EI had been confirmed in the general horse population, a control and eradication program based on movement restrictions and subsequently vaccination was initiated. Although only two states were affected, a complete national ban on all horse movements was put in place immediately, and all race meetings and other horse events were cancelled. Horses already at events were not permitted to leave until cleared by government veterinarians. Movement restrictions were highly effective in preventing the spread of virus beyond those areas affected in the first week of the outbreak but were extremely damaging financially to horse-related businesses. To alleviate some of the economic hardship, especially among the breeding industry, some movement restrictions were eased to allow the breeding season to proceed.

At the time of the outbreak in August 2007, there were no EI vaccines registered for use in the Australian general horse population. When additional measures were required to contain the outbreak, an emergency-use permit was issued for a canarypox-vectored recombinant EI vaccine (ProteqFlu, ProteqFlu-TE [Merial, Lyon, France]). This vaccine was selected for several reasons, including rapid onset of immunity,[1] the ability to differentiate vaccinated horses from those naturally infected, and reports of efficacy in the South African 2003–2004 outbreak.[2] Vaccination was initially used to create buffer zones around infected areas to contain spread of the epidemic. Horses inside the infected areas on unaffected properties were subsequently also vaccinated. Most horses received a primary course booster at the recommended interval of 4 weeks; however, some horses received an accelerated primary course schedule with the interdose interval reduced to 14 days.[3,4]

The last reported detection of EI occurred approximately 4 months after the outbreak began. Provisional freedom from disease was declared in March 2008, and EI-free status was confirmed by the World Organisation for Animal Health (OIE) the following year.

The EI virus isolated from horses in the quarantine station and horses in the general population was named A/equine/Sydney/2888-8/2007 (H3N8).[5] Following molecular characterization, the virus was classified as an American lineage, Florida sublineage, Clade 1 type[6] and is phylogenetically similar to the EI viruses that were circulating in Japan and the United States at the time.[7]

Clinical disease caused by the EI virus in adult horses was considered mild in the vast majority of cases; however, secondary bacterial bronchopneumonia was described as a complication and occasional cause of death in predominantly mature horses.[8] Infection of late-gestation mares was associated with increased severity of clinical signs in the infected mare and neonatal morbidity.[8,9] A fatal bronchointerstitial pneumonia associated with EI virus infection was reported in several foals from infected properties.[10]

Hendra Virus

Brett Tennent-Brown • Andrew W. Van Eps • Gabrielle Landolt

Hendra virus (HeV) was first identified in September 1994 following the deaths of 14 Thoroughbred horses and 1 human

*Previous contributions by James R. Gilkerson and Charles Mark El-Hage are acknowledged.

VetBooks.ir

during an outbreak of respiratory disease at racing stables located in Hendra, Queensland, Australia.[1] Severe, acute respiratory disease due to HeV occurred sporadically over the subsequent 14 years; however, neurologic signs have predominated in cases since 2008. In 2011 there was a marked increase in HeV incidence, and disease occurred over a wider geographic area than previously reported. At the time of writing, infection has been confirmed in more than 100 horses, 7 humans (with 4 human fatalities), and at least 1 dog (seroconversion without clinical signs) in the states of Queensland and New South Wales.

Etiology and Epidemiology HeV and the closely related Nipah virus together form the genus *Henipavirus* in the family Paramyxoviridae. *Henipavirus* infection is dependent on the G and F viral glycoproteins. The G glycoprotein is a receptor binding protein that binds ephrin-B2 and ephrin-B3, whereas the F protein mediates fusion of the viral and host cell membranes.[2] Ephrin-B2 and ephrin-B3 are widespread on host's vascular endothelial cells, and as a consequence, HeV infection results in a vasculitis that particularly affects the respiratory and central nervous systems.[3,4]

HeV causes natural disease in horses and humans,[1] and disease has been experimentally induced in cats, guinea pigs, and mice.[5] The natural reservoirs for HeV are four species of pteropid bats (fruit bats or flying foxes) that are widely distributed throughout northern and eastern Australian.[6] HeV infection of bats is asymptomatic and apparently widespread; serologic surveys indicate a high prevalence of HeV antibodies in bats, including those in areas where equine or human disease has not been documented.[7] Following experimental infection of bats, virus can be detected in blood, saliva, urine, feces, placental tissues, and aborted pups.[8] Transmission between bats is thought to occur by exposure of naive animals to virus-contaminated urine or feces within the roost.[9]

Most equine cases have occurred between June and December, although the reason for this apparent seasonality is unclear. On many occasions the index case has been a horse that is kept outdoors in an area attractive to fruit bats. The mechanism of virus transmission to horses is not completely understood but likely follows ingestion of contaminated feed or water.[10] Horse-to-horse transmission requires close contact with body fluids (particularly respiratory secretions) and appears to occur infrequently in horses kept at pasture but more efficiently in stabled horses.[9]

HeV poses a serious zoonotic risk to animal caretakers and attending veterinarians. All reported human HeV infections have been linked to close contact with infected horses, and direct bat-to-human or human-to-human transmission has not been reported.[1,11,12] Although the risk of viral transmission appears to increase as the disease progresses, virus is shed at low levels prior to the appearance of clinical signs in experimental infections. Horse-to-human transmission is thought to require direct physical contact with nasopharyngeal secretions[13]; however, the virus can survive for several hours in the environment, and transmission by fomites might be possible. The risk of human infection is particularly high in the terminal stages of disease, and postmortem examinations should be postponed in suspect cases until HeV infection has been ruled out by appropriate testing.

Clinical Signs The incubation period in experimentally infected horses ranges between 5 and 16 days and in humans appears to be between 5 and 21 days.[13-15] Prior to 2008, signs of acute severe respiratory disease predominated in equine HeV infections. However, since 2008, neurologic signs have been described more commonly and might be the result of a minor genetic change to the virus. Approximately 75% of cases are fatal, and these typically progress rapidly. although recently several HeV-positive horses have been described with a more gradual disease progression. Sudden death of one or more horses without obvious signs of illness should raise suspicion of HeV infection. Clinical signs in animals that survive beyond the peracute stages include pyrexia, depression, and signs of respiratory and/or neurologic disease. Signs related to respiratory tract involvement include tachypnea, respiratory distress, and a frothy nasal discharge. Commonly described neurologic signs include weakness, collapse, and an inability to rise; ataxia; altered mentation; central blindness; head tilt and circling; and urinary incontinence. Additional clinical signs may include tachycardia, frequent weight shifting or restlessness, muscle fasciculation, colic, and facial swelling or edema.

Pathology Gross changes at postmortem include edematous (submandibular and bronchial) lymph nodes, dilated pulmonary lymphatics, subpleural hemorrhages, and pulmonary consolidation and edema. Edema of other tissues may also be apparent. Histologically, HeV infection is characterized by a systemic vasculitis, particularly of the respiratory tract, brain, and meninges. Perivascular lymphocyte cuffing, neuronal necrosis, and focal gliosis have been observed in the brain. Perhaps the most notable histologic finding in HeV infection is the presence of syncytial giant cells containing cytoplasmic inclusion bodies in the pulmonary vascular endothelium.[16] Using electron microscopy, pleomorphic enveloped particles containing the helical nucleocapsid characteristic of the paramyxoviruses can be observed within cytoplasmic inclusions.[17,18] Hendra virus has unique morphologic characteristics that can be useful for diagnosis; the envelope is covered with spikes of 10 and 18 nm length, which gives the particle a unique "double fringed" appearance.[17,19]

Diagnosis In regions where the virus is known to occur, HeV infection should be considered in any horse exhibiting a high fever and signs of acute lower respiratory tract or neurologic disease. It should be noted that not all infected horses have a fever when evaluated. HeV infection should also be considered in cases of sudden death. Differential diagnoses for HeV infection include plant (e.g., Crofton weed, avocado) or ionophore toxicity, bacterial pneumonia, and viral encephalitis or meningoencephalitis.

Laboratory testing is essential for confirmation or exclusion of HeV infection and includes virus isolation, detection of viral nucleic acid in body fluids or tissues, and demonstration of specific serum antibodies. Blood, nasal swabs, oral swabs, or vaginal or rectal mucosal swabs are suitable for quantitative real-time reverse transcriptase PCR (qRT-PCR) testing of both living and dead horses. However, samples collected very early in the disease incubation period can be negative by qRT-PCR testing. Furthermore, not all samples are positive simultaneously, and so collection of multiple samples for PCR is recommended. Detailed guidelines for sample collection, handling, and submission are available from local government sources such as the Queensland Government Department of Agriculture and Fisheries (http://www.daf.qld.gov.au). Appropriate personal protective equipment (protective eyewear, particulate mask, impervious gloves and gown) must be worn when collecting samples from suspect horses. Postmortem examinations pose the highest transmission risk for humans, and necropsies of suspect cases should be postponed until HeV infection has been ruled out.

Treatment and Prevention In regions where HeV occurs, owners are advised to reduce contact between fruit bats and horses. Recommendations include to avoid placing feed or water beneath trees in which fruit bats might roost, limit horse access to flowering or fruiting trees that might attract fruit bats, and stable horses at dusk and overnight when fruit bats are most active. Since HeV contains a host cell–derived lipid envelope, inactivation of the virus is possible using

compounds that disrupt the lipid envelope (e.g., lysol, sodium dodecyl sulphate [SDS], acetone, methanol).[18]

In November 2012, a subunit adjuvanted vaccine containing soluble HeV G proteins was released under a "minor permit" requiring strict conditions for its use.[2] The vaccine, Equivac® HeV (Zoetis, Parsippany, N.J.), is now fully registered, and the dosing schedule has been adjusted based on studies evaluating the duration of immunity.[20] The vaccine can be administered to healthy horses older than 4 months of age; the initial vaccination and booster are administered 21 to 42 days apart, followed by an additional booster at 6 months with annual boosters thereafter. Effective antibody levels are present 21 days after administration of the second dose. All vaccinated horses must be identified by microchip prior to vaccination and are registered in a central database. Vaccination has prevented infection in limited experimental trials, and since its release, all confirmed cases of HeV infection have occurred in unvaccinated horses. Several drugs (e.g., ribavirin, chloroquine) have been tested for their activities against HeV[9,21]; however, treatment of confirmed HeV cases is not permitted in Australia, and infected horses must be euthanized.

Crofton Weed Poisoning (Numinbah Horse Sickness, Tallebudgera Horse Disease)

Andrew W. Van Eps • Brett Tennent-Brown

The plant *Eupatorium (Ageratina) adenophora* is native to Central America but now appears as an intractable weed in many countries, including Australia and New Zealand.[1] Ingestion of large quantities of *E. adenophora* causes a pneumotoxicosis characterized by increased respiratory effort and rate. Outbreaks of respiratory disease caused by *E. adenophora* were reported in Southern Queensland and New South Wales in the 1940s and have occurred periodically since then.[1] Respiratory disease caused by *E. adenophora* has also been reported in New Zealand. The related species *Eupatorium riparium* is a perennial weed in Queensland and New South Wales and causes a similar syndrome in feeding trials. However, field cases of disease caused by *E. riparium* have not been reported.[2]

Epidemiology Respiratory disease caused by *E. adenophora* has been described in horses between ages 18 months and 12 years with no gender predilection. Horses appear to be the only large animal species affected. Flowering stages are more toxic than nonflowering stages, and most cases occur during the summer after ingestion of the plant in spring.[1,3] There is typically a minimum of 2 months between plant ingestion and the appearance of clinical signs.[2]

Clinical Signs The earliest clinical sign noted in affected animals is coughing that is exacerbated by exercise.[1,3] Respiratory rate and effort are markedly increased, and in some cases a double expiratory effort is apparent. Affected horses have reduced exercise tolerance, and adventitial sounds may be appreciated on thoracic auscultation. Severely affected horses experience weight loss and may be cyanotic. Cardiac arrhythmias that can result in sudden death develop in some horses.[1,3]

Pathology The toxic principle of *E. adenophora* is unknown.[2] Pyrrolizidine alkaloids are suspected because of the condition's similarity to *Crotalaria*-associated lung disease ("jaagsiekte") seen in South African horses. The toxin (or toxins) appears to be absorbed from the GI tract, and inhalation of plant material (e.g., pollen) is not required for disease.

At necropsy, the lungs are firm and do not collapse on opening the thorax. Pulmonary fibrosis is widespread, and there may be cavities containing necrotic material within the parenchyma. The visceral pleura are often thickened and white in appearance, with focal adhesions to the parietal pleura. Hydrothorax, pulmonary edema and emphysema, hydropericardium, and cardiac dilation may be found in horses that die suddenly.[1,3]

Sheets of epithelial-like cells lining the alveoli are apparent on histologic examination. Accumulations of inspissated protein are present within the alveoli of most chronic cases, and eosinophils and neutrophils commonly fill the bronchioles and surrounding alveoli.

Treatment No effective treatment is known; once diagnosed, the condition is irreversible, although antimicrobials and corticosteroids have improved clinical signs in some cases.

Ruminant Respiratory System

Amelia R. Woolums

Upper Respiratory Tract Diseases*

Amelia R. Woolums

Diseases of the Nasal Cavity

Amelia R. Woolums

Mycotic or Bacterial Nasal Granuloma

Infectious granulomas in the nasal cavity of ruminants are not common. Documented causes include the fungal organisms *Rhinosporidium seeberi* and other *Rhinosporidium* spp. (which cause rhinosporidiosis), *Helminthosporium* spp. (which cause maduromycosis), *Drechslera rostrata*, *Aspergillus* spp., *Phycomycetes* spp., *Stachybotrys* spp., and *Bipolaris* spp. Nasal granuloma caused by *Nocardia* spp. bacteria has also been reported. There is no apparent age, breed, or seasonal predilection, and cases are sporadic. The major clinical signs are upper respiratory noise (stridor), dyspnea, and mucopurulent nasal discharge, sometimes with epistaxis. Affected animals may rub the nose, suggesting pruritus or irritation. Nasal airflow may be reduced, and open-mouth breathing may occur in advanced cases. Hot or dusty weather may accentuate the signs, giving the appearance of seasonal exacerbation, but the lesions are progressive. The granulomas may be single or multiple, unilateral or bilateral, and located anywhere in the nasal cavity. They consist of 0.5- to 5-cm yellow to yellow-green or red nodules or polyps, which may be sessile or pedunculated. Rhinosporidiosis tends to be a single, unilateral polyp in the posterior nasal cavity, and

*Previous contributions by John C. Baker and John A. Smith are acknowledged.

VetBooks.ir

maduromycosis tends to occur in the anterior cavity, but these distinctions are not consistent. Red and black spots (spores) may occur on the masses, and some may become secondarily infected with bacteria and ulcerate. Differential diagnoses include allergic rhinitis, foreign bodies, tumors, nasal actinobacillosis, nasal actinomycosis, and *Oestrus ovis* infection in small ruminants.

Endoscopy, biopsy, and culture of the lesions aid in the diagnosis. Histopathologic analysis reveals granulation tissue containing eosinophils, mononuclear cells, round sporangia, and sometimes hyphae or filamentous bacteria. The pathogenesis of the disease involves inoculation of eroded nasal mucosa with fungal spores or filamentous bacteria from the environment. The infectious agent causes a chronic delayed (type IV) hypersensitivity reaction, which eventually leads to the formation of a granuloma. Fungal granulomas can be more common in warm, wet climates. The granulomas can be difficult to treat, and although rarely fatal, the disease is chronically debilitating, with salvage often being the most practical solution.

Recommended treatments include surgical removal of the granulomas when possible and long-term sodium iodide (NaI) therapy. NaI can be administered at a dose of 66 mg/kg IV as a 20% solution, repeated at 10- to 14-day intervals until remission or iodism occurs. Iodism is characterized by lacrimation, cough, and scaling of the skin. The use of antifungal drugs to treat this condition in ruminants has not been reported.

Allergic Rhinitis and Enzootic Nasal Granuloma

Allergic rhinitis occurs in cattle and in its chronic stages may lead to the formation of granulomas. A similar condition may occur in sheep. The inciting antigen is frequently a plant pollen or more likely a fungal spore. Once homocytotropic antibody (IgE or possibly other classes in cattle) to the allergen has developed, subsequent exposure results in a localized, ongoing, immediate (type I) hypersensitivity reaction. If recurrent exposure to the allergen occurs, repeated tissue damage by mast cell factors results in chronic epithelial, duct, and goblet cell hyperplasia and metaplasia, as well as mucous hypersecretion and granulomatous inflammation, suggesting that a type IV hypersensitivity reaction contributes to the chronic lesion.[1]

Any breed may be affected, but Channel Island breeds and Friesians seem most susceptible. The disease occurs sporadically in the United States. A familial predisposition has been reported.[2] Most affected animals are between 6 months and 2 years of age. The signs are initially seasonal, usually occurring in warm, moist conditions; they include rhinorrhea, sneezing, nasal pruritus, a sudden onset of dyspnea, and stertorous inspiration. There is a profuse bilateral nasal discharge. Intense pruritus is characteristic and associated with sneezing, headshaking, and nose rubbing. In severe cases facial swelling, tachypnea, hyperpnea, and ulceration of the nasal mucosa may occur. Nasal foreign objects may result from the animal's attempts to scratch the nasal mucosa. Lacrimation, chemosis, and blepharitis may also be present. In the chronic stages (the "enzootic nasal granuloma"), the signs are more constant, with seasonal exacerbations. The granulomas tend to be multiple, firm, white, raised nodules 1 to 2 mm in diameter with an intact mucosa, or pale pink, flat plaques scattered throughout the nasal cavity. Differential diagnoses include fungal granulomas, foreign bodies, respiratory viruses, nasal actinomycosis or actinobacillosis, tumors, *O. ovis* infection (small ruminants), and irritation caused by inhalation of hot or irritant gases.

Endoscopy; biopsies; cultures; antigen detection tests for viruses, bacteria, or fungi; and serologic analysis can be used to rule out these differential diagnoses. Eosinophil counts in nasal secretions correlate with the susceptibility of the animal and activity of the disease, but no absolute level is diagnostic. Intradermal allergen testing has been suggested to aid in diagnosis, but interpretation of results needs to be done in conjunction with historical and clinical findings.[3] This condition should be differentiated from fungal or bacterial granuloma because the therapy is different.

Treatment and control entail removal of the allergen, or removal of the animal from the allergen, and therapy to block the hypersensitivity reaction. Recommended drugs include various antihistamines, meclofenamic acid, and corticosteroids at standard antiinflammatory doses (0.05 to 0.2 mg of dexamethasone per kilogram IM or IV or 1 to 2.2 mg of prednisolone per kilogram IM or IV daily). Topical corticosteroid therapy can be considered in severe, acute occurrences of the disease. The adverse effects of corticosteroids on milk production and their potential to induce abortion or parturition should be considered before their use. Antihistamine therapy has had equivocal results.[3]

Nasal Foreign Bodies

Cattle are more prone than small ruminants to the acquisition of nasal foreign bodies. Foreign objects may be acquired as a result of attempts to scratch the nose in cases of allergic rhinitis or because of the cow's aggressive eating habits. Depending on the size and duration of residence of the object, signs may include headshaking, stridor, sneezing, snorting, frequent nose licking, unilateral decreases in airflow, foul odors, and serous, mucopurulent, or hemorrhagic discharges. Differential diagnoses include fungal granulomas, allergic rhinitis, tumors, nasal actinomycosis or actinobacillosis, and *O. ovis* infection (small ruminants). Many objects can be visualized on careful examination of the nasal cavity with an adequate light source, but some may require endoscopy for diagnosis and removal.

Nasal Trauma and Fractures

Trauma to the facial bones, sinuses, and turbinates may result from fighting, accidents caused by improper restraint, farm machinery accidents, human maliciousness, and passage of excessively large nasogastric tubes. Severe fractures can lead to facial swelling, subcutaneous emphysema, obstruction of airflow, stertor, and epistaxis. Secondary infection causes foul odors and mucopurulent nasal discharge. Differential diagnoses for the acute external swelling of the head with stertor include snakebite, actinobacillosis, actinomycosis, and phlegmon (*Fusobacterium*, *Clostridium* spp.). Unless the development of severe depression fractures, formation of sequestra, or severe obstruction of airflow occurs, surgery is usually not indicated. Radiographs confirm the diagnosis and help determine the need for surgical removal of potential sequestra or elevation and fixation of large displaced segments. Prophylactic antibiotics (typically penicillin, 22,000 IU/kg IM q12-24h) are recommended to prevent fracture infection and sinusitis, and NSAIDs (flunixin meglumine, 1.1 to 2.2 mg/kg IV daily or divided twice daily) may help relieve pain, swelling, and stridor. The prognosis is usually good.

Nasal Tumors and Polyps

Tumors and polyps of the nasal cavity and sinuses are rare in ruminants. Nasal tumors reported in cattle include osteomas and osteosarcomas of the sinuses, squamous cell carcinomas, neuroblastomas, and adenocarcinomas of the ethmoid mucosa. Ethmoid adenocarcinomas are speculated to be caused by viruses on the basis of an endemic pattern in some cases. They tend to occur in cattle 6 to 9 years of age and are frequently unilateral. Metastasis occurs to the lymph nodes and lungs. Signs common to all nasal tumors include mixed or inspiratory dyspnea, stridor, nasal discharge, epistaxis, foul breath odors, unilateral decreases in airflow, open-mouth breathing, and distortion of the facial bones. Differential diagnoses include fungal granulomas, atopic granulomas, foreign bodies, sinusitis, fractures, and nasal actinobacillosis and actinomycosis. Treatment has not been investigated.

VetBooks.ir

VetBooks.ir

The majority of nasal neoplasms in sheep and goats are adenopapillomas, adenomas, or adenocarcinomas. Squamous cell carcinoma has also been reported. An enzootic form of nasal adenocarcinoma occurs in both sheep and goats and is associated with ovine nasal adenocarcinoma virus (ONAV)[4] or caprine nasal adenocarcinoma virus (CNAV),[5] respectively. These agents are β-retroviruses that are closely related to but distinct from jaagsiekte sheep retrovirus (JSRV), the cause of ovine pulmonary adenocarcinoma (OPA). Although nasal adenocarcinoma has been difficult to consistently reproduce experimentally, inoculation of kids with concentrated cell-free and bacteria-free filtrate containing virus from naturally infected goats has resulted in disease.[6] Neoplastic transformation is limited to secretory epithelial cells of the nasal turbinates, but CNAV appears to have a wider tissue tropism than ONAV; in one study viral provirus incorporated into host DNA was found in many tissues of infected goats but was largely confined to tumor tissue of infected sheep.[5] There is no breed or sex predisposition for enzootic nasal adenocarcinoma; affected animals are most commonly young adults, but the tumor has been identified as early as 4 months of age. Signs include progressive inspiratory dyspnea; stridor; exercise intolerance; mouth breathing; serous, mucoid, or mucopurulent nasal discharge, which is typically profuse; tachypnea; decreased airflow; headshaking; sneezing; exophthalmos; and facial asymmetry. The lesions may be unilateral or bilateral, originating in the olfactory region of the ethmoid turbinates. The neoplasia arises either from Bowman's glands or serous glands of the nasal mucosa. The tumor begins as a small nodule that can grossly resemble the mucoid polyps that occur in animals with chronic rhinitis. Over time the adenocarcinoma grows into a soft, gray to grayish-pink, mucoid, nodular, cystic mass. The tumor is benign but locally expansive, often entering the sinuses and eroding overlying bone. Histologically the tumor is typically classified as a low-grade adenocarcinoma, but it may also be identified as an adenopapilloma or adenoma. Initially affected animals eat and drink normally and maintain body condition, but as the tumor expands, the animal begins to lose condition, and death eventually occurs as a result of inanition, asphyxia, or aspiration pneumonia. Necrosis or secondary bacterial infection of the tumor can occur and may lead to the production of foul-smelling, purulent discharge and systemic signs related to bacterial infection, such as fever, depression, and hyperemic mucous membranes.

Differential diagnoses for nasal neoplasia in small ruminants include nasal fungal or bacterial granuloma, actinobacillosis, actinomycosis, *O. ovis* infection, and sinusitis. Endoscopy and radiology are helpful in establishing an initial diagnosis of a nasal mass. Preoperative or antemortem pinch biopsies and exfoliative cytologic analysis frequently are nondiagnostic, and findings may be misleading. Identification of tumors in multiple animals in a herd or flock supports a diagnosis of enzootic nasal adenocarcinoma. Definitive identification of infection with ONAV or CNAV can be difficult. Serologic tests are not reliable because animals do not consistently produce antibody to the viruses, possibly because of the presence of endogenous retroviruses that share epitopes with ONAV and CNAV and induce the development of immunologic tolerance. PCR has been used to specifically identify and differentiate ONAV, CNAV, and JSRV in tissues of affected animals. Surgical management of nasal adenocarcinoma in sheep has been described.[7]

Oestrus ovis Infestation

Amelia R. Woolums

Definition and Etiology *Oestrus ovis* is a parasite of the nasal passages and sinuses of sheep and, less commonly, goats. Goats are relatively resistant to infection and, even when housed with sheep, tend to have a lower prevalence of infection. Occasionally humans and other animals are accidentally infected, with conjunctival infection the most common form of disease in humans.[8] The pathogenic stage of the parasite is the larval stage. The first instar larvae are deposited near the nostrils of sheep by the adult female fly and migrate into the nasal and ethmoid turbinates; in the ethmoids the larvae molt to second instars, which migrate to the sinuses before molting again and becoming third instar larvae. Third instar larvae, which are yellow-white in color and have a dark dorsal stripe with rows of spines on the ventrum of each segment, return to the nasal passages and are sneezed out onto the ground, where they pupate and eventually develop into adult flies. The adult is active during warm months, and the parasite may overwinter either as a first instar larva in the host or as a pupa in the ground. Larvae can persist in the upper airways for weeks to months and appear to be able to arrest development for a period if necessary to avoid climate extremes. Adult flies have a rudimentary mouthpiece and are not able to feed; thus the larvae must ingest adequate nutrients while in the host to support the life of the adult fly.

Clinical Signs The larvae cause irritation of the nasal passages and sinuses, leading to mucoid to mucopurulent and sometimes blood-tinged nasal discharge, sneezing, nose rubbing, and inspiratory stridor. Adults flies cause annoyance by flying around the heads of animals; thus both stages can lead to decreased productivity by decreasing the time spent grazing by affected animals. Occasionally the larvae may cause sinusitis or pneumonia owing to secondary bacterial infection associated with irritation caused by the larval infestation. Differential diagnoses to consider include nasal foreign bodies, allergic rhinitis, nasal adenocarcinoma, fungal rhinitis, trauma, sinusitis, actinobacillosis, and actinomycosis.

Pathogenesis The larvae cause direct irritation to the nasal passages and sinuses, and this irritation may predispose animals to the development of secondary bacterial rhinitis, sinusitis, and/or pneumonia. Interstitial pneumonia has also been seen on occasion in affected sheep, presumably induced by inhalation of parasite antigens and inflammatory mediators from the upper respiratory tract.

Epidemiology Infection is more common in warm climates. European surveys have identified *O. ovis* in 35% to 91% of sheep surveyed,[9,10] with seroprevalences of 46% to 69%.[11] A majority of flocks surveyed had at least one infected animal. No North American reports describing the prevalence of *O. ovis* infestation have been published in recent decades.

Diagnosis Diagnosis is usually presumptive, based on typical clinical signs. The larvae can also be identified via radiographs of the head or by endoscopy, but these tests may not be practical for field use. Serologic diagnosis has been used for research studies of the epidemiology of *O. ovis* infection, but these tests are unlikely to be available at most diagnostic laboratories.

Treatment and Prevention The larvae are susceptible to ivermectin at 200 µg/kg PO. Moxidectin at 0.2 mg/kg as a 0.1% oral drench was not effective against *O. ovis*[12]; these investigators found that the same dose given as a 1% injectable solution was effective, but this route is not approved in the United States. Pour-on eprinomectin at 0.5 mg/kg (applied immediately after shearing)[13] and injectable doramectin at 200 µg/kg IM[14] have also been shown to be effective in sheep, but these treatments are also not approved for use in sheep or goats in the United States. Because the adult fly should be

killed by freezing weather, in areas with a season of freezing weather it is logical to treat after the first hard freeze, when sheep will no longer be susceptible to infection until warm weather returns. Prevention is aimed at regular strategic treatment with effective anthelmintics to prevent long-term infection with the larvae.

Diseases of the Sinuses*

Gretchen P. Grissett

Sinusitis

Definition and Etiology The paranasal sinuses of ruminants consist of the following sinuses: sphenoid, lacrimal, conchal, palatine, frontal, and maxillary.[15] The maxillary sinus lies on the upper jawline and contains the roots of the premolar and molar teeth. The frontal sinus consists of a rostral and caudal compartment, with the caudal being the largest and expanding into the horn core. In sheep and in goats, the frontal sinus consists of a medial and lateral compartment, with the lateral compartment being analogous to cattle's caudal compartment.[15] Despite the potential for infection in any sinus, the maxillary and frontal sinuses are the ones of most clinical significance.[15]

Frontal sinusitis most commonly occurs secondary to a dehorning procedure that entered the sinus. Other common causes include traumatic fracture or injury of the horn, horn tipping, bone sequestrum secondary to dehorning, facial fracture,[16] or *O. ovis* infection in sheep (in goats less commonly). Bucking bulls were more likely to present with horn and sinus disorders than nonbucking bulls in one study.[17] Maxillary sinusitis most commonly results from an infected tooth root. Other causes of maxillary or frontal sinusitis include extension of actinomycosis or neoplasia, hematogenous extension of respiratory pathogen,[18] sinus cysts,[19] and lymphosarcoma.[20] One study evaluated the paranasal sinus microbial flora of clinically normal cattle and cattle presented for portmortem examination, finding that 83.5% of the study individuals did not contain detectable microbes. The organisms isolated from the paranasal sinuses in this study included bovine respiratory disease pathogens *Haemolytica*, *Trueperella pyogenes*, *Pasteurella multocida*, *Bibersteinia trehalosi*, and parainfluenza virus type 3 (PIV-3).[18]

Clinical Signs and Differential Diagnosis Acute or chronic sinusitis can result following dehorning. Generally only one sinus is affected. Clinical signs associated with acute sinusitis include lethargy, inappetence, pyrexia (39.4° to 41.1° C), unilateral or bilateral mucopurulent discharge, head pressing, and head tilt. Typically, purulent discharge and/or foul-smelling crusting is present at the cornual portion of the sinus. With chronic sinusitis, clinical signs can occur weeks to months after dehorning. Chronic frontal sinusitis can also occur unrelated to dehorning. One study found 4 of the 12 individuals presented for chronic frontal sinusitis had horns, had no record of dehorning, or were dehorned as calves without entering the sinus, but 3 of the 4 did have a recent history of respiratory disease.[21] Clinical signs potentially associated with chronicity include the aforementioned signs, as well as intermittent or consistent pyrexia, stridor, alterations in airflow (typically unilateral), halitosis, reluctance to move, abnormal posture, extended head and neck, partially closed eyes with tendency to rest the head on stationary objects as a sign of pain, frontal bone distortion, exophthalmos, and intolerance of head manipulation. Neurologic signs may result if extension causes impingement or infection of the central nervous system with possible sequelae, including intracranial abscess and septic meningitis.[21]

Maxillary sinusitis is uncommon. Clinical signs include facial swelling and possible deformation over the affected sinus, unilateral mucopurulent discharge, and occasionally decreased appetite secondary to pain during mastication.[16] Maxillary sinusitis is usually associated with a tooth root infection. However, in one report a cow with maxillary sinusitis unassociated with a tooth root fracture or infection was successfully treated. Bacteria cultures were negative, and the etiology was idiopathic.[22] Differential diagnoses for sinusitis include facial fractures, actinomycosis, actinobacillosis, retrobulbar abscess, lymphosarcoma, nasal or sinus neoplasia, and sinus cysts.

Diagnosis Typically, diagnosis can be reached based on history and clinical signs. Certainly, a history of recent dehorning or chronic nasal discharge (especially unilateral) should create a high suspicion of sinusitis. Percussion of the affected sinus may reveal a dull, full resonance and may be painful to the individual. A hyperresonant sound may occur if gas is present under severely thinned bone. Radiographs reveal fluid in the sinuses and may reveal lysis and/or deviations of bony septa (Fig. 31.62). In cases of maxillary sinusitis, radiography will determine if dental disease is involved. In addition, radiography will diagnose presence of facial fractures, masses, and actinomycosis. Endoscopy can assist with localization and etiology of the clinical signs. In one report endoscopy was used to confirm maxillary sinusitis by visualizing purulent drainage from the ostia of the nasomaxillary opening, as well as visualizing the sinus after sinus trephination to rule out

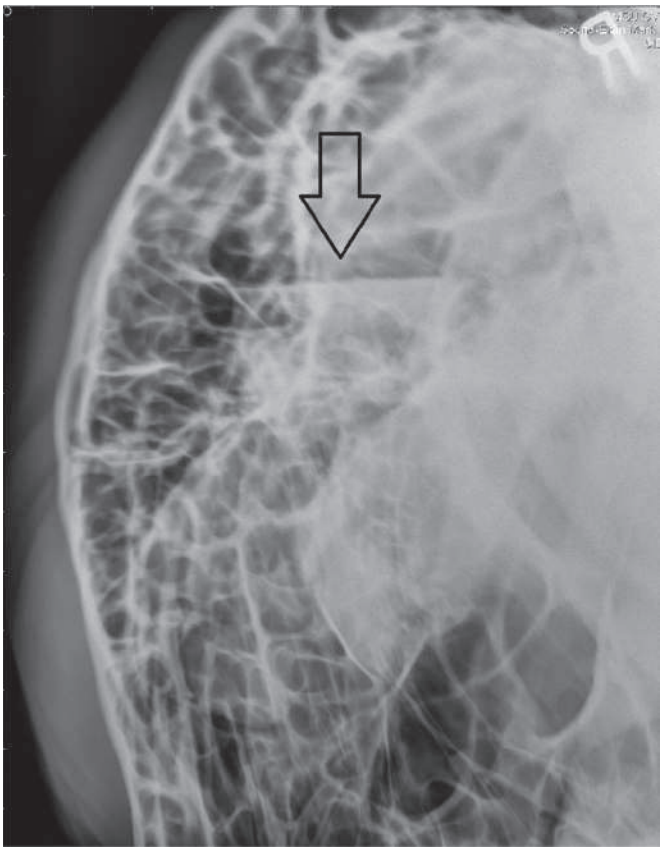

FIG. 31.62 Right lateral radiograph with a horizontal fluid line *(arrow)* in the right frontal sinus of a mature Brahman bull with sinusitis secondary to horn tipping. *(Courtesy Dr. Gretchen Grissett, Mississippi State University, Starkville, Miss.)*

*Previous contributions by John R. Pascoe are acknowledged.

VetBooks.ir

diagnoses such as sinonasal cyst or neoplasia. CT gives the most precise localization and definition, especially with regard to cysts, masses, and dental disease.[23] Sinocentesis can be performed for culture and cytologic examination.[19] For sinocentesis, a Steinmann pin is used to create a hole into the sinus to facilitate fluid aspiration.[19] A culture and sensitivity of the fluid should be performed to direct antibiotic selection. *T. pyogenes* is isolated most commonly with dehorning-associated sinusitis.[21] *P. multocida* is most commonly isolated in individuals with sinusitis not associated with dehorning.[21] However, a multitude of other agents have been reported, including *Proteus*, *Pseudomonas*, *E. coli*, *Moraxella* spp., *Aerococcus viridans*, *Bacillus* spp., *Fusobacterium* spp., *Prevotella* spp., *Porphyromonas levii*, and *Bacteriodes* spp.[17,21] A CBC and serum biochemical profile is often variable and offers minimal assistance with definitive diagnosis.

Treatment and Prognosis Establishing drainage and sinus lavage are the treatment goals for sinusitis. For acute sinusitis associated with dehorning, conservative management can be used by thorough cleansing; débridement; removal of sequestered, devitalized bone; and lavage of the cornual wounds. If cornual drainage is inadequate, placement of a 4-mm Steinmann pin into the caudal frontal sinus is another conservative technique for treatment of acute sinusitis.[16] After local anesthesia and a stab incision, a hand chuck or drill is used to create the hole into the affected sinus with the Steinmann pin. Polyethylene tubing (Foley catheter, fluid administration set) is used for daily sinus lavage.

For chronic cases, access to the paranasal sinuses is achieved with trephination or bone flap over the affected sinuses.[16] Trephination is ideal because it can be performed standing with sedation and local anesthesia under field conditions, whereas a bone flap requires general anesthesia. Unfortunately, a bone flap may be necessary in cases with pyogranulomatous inflammation that would be insufficiently lavaged with trephination alone. In addition, the numerous septa of the frontal sinus and high location of the nasomaxillary opening in the maxillary sinus may necessitate a bone flap to allot adequate access and drainage.[15] Sinusotomy locations for trephination include the dorsal frontal sinus, postorbital diverticulum, rostral frontal sinus, turbinate portion of the frontal sinus, and the maxillary sinus (Fig. 31.63).

Frontal sinusotomy sites are based on known anatomic landmarks and modified as needed to accommodate frontal bone distortion and dehorning wounds.[21] The individual should be restrained appropriately in a chute and sedated. The sinusotomy location is 3 to 4 cm from midline intersecting a line drawn between the caudal aspect of the orbits. The proposed site should be surgically prepared and instilled with 2% lidocaine HCl for local anesthesia. A full-thickness circular area of skin large enough to accommodate the trephine (approximately 2 cm in diameter) extending to the periosteum should be excised. A Galt trephine should then be used to remove a section of bone to access the sinus. After entering the sinus, samples should be obtained for culture and cytology. If draining tracts are present, a second sinusotomy can be performed at the cornual portion of the sinus. The postorbital diverticulum is accessed approximately 4 cm caudal to the dorsal rim of the orbit just above the temporal crest of the frontal bone.[24,25] The rostral frontal sinus is entered just caudal to a line drawn between the center of the orbits and just off midline, with the turbinate portion of the frontal sinus entered just rostral to this line and to either side of midline. The numerous septae in the frontal sinus can often make drainage difficult, especially with postoribital diverticulum involved, meaning that one trephination can be insufficient. Often two trephination sites are required for an ingress and egress lavage system. For sheep and goats, the frontal sinus is even more compartmentalized

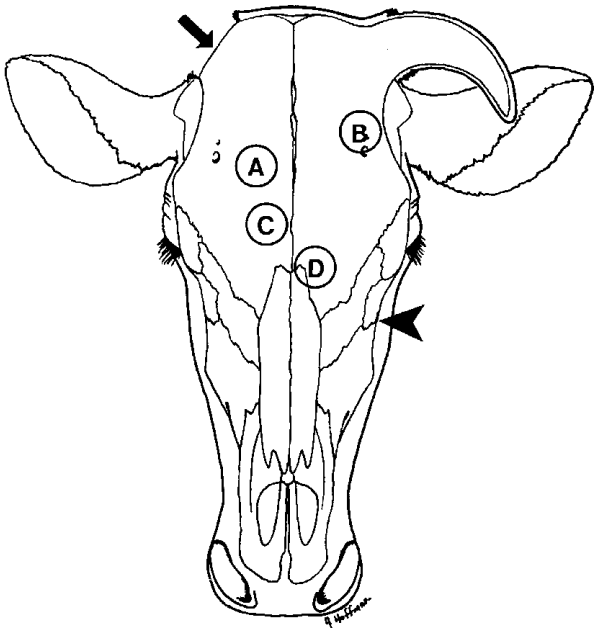

FIG. 31.63 Trephine sites for sinusotomy. **A,** Dorsal frontal sinus. **B,** Postorbital diverticulum. **C,** Rostral frontal sinus. **D,** Turbinate portion of frontal sinus. The maxillary sinus is trephined ventral to a line from the infraorbital foramen to the medial canthus *(arrowhead)*. If draining tracts are present at the poll, an additional sinusotomy can be made in the cornual portion of the frontal sinus *(arrow)*.

than cattle, making effective drainage very difficult. In addition, sheep and goats have a thin calvarium, meaning that chronic sinusitis leads to meningitis more easily than in the bovine patient. Therefore early, aggressive treatment in sheep and goats is essential, including consideration of a bone flap procedure and two trephination sites. Preferred trephination sites are rostral to the horn or medial to the middle of the orbital rim, avoiding risk of injury to the frontal vein.[15]

The maxillary sinus is accessed by drawing a line from the medial canthus to the infraorbital foramen. The trephine is positioned just ventral to this line, lining up just dorsal and caudal to the facial tuberosity.[22] If an infected tooth cannot be removed orally, the sinusotomy site should be positioned over the affected tooth to allow axial alignment and repulsion of the tooth.[25] In immature animals, the tooth roots are longer and occupy much of the maxillary sinus. Therefore care should be taken and the trephine site should be positioned higher to avoid the tooth roots.[16] If a tooth is repelled, a roll of gauze or methyl methacrylate plug should be used to pack the alveolar socket to prevent feed material entering the side. If rolled gauze is used, the gauze can be passed from the socket, into the sinus, and out the trephine hole and secured to the individual's face. The packing should be changed with each lavage. Since the maxillary sinus has fewer septae than the frontal sinus, typically one sinusotomy site is sufficient for drainage and lavage. With chronic maxillary sinusitis, damage to the lacrimal and infraorbital canals and infraorbital nerve is possible.[15,23]

Drains can be placed in communicating trephination sites to prevent premature closure and facilitate lavage and drainage of the affected sinus. Sinus lavage should occur once to twice daily with saline, dilute povidone-iodine, or dilute chlorhexidine solution. One study evaluated sinus lavage solutions and found that individuals treated with the 5% diluted povidone-iodine solution had better clinical resolution that the individuals lavaged with saline alone.[26] A stent bandage can be used to cover the trephination sites to prevent debris and environmental contamination entering the sinus until sufficient granulation

has occurred.[16] Parenteral antibiotics and NSAIDs are indicated in individuals with systemic signs. Flunixin meglumine (1.1 mg/kg IV q24h) is recommended for individuals in the acute phase of the disease course and those that are perioperative. For individuals with chronic sinusitis treatment, meloxicam (0.5 to 1 mg/kg PO q48h) is recommended for protracted treatment. Since sinusitis caused by dehorning is most commonly associated with *T. pyogenes*, penicillin G procaine (22,000 U/kg IM q12h, or 44,000 U/kg IM q24h) is the empirical antibiotic choice.[21] *P. multocida* is most commonly isolated in frontal sinusitis not associated with dehorning.[21] Penicillin may be effective against some *P. multocida* isolates, but oxytetracycline (11 mg/kg IV q24h for 5 days, or 20 mg/kg SC long-acting oxytetracycline q72h) can be administered with nondehorning-related sinusitis. Florfenicol (40 mg/kg SC q96h) is also a reasonable choice, as it has bacteriostatic activity against both *T. pyogenes* and *P. multocida*. Antimicrobial therapy should always be modified to culture and sensitivity results when available. Prognosis is good for individuals early in the disease course, usually resolving in 7 to 14 days with appropriate therapy and systemic antibiotics. For chronic cases the prognosis is fair to guarded, with weeks of aggressive therapy required for a successful outcome. Individuals with neurologic signs typically have a grave prognosis, and humane euthanasia should be considered.

Prevention and Control The best prevention for frontal sinusitis in ruminants is dehorning as neonates prior to communication of the horn with the frontal sinus. Ideally, dehorning occurs with electrocautery (dehorning iron) or a Barnes dehorner prior to communication with the frontal sinus. For mature cattle, a surgical (cosmetic) dehorn using aseptic technique is recommended. A cosmetic dehorn allows primary skin closure, minimizing environmental contamination and expediting healing time.[27] If a surgical dehorn is not performed, avoid dehorning during fly season or windy or rainy conditions to help prevent mydriasis and sinusitis. Disbudding of sheep and goats should occur in the first week of life due to the rapid growth of horns. For mature sheep and goats, cosmetic dehorning can also be performed, minimizing the risk of sinusitis and expediting healing time.[28] Without cosmetic dehorning, dehorning of mature sheep and goats requires intensive bandage management and 4 to 6 weeks for healing by second intention.[29]

Diseases of the Pharynx, Larynx, and Trachea*

Amelia R. Woolums

Pharyngeal Trauma, Abscesses, Cellulitis, and Granulomas

Definition and Etiology Pharyngeal trauma may result in hematomas, foreign body granulomas, cellulitis, or abscesses. Trauma usually results from careless use of balling guns, dose syringes, paste-type anthelmintics or calcium preparations, specula, and stomach tubes. Rough, stemmy feeds (especially when chopped), grass awns, briars, and foreign objects (e.g., nails, baling wire) may also cause punctures. Migrating foreign objects or medications (e.g., mineral oil, anthelmintics) may cause pharyngeal granulomas. Hematomas and puncture wounds often result in abscess formation. Diffuse cellulitis may also result. Common bacteria involved include *Arcanobacterium pyogenes*, *Actinobacillus* spp., *Pasteurella* spp., *Bordetella* spp., *Fusobacterium necrophorum*, and *Streptococcus* spp. In cases of particularly virulent bacterial invasion, the condition can become rapidly fatal. *C. pseudotuberculosis* (caseous lymphadenitis) may localize in the pharyngeal nodes of sheep and especially goats. Caseous lymphadenitis is discussed later in this chapter and also in relation to the hemolymphatic system in Chapter 37.

Clinical Signs and Differential Diagnosis Signs of pharyngeal trauma vary with the severity of the resulting reaction (e.g., peracute cellulitis versus chronic abscess or granuloma). Prominent signs include inspiratory dyspnea with stertorous inspiratory sounds and a prolonged inspiratory phase; extended head and neck; ptyalism, which is often profuse; quidding; evident pain on swallowing or reluctance to swallow solid feed but willingness to drink liquids; prolonged chewing of boluses; regurgitation of food or saliva through the nostrils caused by pharyngeal paresis; mucopurulent to bloody nasal discharge and fetid odors, usually bilateral; cough; bloat; and visible or palpable swelling in the pharyngeal area. Megaesophagus has been reported subsequent to pharyngeal trauma. Palpation of the pharynx may increase the stertor and cause pain. In severe cases, systemic signs of fever, anorexia, depression, dehydration, and forestomach stasis may be present. Aspiration pneumonia may be a secondary complication.

Differential diagnoses include pharyngeal tumors; lymphosarcoma; sialoliths; rabies; botulism; actinobacillosis; necrotic laryngitis; laryngeal abscesses, trauma, edema, or paralysis; and laryngeal tumors.

Diagnosis A thorough manual examination of the oropharynx or a visual examination with an adequate speculum and light source usually confirms the diagnosis of a pharyngeal swelling and often reveals a puncture that is discharging pus. Cases in which the infection is diffuse can be more difficult to recognize, and endoscopy or radiography can be particularly helpful. Restraining the jaws with a McCallum speculum allows a guarded needle attached to a length of tubing and a syringe to be inserted into the swelling for aspiration of any swelling identified. This helps differentiate localized abscesses from granulomas, hematomas, cellulitis, and tumors; allows culture and sensitivity determinations on abscesses; and may aid in cytologic diagnosis of granulomas or tumors. Radiographs may reveal foreign bodies (Fig. 31.64) or air densities (Fig. 31.65) in the pharyngeal tissues. The CBC usually reflects an inflammatory process, with a neutrophilic leukocytosis and a left shift, or a neutrophil-lymphocyte reversal. Dehydration is frequently evident. If the animal is unable to swallow, large

amounts of bicarbonate may be lost through the saliva, which may lead to evidence of metabolic acidosis on blood gas analysis or serum biochemical profile.

Treatment and Prognosis Discrete pharyngeal abscesses are usually best drained into the pharynx. Whenever possible the procedure should be done on the standing animal without sedation to preserve the cough reflex and prevent aspiration. A good oral speculum and excellent restraint are needed. The head should be kept lowered. A guarded blade such as a hook blade from a fetotomy set is introduced into the pharynx, and the abscess is lanced. The cavity is flushed with a mild antiseptic such as 0.2% povidone-iodine in saline solution, again taking care to prevent aspiration. Other options include drainage to the exterior, drainage and flushing with a large-gauge needle and tubing, and extirpation.[2] Removal of a bacterial granuloma from the pharynx of a cow via electrocautery has been described.[4] Systemic antibiotics are administered in accordance with culture and sensitivity results, or in their absence, procaine penicillin G (22,000 to 44,000 U/kg IM q12-24h) or tetracycline (11 mg/kg IV or SC daily, or 20 mg/kg of long-acting oxytetracycline SC q72h) are used. NSAIDs (flunixin meglumine, 1.1 to 2.2 mg/kg IV daily or divided twice daily) help relieve pain, swelling, and stertor. In animals with severe, persistent dyspnea, tracheostomy may be necessary. Granulomas and diffuse cellulitis are likewise treated medically with appropriate antimicrobials and antiinflammatory drugs. Supportive therapy such as IV fluids or feeding through a rumenostomy site may be necessary if the animal refuses to eat or drink. The prognosis for most pharyngeal abscesses, hematomas, cellulitis, and granulomas is usually good with appropriate therapy.

Dorsal Displacement of the Soft Palate

Although rare, dorsal displacement of the soft palate has been reported in cattle.[30] Respiratory noise is apparent on inspiration and expiration but is loudest on inspiration. Diagnosis can be made by endoscopic examination. Treatment is similar to that used in horses and can include conservative therapy, which consists of antiinflammatory drug therapy and rest, or the condition can be surgically corrected.

Necrotic Laryngitis (Calf Diphtheria, Laryngeal Necrobacillosis)

Definition, Etiology, and Epidemiology Acute to chronic infection of the laryngeal mucosa and cartilage of young cattle is very common, particularly in feedlots. Laryngeal contact ulcers probably provide a damaged mucosal surface, which then allows invasion of the cartilage by *F. necrophorum*, which is the proximate cause of the lesions. Alternatively, *Histophilus somni* may be the primary agent inducing a perilaryngeal vasculitis, with *F. necrophorum* representing a secondary bacterial invader.

The disease is most common where cattle are housed in dirty or crowded conditions and in feedlots. Most feedlot cases occur in animals on feed for longer than 30 days. The incidence is sporadic. Cases occur year round, but there appears to be a higher incidence in fall and winter. The disease has a worldwide distribution.

Clinical Signs and Differential Diagnosis The problem occurs most commonly in calves from 3 to 18 months of age, up to about 24 months. It is characterized by an acute onset of a moist, painful cough, which the animal may attempt to suppress because of pain. Frequently a severe inspiratory dyspnea with a loud guttural stertor and open-mouth breathing with the head and neck extended are observed. The animal may salivate, make frequent painful swallowing movements, and stand and sip water continually. Signs of systemic disease, including anorexia, depression, fever (as high as 106° F [41.1° C]), and hyperemic mucous membranes, are present. There is often a bilateral nasal discharge and a fetid odor to the breath. The larynx may be visibly or palpably swollen, and palpation may elicit a cough, cause pain, and markedly increase the dyspnea and stertor. If untreated, many calves will die in 2 to 7 days as a result of systemic effects of bacterial toxins and upper airway obstruction. Recovered cases may have a chronic roaring respiration and a harsh, dry cough because of the misshapen larynx. Aspiration pneumonia and chronic "poor doers" are common sequelae. Differential diagnoses include pharyngeal trauma (abscess, cellulitis), severe viral laryngitis (e.g., IBR), actinobacillosis, and laryngeal edema, abscesses, trauma, paralysis, and tumors.

Diagnosis The diagnosis is usually made presumptively based on clinical signs alone. A laryngoscopic or endoscopic examination can help confirm the diagnosis, but care must be taken to prevent further stress and respiratory embarrassment. Acute cases show changes in the CBC consistent with any acute septic condition: leukopenia caused by neutropenia with a left shift. In chronic or ongoing cases, leukocytosis with neutrophilia, monocytosis, and hyperfibrinogenemia may be present.

Pathophysiology *F. necrophorum* normally does not penetrate intact mucous membranes. Laryngeal contact ulcers are thought to provide the portal of entry for *F. necrophorum*, which is ubiquitous. Laryngeal contact ulcers are also very common in slaughter cattle and are speculated to be caused by the following combination of factors: (1) an acute mucositis from mixed upper respiratory infections; (2) reflex coughing and swallowing, which accelerate the rate of laryngeal closure; and (3) resulting erosion of the swollen membranes over the vocal processes and medial angles of the arytenoid cartilages. Necrotic laryngitis can alter pulmonary function such that the growth rate is impeded and also predisposes to secondary bacterial pneumonia.

Necropsy Lesions The lesions are typically located over the vocal processes and medial angles of the arytenoid cartilages. Acute lesions consist of marked edema, hyperemia, and swelling of the mucous membrane around a necrotic ulcer, with accumulated exudate. The lesions spread along the vocal processes and vocal folds and may extend into the cricoarytenoideus dorsalis muscles. In chronic cases the lesions consist of a focus of necrotic cartilage surrounded by

purulent exudate, which may be inspissated. The tract opening may be surrounded by granulation tissue and may drain pus. The arytenoid cartilage may be rotated into the lumen or may contain mucosal cavities lined with thin, hyperemic epithelium.

Treatment, Prognosis, Prevention, and Control

Oxytetracycline (11 mg/kg IV or SC q24h, or 20 mg/kg of long-acting oxytetracycline SC q72h), procaine penicillin G (22,000 to 44,000 U/kg IM q12-24h), or florfenicol (20 mg/kg IM q48h or 40 mg/kg SC q96h) are appropriate. NSAIDs (flunixin meglumine, 1.1 to 2.2 mg/kg IV once daily or divided twice daily) may reduce swelling, inflammation, and fever. Cases with severe respiratory distress may benefit from one or two doses of steroids (dexamethasone, 0.05 to 0.2 mg/kg IV or IM once or twice), but repeated doses of steroids are not recommended. A tracheostomy may be necessary in severe cases to relieve dyspnea and rest the larynx. Good nursing and supportive care are also important, including shelter, adequate ventilation, easy access to feed and water, and oral or IV fluids if needed. The prognosis is guarded; even when the condition is detected early and treated vigorously, cattle sometimes relapse. When extensive cartilage necrosis occurs, a fatal outcome or chronic ill-thrift is expected. There are no specific control measures. The proposed pathogenesis would suggest that measures to control other respiratory diseases may reduce the incidence of necrotic laryngitis.

Laryngeal Papillomatosis

Papillomas of the larynx have been reported in feedlot cattle. They are caused by a papovavirus, which is thought to enter laryngeal contact ulcers (see the previous Necrotic Laryngitis section). Characteristic signs of laryngeal papillomatosis are stertorous respiration and cough. Differential diagnoses include necrotic laryngitis, pharyngeal trauma, abscess, or granuloma; actinobacillosis; and laryngeal abscesses, trauma, edema, paralysis, and tumors. The lesions are sessile to pedunculated, yellow, frondlike, 1- to 10-mm growths over the vocal processes of the arytenoid cartilages.Treatment usually is not indicated but involves surgical removal. Measures to decrease other respiratory infections and thereby decrease contact ulcers may lower the incidence of papillomas.

Laryngeal Abscesses

Abscessation of the arytenoid cartilages caused by *A. pyogenes* has been reported in calves and sheep. Clinical signs include tachypnea, extension of the head and neck, cyanosis, and a severe progressive dyspnea with marked stertor that can be localized to the larynx. Many affected animals remain alert and afebrile and continue to eat until the terminal stages of severe dyspnea. Endoscopy reveals generalized edema and hyperemia of the laryngeal mucosa and obstruction of the rima glottidis by swelling of one or both arytenoids. Radiographs may demonstrate soft-tissue swelling of the larynx. The condition has been speculated to be initiated by grass awns, trauma, hereditary predisposition, or congenital cavitations in the cartilages. In sheep, rams appear to be more commonly affected than ewes, and two reports found a breed predisposition in Texels and Southdowns, although other reports have indicated that various breeds are affected.[31] The necropsy lesions consist of encapsulated abscesses containing pus and necrotic debris in the arytenoid cartilage, usually in the vicinity of the vocal cord. A tract from the abscess typically opens in an area of granulation tissue in the laryngeal mucosa. Treatment consists of tracheostomy, antibiotics (usually penicillin at 22,000 to 44,000 U/kg IM q12-24h), and antiinflammatory drugs (flunixin meglumine, 1.1 to 2.2 mg/kg IV daily or divided twice daily). The prognosis for recovery is considered guarded unless the condition is detected in the earliest stages and treated vigorously; however, one affected heifer lived for at least 1 year and was bred successfully after permanent surgical tracheostomy for chronic arytenoid abscessation.[32]

Other Laryngeal Obstructions (Laryngeal Trauma, Edema, Paralysis, and Foreign Objects)

Other laryngeal obstructions are all sporadic and may manifest with similar signs. Trauma to the larynx may result from roping or injury in restraint devices. Inappropriate placement of an endotracheal tube can potentially damage the larynx. The respiratory system is the main target organ for anaphylaxis in ruminants, and laryngeal edema can be a prominent component of this syndrome. Inhalation of smoke or other noxious gases also may cause laryngeal edema. Laryngeal hemiplegia has been reported in association with *Sarcocystis* species infection of the muscles of the larynx and pharynx in a ram.[33] Foreign objects more commonly lodge in the pharynx, but sharp objects and food materials may be aspirated and lodge in the larynx. Signs common to these laryngeal obstructions include inspiratory dyspnea, prolongation of the inspiratory phase, mouth breathing, stertor, cyanosis, salivation, and extension of the head and neck. Palpation of the larynx may reveal swelling and may exaggerate the dyspnea and stertor. Differential diagnoses include necrotic laryngitis, laryngeal abscesses, severe viral laryngitis, actinobacillosis, and tumors. Endoscopy and radiology are required in most cases to differentiate these conditions. Hematologic analysis may give some indication of the presence of bacterial infection; a stress leukogram may also be seen. Tracheostomy is indicated in all severe cases. Surgical correction of laryngeal obstruction by tracheolaryngostomy has been described in cattle.[34]

Laryngeal trauma and paralysis may resolve spontaneously or may require reconstructive surgery. The therapy of anaphylaxis is discussed in the Anaphylaxis section later in this chapter. Foreign objects should be removed surgically or endoscopically. NSAIDs (flunixin meglumine, 1.1 to 2.2 mg/kg IV daily or divided twice daily) may help reduce swelling, edema, and respiratory embarrassment in all forms of obstruction.

Tracheal Collapse and Stenosis

Definition and Etiology

Tracheal collapse or stenosis is infrequently reported in cattle and goats.[35] The cause is usually unknown, but the problem may result from cranial thoracic trauma, roping, tracheostomies, or possibly congenital defects. In cattle the majority of reports have described tracheal collapse in calves in which signs were usually first evident at several weeks of age. The majority of these cases also involved the thoracic trachea (Fig. 31.66), suggesting a congenital lesion. However, in most calves with tracheal collapse the condition has been a result of dystocia at birth, especially breech presentations, which suggests a traumatic cause. In contrast to reports in cattle, tracheal collapse has been reported in a mature goat that showed no previous signs of respiratory abnormality.[36]

Tracheal collapse has also been reported in Texel-cross lambs with inherited chondrodysplasia[37]; affected lambs were normal at birth but developed exercise intolerance as early as 1 week of age. Severely affected lambs developed fatal respiratory compromise when exercised. Tracheal stenosis can also occur in lambs born to ewes that ingest *Veratrum californicum* root and rhizome material at days 31 through 33 of gestation.[38]

VetBooks.ir

FIG. 31.66 Radiograph demonstrating collapse of the thoracic trachea in a calf.

Clinical Signs and Differential Diagnosis Clinical signs of tracheal collapse may include fever, tachycardia, tachypnea, cyanosis, and mucosal hyperemia with vessel engorgement, but affected animals may have normal vital signs and are otherwise alert and in good condition. Dyspnea is usually induced or exacerbated by excitement or exercise or may be severe at rest. Stertorous respiration is usually evident, is frequently worse on inspiration, and can often be localized to the trachea on auscultation. The inspiratory phase is prolonged, and a "honking" cough is characteristic, especially with intrathoracic collapse. Palpation may reveal or induce the collapse when the cervical trachea is involved. Tracheal palpation or elevation of the head may increase the stertor or induce the honking cough. In some cases there may be other evidence of trauma (fractured ribs, sternebrae), and in some animals pneumonia may be present. There is no response to antibiotics, steroids, or tracheostomy.

Texel-cross lambs with tracheal collapse resulting from inherited chondrodysplasia also exhibited retarded growth, forelimb varus, and reluctance to walk. Severity of signs varied among affected individuals; some died or were euthanized within weeks because of respiratory compromise, whereas others survived to breeding age.[37] Animals that survived for several months often developed arthritis characterized by severe erosive lesions of the articular cartilage of major joints, including the shoulder, hip, and stifle. Lambs with congenital tracheal stenosis resulting from maternal ingestion of *V. californicum* died within 5 minutes of birth after signs of severe respiratory distress.[38]

Other possible disorders with signs similar to those seen in animals with tracheal collapse or stenosis are tracheal foreign bodies, tracheal actinobacillosis, neoplasms, bronchopneumonia, necrotic laryngitis, and extratracheal compressive lesions (e.g., abscesses, tuberculosis, hematomas).

Diagnosis Any deviation of the hemogram from normal is probably a reflection of associated pneumonia or stress. Endoscopy and radiography are the most helpful ancillary aids. Care must be taken when restraining, sedating, and passing the endoscope in these animals; oxygen should be available. In cattle with idiopathic tracheal collapse, radiography and endoscopy usually reveal a dorsoventral flattening, most typically in the caudal cervical and cranial thoracic trachea, although lateral collapse and collapse in other locations (cranial cervical, intrathoracic) are occasionally encountered.

Pathophysiology Proposed causes of tracheal collapse in other species include congenital malformations, genetic or nutritionally induced weakness of cartilage, deficient innervation of the trachealis muscles, trauma, ischemic lesions from endotracheal tube cuffs, and primary pulmonary disease. No histologic differences were noted in tracheal rings from collapsed and normal segments when this has been assessed. As previously mentioned, most calves with tracheal collapse have a history of dystocia at birth. During delivery, compression of the chest wall with fracture of the first pair of ribs may cause injury at the thoracic inlet. However, signs of tracheal collapse are not immediately evident at birth but develop over time.

Lambs with tracheal collapse associated with inherited chondrodysplasia had clinical signs most similar to a condition in humans that results from a mutation in the diastrophic dysplasia sulphate transporter gene,[39] but the causative mutation in sheep has not yet been reported. Preliminary data indicated that the chondrodysplasia was inherited via a recessive mode of inheritance.[37] Tracheal stenosis in lambs born to ewes fed *V. californicum* was presumed to be caused by cyclopamine, a steroidal alkaloid that is the toxic principle in highest concentration in *V. californicum*. It was notable that lambs developed tracheal stenosis when ewes were fed *V. californicum* at 31 to 33 days of gestation, whereas craniofacial defects typically recognized in lambs born to exposed dams are seen when the ewe ingests the toxic plant by day 14 of gestation.[38]

Necropsy Lesions At necropsy, affected animals may have either a laterally or dorsally compressed trachea; typically several centimeters of the trachea are affected. Necropsy of sheep with inherited chondrodysplasia reveals a trachea that is flaccid, flattened, and sometimes irregularly kinked. Tracheal rings are markedly thickened, and the lumen is narrow, possibly extremely so. Diffuse pulmonary congestion and edema, with epidcardial ecchymoses, may occur as a result of terminal anoxia and respiratory distress. Other lesions include exaggerated convex curvature of the ribs, anglular limb deformities, and erosive arthritis with exposure of the subchondral bone in one or more joints. Histologically, hyaline cartilage in affected organs is hypercellular and disorganized, with foci of apparent chondrolysis. Chondrocytes are larger than normal, although shrunken, apparently necrotic chondrocytes are also seen. Necropsy of lambs with congenital tracheal stenosis resulting from maternal ingestion of *V. californicum* reveals pronounced lateral flattening of the trachea. Tracheal rings are reduced in number, with abnormal size and shape and irregular spacing. Histologically, the cartilage rings in affected lambs were flattened and thin and had a thinner zone of proliferating chondrocytes on their outer surface compared with normal age-matched controls.

Treatment and Prognosis Mild cases may respond to confinement sufficiently to be fed out for slaughter. A number of surgical treatments have been proposed in other species, including anastomosis, bisection of tracheal rings, internal and external prostheses, and plication of the dorsal membrane. External prostheses have been used successfully in calves,[35] adult cattle, and a goat.[40] A favorable prognosis for surgical correction is estimated at approximately 30%.[23] A detailed description of surgical repair in calves by external prostheses has been published.[23] Successful management of lambs with congenital tracheal collapse or stenosis has not been reported, although mildly affected lambs with congenital chondrodysplasia survived into adulthood. Because of the apparent genetic basis for the disease, breeding of affected animals should not be recommended.

Tracheal Foreign Bodies and Masses

Ruminants may occasionally inhale foreign objects that lodge in the trachea. Tracheal actinomycosis has been reported to result in signs of tracheal obstruction.[41] Signs include a chronic cough, inspiratory dyspnea, audible stridor that can be localized to the trachea, extension of the head and neck, open-mouth breathing,

VetBooks.ir

and salivation. Differential diagnoses should include pharyngeal trauma; necrotic laryngitis; laryngeal abscesses, trauma, edema, or paralysis; tracheal collapse; and extratracheal compressive lesions. Endoscopy and radiology are important aids to diagnosis. Care must be exercised in restraint and in passage of the endoscope. Some small objects may be retrieved by a snare passed through an endoscope; others may require tracheostomy. When possible, the tracheostomy should be performed below the object. The actinomycotic masses are soft, pedunculated lesions with a granular surface containing small yellow foci.

Tracheal Edema Syndrome of Feedlot Cattle

Tracheal edema syndrome has also been referred to as *tracheal stenosis* in feedlot cattle. In this condition extensive edema and hemorrhage in the dorsal wall of the trachea result in coughing, dyspnea, and stertor, which has given rise to the term *honker cattle*.[42] Tracheal edema syndrome occurs in two forms, characterized by either acute dyspnea or a chronic cough. It is not known whether the two forms are related. Although the syndrome has been recognized for years, no controlled research has been undertaken to determine the cause or risk factors of this syndrome, and the cause is unknown. Theories regarding possible causes include infections with upper respiratory viruses or bacteria such as *P. multocida* or *H. somni*, trauma to the trachea from feedbunks, passive congestion and edema from excessive fat accumulation in the thoracic inlet, hypersensitivity reactions, and mycotoxins.

The acute dyspnea syndrome occurs mainly in heavy feedlot cattle in the latter two thirds of the feeding period and is most common in Southern Plains feedlots. It is sporadic and more common in summer, possibly because of exacerbation by hot weather. At one extreme, sudden deaths without the onset of noticeable clinical signs have been reported, and at the other extreme subclinical disease was evidenced by lesions in animals at slaughter that did not have clinical signs. Other factors that increase respirations also may cause signs to appear. Signs include an acute onset of dyspnea and loud guttural inspiratory sounds that can be localized to the lower trachea. Open-mouth breathing, extension of the head and neck, and cyanosis, leading to recumbency and death by asphyxiation, are present. Differential diagnoses for this form include pharyngeal trauma or abscess; necrotic laryngitis; IBR; laryngeal abscess, tumor, foreign object, edema, or paralysis; tracheal foreign object, mass, or collapse; and AIP.

The chronic form occurs in lighter cattle (135 to 400 kg [300 to 900 lb]) and is more common in western plains feedlots. It is also sporadic but less seasonal. Affected animals may have a history of IBR or pneumonia. The main sign is a continuous, frequent, deep, hacking, nonproductive cough. The animal may be unthrifty but is otherwise normal in appearance. The main differential diagnoses are necrotic laryngitis or mild, chronic suppurative pneumonia. Endoscopy and visualization of the lesions subsequently described aid in the diagnosis. Necropsy of the acute form reveals an edematous thickening of the submucosa and mucosa of the dorsal trachea (Color Plate 31.1), as much as 5 cm thick and extending 20 to 30 cm from the midcervical area to the thoracic inlet or tracheal bifurcation. There is also extensive mucosal, submucosal, and peritracheal edema and/or hemorrhage, possibly related at least in part to agonal breathing. There may be no other lesions of the airway or lungs, or abnormalities (e.g., pulmonary edema, bronchitis, interlobular edema and emphysema, alveolar hemorrhage) may be seen. Lesions in the chronic form consist of hyperemia of the mucosa of the caudal third of the trachea, with a thin layer of mucopurulent exudate. The mucosa may have a cobblestone appearance or even large, fiberlike projections and polyps. No effective treatment exists for the chronic form. Corticosteroids (dexamethasone, 0.05 to 0.2 mg/kg IM or IV; prednisolone, 1 to 2.2 mg/kg IM or IV daily) are recommended for the acute form, as are such practices as preventing stress, providing shade, and cooling with water sprays and fans. Opinions are divided regarding the value of antimicrobial therapy. However, because animals with tracheal edema syndrome may be difficult to distinguish clinically from animals with conditions that could respond to antimicrobials (such as necrotic laryngitis), antimicrobials are often administered. Because withdrawal times associated with antimicrobial administration could delay shipment of affected animals to slaughter, drugs with a short withdrawal time should be used if salvage is an option. Tracheostomy may not be helpful if placed proximal to the obstruction, and relief of dyspnea via tracheostomy may require insertion of an endotracheal tube to the tracheal bifurcation. Oxygen administration could be beneficial if available. Recovered patients tend to relapse and should be salvaged.

Lower Respiratory Tract Diseases*

Amelia R. Woolums

Clinical Classification of Pneumonia

Amelia R. Woolums

In an effort to simplify the differential diagnosis of the array of lower respiratory diseases of cattle, a classification system based on pathophysiology and clinical signs can be used:

1. Bronchopneumonia is characterized pathophysiologically by invasion of pathogenic organisms that gain access to the lung through the pulmonary tree. It is characterized clinically by depression, fever, and other signs of sepsis such as hyperemic mucous membranes or scleral injection and by an anterior-ventral distribution of abnormal lung sounds and lesions. Bronchopneumonia is the final outcome of the *respiratory disease complex* of ruminants, and because viruses play an important role in this disease complex, viral causes of respiratory tract disease in ruminants are placed in this category.
2. The interstitial pneumonias are a very diverse group of (usually) noninfectious diseases. Although it is difficult to make generalizations, these diseases are characterized pathophysiologically by an interstitial reaction that usually results from ingestion or inhalation of toxins or allergens. Clinically affected animals tend not to be as depressed and septic, although dyspnea may be severe and disease can be rapidly fatal. Abnormal lung sounds and lesions are diffusely distributed, and there is little or no response to antibiotic therapy.
3. Metastatic pneumonia is characterized pathophysiologically by septic embolization of the lungs from other foci in the body, classically liver abscesses and postcaval thrombi. Clinically, cases of metastatic pneumonia exhibit signs of sepsis as with bronchopneumonia, but with widespread pulmonary lesions and abnormal lung sounds, and the eventual development of hemoptysis (see the Vena Caval Thrombosis and Metastatic Pneumonia section later).

The Bronchopneumonias (Respiratory Disease Complex of Cattle, Sheep, and Goats)

Amelia R. Woolums

The respiratory disease complex of ruminants consists of the single clinical entity of bronchopneumonia or pleuropneumonia

*Previous contributions of John C. Baker and Trevor R. Ames are acknowledged.

VetBooks.ir

but is caused by numerous combinations of infectious agents, compromised host defenses, and environmental conditions. Bronchopneumonia causes greater economic losses than any other disease of feedlot cattle or lambs and is one of the most common causes of mortality in other ruminant populations.

In dairy calves, bronchopneumonia, sometimes called *enzootic pneumonia*, is most common in group-housed calves. It is called *shipping fever* in beef calves because the greatest incidence of bronchopneumonia occurs after shipment to stocker operations or feedlots; the term *bovine respiratory disease* (BRD) or *bovine respiratory disease complex* (BRDC) is also used to describe bronchopneumonia in cattle. Bronchopneumonia also occurs in nursing beef calves, in mature beef or dairy cows, and in young or mature sheep and goats, sometimes in outbreaks that can have significant morbidity and mortality. The infectious agents and risk factors of bronchopneumonia of sheep and goats are similar to those of calves.

Bronchopneumonia of ruminants is a disease of multifactorial causation that occurs when a certain combination of host, environment, and infectious agent characteristics (risk factors) is active. The numerous infectious agents (Boxes 31.3 and 31.4) associated with bronchopneumonia are ubiquitous in ruminant populations, and the bacteria most often associated with pneumonic lesions are part of the normal resident flora of the ruminant nasopharynx. In addition to recognition of the microbial agents that contribute to the development of bronchopneumonia in ruminants, an understanding of the management practices and host factors that also play a role is necessary for developing successful programs of prevention. Management practices and other risk factors for bronchopneumonia are discussed in the Host and Environmental Risk Factors for Undifferentiated Ruminant Respiratory Disease section later.

Infectious Agents Associated With the Respiratory Disease Complex of Cattle, Sheep, and Goats

Etiology Numerous infectious agents have been isolated from cases of bronchopneumonia in ruminants. Although infectious bronchopneumonia of ruminants is usually caused by two or more infectious agents acting together, some agents can also cause significant disease alone. Therefore the clinical and epidemiologic characteristics, means of diagnosis, and treatment and prevention of the infectious agents will be first considered individually. A description of epidemiology, diagnosis, and treatment of "undifferentiated" bronchopneumonia (bronchopneumonia with no specific causative diagnosis attempted) will then follow. The clinical signs, gross pathologic lesions, and recommended methods of diagnosis for the major infectious causes of ruminant respiratory disease are listed in Table 31.14.

Viral Agents

Many different viruses have been identified in nasal secretions or respiratory tissues of cattle, sheep, or goats with or without respiratory disease. Recent development of next-generation sequencing approaches that allow identication of all viral genomes present in a sample (the "virome" or "viral metagenome") has revealed even more, sometimes newly recognized respiratory viruses.[1] Historically, five viruses have been considered the most important contributors to the bovine respiratory disease complex: bovine herpesvirus type 1 (BHV-1), bovine respiratory syncytial virus (BRSV), bovine viral diarrhea virus types 1 and 2 (BVDV1 and BVDV2), and parainfluenza virus

BOX 31.3

Viral Agents Associated With Respiratory Tract Diseases in Ruminants

Bovine

Viruses of Major Importance (Commonly Isolated or Generally Accepted to Be Important Contributors to Ruminant Respiratory Disease)

Bovine herpesvirus type 1 (BHV-1, also known as infectious bovine rhinotracheitis virus [IBRV])
Bovine respiratory syncytial virus (BRSV)
Bovine viral diarrhea virus (BVDV)
Bovine parainfluenza virus type 3 (PIV-3)
Bovine respiratory coronavirus
Alcelaphine herpesvirus types 1 and 2/ovine herpesvirus type 2 (malignant catarrhal fever)

Viruses of Minor Importance (Uncommonly Isolated or of Uncertain Importance in Ruminant Respiratory Disease)

Bovine herpesvirus type 4 (BHV-4)
Bovine adenovirus
Bovine rhinitis virus
Bovine reovirus
Calicivirus
Influenza virus

Ovine and Caprine

Bovine respiratory syncytial virus (BRSV)
Parainfluenza virus type 3 (PIV-3)
Adenovirus
Bluetongue virus
Ovine progressive pneumonia (maedi-visna) virus of sheep[a]
Pulmonary carcinoma of sheep[a]

[a]Cause of chronic progressive respiratory disease.

BOX 31.4

Bacteria, Mycoplasma, Ureaplasma, and Chlamydophila Species Associated With Bronchopneumonia of Cattle, Sheep, and Goats

Bacteria of Major Importance (Commonly Isolated or Generally Accepted to Be Important Contributors to Ruminant Respiratory Disease)

Mannheimia haemolytica
Pasteurella multocida
Histophilus somni
Mycoplasma bovis
Bibersteinia trehalosi
Mycoplasma dispar
Ureaplasma spp.
Mycoplasma ovipneumoniae (sheep and goats only)
Mycoplasma mycoides subsp. *mycoides*, large colony variant (goats)
Trueperella pyogenes (formerly *Arcanobacterium pyogenes*) (secondary opportunistic pathogen)

Bacteria of Minor Importance (Uncommonly Isolated or of Uncertain Importance in Ruminant Respiratory Disease)

Pseudomonas aeruginosa
Escherichia coli
Streptococcus spp.
Staphylococcus spp.
Moraxella spp.
Salmonella spp.
Bacteroides spp. (anaerobe)
Peptococcus indolicus (anaerobe)
Fusobacterium spp. (anaerobe)
Chlamydophila spp.

type 3 (PIV-3). In sheep and goats, BRSV and PIV-3 have been considered important. However, in some recent surveys of cattle or cattle populations with respiratory disease, other viruses have been more prevalent than these five viruses. Also, anecdotal reports suggest that, at least in North America, BHV-1 and PIV-3 are less commonly found in cattle with respiratory disease than they were in the second half of the twentieth century. This may be related to broad population immunity induced by widespread use of vaccines containing these viruses. Thus the relative importance ascribed to the viruses described below may be changing.

Bovine Herpesvirus Type 1 (Infectious Bovine Rhinotracheitis Virus)

Definition and Etiology Bovine herpesvirus type 1 (BHV-1) is an enveloped DNA virus of the family *Herpesviridae*, subfamily *Alphaherpesvirinae*, genus *Varicellovirus*. It is associated with multiple, distinct disease syndromes of cattle that include infectious bovine rhinotracheitis (IBR), conjunctivitis (see Chapter 39), infectious pustular vulvovaginitis (IPV), balanoposthitis, abortion (see Chapter 43), encephalomyelitis (see Chapter 35), and mastitis. Two subtypes have been identified on the basis of restriction endonuclease cleavage patterns. These subtypes are referred to as BHV-1.1 and BHV-1.2; BHV-1.2 can be further divided into BHV-1.2a and BHV-1.2b. Either subtype can cause respiratory or genital disease; only the respiratory manifestations of infection are discussed here. The respiratory form is characterized by rhinitis, tracheitis, and pyrexia and is referred to as IBR. BHV-1 can also cause pneumonia as part of a severe generalized infection in young calves.[2,3] The virus is also of importance in the bovine respiratory disease complex because of its role in enhancing secondary bacterial bronchopneumonia by causing respiratory injury and immunosuppression, as discussed later.

Clinical Signs Clinical signs from infection with BHV-1 alone can range from inapparent to severe. Clinical signs can include any combination of pyrexia, anorexia, sharp drop in milk production in dairy cattle, increased respiratory rate, a slight degree of hyperexcitability, ptyalism, coughing, and nasal discharge that progresses from serous to mucopurulent. Clinical signs of lower respiratory tract infection may be caused by secondary bacterial pneumonia, which is a common sequela

Table 31.14

Clinical and Gross Pathologic Characteristics of Common Infectious Agents That Cause Respiratory Disease in Ruminants

Agent	Species	Clinical Signs[a]	Gross Pathology[a]	Diagnosis
Viruses				
BHV-1 (IBR)	Cattle	Fever, depression, anorexia, serous to mucopurulent nasal discharge, muzzle hyperemia, nasal plaques, coughing, inspiratory stridor (conjunctivitis ± keratitis, abortion)	Congestion; fibrinopurulent exudate of nasal passages, larynx, trachea; in young calves, pneumonia and involvement with other organs	VI or IFA nasal swabs, conjunctival scrapings PS VI, IFA, or IHC of tissue from upper airways or lungs collected at necropsy
BRSV[b]	Cattle, sheep, goats	Fever, depression, anorexia, tachypnea, nasal discharge (±), coughing, expiratory dyspnea, harsh bronchovesicular sounds over cranioventral lung, crackles and wheezes rarely, quiet lung sounds caused by pneumothorax, subcutaneous emphysema	Lobules in cranioventral lung collapsed, firm, dark red; caudodorsal lung fails to collapse, rubbery texture (suggestive of acute interstitial pneumonia); dorsocaudal emphysema	IFA or RT-PCR of nasal swabs (VI unreliable) PS IFA or IHC of lung at necropsy (most reliable in acute stage of disease)
PIV-3	Cattle, sheep, goats	Like BRSV but more mild, commonly asymptomatic; contributes with other agents to enzootic calf pneumonia or shipping fever	Scattered lobules of cranioventral lung collapsed, firm, dark red	VI or IFA of nasal swabs PS VI, IFA, or IHC of lung at necropsy
BVDV	Cattle	Fever, depression, anorexia, nasal discharge, tachypnea, coughing (±); contributes with other agents to enzootic calf pneumonia or shipping fever (diarrhea, abortion, congenital defects, persistently infected calves, hemorrhagic syndrome)	Scattered lobules of cranioventral lung collapsed, firm, dark red	VI, ELISA. or PCR of peripheral blood buffy coat PS VI, IFA, or IHC of lung at necropsy
Respiratory coronavirus[b]	Cattle	Contributes with other agents to enzootic calf pneumonia or shipping fever	Not yet well characterized, probably as for PI3	VI (need special cells) or RT-PCR of nasal swabs PS VI or IFA of lung at necropsy

Table 31.14

Clinical and Gross Pathologic Characteristics of Common Infectious Agents That Cause Respiratory Disease in Ruminants—cont'd

Agent	Species	Clinical Signs[a]	Gross Pathology[a]	Diagnosis
Bacteria				
Mannheimia haemolytica	Cattle, sheep, goats	Fever, depression, anorexia, signs of endotoxemia, tachypnea, evidence of pleural pain, mucoid to mucopurulent nasal discharge, harsh bronchovesicular sounds over cranioventral lung ± crackles (coughing not prominent)	Cranioventral lung lobes firm, dark red to gray-brown; fibrin on pleura; yellow pleural fluid that may be gelatinous; infarct-like (wedge-shaped) lesions sometimes seen	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret) Culture from characteristic lesions at necropsy
Pasteurella multocida	Cattle, sheep, goats	Fever, tachypnea, cough, depression, mucoid to mucopurulent nasal discharge, harsh bronchovesicular sounds over cranioventral lung ± crackles	Cranioventral lobules (sometimes lobes) firm, dark red to purple; purulent exudate in airways; fibrin on pleura not expected	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret) Culture from characteristic lesions at necropsy
Histophilus somni[b]	Cattle, (uncommon in sheep, goats)	As for *P. multocida;* possibly also evidence of pleural pain (joint effusion, infertility or abortion, otitis, conjunctivitis, neurologic signs)	As for *M. haemolytica*, although fibrinous pleuritis not as consistent; fibrinopurulent arthritis, myocarditis often seen in respiratory cases	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret); culture from characteristic lesions at necropsy
Mycoplasma bovis[c]	Cattle	Fever, anorexia, tachypnea, cough, nasal discharge; chronic or ongoing pneumonia that fails to respond as expected to therapy (joint or tendon sheath effusion, otitis, conjunctivitis)	Cranioventral lobules collapsed, firm, dark red; multiple grossly visible raised nodules filled with caseous material (abscesses or caseous necrosis); (fibrinopurulent arthritis, tenosynovitis, or otitis common in respiratory cases; myocarditis or pericarditis)	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret; more meaningful if several in group have positive culture from characteristic lesions at necropsy)

[a]Clinical signs not related to the respiratory system but possibly also prevalent are listed in parentheses. Note that respiratory disease is often caused by two or more agents, so clinical signs and gross pathology in an individual or herd may be any combination of those listed for individual agents.

[b]Agent does not survive transport well or can be difficult to isolate; requires special handling or culture techniques to maximize likelihood of isolation.

[c]Usually need to specifically request tests to isolate mycoplasmas and to specifically identify the species *M. bovis.*

BHV-1, Bovine herpesvirus type 1; *BRSV,* bovine respiratory syncytial virus; *BVDV*, bovine viral diarrhea virus; *ELISA*, enzyme-linked immunosorbent assay; *IBR*, infectious bovine rhinotracheitis; *IFA*, immunofluorescent assay; *IHC*, immunohistochemistry, most commonly used on formalin-fixed lung tissue collected at necropsy; *PCR*, polymerase chain reaction; *PIV-3*, parainfluenza type 3; *PS*, paired serology; *RT-PCR*, reverse transcriptase PCR; *TTA*, transtracheal aspirate; *VI*, virus isolation.

to BHV-1 infection. Severe hyperemia and reddening of the muzzle can occur, which is the reason for the common name of "red nose" to describe BHV-1 infection. Pustules may develop on the nasal mucosa and later form diphtheritic plaques. Conjunctivitis with excessive ocular discharge may be present. Conjunctivitis with corneal opacity can also occur as the principal manifestation of BHV-1 infection and may be misdiagnosed as infectious bovine keratoconjunctivitis (pink eye). Abortions may occur concurrently with respiratory disease, but they can also occur well after infection. Abortions may also occur in cattle that escape serious respiratory disease.

On rare occasions, neonatal calves may suffer from an acute respiratory and/or systemic form of BHV-1 infection characterized by rhinitis, marked lacrimation, inflammation and necrosis of the soft palate, laryngotracheitis, and ulceration of the GI tract.[2,3] Vaccination of calves within 3 days of age with modified live viral vaccines has also been associated with severe, fatal systemic BHV-1 infection.[4] The severity of disease in vaccinated calves was suspected to be caused by lack of maternal antibody and resultant widespread multiplication of the vaccine virus.

Pathogenesis The route of infection is by direct contact with infected cattle or aerosol; apparent transmission by aerosol has been recognized among calves separated by as little as 4 m.[5] At least three of the surface glycoproteins of BHV-1, gC, gD, and gB, mediate attachment to host cells and entry through interaction with heparan sulfate proteoglycans and other host cell proteins. Epithelial cells of the respiratory tract are the initial target of infection after respiratory exposure, and after initial infection the virus can spread intracellularly to neighboring cells. Lymphocytes and monocytes are also susceptible to infection; although infection with these cells produces little virus, they appear to be a means by which the virus reaches extrarespiratory sites after respiratory infection. In severe field cases of BHV-1 infection the virus can be found in multiple organs, including the esophagus, spleen, and liver.[6]

Respiratory disease caused by BHV-1 is mediated by two major mechanisms: (1) direct injury and destruction of infected epithelial cells in the upper respiratory tract and bronchi, with resultant inflammation and increased susceptibility to infection with secondary opportunistic pathogens; and (2)

immunosuppression resulting from dysfunction of neutrophils, lymphocytes, and macrophages. Immunosuppressive actions of BHV-1 include decreased neutrophil chemotaxis and mitogen-induced blastogenesis of lymphocytes, decreased expression of MHC class I molecules, and induction of apoptotic death of lymphocytes and monocytes.[7]

Another important mechanism of pathogenesis of BHV-1 is the ability to establish latent infection.[8] After acute infection, BHV-1 can be found in a latent state in the trigeminal ganglia; the virus may also persist latently in the tonsil.[9] During latent BHV-1 infection, virus is not actively produced in infected cells; thus latently infected cattle do not shed virus. However, an RNA molecule called the *latency related transcript* (LRT) is abundantly produced in latently infected cells, which prevents apoptosis in cells receiving signals that should trigger apoptosis.[8] One or more proteins encoded by the LRT appear to be required for the virus to reactivate from latency. Stress or administration of glucocorticoids causes reactivation of the latent virus, leading to shedding of virus and the possibility of infection of in-contact susceptible animals. Latency appears to occur in effectively all cattle that are infected with BHV-1, thus ensuring that the virus can be spread during times of stress by animals that have been free of clinical disease from BHV-1 infection for months to years. Modified live BHV-1 vaccines are also capable of causing latent infections.[10] Calves that are exposed to BHV-1 when they have moderate levels of circulating maternal antibody can develop latent infection while never showing signs of clinical disease.[11] Latency of BHV-1 is thus an important mechanism by which the virus can persist and spread in a group of cattle.

Epidemiology Studies of antibody prevalence to BHV-1 indicate that infection is widely distributed in the cattle population. Latently infected adult cattle are thought to be the principal reservoirs of infection. Infections of the respiratory tract by BHV-1 are prevalent when large concentrations of beef or dairy cattle are assembled, although BHV-1 does not appear to have an important role in enzootic pneumonia of calves. Decreaed milk production has been linked to subclinical BHV-1 infection in dairy cows.[12] In feedlots, "late breaks" of BHV-1 infection and disease can be seen to occur in cattle previously vaccinated against BHV-1.[13] Although BHV-1 is a relatively genetically stable virus, there is evidence that mutations are occurring in BHV-1 isolates currently circulating in cattle populations, which may help the virus escape host immunity.[13] Although commercially available vaccines can still prevent disease resulting from experimental challenge with modern BHV-1 isolates, viral shedding is increased relative to cattle challenged with older BHV-1 isolates that are more similar to the strains included in vaccines.[13,14] Repeat vaccination later in the feeding period has been recommended to decrease risk of late BHV-1 breaks.[15]

Necropsy Findings IBR is rarely fatal in mature cattle unless it is complicated by secondary bacterial infection of the lung. Lesions include rhinitis, laryngitis, and tracheobronchitis. The mucosa of the nasal passages and trachea can be congested or hemorrhagic. Pustular lesions (sometimes referred to as "plaques") may be observed, and these lesions may coalesce to form adherent necrotic material on respiratory (Color Plate 31.2), ocular, and reproductive mucosa. Usually the inflammatory lesions induced by BHV-1 do not extend into airways contained within the lung, but secondary bacterial bronchopneumonia with the expected pathology is common. Conjunctivitis and, less commonly, keratitis may be present. Esophageal erosions have been identified in severe natural outbreaks.[6] Perinatal infection of calves can lead to fatal systemic disease, with necrotic foci found in the liver, adrenal glands, kidneys, and other organs.[3,4] Although intranuclear inclusion bodies are a feature of herpesvirus infections, they are not a common histologic feature of BHV-1.

Diagnosis BHV-1 can be diagnosed by PCR, virus isolation, immunofluorescent antibody (IFA) testing, or immunohistochemistry (IHC) to identify virus or viral nucleic acid in nasal swabs or conjunctival scrapings antemortem or in tissues collected postmortem. Infection can also be diagnosed by paired serology, with tests for serum neutralizing (SN) antibodies most commonly used.

Treatment and Prevention Cattle infected with BHV-1 should receive supportive care. Good-quality feed and water should be made easily available, and additional stressors such as transport, castration or dehorning, or introducing new cattle to the group should be avoided or postponed. NSAIDs such as flunixin meglumine (1.1 to 2.2 mg/kg IV daily or divided twice daily) may help severely affected individuals maintain water and feed consumption. Administration of antimicrobials to treat or prevent secondary bacterial pneumonia may be appropriate (Table 31.15), although these are not invariably required. Steroids should not be administered. Because protective immunity develops rapidly after either intranasal or IM vaccination,[16,17] BHV-1 vaccination in the face of an outbreak may help limit disease, although the efficacy of this practice has not been tested in a controlled study.

Efforts to prevent BHV-1 infection should include practices that optimize host immunity and avoiding management practices that put cattle at risk, such as mixing newly introduced cattle with established populations. Many brands of inactivated and attenuated BHV-1 vaccines for SC or IM administration are commercially available; products that contain BHV-1 alone or in combination with other pathogens are available. Modified live vaccines are also available for intranasal administration; intranasal vaccines also include PIV-3 with or without BRSV. Vaccination to prevent disease due to BHV-1 infection is discussed in detail in Chapter 48. It is important to remember that vaccination can complicate efforts to identify viruses that may be causing outbreaks of bovine respiratory disease. It appears that live virus is more likely to be shed from cattle vaccinated with modified live vaccines given intranasally, as compared to vaccines given by injection.[18] However, viral DNA can be identified by PCR of nasopharngeal swabs or transtracheal aspirates for 28 days after cattle are vaccinated either intranasally or subcutaneously with modified live virus vaccine.[19] This makes it difficult to interpret the results of PCR testing of respiratory samples when trying to diagnose BHV-1 infection in cattle that have been recently given modified live vaccines.

Other Herpesviruses

Bovine Herpesvirus Type 4

Bovine herpesvirus type 4 (BHV-4) is in the subfamily *Gammaherpesvirinae*, genus *Rhadinovirus;* therefore it is serologically distinct from BHV-1. The seroprevalence of BHV-4 is high in the cattle population of the United States, and it has been implicated in several disease conditions of cattle, including reproductive disorders (abortions and metritis), mammillitis, enteric disease, and respiratory disease. However, BHV-4 can also be isolated from apparently healthy cattle. The role of BHV-4 in bovine respiratory disease has not been well defined.

Herpesviruses Causing Malignant Catarrhal Fever

Malignant catarrhal fever (MCF) is a sporadic disease of cattle with systemic manifestations that can include signs of respiratory disease. In North America, MCF is usually caused by ovine herpesvirus type 2, a gammaherpesvirus acquired by cattle exposed to sheep shedding the virus. MCF can also occur in cattle infected with alcelaphine herpesvirus types 1 and 2 or other related viruses, which can be acquired by exposure

Table 31.15

Antimicrobials Approved by the U.S. Food and Drug Administration for Treatment of Bovine Respiratory Disease

Antimicrobial	Label Dose	Route of Administration	Treatment Interval	Slaughter/Milk Withdrawal	Approved for Control of BRD? (Metaphylaxis)	Approved for Sheep and Goats?
Long-Acting Preparations						
Ceftiofur crystalline free acid[a] (Excede)	6.6 mg ceftiofur equivalent/kg (1.5 mL/45 kg)	SC in the ear	Once	13 days/0 days	Yes	No
Danofloxacin[b] (Advocin)	8 mg/kg	SC	Once	4 days/not approved	No	No
	6 mg/kg	SC	48 h (no more than 2 doses total)	4 days/not approved	No	No
Enrofloxacin[b] (Baytril 100)	7.5-12.5 mg/kg	SC	Once	28 days/not approved	Yes (7.5 mg/kg dose only)	No
Florfenicol (Nuflor)	20 mg/kg	IM	48 h	28 days/not approved	No	No
	40 mg/kg	SC	Once	38 days/not approved	Yes	No
Florfenicol (Nuflor Gold	40 mg/kg	SC	Once	44 days/not approved	No	No
Gamithromycin (Zactran)	6 mg/kg	SC	Once	35 days/not approved	Yes	No
Oxytetracycline (Liquamycin LA-200	20 mg/kg	IM, IV, SC	48-72 h	28 days/96 h	No	No
Oxytetracycline (Tetradure 300)	30 mg/kg	IM, SC	Once	28 days/not approved	Yes	No
Tildipirosin (Zuprevo)	4 mg/kg	SC	Once	21 days/not approved	Yes	No
Tilmicosin (injectable: Micotil 300)	10-15 mg/kg	SC	Once	42 days/not approved	Yes	Sheep; toxic to goats
Tulathromycin (Draxxin)	2.5 mg/kg	SC	Once	18 days/not approved	Yes No	No
Preparations for Daily Use						
Ampicillin (Polyflex)	4.4-11 mg/kg	IM	24 h	6 days/48 h	No	No
Ceftiofur sodium[a] (Naxcel)	1.1-2.2 mg/kg	IM, SC (cattle) IM (sheep and goats)	24 h for 3 days, with 2 more days allowed if not yet recovered	Cattle: 4 days/0 days Sheep and goats: 0 days/0 days	No	Yes
Ceftiofur HCl[a] (Excenel RTU)	1.1-2.2 mg/kg	IM, SC	24 h for 3 days, with 2 more days allowed if not yet recovered	3 days/0 days	No	No
	2.2 mg/kg	IM, SC	48 h for 2 doses total	3 days/0 days	No	No
Enrofloxacin[b] (Baytril 100)	2.5-5 mg/kg multiday therapy	SC	24 h for 3 days, with 2 more days allowed if clinical improvement	28 days/not approved	No	No
Erythromycin (Gallimycin-100)	9 mg/kg	IM	24 h	6 days/not approved	No	Sheep
Oxytetracycline(various preparations)	6.6-11 mg/kg	IV,[c] IM,[c] SC[c]	24 h	Varies with preparation	No	Not for injection[d]
Procaine penicillin G (various preparations)	6600 U/kg (22,000 U/kg)[e]	IM	24 h	Varies with preparation	No	Sheep
Sulfadimethoxine (Albon, Di-Methox)	55 mg/kg, initial treatment 27.5 mg/kg thereafter	IV, PO	24 h	Varies with preparation	No	No
Tylosin (Tylan-200)	17.6 mg/kg	IM	24 h	21 days/not approved	No	No

Note: Many of the drugs listed in this table are not approved for use in veal calves; some are not approved for use in lactating dairy cattle.

[a]In cattle, use of an extralabel dose level, frequency, duration, or route prohibited by law.

[b]Extralabel use in food animals prohibited by law.

[c]Varies with preparation.

[d]Oxytetracycline is labeled for administration to sheep in feed; not a recommended route for treatment of respiratory disease.

[e]Dose that has been shown to be more effective than label-approved dose. Higher dose can be given by the same route of administration and with the same treatment interval, but use of extralabel dosages must comply with the Animal Medicinal Drug Use Clarification Act (AMDUCA) and withdrawal times must be extended.

BRD, Bovine respiratory disease; *IM*, intramuscular; *IV*, intravenous; *PO*, oral; *SC*, subcutaneous.

to infected exotic hoofstock. MCF is discussed in detail in Chapter 32.

Bovine Respiratory Syncytial Virus

Definition and Etiology Bovine respiratory syncytial virus (BRSV) is an enveloped RNA virus recently moved from the family *Paramyxoviridae* to the new family *Pneumoviridae*, genus *Orthopneumovirus*.[20] This virus is named for the characteristic cytopathic effect it produces in vitro and in vivo, which is the formation of syncytial cells. BRSV shares many similarities in its biology and epidemiology with the human respiratory syncytial virus (HRSV), a common respiratory pathogen of humans with particular importance in disease of young children and the elderly. Although BRSV and HRSV are closely related, they are distinct viruses. BRSV has also been isolated from sheep and goats with respiratory disease. Research suggests that ovine respiratory syncytial virus (also known as ovine pneumovirus) may be distinct from HRSV and BRSV, whereas caprine respiratory syncytial virus (also known as caprine pneumovirus) may be more closely related to BRSV.[21] A European serologic survey undertaken to determine whether nonbovine species were likely to harbor BRSV infection found that only goats, in addition to cattle, were commonly seropositive.[22] These results indicate either that goats are commonly infected with BRSV or that antigenic similarities between caprine respiratory syncytial virus and BRSV led to production of cross-reactive antibodies in many goats. In spite of minimal to moderate differences among BRSV isolates at the genetic level, isolates can differ notably in their reactivity, with monoclonal antibodies directed against individual BRSV proteins; this indicates that apparently minor genetic differences could lead to changes that allow the virus to evade host immunity. Genetic variability is evident in BRSV isolates collected over several decades, and BRSV isolates commonly included in commercial vaccines can differ a relatively large amount from isolates collected from recent natural outbreaks.[23,24] Studies have also shown that genetic differences in BRSV isolates can be grouped by geographic origin, with some European isolates differing to a notable degree from isolates from the United States or Japan.[23] These changes appear to be driven by vaccination; thus commercial vaccines may need to be reformulated periodically to include BRSV similar to isolates currently circulating.

Clinical Signs Clinical signs of BRSV infection alone can vary from inapparent to severe in an infected group of cattle. Signs of disease are limited to the respiratory system. Infected animals may display elevated rectal temperature, depression, decreased feed intake, elevated respiratory rates, ptyalism, cough, and nasal and lacrimal discharges. Signs of disease may progress rapidly, and early signs may be missed. Thoracic auscultation may reveal increased bronchial and bronchovesicular sounds; fine crackles or wheezes may be heard, particularly in the middle or dorsocaudal lung fields. Absence of bronchovesicular sounds may be noticed in the dorsal or dorsocaudal lung fields if an emphysematous bulla is present, or if a bulla has ruptured, leading to pneumothorax. In later stages of the disease, dyspnea can become pronounced and is characterized by increased expiratory effort and mouth breathing. Subcutaneous emphysema and intermandibular edema are sometimes noted. Dramatic reduction in milk production has been reported in dairy cattle. Duration of disease is variable (1 to 2 weeks). A biphasic clinical course has been described but does not appear to be a consistent finding. Infection can also cause clinical signs of respiratory disease in sheep, goats, and deer; however, the severe clinical signs, including dyspnea and subcutaneous emphysema, which are sometimes seen in cattle and suggest AIP, do not seem to be seen in small ruminants or cervids.

Pathogenesis The means of transmission appears to be contact with infected cattle and aerosols. Fomites such as bottles and buckets are also a likely means of transmission, as HRSV is spread by fomites. The incubation period is 3 to 5 days. Infection with BRSV can cause bronchitis, bronchiolitis, alveolitis, and interstitial pneumonia, leading to clinical signs referable to small airway and alveolar disease, including expiratory dyspnea, auscultable wheezing, and hypoxemia. The virus causes epithelial cells to fuse, resulting in the characteristic multinucleated cells, or syncytia, which are seen in airways and alveoli. Epithelial cells, which may undergo apoptosis after BRSV infection, slough into the lumen of airways and are phagocytized by neutrophils or alveolar macrophages. Infection of alveolar macrophages and circulating peripheral blood mononuclear cells occasionally occurs,[25,26] and BRSV infection of macrophages decreases important functions of these cells, including Fc receptor expression, phagocytosis, phagosome-lysosome fusion, and production of factors that induce neutrophil chemotaxis.[27,28]

The severity of disease after BRSV infection is related to host immunity. Both humoral and cell-mediated immunity contribute to protection. Clinical signs of infection are less severe in animals with moderate to high levels of serum antibody against BRSV,[29,30] and more extensive pathology is seen in calves depleted of CD8+ T cells before infection.[31] Protection after intranasal vaccination is related to rapid onset of BRSV-specific IgA production in nasal secretions,[32] indicating that mucosal immunity is likely also important in protection against naturally occurring disease. Host immunity after exposure to BRSV can minimize disease, and clinical signs are usually the most noticeable in calves younger than 6 months of age. However, very young calves are not necessarily most likely to have the most severe disease; clinical signs after experimental infection were less severe in 1-day-old calves than in 6-week-old calves, apparently due to a less robust inflammatory response in younger calves.[33] Ruminants appear to be susceptible to reinfection with BRSV throughout their lives, and adult cattle can develop severe disease after BRSV infection.[34,35] Because genetic variability among BRSV isolates is not great, reinfection does not seem to be largely due to viral strain variation. It appears that natural infection does not confer lifelong immunity, and some cattle may be reinfected annually,[36] although clinical signs are not always apparent.

Although host immunity can protect ruminants from severe disease after BRSV infection, the host immune response can also contribute to disease. Cattle with severe disease after natural infection have a higher proportion of degranulated mast cells in their lungs than less severely affected cattle,[37] indicating that mast cell mediators contribute to physiologic and pathologic changes seen in severe cases. In experimentally challenged cattle, BRSV-specific IgE has been associated with disease severity.[38] Exposure to the fungus *Saccharopolyspora rectivirgula* (formerly *M. faeni*), the spores of which induce pulmonary hypersensitivity in cattle and other species, enhanced BRSV-specific IgE production in calves,[38] indicating that environmental allergens can affect the immune response to BRSV infection. Calves infected with BRSV before infection with *Histophilus somni* developed higher levels of *H. somni*–specific serum IgE than did calves infected with *H. somni* alone.[39] Thus BRSV infection can lead to production of virus-specific IgE, which may be enhanced by coexposure to allergens, and BRSV infection may also increase IgE production in response to infection with other agents. Crosslinking of IgE bound to mast cells by binding of BRSV or other specific antigen is expected to lead to mast cell degranulation and subsequent bronchoconstriction, pulmonary edema, and other sequelae of mast cell mediator release and immediate hypersensitivity.

Other evidence that BRSV can trigger immunopathogenesis is the fact that certain BRSV vaccines have on rare occasion

VetBooks.ir

been shown to cause enhanced disease when vaccinated animals are subsequently infected with BRSV. Vaccine-enhanced disease has been seen after both natural[40,41] and experimental infection.[42,43] It appears that the dose of BRSV protein, the adjuvant included in the vaccine, and probably also other factors related to the formulation of the vaccine and the genetics of vaccinated cattle determine whether enhanced disease is likely after infection of cattle given a particular BRSV vaccine. Apparent vaccine-enhanced disease was reported in cattle that received a modified live vaccine in the early stage of a natural BRSV outbreak, which suggests that BRSV vaccination in the face of a BRSV outbreak could be harmful.[40] It is important to note that BRSV vaccines are commonly used, and vaccine-enhanced disease is rarely reported; thus vaccination is still recommended as part of any plan to control disease caused by BRSV. Many gaps exist in our understanding of what aspects of the immune response contribute to disease severity after BRSV infection or vaccination. Most research completed to date has focused on enhanced disease in calves that received formalin-inactivated BRSV. The data suggest that when enhanced disease occurs in calves vaccinated with formalin-inactivated BRSV, it is related to a relatively strong response by T-helper type 2 (Th2) cells, as evidenced by decreased production of the Th1 prototype cytokine interferon gamma,[44] increased production of BRSV-specific IgE,[45] and pulmonary eosinophil infiltration.[42] The association of BRSV-specific IgE production with disease severity in some experimental studies indicates that at least some individual ruminants will produce IgE after BRSV vaccination or infection, which may contribute to severe disease in these individuals.

The presence of co-infection with other pathogens such as *M. haemolytica* or bovine viral diarrhea virus (BVDV) can also increase the severity of disease after BRSV infection. Although genetic variation among BRSV isolates is not extensive, experimental challenge with certain isolates of BRSV can lead to serious disease, whereas challenge with other isolates leads to only minimal disease. This indicates that, despite limited differences among viral isolates at the genetic level, variation among BRSV isolates may still contribute to variations in disease severity.

Epidemiology

Prevalence of antibodies to BRSV in the cattle population of the United States ranges from approximately 60% to 80%. Seropositive sheep, goats, and deer are commonly identified in domestic or wild populations, confirming that infection occurs in these species. Cattle of any age are susceptible to disease following BRSV infection. BRSV was demonstrated to be involved in 14% to 71% of respiratory disease outbreaks in North American and European studies of calf pneumonia outbreaks involving several farms. In a recent survey of more than 1300 dairy herds in Norway, herd size, geographic location, and closer proximity to neighboring herds were related to increased risk for a herd to have evidence of BRSV exposure, based on antibodies in bulk tank milk.[46] Herds that were positive for BRSV antibodies in bulk tank milk were more likely also to be positive for antibodies to bovine coronavirus. Seroconversion to BRSV has been significantly associated with treatment for respiratory disease in feedlot cattle,[47] and cattle with low antibody titers to BRSV at feedlot entry have increased risk of developing disease.[48] Although feedlot cattle are commonly infected with BRSV after arrival, a survey of necropsy findings at 72 Canadian feedlots found BRSV at postmortem of only 11% of the cattle that died or were euthanized because of pneumonia.[49] The low rate of isolation at necropsy suggests that if the virus contributes to disease in feedlot cattle, it is often no longer present by the time the animal dies or is euthanized. In general, morbidity rate tends to be high in outbreaks of BRSV, whereas case fatality rate is variable, ranging from 0% to as high as 20%.[50]

Cattle are most likely the principal reservoirs of infection, although a European serologic survey of different species found that goats were also often seropositive,[22] indicating that goats may be a source of BRSV infection for cattle, and vice versa. The mechanism by which BRSV persists in the cattle population is not known. Possibly a similar epidemiologic pattern to that described for HRSV also exists for BRSV. HRSV is capable of reinfecting the host throughout his or her life, with the most severe disease occurring in the very young or elderly. Subsequent exposure results in mild upper respiratory tract disease. Similarly, adult cattle may periodically undergo subclinical to mild infections and serve as a source of infection for susceptible young stock. However, one study concluded that transmission among seropositive cattle was not a plausible mechanism of BRSV persistence in a dairy herd.[51] These authors suggested that persistent BRSV infection in individuals is a more plausible explanation of population persistence of BRSV. BRSV has been identified in B lymphocytes in tracheobronchial and mediastinal lymph nodes of calves 71 days after experimental infection,[52] so it may be that individual cattle harbor the virus long term and periodically begin shedding it, allowing it to periodically reappear in herds even if they are closed to new introductions.

Necropsy Findings

Grossly, in cattle that die or are euthanized after BRSV infection, individual cranioventral lobules may appear dark and collapsed because of atelectasis or consolidation. Dorsocaudal lung often fails collapse and may have a rubbery texture suggesting AIP. In severe cases, interstitial or bullous emphysema is often present in the dorsocaudal lung (Color Plate 31.3). Pathologic emphysema must be differentiated from that sometimes caused by agonal breathing of cattle. Histologic lesions depend on the stage of infection. Neutrophilic and later mononuclear bronchitis, bronchiolitis, and alveolitis are present in infected animals. Syncytial cells may be seen in the airways or alveoli; intracytoplasmic inclusion bodies are rarely present. BRSV infection can cause lesions consistent with AIP; therefore differential diagnoses for the typical gross lesions include other causes of AIP (see the Feedlot Acute Interstitial Pneumonia section later in this chapter). Histologic changes consistent with AIP include alveolar epithelial hyperplasia, hyaline membrane formation, and interstitial inflammatory cell infiltrate, hemorrhage, and edema. Later, evidence of chronic bronchitis and bronchiolitis obliterans can be found.

Diagnosis

Infection is diagnosed by identification of the virus in nasal secretions, tracheal aspirates, or lung lavage fluid from live calves or in lung tissue collected postmortem. BRSV is difficult to isolate, as it does not survive transport well; thus methods of identification that do not require the virus to be alive (such as IFA, IHC, and RT-PCR) are preferable to virus isolation for the identification of BRSV. IHC of formalin-fixed tissue is convenient because the virus can be identified in tissue processed for histopathologic evaluation. Although virus is readily identifiable in the first days after infection, virus is less likely to be found by 10 to 15 days postinfection, even when lung tissue collected postmortem is tested by IHC.

Seroconversion as evidenced by paired serology also supports a diagnosis; virus neutralization or ELISA assays are most commonly used to identify BRSV-specific antibody. In live cattle, the arterial partial pressure of oxygen (PaO_2) is highly negatively correlated with the extent of lung pathology.[53]

Treatment and Prevention

Treatment of BRSV is supportive and aimed at limiting the inflammatory response in bronchioles and alveoli and preventing secondary bacterial infection. Antiinflammatory therapy with NSAIDs (such as flunixin meglumine at 1.1 to 2.2 mg/kg IV daily or divided

twice daily) is considered appropriate. Administration of one or two doses of steroid therapy (dexamethasone, 0.05 to 0.2 mg/kg IV or IM once or twice) is appropriate in selected individuals with severe respiratory distress or evidence of AIP. Antimicrobials to treat or prevent secondary bacterial infection may be indicated, although these are not invariably required. For rare individuals with severe signs suggesting AIP, insufflation with intranasal oxygen, if available, and diuretic therapy with furosemide (0.5 to 1 mg/kg IM or IV once or twice daily) may be helpful. Although the prognosis for animals with uncomplicated BRSV infection is good, the prognosis for animals with AIP is guarded. Animals with severe respiratory distress should be handled with care, as even careful manipulation to administer treatment can lead to rapid respiratory decompensation and death.

Both modified live and inactivated BRSV vaccines for intramuscular or subcutaneous administration are commercially available, as are modified live multivalent vaccines for intranasal administration. More information on the use of vaccines to prevent disease due to BRSV is presented in Chapter 48. There is no respiratory syncytial virus vaccine licensed for use in small ruminants, although BRSV vaccines ares sometimes administered to sheep or goats in an extralabel manner. Controlled studies of the effects of BRSV vaccines licensed for cattle on respiratory disease in sheep or goats have not been published.

Bovine Viral Diarrhea Virus

BVDV is an enveloped RNA virus of the genus *Pestivirus* in the family *Flaviviridae*. A wide spectrum of disease has been associated with BVDV infection, including subclinical infection, bovine viral diarrhea and mucosal disease (see Chapter 32), immunosuppression, repeat breeding problems, abortion, fetal mummification (see Chapter 43), congenital defects, immunotolerance, and persistent infections. Only the contribution of this virus to respiratory disease is discussed here.

Historically the role of BVDV in the bovine respiratory disease complex was controversial, but research provides good evidence that the virus contributes to bovine respiratory disease and related decreased productivity of cattle in the field in at least some cases. Experimental challenge of cattle with BVDV alone can lead to mild pneumonia,[54] and occasionally herd outbreaks of BVDV are first identified by the presence solely of signs that are likely to be interpreted as evidence of respiratory disease, such as fever, tachypnea, and loud bronchovesicular sounds.[55] Experimental infection studies have also shown that respiratory disease caused by *M. haemolytica*, BHV-1, or BRSV is significantly more serious when cattle are co-infected with BVDV. This synergistic effect of BVDV with other respiratory pathogens is believed to be a result of immunosuppression caused by BVDV, which is discussed in detail in Chapter 32. The ability of BVDV to cause respiratory disease appears to depend in part on the strain of infecting virus.[56,57]

Studies of naturally occurring bovine respiratory disease have shown that in some situations BVDV can be isolated from a majority of cattle affected with shipping fever pneumonia, particularly in association with *M. haemolytica*[49] or in association with *Mycoplasma bovis* in animals with chronic pneumonia.[58] Seroepidemiologic studies have also indicated an association of BVDV with respiratory disease. The most convincing data have come from studies of calves purchased and assembled at sale barns for shipment to feedyards across several states.[59] In 2 consecutive years BVDV was significantly more likely to be isolated from calves that were treated for respiratory disease than calves in the same group that were not treated; calves treated for respiratory disease were also significantly more likely to seroconvert to BVDV than penmates who were not treated for respiratory disease.

In addition to contributing directly to bovine respiratory disease by infecting the respiratory tract and enhancing the pathogenicity of co-infecting bacteria or viruses, BVDV may also contribute to respiratory disease by impairing the ability of cattle to respond properly to vaccination against other respiratory pathogens. Calves infected with BVDV before BHV-1 vaccination shed BHV-1 longer after subsequent BHV-1 infection than calves that were not co-infected with BVDV.[60] In another study, calves persistently infected with BVDV failed to develop a serologic response to a *M. haemolytica* vaccine, in contrast to control animals not infected with BVDV.[61]

In summary, BVDV infection is significantly associated with the development of bovine respiratory disease in some cases. Although experimental challenge studies indicate that BVDV may cause mild respiratory disease when acting alone, the virus appears to contribute most importantly by impairing the host's ability to resist infection and limit disease caused by other pathogens.

Bovine Parainfluenza Virus 3

Definition and Etiology Bovine parainfluenza virus 3 (PIV-3) (also known as bovine respirovirus 3) is an enveloped RNA virus classified in the family *Paramyxoviridae*, genus *Respirovirus*. The virus has been associated with respiratory tract disease in cattle, sheep, and goats. It hemagglutinates and hemadsorbs red blood cells of certain species, which means that serum antibodies can be identified by hemagglutination inhibition assays. Variation in virulence among strains of PIV-3 has been reported, with types A, B, and C being characterized.[62] Naturally circulating isolates appear to be diverging genetically from strains in vaccines, likely due to immune pressure associated with vaccination.[62,63] Significant similarities between bovine PIV-3 and human PIV-3 have led to efforts to use bovine PIV-3 as a modified live intranasal vaccine for humans.[64]

Clinical Signs Uncomplicated PIV-3 infections result in mild signs of disease at most. Clinical signs, if present, may include fever, cough, nasal and ocular discharge, increased respiratory rate, increased bronchovesicular sounds, and wheezes. The most important role of PIV-3 is in predisposing the respiratory tract to subsequent infection by other viruses and bacteria such as *Mannheimia (Pasteurella) haemolytica*. Severity of signs increases with the development of secondary bacterial pneumonia, and if death occurs it is usually the result of secondary bacterial infection. Infection with PIV-3 is widespread in sheep and goats. Only one serotype of ovine PIV-3 has been identified, and it is related to but distinct from the bovine strain. Most infections are inapparent to mild.

Pathogenesis Infection with PIV-3 can lead to signs referable to both upper and lower respiratory tract infection. After experimental infection of calves, clinical signs are evident by 2 days post infection, and signs peak at 4 days post infection. Virus is found in the nasal passages, trachea, and bronchiolar and alveolar epithelial cells. The virus damages the pulmonary mucociliary apparatus[65] and depresses several important functions of alveolar macrophages such as Fc receptor expression, phagocytosis, and microbicidal activity,[66] which likely predisposes infected animals to secondary bacterial pneumonia.

Epidemiology The widespread prevalence of antibodies to PIV-3 indicates that it commonly circulates in ruminant populations. A recent survey of unvaccinated ungulates in one U.S. state indicated that circulating PIV-3 strains may be diverging antigenically from the strains included in vaccines.[63] Inapparent or subclinical infections with PIV-3 are common; in one report, 28 groups of calves seroconverted to PIV-3 over 8 months, but respiratory disease was seen in association with PIV-3 infection in only four of these groups.[67] Infection appears

VetBooks.ir

to spread rapidly in susceptible cattle housed at high population densities and in close contact. Feedlot cattle commonly seroconvert to PIV-3 soon after feedlot arrival, and seroconversion has been associated with treatment for respiratory disease in some[48] but not other[47] cases. In spite of the fact that feedlot cattle frequently become infected with PIV-3 after feedlot entry, a survey of necropsy findings at 72 Canadian feedlots found PIV-3 at postmortem examination in only 4% of the cases with pneumonia.[49] The low rate of isolation at necropsy suggests that if the virus contributes to the development of pneumonia, it may no longer be present by the time the animal dies.

Necropsy Findings Lesions of PIV-3 infection alone are rarely seen during postmortem examination of naturally affected cases. Experimental PIV-3 infection results in congestion of the respiratory mucosa, swelling of lymph nodes associated with the respiratory tract, and lobular consolidation concentrated in the cranioventral lung.[68] Bronchiolitis and alveolitis are seen histologically with both proliferative and degenerative changes in the epithelial cells of the bronchioles and alveoli. Syncytia and intranuclear and intracytoplasmic inclusion bodies may be seen. In many respects, pathologic features of experimental PIV-3 infection are similar to but more mild than those caused by BRSV.

Diagnosis PIV-3 can be identified by virus isolation or RT-PCR of nasal swabs from infected animals. Unlike BRSV, which is also a paramyxovirus, PIV-3 is not particularly difficult to isolate. Diagnosis can also be confirmed with paired serology, with virus neutralization or hemagglutination inhibition assays most commonly used.

Treatment and Prevention There is no specific treatment for infection with PIV-3; as described for BHV-1 and BRSV, supportive care is indicated. Other management practices to prevent or control respiratory disease in calves or feedlot cattle are also appropriate.

Both inactivated and modified live multivalent vaccines containing PIV-3 with other viruses are available for parenteral administration, and modified live vaccines containing PIV-3 and BHV-1, with or without BRSV, are available for intranasal administration; these vaccines are labeled for use in cattle but not in sheep or goats. More information regarding the use of vaccines to control disease due to parainfluenza virus infection is presented in Chapter 48.

Bovine Coronavirus

Definition and Etiology Bovine coronavirus (BCoV) is an enveloped positive-sense RNA virus in the family *Coronaviridae*, genus *Betacoronavirus*, species *Betacoronavirus 1*. Other coronaviruses also classified in the species *Betacoronavirus 1* include equine coronavirus, porcine hemagglutinating encephalomyelitis virus, and human coronavirus OC43, one of the causes of the common cold. Although BCoV is not zoonotic, the virus is thought to have evolved from a human coronavirus, possibly in the late nineteenth century.[69] BCoV causes calf diarrhea and winter dysentery, and the virus also has been associated with respiratory disease outbreaks in calves and feedlot cattle. Sequencing of the gene encoding the spike (S) protein, which the virus uses to attach to and enter host cells, indicates that recent isolates from outbreaks of respiratory disease, winter dysentery, and hemorrhagic colitis in postweaned calves are divergent from older calf diarrhea isolates, including one BCoV included in a modified live virus vaccine currently marketed for control of calf diarrhea.[70,71] It has been postulated that BCoV is evolving over time and now is more prone to causing respiratory disease while also causing enteric disease—a "pneumoenteric" tropism. Outbreaks of respiratory disease associated with BCoV infection are usually due to a single dominant genotype. Recent studies in Scandinavia indicate that strains circulating on farms in a region can be genetically closely related, with more than 95% similarity in the sequence of the S gene.[69]

Antibodies to older BCoV isolates can cross-react with more recent isolates but incompletely; thus animals vaccinated with the modified live vaccine for control of calf diarrhea may not be completely protected from newer genetically divergent isolates.

Clinical Signs Infection with BCoV has been associated with outbreaks of calf diarrhea (Chapter 20) and winter dysentery (Chapter 32), as well as respiratory disease in dairy and beef calves and feedlot and stocker cattle. Although it has long been known that BCoV can be identified on nasal swabs collected from calves with signs of respiratory disease or diarrhea, the role of BCoV as a "cause" of bovine respiratory disease has been controversial. Calves with diarrhea due to BCoV infection can shed the virus in nasal secretions as well as feces (though not always from both sites at the same time) in the absence of signs of respiratory disease. Moreover, experimental infection of seronegative naive calves can reliably cause diarrhea but inconsistently leads to respiratory disease, with respiratory signs being mild at most. This failure to clearly fulfill Koch's postulates has contributed to skepticism regarding BCoV as a cause of bovine respiratory disease. However, one group of researchers used Evans' criteria of causation to support a role for BCoV in feedlot respiratory disease.[72] A relevant role for BCoV in bovine respiratory disease has also been inferred by identification of BCoV in multiple animals during acute respiratory disease outbreaks,[72,73] by identification of BCoV infection or seroconversion as a significant risk factor for respiratory disease in individuals or herds,[74-76] or by finding cattle with preexisting serum antibodies to BCoV to be protected from respiratory disease when seronegative cattle are not.[77] However, other studies have failed to identify a relationshiop between BCoV infection or seroconversion and respiratory disease. At this time it seems that BCoV is likely a contributor to bovine respiratory disease outbreaks in some cases, but finding the virus may not mean that it is the primary cause of disease. Variation in respiratory virulence among BCoV strains may be important, but if so the features that make a strain more or less likely to cause respiratory disease have not yet been defined.

Clinical signs of respiratory disease attributed to BCoV are nonspecific and may include fever, nasal discharge, rapid respiratory rate, and coughing. Rectal temperatures may be high (up to 107° F [41.7° C]). Although mortality rates in uncomplicated outbreaks are usually low, secondary bacterial infection due to *Mannheimia haemolytica*, *Histophilus somni*, or other opportunistic respiratory pathogens can lead to fatal disease in multiple individuals.[78,79] Coinfection with other respiratory viruses may also occur.

Pathogenesis The lack of a reliable experimental model of respiratory disease following BCoV infection, as well as the fact that fatal, naturally occurring cases are typically affected by secondary bacterial infection, makes it difficult to clearly define the pathogenesis of respiratory disease specifically due to BCoV infection. The virus infects respiratory epithelial cells, presumably inducing a host response that leads to clinical signs of airway inflammation. Infection of respiratory epithelial cells may increase susceptibility of cattle to secondary bacterial infection through inhibition or the mucociliary elevator.

Epidemiology Respiratory disease has been attributed to BCoV infection in dairy calves,[74] preweaning beef calves,[75] and feedlot and stocker cattle.[79] Coronaviruses similar to

BCoV have also been identified in wild ruminants, cervids, and camelids,[80] suggesting that cross-infection among different species may be possible. In dairy calves and preweaning beef calves the virus appears to contribute to enzootic pneumonia as well as to epizootics (outbreaks) of variable morbidity and usually low mortality. Two naturally occurring outbreaks of respiratory disease (shipping fever) attributed to BCoV in feedlot cattle were described in a detailed report.[79] In these outbreaks, characterized by high morbidity and mortality, BCoV was isolated from the nasal passages of more than 80% of the cattle in the early stages of the outbreaks. No other respiratory viruses were identified in most of the cattle, but *M. haemolytica* was also isolated from a majority of cattle as the two epizootics progressed. In another report, calves with low antibody titers to BCoV at feedlot entry were more likely to be treated for respiratory disease than calves entering the feedlot with higher titers.[77] Other researchers have commonly found the virus when cattle are sampled soon after feedlot entry.[81] Moreover, it is common for a majority of cattle to have serum antibody titers to BCoV at feedlot arrival or to seroconvert soon after arrival; therefore it is clear that cattle are often infected with BCoV shortly before or after feedlot entry.[81-83] However, seroconversion or viral shedding has not always been significantly associated with treatment for respiratory disease.[83]

Surveys of antibodies in pooled milk samples or bulk tank milk on dairies indicated that large herd size, geographic location, and closer proximity to neighboring herds were risk factors for BCoV exposure.[46,84] Dairy herds positive for BCoV antibodies in bulk tank milk were more likely also to be positive for antibodies to BRSV. Genetically identical isolates can be isolated from different dairies in a region in the same period, suggesting that the BCoV may transfer between some farms by the sale of cattle or on fomites.[71] However, it has also been shown that farms in an area may remain free from BCoV infection when the virus is circulating on nearby farms.[84]

Necropsy Findings Following experimental infection, BCoV can be found in epithelial cells of the nasal passages and lung.[85] Grossly, small areas of cranioventral lobular collapse may be seen.[86] In naturally occuring cases of fatal disease, pathologic changes consisent with secondary bacterial infection will likely obscure any changes primarily attributable to BCoV.

Diagnosis BCoV is most commonly identified by PCR in respiratory secretions or tissues collected at postmortem. The virus is not easy to isolate; standard cell lines used for isolation of other respiratory viruses are often not permissive to BCoV, but the virus can be isolated on human rectal tumor-18G cell lines.[87]

Treatment and Prevention As for other respiratory viruses, there is no specific treatment for BCoV infection; supportive care as described for BHV-1 and BRSV is indicated. Although licensed vaccines labeled for the prevention or control of respiratory disease due to BCoV are not currently marketed in the United States or Canada, vaccines labeled for control of calf diarrhea due to the virus are available. A research trial tested the extralabel intranasal administration of a modified live bovine coronavirus and rotavirus vaccine (Calf-Guard [Zoetis, Parsippany, N.J.]) to control respiratory disease in feedlot cattle.[88] Vaccination significantly decreased the subsequent rate of treatment for respiratory disease in cattle that had relatively low serum antibody titers against coronavirus at arrival. Recently a modified live coronavirus vaccine was approved for intranasal adminstration to aid in the reduction of enteric disease due to BCoV (Bovilis Coronavirus [Merck Animal Health, Madison, N.J.]). Anecdotal reports indicate that this vaccine is also administered to control or prevent outbreaks of respiratory disease, an extralabel use; no published clinical trials have yet described benefits of this application.

Infectious BCoV can be identified on boots and clothing of personnel 24 hours after they have handled infected calves, indicating that fomites could be a means of transmission.[89] Thus boots and other fomites should be disinfected or changed after examining calves or cattle likely to be infected with BCoV. Other management practices to prevent or control respiratory disease in calves or feedlot cattle are also appropriate.

Influenza Viruses

Influenza viruses are enveloped RNA viruses in the family *Orthomyxoviridae*. Currently there are four genera in this family: *Alphainfluenzavirus*, *Betainfluenzavirus*, *Gammainfluenzavirus*, and *Deltainfluenzavirus*, which contain the influenza A, B, C, and D viruses, respectively. Influenza A viruses (IAV) circulate widely in various avian reservoir hosts and cause important seasonal disease in humans; IAV also cause important disease in poultry, swine, horses, and dogs. With IAV, influenza B viruses (IBV) contribute to seasonal disease in humans; influenza C viruses (ICV) primarily cause respiratory infection in young children. Humans appear to be the primary reservoir hosts for IBV and ICV, but infection with either IBV or ICV has occasionally been identified in other species. Antibodies to IAV, IBV, and ICV have been identified in cattle, indicating that cattle can be infected with these viruses.[90-92] Seroconversion to IAV has followed outbreaks of respiratory disease in cattle when no other respiratory pathogens could readily be found,[91] suggesting that IAV infection may rarely cause disease in cattle. However, only IDV have been commonly identified in surveys of respiratory viruses in cattle.

Influenza D Virus

In 2011, an influenza virus was isolated from a pig with respiratory disease that was initially thought to be ICV.[93] However, the isolate was subsequently shown by in vitro testing to fail to reassort genome segments with confirmed ICV isolates, indicating that it was not a member of the genus *Gammainfluenzavirus*. The new virus was classified as IDV of the genus *Deltainfluenzavirus*. Seroprevalence to IDV was found to be low when serum samples from humans or swine were tested but high when serum samples from cattle were tested, suggesting that cattle but not swine or humans are a reservoir host. IDV infection appears to occur commonly in cattle around the world. Serum or other samples from cattle have been found to be positive for IDV or antibodies to IDV in the United States, Europe, and Japan.[94-96] Surveys to date have found that many herds contain at least one seropositive animal, with the percent of seropositive cattle within a herd typically in the range of 30% to 50%, although this varies with location of the herd and age of the animals.[94,96] In some cow-calf herds, more than 90% of young calves have been found to be seropositive, suggesting that most calves receive antibodies to IDV from colostrum.[94,97] A survey of historically banked samples indicated that herd level seroprevalence in Nebraska was likely greater than 90% in 2004.[97] IDV currently circulating in North America have been defined to occur in one of two genetic clades[93,94]; antibodies to viruses in one clade react partially to viruses in the other clade. European IDV isolates to date have been antigenically similar to North American isolates,[95] whereas Japanese isolates have been more distinct.[98]

Horses, sheep, and goats have also been shown to be seropositive to IDV at low prevalence[99,100]; poultry have not yet been reported to be seropositive. An early report found only 1.3% of 316 human serum samples from the United States and Canada to be seropositive to IDV,[93] suggesting that infection of humans is uncommon. However, a recent small

VetBooks.ir

survey testing 35 people who have regular contact with cattle and 11 people who do not found 91% of the people with cattle contact to be seropositive versus 18% of the people without cattle contact.[101] Thus the information available to date suggests that humans are not a reservoir for IDV, but they are susceptible to infection, which may occur commonly in individuals with frequent contact with cattle. This is relevant because of the known possibility of species to share influenza viruses, with reassortment of gene segments leading to development of new, possibly more virulent variants. The importance of this in the ecology of IDV is not yet known.

The importance of IDV as a contributor to bovine respiratory disease is still under investigation. Seroconversion has been associated with development of bovine respiratory disease,[94] and IDV has been found in materials collected from cattle with respiratory disease.[94,95,102] Viral metagenomic sequencing of nasal or nasopharyngeal swabs identified IDV as significantly associated with respiratory disease in dairy calves,[103] and IDV tended to be associated with respiratory disease in feedlot cattle.[1] When IDV is found in respiratory secretions or tissues of cattle with naturally acquired disease, it is common to find other respiratory pathogens also present, making it difficult to particularly ascribe disease to IDV alone. IDV and BCoV, another virus commonly isolated from cattle during respiratory disease outbreaks, can both use the same cellular receptor, 9-*O*-acetyl-*N*-acetylneuraminic acid (Neu5,9Ac2), to attach to and enter cells. The significance of this in the ecology of these viruses in cattle populations is not clear.

Experimental challenge of seronegative cattle with IDV alone has induced disease that is mild at most, with viral replication and inflammation generally confined to the nasal passages and trachea.[104,105] In this regard, IDV is also similar to BCoV, which is commonly identified in cattle with respiratory disease but causes little if any respiratory disease when seronegative cattle are purposely exposed to the virus alone. This is currently interpreted to indicate that infection with IDV alone is unlikely to cause identifiable respiratory disease in cattle, but IDV infection can contribute to disease when it occurs concurrently with other factors that that impair or challenge respiratory defense. For example, IDV infection of nasal and trachea epithelial cells may impair function of the mucociliary elevator, increasing the likelihood of secondary bacterial infection by *M. haemolytica* or other opportunists.

No vaccine for IDV is currently marketed. An experimentally developed inactivated vaccine decreased clinical signs and virus shedding following experimental challenge of cattle.[105]

Bovine and Ovine Adenovirus

Adenoviruses are nonenveloped DNA viruses of the family *Adenoviridae*. At least 10 serotypes of bovine adenovirus (BAV) have been identified. BAV infection is widespread and frequently subclinical; adenoviruses are also often isolated in association with other viruses and bacteria, making it difficult to assign causation in naturally occurring disease outbreaks. However, a recent survey of viral metagenomes in dairy calves with respiratory disease recently identified adenoviruses as one of the viruses significantly associated with respiratory disease.[103] Adenovirus infection has also been associated with enteritis, conjunctivitis, keratoconjunctivitis, and "weak calf syndrome."

At least six antigenic types of ovine adenovirus and two types of caprine adenovirus have been identified. It appears likely that these viruses cause widespread infection. The majority of isolations of adenovirus have been from young lambs, and it has been isolated in association with respiratory and enteric disease. Experimental infections result in mild disease with anorexia, pyrexia, increased respiratory rates, coughing, and diarrhea. Ovine adenovirus serotype 6 has been shown under experimental conditions to act synergistically with *M. haemolytica* in the production of pneumonia in lambs.

Bovine Rhinitis Virus

Bovine rhinitis virus is a nonenveloped RNA virus in the family *Picornaviridae*. There are two serotypes of bovine rhinitis virus: bovine rhinitis A virus and bovine rhinitis B virus. A recent surveys of viral metagenomes from nasal or nasopharyngeal swabs from dairy calves with and without clinical signs of respiratory disease found bovine rhinitis A virus to be significantly associated with disease.[103] A similar study that evaluated viral metagenomes in U.S. and Mexican feedlot cattle with and without signs of respiratory disease found the viruses to be present in nearly all feedlots sampled, but their presence was not significantly associated with clinical signs of respiratory disease.[1]

Bacterial and Chlamydial Agents

Mannheimia haemolytica

Definition and Etiology

M. haemolytica is a gram-negative aerobic bacteria of the family *Pasteurellaceae*. There are at least 12 serotypes of *M. haemolytica*, and some ruminant isolates are untypable with currently available laboratory tools. Some serotypes of *M. haemolytica* are pathogenic, whereas others are nonpathogenic commensals of the ruminant nasopharynx, and the serotypes that are pathogenic for cattle are not the same as those that are pathogenic for sheep or goats. Serotype A1 is the most common isolate from pneumonic lungs of cattle, and serotype A6 is the next most common; serotype A2 is the most common isolate from the nasopharynx of normal cattle. Serotype is also relevant to pathogenicity of isolates from sheep and goats; serotype A2 is the most common isolate from sheep and goats with pneumonia, and serotypes A7, A9, and several others have also been associated with disease.

Clinical Signs Cattle, sheep, or goats infected with *M. haemolytica* display a dull or depressed attitude and lose interest in eating. Fever, tachypnea, and depression are often the only abnormal signs early in the course of infection; coughing is not a prominent sign in the acute stage of disease unless co-infection with another agent such as BHV-1 or BRSV is present. Animals may display evidence of thoracic pain, such as standing with elbows abducted or catching the breath before expiration; these signs are a result of the painful fibrinous pleuritis caused by *M. haemolytica*. Because *M. haemolytica* is a gram-negative organism, endotoxin (lipopolysaccharide) is produced by the agent, and thus cattle with mannheimiosis may show signs of endotoxemia, including fever, tachycardia, tachypnea, salivation, respiratory distress, pale or dark mucous membranes with prolonged capillary refill time, and cool extremities. Thoracic auscultation may reveal harsh or loud bronchovesicular sounds consistent with pulmonary consolidation, particularly over the cranioventral lung. Disease after *M. haemolytica* infection can be fatal, particularly if it is not treated; it can also lead to chronic pneumonia associated with secondary invasion with agents such as *Pasteurella multocida*, *Mycoplasma bovis*, or *Trueperella pyogenes*.

It is important to remember that naturally occurring disease caused by *M. haemolytica* is commonly preceded by infection with a viral agent such as BHV-1, BRSV, or BCoV; therefore the clinical signs described previously for these or other respiratory viruses may also be present in animals infected with *M. haemolytica*.

Pathogenesis *M. haemolytica* is a normal inhabitant of the nasal and pharyngeal mucosa and is considered an

VetBooks.ir

opportunistic pathogen. Ruminants appear to become infected at an early age and carry *Mannheimia* as a minor part of the upper respiratory tract flora. Only a small percentage of nasal swabs yields positive results for *M. haemolytica* serotype A1 in healthy, unstressed calves,[1] but if several areas of the nasal mucosa are cultured at necropsy, it is often possible to isolate *M. haemolytica* from animals that previously had negative findings on nasal swabs.[2] The stress of transportation or viral infection causes a breakdown of the defense mechanisms that limit normal bacteria flora, resulting in a rapid proliferation of virulent *M. haemolytica* serotype A1. The number of calves yielding a positive nasal swab *M. haemolytica* culture increases after transport, and there is a large increase in the numbers of *M. haemolytica* in positive samples.[1] BHV-1 and PIV-3 viruses have been shown to have the same effect as transportation on *Mannheimia* populations of the nasal mucosa. *M. haemolytica* has been demonstrated in the tracheal air of stressed, healthy calves harboring the organism on their nasal mucosa. Some of these inhaled organisms are deposited deep within the lung and normally are cleared within hours. However, under conditions of impaired pulmonary defenses caused by insults to the upper respiratory tract, preexisting viral infection, or other factors, *M. haemolytica* is able to proliferate rapidly within the lung and, with the aid of its virulence factors and toxins, to produce a severe lobar necrotizing fibrinous pleuropneumonia. Calves infected with respiratory viruses or *Mycoplasma* species have increased susceptibility to severe bronchopneumonia when exposed to *M. haemolytica*. Similarly, infection of lambs with PIV-3 or adenovirus followed in several days by *M. haemolytica* causes severe pneumonia.[3]

Once *M. haemolytica* becomes established in the lungs, interactions between the bacteria and the host defenses result in tissue damage and elimination of the bacteria. A major virulence factor of *M. haemolytica* is an exotoxin that is lethal to ruminant leukocytes, the leukotoxin. Leukotoxin, which is produced by *M. haemolytica* during the logarithmic phase of growth, causes cytolysis of ruminant platelets, lymphocytes, macrophages, and neutrophils.[4] There is diversity in the gene encoding the leukotoxin molecule among *M. haemolytica* serotypes, and genetic diversity is related to differences in toxicity. Leukotoxin binds to cells via CD18, the beta subunit of the β_2 integrins CD11a/CD18 (LFA-1), CD11b/CD18 (Mac-1), and CD11c/CD18 (CR-4); although leukotoxin can bind to cells from nonruminant species, only ruminant cells are killed by the toxin. Contact with leukotoxin increases expression of LFA-1 on ruminant leukocytes, making the cells even more sensitive to injury by leukotoxin. At low concentrations, leukotoxin induces leukocyte death by apoptosis, whereas at higher concentrations the toxin causes cell lysis.[5] *M. haemolytica* expressing a mutant nontoxic leukotoxin induced less lung pathology in calves as compared with *M. haemolytica* producing functional toxin, but clinical signs were not different between the two groups of calves, indicating that leukotoxin is not the only virulence factor of importance in causing disease.[6]

Another virulence factor that contributes to disease resulting from *M. haemolytica* is lipopolysaccharide, or endotoxin. As in other species, exposure of ruminants to endotoxin from gram-negative bacteria induces a multitude of responses leading to inflammation, including initiation of the complement and coagulation cascades, activation of endothelial cells and recruitment of neutrophils, and activation of neutrophils and alveolar macrophages, leading to their production of proinflammatory cytokines, which further amplify the inflammatory response. The proinflammatory cytokines TNF-α, IL-1β, and IL-8 are expressed in the lungs of cattle within 48 hours of *M. haemolytica* infection.[7] Calves exposed to a preparation containing *M. haemolytica* endotoxin develop leukopenia, fever, tachypnea, diarrhea, and dyspnea as early as 2 hours after exposure.[8] Endotoxin potentiates the effects of leukotoxin by inducing increased expression of β_2 integrins on leukocytes, which contain CD18, the receptor for leukotoxin. Bovine alveolar macrophages first exposed to endotoxin were susceptible to death induced by concentrations of leukotoxin too low to cause cell death alone, and macrophages exposed to both endotoxin and leukotoxin produced more of the proinflammatory cytokines IL-8 and TNF-α than did macrophages exposed only to leukotoxin.[9] These data indicate that leukotoxin and endotoxin work in synergy to cause disease in ruminants. The production of IL-8 is of particular importance because IL-8 is a major inducer of neutrophil chemotaxis. The massive influx of neutrophils induced by IL-8 and other inflammatory mediators is a key factor in lung tissue destruction caused by *M. haemolytica*. Calves experimentally depleted of neutrophils can be completely protected from gross and microscopic lesions of the severe fibrinonecrotic bronchopneumonia that is induced by intratracheal inoculation of *M. haemolytica* in calves with normal neutrophil levels.[10] Lysis of neutrophils results in the release of lysosomal products, including elastase, collagenase, and reactive oxygen intermediates. These chemicals are bactericidal but also capable of destroying the neutrophils themselves and surrounding tissues. Neutrophil-mediated damage to the endothelial cells results in exudation and thrombosis, which produce the classic lesions of necrosis and fibrinous exudation.

In addition to leukotoxin and endotoxin, *M. haemolytica* possesses other factors that contribute to its virulence. The bacteria have a polysaccharide capsule that aids in attachment and prevents phagocytosis by neutrophils and iron-regulated outer membrane proteins (IROMPs) that bind transferrin and alter the function of neutrophils. The bacteria produce adhesins that mediate attachment to host cells, and neuraminidase produced by the bacteria may aid in host colonization by decreasing the viscosity of respiratory mucus and decreasing the repellant negative charge on host cells by cleaving sialic acid residues.

Epidemiology

In many studies over several decades, *M. haemolytica* has been found to be a common bacterial isolate from feedlot cattle with fatal fibrinous bronchopneumonia.[11,12] *M. haemolytica* was isolated postmortem from 25% to 30% of cattle that died or were euthanized because of pneumonia in two studies evaluating causes of mortality in feedlot cattle.[12,13] An assessment of bacteria isolated from transtracheal aspirates of live feedlot cattle with respiratory disease and healthy cattle found that *M. haemolytica* was significantly more likely to be isolated from aspirates from cattle with BRD, compared to healthy controls.[13] In contrast, an older study that used BAL to identify bacteria present in the lungs of feedlot cattle before antimicrobial treatment for acute pneumonia found that *M. haemolytica* was not identified more frequently in the lungs of cattle with pneumonia than in normal controls, whereas *P. multocida* was significantly associated with bronchopneumonia.[14] In this study, none of the calves died or were euthanized because of the naturally occurring disease, indicating that disease was not severe. Because *M. haemolytica* is relatively more likely to cause acute fatal pneumonia than other bacterial pathogens of the ruminant lung, it may be overrepresented in necropsy surveys in which only fatal cases of disease are sampled. Seroconversion to *M. haemolytica* or *M. haemolytica* leukotoxin has been significantly associated with treatment for respiratory disease or "undifferentiated fever" in feedlot cattle in some[15,16] but not others.[17]

In contrast to the situation in feedlot cattle, *M. haemolytica* is less commonly associated with pneumonia in dairy calves. In one study, *M. haemolytica* was less frequently isolated from guarded nasopharyngeal swabs collected from dairy calves with acute respiratory disease than *P. multocida* or *Mycoplasma* spp.[18] Isolation of *M. haemolytica* on nasopharyngeal swabs was not significantly associated with clinical signs of respiratory disease

VetBooks.ir

or pulmonary consolidation identified by transthoracic ultrasound in dairy calves in another study.[19] Magnitude of serum antibody titers, or changes in serum antibody titers, to *M. haemolytica* were not significantly associated with treatment for respiratory disease in a third report.[20] Although *M. haemolytica* is not as commonly associated with respiratory disease in dairy calves as other bacteria, it can be a cause of clinical and sometimes fatal bronchopneumonia in dairy calves, as well as in preweaning beef calves, adult dairy or beef cows, sheep, or goats.

Necropsy Findings Infection with *M. haemolytica* causes grossly evident fibrinopurulent bronchopneumonia (Color Plate 31.4). The infection is aerogenous, so disease occurs primarily in the cranioventral lung, but in severe cases caudoventral and even dorsal lung may be affected. Affected areas of lung are dark red to purple or gray-brown, firm, and heavy; discolored areas may be wedge-shaped owing to thrombosis of a vessel supplying the affected region during the severe inflammatory response. The interlobular septa are expanded by clear to yellow gelatinous material that represents proteinaceous fluid that has leaked from blood vessels in the lung. The inflamed areas of lung may be covered with yellow fibrin that may adhere to the pleura of the thoracic wall, and the pleural cavity usually contains straw-colored fluid, which may be voluminous. In cases that have been ongoing for a few days, firm, gritty lumps that are dry and crumbly on sectioning may be identified; these represent areas of necrotic tissue. *M. haemolytica* may also produce pneumonia characterized by firm, dark red pulmonary consolidation without fibrinous pleuritis; this is especially common in dairy calves or sheep and goats. Animals that survive the acute stage of pneumonia caused by *M. haemolytica* may have multiple abscesses and pleural adhesions; in these cases other bacteria such as *P. multocida*, *Mycoplasma bovis*, or *Arcanobacterium pyogenes* may be contributing to pathology.

Histopathologic evaluation of tissues from cattle with pneumonia due to *M. haemolytica* reveals that alveoli are filled with edema and fibrin and that there is massive infiltration of neutrophils and macrophages. Foci of coagulative necrosis may be present; hemorrhage is also often present both within and between alveoli. Bronchioles are filled with leukocytes and may have foci of epithelial necrosis.

Diagnosis Diagnosis of pneumonia due to *M. haemolytica* is most reliably made by culture of lungs with typical gross pathology at postmortem evaluation of animals that die or are euthanized as representative cases in outbreaks. Once bacteria colonies are isolated, MALDI-TOFMS or traditional biochemical methods can be used to identify the bactera; MALDI-TOFMS can also be used to identify the serotype.[21] Some laboratories offer PCR testing to identify the bacteria, which may be more sensitive than culture.[22]

A presumptive antmortem diagnosis in individual animals with clinical signs of bacterial pneumonia can be made by identification of the bacteria by aerobic culture of nasal swab, guarded nasopharyngeal swab, transtracheal aspirate (TTA), or BAL. There is good to very good agreement between the results of culture of nasal or nasopharyngeal swabs and TTA or BAL at the level of the genus and species in calves with respiratory disease.[18,23] Because *M. haemolytica* is a commensal of the upper respiratory tract, finding the bacteria does not necessarily mean it is the only or even the most important cause of disease. However, if the agent is found in respiratory materials collected from an animal with clinical signs consistent with bacterial pneumonia, it is appropriate to assume that *M. haemolytica* is contributing to disease in the patient. Cytologic evaluation of TTA or BAL samples would be expected to reveal septic purulent inflammation characterized by large numbers of neutrophils that may be degenerate, exhibiting toxic change, and possibly containing intracellular bacteria. Thoracocentesis can be used to identify fluid accumulation in the thorax; fluid collected shows a high percentage of neutrophils with a high (>3 g/dL) total protein content if bacterial pleuropneumonia is the cause of fluid accumulation. If an ultrasound machine is available, transthoracic ultrasound evaluation can be used to confirm the presence of consolidated lung tissue, possibly with pleural effusion and fibrin. Thoracic radiography, if possible, is expected to show evidence of consolidation of the cranial lung and possibly pleural fluid accumulation. Evidence of pneumonia identified by either radiography or transthoracic ultrasound evaluation has been shown to correlate strongly with findings on postmortem examination of calves with bacterial bronchopneumonia.[24]

Serologic tests can be used to identify serum antibodies to *M. haemolytica*, and seroconversion identified by paired serologic testing could be used to confirm infection with *M. haemolytica* in one or more ruminants. However, these tests are most commonly used for research applications, and they may not be available at all diagnostic laboratories. Moreover, seroconversion to *M. haemolytica* has not been consistently associated with disease.

Treatment and Prevention Treatment of *M. haemolytica* requires administration of an antimicrobial that is effective against the organism. Many antimicrobials are currently labeled for the treatment of *M. haemolytica* (see Table 31.15). The decision to choose any one of the many approved products is based on multiple factors, including regional susceptibility of *M. haemolytica* isolates, the number of times it is possible to treat animals, withdrawal times, and cost. Recently, *M. haemolytica* that are resistant to multiple antimicrobial classes (multidrug resistant, or MDR) have been identified in lung collected at postmortem from feedlot and stocker cattle in the United States and Canada[25-27] and by guarded nasopharyngeal swabs of some populations of stocker and feedlot cattle.[28-30] Currently, evidence-based guidelines for management of cattle with bronchopneumonia attributed to MDR *M. haemolytica* are lacking; anecdotally it has been reported that cattle can recover despite the presence of *M. haemolytica* resistant to the antimicrobial with which they are treated. This may indicate that the host response can resolve infection and repair pathology in at least some cases of MDR infection.

In addition to appropriate antimicrobial therapy, treatment to prevent the adverse effects of endotoxin should be considered for ruminants suspected or confirmed to have pneumonia caused by *M. haemolytica*. The NSAID flunixin meglumine can ameliorate the inflammatory response to endotoxin, and treatment with flunixin meglumine has been shown to improve outcome in individual animals infected with *M. haemolytica*. However, administration of NSAIDs may not be cost-effective in the treatment of large numbers of cattle with respiratory disease. Thus a consideration of the cost versus expected benefit is appropriate before NSAID therapy is administered to an entire group.

Prevention of infection and disease caused by *M. haemolytica* is approached by three avenues: administering antimicrobials prophylactically to animals at high risk of disease; increasing host immunity by ensuring adequate passive transfer and administering vaccines against *M. haemolytica;* and minimizing factors such as viral respiratory tract infection, mixing of animals from various sources, and long-distance shipment, all of which increase the susceptibility of animals to disease caused by pathogenic serotypes of *M. haemolytica*.

Administration of antimicrobials effective against *M. haemolytica* to an entire group of calves at high risk for disease because of recent weaning, uncertain immune status, mixing with cattle from a variety of sources, and long-distance shipment ("metaphylaxis") has been a reliable means of decreasing

VetBooks.ir

morbidity and mortality associated with respiratory disease in such populations. Administration of tilmicosin to groups of such high-risk calves either before shipment or on arrival at feedlots decreased the proliferation of *M. haemolytica* serotype A1 in the nasopharynx of calves and was associated with decreased treatment for respiratory disease as compared with calves not treated with tilmicoson.[31] In a later study, administration of florfenicol at arrival decreased colonization of the nasopharynx with *M. haemolytica* A1 and delayed treatment for respiratory disease.[1] However, recent reports have described a high prevalence of MDR *M. haemolytica* following metaphylactic antimicrobial administration.[28,30] The degree to which MDR *M. haemolytica* negatively affect outcome in infected cattle is not yet clear, but dissemination of MDR *M. haemolytica* in cattle populations may begin to decrease the benefit of metaphylaxis. Further discussion of the role of metaphylactic administration of antimicrobials to control bovine respiratory disease can be found in the Metaphylactic Antimicrobial Therapy section later in this chapter.

Mixing recently weaned calves from multiple sources and shipping them long distances is a well-known precursor to outbreaks of fibrinous pneumonia[32]; thus efforts to minimize stresses and improve immunity for calves moving through the marketing chain should lessen disease caused by *M. haemolytica.* Preconditioning, wherein vaccination and stressful procedures such as weaning and castration are carried out well in advance of mixing and shipment, can decrease costs associated with fibrinous pneumonia in feedlot cattle.[33] However, preconditioning should not be considered a guarantee against all respiratory disease; severe disease can sometimes occur in preconditioned calves. Further discussion of the role of preconditioning to prevent bovine respiratory disease can be found in the Preconditioning section later in this chapter.

Vaccination can be used as part of a plan to decrease disease caused by *M. haemolytica*. Bacterins, toxoids, and at least one modified live vaccine are currently available in the United States and Canada for the prevention and control of respiratory disease due to *M. haemolytica* in cattle; additional information is presented in Chapter 48. At the time of this writing, it appears that only one vaccine containing *M. haemolytica* and *P. multocida* is specifically labeled for vaccination of sheep and goats in the United States and Canada (Mannheimia Haemolytica–Pasteurella Multocida Bacterin [Colorado Serum Company, Denver, Colo.]). Vaccination of sheep or goats with vaccines labeled for use in cattle may not reliably provide protection against disease, as serotypes of *M. haemolytica* that most commonly cause disease in sheep and goats are not included in vaccines for cattle. However, a recent study found that one licensed cattle vaccine decreased disease in sheep following experimental challenge of sheep with PIV-3 followed by challenge with serotype A2 *M. haemolytica*.

Definition and Etiology

Pasteurella multocida

P. multocida is a gram-negative aerobic bacteria of the family *Pasteurellaceae*. Like *M. haemolytica*, *P. multocida* can be found in the nasopharynx of healthy ruminants. Although *P. multocida* is regularly isolated from the lungs of ruminants with bronchopneumonia, there has been debate over the years as to whether this species is a primary pathogen (i.e., capable of causing disease alone) or whether some other primary stressor or insult is required to occur before this agent can participate in disease. As with *M. haemolytica*, experimental challenge of calves with *P. multocida* alone does cause clinical signs and pathologic change in the lung similar to that seen in natural outbreaks of disease,[34-36] but large numbers of the bacteria must be administered in a way that bypasses the upper respiratory tract (most commonly by intratracheal or intrabronchial instillation). Alternatively, exposure to a viral respiratory pathogen a few days before exposure to *P. multocida* makes ruminants more likely to develop disease. These findings indicate that some insult that weakens respiratory defense is necessary for most if not all cases of naturally occurring disease to occur.

P. multocida is a diverse species of bacteria that is classified into five serogroups (A, B, D, E, and F) based on antigenic differences in the bacterial capsule. Serogroups B and E cause hemorrhagic septicemia, a disease predominantly seen in Asia and Africa; these serogroups are rarely described in North America. Serogroup A is the predominant serogroup associated with ruminant respiratory disease,[37,38] although serogroups D and F may be common in some regions, particularly in sheep.[39] In addition to the alphabetic serogroup designation, isolates may also receive a numeric designation based on cell wall antigen types (for example, *P. multocida* A3 is commonly isolated from cases of bovine pneumonia). A report characterizing 153 *P. multocida* isolates from cases of pneumonia and mastitis in cattle in England and Wales indicated that relatively few strains of *P. multocida* cause the majority of disease in cattle. Moreover, although a few strains isolated from cattle had also been associated with disease in swine and poultry, the majority of strains were uniquely associated with their host species of origin.[38] Other research indicated that certain strains of *P. multocida* had a predilection for the respiratory tract of sheep, whereas others were associated with the reproductive tract.[39] Taken together, these data suggest that differences among strains of *P. multocida* are related to the type of disease caused and the host likely to be affected. Therefore merely isolating *P. multocida* without further characterizing the isolate could make it difficult to know with confidence whether the bacteria isolated was actually contributing to disease. It has been suggested that strain variation is related to differences in severity of respiratory disease occurring in ruminants infected with *P. multocida*.[35]

Clinical Signs

Calves infected with *P. multocida* display clinical signs of fever, increased respiratory rate, and sometimes depression, coughing, and mucoid to mucopurulent nasal discharge. Loud or harsh bronchovesicular sounds may be heard over the cranioventral lung fields owing to pulmonary consolidation, and coarse crackles may be heard as a result of air moving through exudate in large airways. Because *P. multocida* is a gram-negative organism that produces endotoxin, signs of endotoxemia (such as tachypnea, tachycardia, and/or fever) may also contribute to signs that accompany infection with the organism. Compared with calves infected with *M. haemolytica*, calves infected with *P. multocida* tend to have less severe signs, and signs of disease last for a shorter time.

Pathogenesis

Little is known regarding the pathogenesis of *P. multocida* in ruminant respiratory disease. In addition to lipopolysaccharide (LPS), the organism has a capsule that allows it to resist phagocytosis. Outer membrane proteins, particularly IROMPs, are likely to contribute to the ability of the bacteria to establish and proliferate within the host.[40,41] The prominent role of *P. multocida* in dairy calf pneumonia relative to its role in acute fatal bronchopneumonia of feedlot cattle suggests that prolonged impairment of the respiratory defense mechanisms may be necessary for this organism to establish in the lungs in sufficient numbers to cause pathology. *P. multocida* has been shown to overgrow *M. haemolytica* in challenge studies using large doses of pure cultures of *M. haemolytica*.[34] This may be related to the fact that *P. multocida* can inhibit growth of *M. haemolytica* in vitro.[42] Thus when *P. multocida* is identified in lung tissue or other materials from cattle with respiratory disease, it is possible that in at least some cases, the agent has displaced *M. haemolytica* that actually initiated disease.

VetBooks.ir

Epidemiology *P. multocida* is commonly isolated from the lungs of dairy calves that die or are euthanized because of bronchopneumonia, with mycoplasmas being the only bacteria isolated more often in surveys of farms experiencing outbreaks of calf pneumonia.[43,44] Recent studies evaluating respiratory pathogens in individual live dairy calves have also found *P. multocida* to be the agent most commonly identified.[18,19] Although *M. haemolytica* is more commonly isolated than other bacteria from lung tissue of feedlot cattle that die of acute bronchopneumonia,[11] it is interesting to note that two different studies comparing the bacteria identified in transtracheal aspirates or BALs collected from live feedlot cattle with respiratory disease, and also from normal control cattle, found *P. multocida* to be most strongly associated with respiratory disease.[13,14] This may indicate that *P. multocida* is an important contributor to feedlot respiratory disease but *M. haemolytica* is more likely to lead to disease that ends in death, causing *M. haemolytica* to be overrepresented in surveys of bacteria in tissues collected at postmortem.

Necropsy Findings *P. multocida* produces a purulent bronchopneumonia with plum-colored cranioventral consolidation and purulent exudate on cut section within the airways; when calves are experimentally infected with *P. multocida* alone, the lesion is usually not extensive and is typically confined to the cranioventral lung lobes. Histologically, bronchopneumonia characterized by infiltration of neutrophils and macrophages into alveoli and airways is seen. Microscopic evidence of abscesses may be present. Fibrin deposition with expansion of lymphatics and interlobular septa with edema, and focal areas of coagulative necrosis, can be seen in calves infected with *P. multocida*, but this lesion is more typical of infection with *M. haemolytica*.

Diagnosis Bronchopneumonia caused by *P. multocida* is diagnosed as described for *M. haemolytica*. The species is most commonly identified by culture of lung lesions identified at postmortem examination of affected animals or from guarded nasopharyngeal swabs or other respiratory materials collected antemortem. Because of the association of *P. multocida* with chronic or ongoing pneumonia, identification of this agent may indicate that the animal has been affected with bronchopneumonia for several days to weeks.

Treatment and Prevention Treatment of *P. multocida* is as described for *M. haemolytica*. Several antimicrobials are labeled specifically for the treatment of *P. multocida*, and products labeled for the treatment of *M. haemolytica* are also likely to be effective against this organism (see Table 31.15). Because *P. multocida* seems to be associated with chronic or ongoing pneumonia, effective treatment of infection may require longer therapy than the 3 to 5 days historically recommended for ruminants with bronchopneumonia, but this recommendation has not been tested in controlled studies and would be an extralabel use of some antimicrobials. Although antimicrobial resistance has historically been uncommon in *P. multocida* associated with ruminant respiratory disease, recent surveys of bacteria recovered from lung tissue or other respiratory materials collected from feedlot cattle have revealed *P. multocida* isolates that are resistant to multiple classes of antimicrobials.[25,26,29] MDR in *P. multocida* as well as *M. haemolytica* has been attributed to genetic elements called integrative conjugative elements (ICEs), which are integrated into the bacterial genome, include multiple genes encoding resistance to multiple antimicrobial classes, and can be transferred between bacteria of different genera.[45] The clinical significance of MDR *P. multocida* is not clear at this time, but these findings suggest that respiratory disease due to *P. multocida* may become more difficult to treat effectively if resistant bacteria become widely distributed in cattle populations.

Because prior insult to respiratory defense mechanisms appears necessary for *P. multocida* to cause disease in cattle, prevention of disease is likely to be aided by undertaking efforts to prevent other primary respiratory injury. This could include efforts to prevent infection with viral respiratory pathogens and to establish management practices that help minimize respiratory tract disease.

Relatively little is known about protective immunity that limits respiratory disease due to *P. multocida* in ruminants. Modified live vaccines can protect calves from disease caused by experimental challenge.[46,47] Antibody responses to several outer membrane proteins were associated with protection in one study, and these were induced by live but not inactivated vaccine.[47] Several commercial vaccines are marketed for administration to cattle that contain *P. multocida* in combination with *M. haemolytica*, with or without other agents. It appears at present that one vaccine is licensed for administration to sheep and goats (Mannheimia Haemolytica–Pasteurella Multocida Bacterin [Colorado Serum Company, Denver, Colo.]). At this time no properly designed clinical trials have been reported that allow identification of any beneficial effect of the *P. multocida* component of available vaccines for ruminant respiratory disease in the field. More information about vaccination against *P. multocida* is presented in Chapter 48.

Definition and Etiology

Histophilus somni

H. somni is a gram-negative aerobic bacteria of the family *Pasteurellaceae*. *H. somni* can be found on the genital and upper respiratory mucosa of normal ruminants,[48-51] but it can also cause a variety of diseases, including septicemia, thrombotic meningoencephalitis (TME), endometritis, abortion and infertility, pneumonia, pleuritis, laryngitis, otitis, conjunctivitis, myocarditis, mastitis, and polyarthritis.[52] Only pneumonia and pleuritis resulting from this organism are considered here. Two bacteria very similar to *H. somni*, *Haemophilus agni* and *Haemophilus ovis*, have been isolated from sheep with septicemia, meningitis, mastitis, and reproductive abnormalities; DNA hybridization studies have indicated that these three organisms should all be classified as *H. somni*. Although specific serotypes of *H. somni* have not been associated with disease as is the case for *M. haemolytica* and *P. multocida*, differences in virulence among different strains have been demonstrated in experimental challenge studies.[53] Moreover, differences in expression of molecules considered to be virulence factors have been demonstrated when strains from healthy animals are compared with strains from diseased animals.[54] Thus it appears that some isolates of *H. somni* are more likely to cause disease than others, but more research is needed to confirm the characteristics that define a pathogenic isolate.

Clinical Signs *H. somni* can cause disease in a variety of organ systems, and the clinical signs of infection will depend on the organ system affected. The possibility of concurrent infection of multiple systems should be considered in patients suspected to have disease caused by *H. somni*. In a Canadian retrospective study from the early 1990s, the majority of animals presented to a regional diagnostic laboratory for necropsy as a result of haemophilosis had disease in more than one organ system.[55] Signs of respiratory tract infection can range from mild to severe and can include fever, tachypnea, cough, nasal discharge, and depression. Severe cases of disease can be fatal.[53,56] Harsh or loud bronchovesicular sounds may be heard on thoracic auscultation because of pulmonary consolidation, particularly over the cranioventral lung fields. Affected animals may have signs of pain owing to fibrinous pleuritis,[56] including reluctance to move, standing with elbows abducted, and catching the breath before expiration. The cell wall of *H. somni* contains lipooligosaccharide (LOS), which induces

VetBooks.ir

inflammatory responses identical to those induced by LPS from *E. coli*[57]; therefore animals with pleuritis or pneumonia caused by *H. somni* could also have clinical signs referable to endotoxemia, including tachypnea, tachycardia, dark or pale mucous membranes with prolonged capillary refill time, salivation, or dyspnea.

Pathogenesis *H. somni* can live on respiratory or genital mucous membranes without causing disease, and it is not entirely clear what factors related to the pathogen or host must change for disease to occur. The physical and immunologic barriers presented by the upper respiratory tract are apparently of major significance; calves exposed to *H. somni* by aerosol did not develop disease,[58] whereas instillation of the bacteria directly into the trachea or bronchi led to disease that could be severe.[53,56] As has been shown for *M. haemolytica* and *P. multocida*, primary infection by a viral respiratory pathogen is likely a predisposing factor that allows *H. somni* to advance and establish in the lower respiratory tract in many cases. Calves infected with BRSV before infection with *H. somni* had disease of greater severity than that seen in calves infected with either BRSV or *H. somni* alone.[56,59]

H. somni has many features that help the bacteria escape the immune response.[60] The bacteria have outer membrane proteins that bind to the Fc region of antibody, allowing them to escape opsonization.[54] When the bacteria are ingested by neutrophils or macrophages, they are able to resist being killed.[61] The bacterial LOS induces inflammatory responses similar to the LPS of other gram-negative bacteria,[57] and *H. somni* is able to periodically change the structure and antigenicity of its LOS, which is likely to be important in evading the host immune response.[62]

An important aspect of the pathology caused by *H. somni* is the formation of vasculitis and vascular thrombi. *H. somni* can induce programmed cell death (apopotosis) of vascular endothelial cells, stimulate endothelial cell tissue factor activity, and disrupt intercellular junctions.[63] These effects lead to exposure of the vascular basement membrane, activation of platelets and the coagulation cascade, and thrombosis. These processes presumably contribute to pathology through release of inflammatory mediators by activated platelets and endothelial cells and through impaired blood flow due to microscopic thrombi.

Another important aspect of *H. somni* is the propensity of infection to induce IgE production by the host.[59,64] Infection with BRSV before infection with *H. somni* led to production of high levels of *H. somni*–specific IgE, which was associated with disease of increased severity as compared with control calves.[59] Cattle vaccinated with four different *H. somni* bacterins were all found to develop serum levels of *H. somni*–specific IgE that were significantly higher than levels seen in control unvaccinated cattle.[64] Because IgE mediates type I (immediate) hypersensitivity, animals that produce IgE against *H. somni* after vaccination or primary infection could have signs of an allergic or anaphylactic response on subsequent revaccination or reinfection. Such IgE-mediated hypersensitivity reactions have been proposed to contribute to the adverse reactions sometimes seen in cattle after vaccination for *H. somni*.[64] In addition to inducing IgE production, *H. somni* directly produces histamine,[65] which could further contribute to the development of hypersensitivity-like signs during *H. somni* infection. Among other actions, histamine increases permeability of bronchial epithelium; this may help the bacteria move out of the airways and into the lung parenchyma.

Epidemiology Exposure to *H. somni* is common, with 25% to 100% of cattle in various populations having serum antibodies.[66] It is common for feedlot cattle to have measurable antibody titers to *H. somni* at feedlot entry,[16,67] indicating that cattle are commonly exposed on the farm of origin or in transit to the feedlot. Seroconversion is also common in the first few weeks after feedlot entry,[16,17] indicating that cattle also continue to be exposed to *H. somni* in the feedlot. Several Canadian reports have indicated that *H. somni* can be a significant contributor to the development of respiratory disease or undifferentiated fever in feedlot cattle.[13,68-70] A causative association is typically inferred either by the association of seroconversion with respiratory morbidity and mortality during the period of study or by the association of *H. somni* vaccination with decreased respiratory morbidity and mortality. By these measures it appears that most disease resulting from *H. somni* occurs within the first 2 months of the feeding period,[70] and perhaps even within the first 2 weeks.[17] High-quality field research on the role of *H. somni* in feedlot respiratory disease in recent years has come almost entirely from Canada; it is not clear whether this indicates that *H. somni* is a less significant contributor to disease in the United States or the research has just not been done.

H. somni is usually less prevalent than *P. multocida* and *Mycoplasma* spp. in surveys of the causes of pneumonia in dairy calves,[19,44,71] but it can cause bronchopneumonia that is significant; one necropsy survey found pneumonia in 12 of 15 calves younger than 8 weeks of age submitted because of disease resulting from *H. somni*.[55]

Necropsy Findings *H. somni* usually produces lung lesions similar to those due to *P. multocida;* rarely it may produce lesions that resemble *M. haemolytica*, including fibrinous pleuropneumonia.[52,53,56] Grossly, plum or red to brown consolidated lobules are seen in the cranioventral lung, sometimes with abscesses containing brown-red fluid material. Interlobular septa can be distended with edema and fibrin (Color Plate 31.5), and hemorrhage may be grossly visible. Purulent material is seen within airways on the cut surface of lung. The surface of the pleura may be flecked with fibrin, or in some cases fibrin deposition may be extensive, with varying amounts of straw-colored fluid in the pleural cavity. Bronchial lymph nodes may be enlarged, with ecchymotic hemorrhages on the cut surface.

Histologically, inflammatory cells predominately made up of neutrophils infiltrate the alveoli and airways. Edema, hemorrhage, and fibrin can be seen in alveoli and interstitial spaces, and areas of coagulation necrosis surrounded by inflammatory cells may be found. Interlobular septa are expanded with fibrin, and thrombi are seen in blood vessels.

A massive fibrinous pleuritis with pleural effusion sometimes results from septicemic spread of *H. somni.* This condition can be differentiated from the fibrinous necrotizing lobar pleuropneumonia of shipping fever caused by *M. haemolytica* because the *H. somni* lesion involves only the pleural surface, not the lung.

Diagnosis Bronchopneumonia or pleuropneumonia caused by *H. somni* is diagnosed as described for *M. haemolytica.* The bacteria can be difficult to isolate, so samples collected for culture should be transported to the diagnostic laboratory without delay, and the diagnostic bacteriology laboratory should be specifically requested to attempt to isolate *H. somni* if involvement of the agent is suspected. PCR tests for the bacteria are available at some laboratories, and these may be more sensitive than culture.[22] Samples are ideally taken from animals before antimicrobial treatment, as *H. somni* is usually susceptible to a wide variety of antimicrobials and treatment makes it difficult to isolate the bacteria.[52] Serologic tests have been used to identify antibodies to *H. somni* for research,[16,17] and seroconversion could be used to confirm infection in a group of cattle, but these assays are unlikely to be available at most diagnostic laboratories. IHC has been used to identify *H. somni* in association with lesions in formalin-fixed tissues,[72] and this may be an additional test available at some diagnostic laboratories.

VetBooks.ir

Treatment and Prevention

Historically *H. somni* has been found to be susceptible to a variety of antimicrobials, including tetracycline, penicillin, and sulfonamides, as well as newer antimicrobials, many of which are labeled for use in the treatment of *H. somni* (see Table 31.15). However, recent surveys of bacteria recovered from lung tissue or other respiratory materials collected from feedlot cattle have revealed some *H. somni* isolates that are resistant to multiple classes of antimicrobials, although MDR *H. somni* have not been as prevealent as MDR *M. haemolytica* or *P. multocida* in these reports.[25,26,29] The impact of MDR on the efficacy of treatment of *H. somni* is not yet clear.

Several *H. somni* vaccines for use in cattle are commercially available; all are killed whole bacteria preparations (bacterins). More information about vaccination to control disease due to *H. somni* is presented in Chapter 48.

Definition and Etiology

Mycoplasma bovis

Mycoplasma bovis is a member of the genus *Mycoplasma* of the class Mollicutes, and as such it is among the smallest free-living organisms. *M. bovis* was first identified in 1961 in the United States, where it was isolated from a case of mastitis.[73] It has since spread worldwide. The bacterium was originally considered a subspecies of *Mycoplasma agalactiae*, and the two agents can be difficult to distinguish. However, *M. agalactiae* is a pathogen of sheep and goats and is rarely isolated in the United States, whereas *M. bovis* is regularly isolated in cases of pneumonia, respiratory disease, arthritis, tenosynovitis, and other disorders of cattle. *M. bovis* can rarely cause disease in sheep, goats, and other species.

Clinical Signs

The clinical syndromes associated with *M. bovis* and the approach to their treatment and prevention have been reviewed.[74] Respiratory infection with *M. bovis* causes fever, tachypnea, inappetence, and sometimes respiratory distress.[75] Coughing and nasal discharge are reported in some cases.[76,77] Respiratory disease caused by *M. bovis* can occur in outbreaks; in young calves, a subset of calves affected often develops otitis, characterized by unilateral or bilateral drooping of ears with purulent aural discharge, possibly with vestibular signs such as head tilt, nystagmus, and ataxia.[76-78] In weaned beef calves and cattle entering feedlots, a subset of affected animals may develop arthritis and tenosynovitis[79-81]; this syndrome is sometimes referred to as chronic pneumonia and polyarthritis syndrome.[81,82] Young calves can also develop arthritis or tenosynovitis.[77] A typical complaint by the producer experiencing a respiratory disease outbreak involving *M. bovis* is that cattle do not respond to therapy as expected, and a significant proportion of affected animals remain chronically ill and unthrifty for weeks after the onset of disease.[79,80] In addition to respiratory disease, *M. bovis* can also cause mastitis, arthritis and tenosynovitis, conjunctivitis, otitis, sinusitis, and myocarditis and/or pericarditis. The bacteria can also be isolated from aborted fetuses and from semen, linking the agent to reproductive failure; infected semen can also be a vehicle for introduction of *M. bovis* into a herd.[83] North American bison *(Bison bison)* can develop severe and sometimes fatal disease following *M. bovis* infection, with mature adults often being predominantly affected.[84]

The ability of *M. bovis* to act as a primary respiratory pathogen has been debated. Classically the agent has been understood to be an opportunist, establishing itself after primary infection with viral pathogens or other bacteria. However, experimental challenge of gnotobiotic calves with *M. bovis* alone induced respiratory disease with clinical signs of fever, tachypnea, and inappetence and grossly evident lung lesions.[75] These findings indicate that *M. bovis* can cause disease while acting alone; however, as for other bacterial respiratory pathogens of cattle, it is likely that natural infection and disease often follows another primary insult.

Pathogenesis

Much is still unclear about the mechanisms by which *M. bovis* causes disease. In vitro studies suggest that pathogenicity is associated with the ability of *M. bovis* to attach to host cells.[85] Antibodies against several of the variable surface proteins (VSPs) expressed by *M. bovis* were able to partially but not completely block attachment, indicating that the VSPs play a role in attachment.[85] *M. bovis* is able to migrate between ciliated respiratory epithelial cells,[86] which likely facilitates transfer from the respiratory mucosa to deeper sites such as joints and tendon sheaths. *M. bovis* was found to colonize the tonsils of calves fed colostrum contaminated with the bacteria[87]; thus infected tonsils may serve as a reservoir leading to otitis media and possibly respiratory disease in calves fed milk or colostrum containing *M. bovis*. Caseous necrosis, often found in the lungs of calves with pneumonia associated with *M. bovis* infection, appears to be due at least in part to tissue damage induced by oxygen and nitrogen radicals released by leukocytes attempting to clear the infection.[88]

M. bovis has a variety of ways to evade the host immune response, which likely contributes to persistent infection and poor response to therapy. VSP expression has been shown to be an important pathogenic mechanism.[89] *M. bovis* expresses at least three VSPs—VspA, VspB, and VspC—and isolates have been found that express some or all of these proteins.[90] *M. bovis* isolates show extensive variability in VSPs at both the genetic and the antigenic level. In addition, *M. bovis* can directly impair the activity of neutrophils[91] and monocytes[92] and can kill lymphocytes by inducing them to undergo apoptosis (programmed cell death).[93] Induction of proinflammatory cytokine production by the host may also contribute to disease caused by *M. bovis*.[94]

Epidemiology

M. bovis can be isolated from the respiratory tracts of normal cattle[95,96] as well as those of cattle with respiratory disease.[97-99] Surveys of nasopharyngeal swabs taken from dairy calves with no clinical signs of respiratory disease found *M. bovis* in 0% to 34% of the animals sampled.[99,100] A survey of multiple-source weaned beef calves sampled soon after arrival at nine different backgrounding or stocker operations identified nasal shedding of *M. bovis* in 0% to 6% of animals at each operation.[101] *M. bovis* can also be found in bovine lungs without evidence of disease at postmortem examination.[12] The fact that *M. bovis* can be isolated from animals with no clinical or pathologic signs of pneumonia has led some to question whether the agent is a true respiratory pathogen. However, a consistent association of *M. bovis* with a clinical syndrome of chronic nonresponsive pneumonia with or without otitis, arthritis, or tenosynovitis and with a pathologic syndrome of bronchopneumonia with multifocal caseous necrosis has led to general acceptance that *M. bovis* contributes importantly to significant morbidity and mortality in some situations.

M. bovis has been identified in dairy calves and feedlot cattle with respiratory disease in multiple reports. For example, in a survey of pathogens in calves in dairy herds in Quebec, only *M. bovis* was significantly associated with higher odds of clinical signs of respiratory disease, lung consolidation identified by transthoracic ultrasound, and decreased weight gain.[19] A survey of causes of death in cattle in Ontario feedlots identified caseonecrotic pneumonia caused by *M. bovis* as a cause of more fatalities within the first 60 days of the feeding period than acute fibrinosuppurative pneumonia typical of disease caused by *M. haemolytica* or *H. somni*.[12] A large proportion of cattle can be infected with *M. bovis* in the first weeks after feedlot entry,[102,103] and infection can be associated with decrased weight gain.[102] *M. bovis* infection of the respiratory tract appears to

VetBooks.ir

persist for weeks in cattle, but data are mixed in terms of whether cattle clear one infection only to be infected with a new isolate[103] or a single isolate persists for several weeks.[104] In 49 chronically sick cattle from a single feedlot, *M. bovis* was identified in the lungs of 82% of the cases and in the joints of 45% of the cases.[105] BVDV was also present in 39% of the cases from which *M. bovis* was isolated. A later retrospective study by the same authors found BVDV in the lungs of 44% of cattle subjected to necropsy with a final diagnosis of pneumonia caused by *M. bovis;* these data led the authors to suggest that immunosuppression resulting from BVDV may predispose a subset of animals to chronic pneumonia and/or arthritis caused by *M. bovis*. In contrast, others found that BVDV infection was not more common in feedlot cattle with caseonecrotic lesions typical of *M. bovis* infection.[98]

Currently available data indicate that *M. bovis* can spread from a few animals carrying the bacteria to others until a large proportion of a group is infected; transmission in these cases is most likely via respiratory infection by direct contact or short-distance aerosol.[79,80,95] Long-term persistence of bacteria in pneumonic lung of a few individuals may facilitate transmission to others in the herd.[106] Feeding milk infected with *M. bovis* appears to be an important source of infection for dairy calves.[77-79] Multiple reports have indicated that outbreaks can be caused by a single genotype of *M. bovis*,[107,108] although more than one genotype of *M. bovis* can also be isolated during outbreaks.[109]

Necropsy Findings Grossly, lungs of cattle with pneumonia caused by *M. bovis* have dark red, firm consolidated lobules of the cranioventral lung. Raised white to yellow, firm nodules that range from 0.5 to several centimeters in diameter are often but not invariably seen clustering in the cranioventral lung (Color Plate 31.6).[75,82,110] These nodules may appear to be abscesses, but in most cases they are actually foci of coagulation (caseous) necrosis (Color Plate 31.7).[75,98] Differential diagnoses for gross lesions of abscessing pneumonia in cattle include infection with *Trueperella pyogenes* and *Fusobacterium necrophorum* (both of which are more likely to be associated with a foul odor than *M. bovis*) and *Mycobacterium bovis* (tuberculosis). Other gross lesions include enlargement of interlobular septa by edema and fibrin. Fibrinous or fibrous pleural adhesions are unusual and if present may signal co-infection with *M. haemolytica* or *H. somni*. Animals with pneumonia typical of *M. bovis* may also have arthritis, tenosynovitis, myocardial abscesses, and/or otitis. Microscopic evaluation of affected lung reveals purulent pneumonia and bronchiolitis, with extensive infiltration of neutrophils in airways, and peribronchiolar cuffing with lymphocytes and mononuclear cells. Foci of eosinophilic coagulation necrosis are surrounded by a rim of dark pyknotic inflammatory cells and, farther out, a region of primarily macrophages and some plasma cells.[75,82] IHC staining for the organism may reveal large numbers surrounding the periphery of areas of coagulation necrosis as well as in association with bronchiolar and alveolar epithelial cells.[82,111]

Diagnosis Confirmation of respiratory disease caused by *M. bovis* is most reliably made by identification of the agent by culture or PCR of respiratory materials collected antemortem from cattle with clinical signs of bronchopneumonia or in lung tissue with typical gross lesions collected postmortem. For antemortem diagnosis, materials are ideally collected from the lower respiratory tract (TTA or BAL). The reliability of nasal swabs or guarded nasopharyngeal swabs for confirmation of disease due to *M. bovis* is less certain; the agreement between the results of nasal swab culture and the presence of lung disease caused by *M. bovis* was good in one study[97] and only moderate to poor in two other studies.[14,112] A recent report indicated very good agreement between between the results of nasal swabs or guarded nasopharyngeal swabs and the TTA if mycoplasma culture was followed by PCR to specifically identify *M. bovis* but not when culture alone was used.[18] The reliability of nasal swabs or guarded nasopharyngeal swabs for identification of *M. bovis* in respiratory disease outbreaks may be greater if multiople animals in a group are sampled and found to be positive. When samples are submitted for identification of *M. bovis*, it is important to request that the diagnostic laboratory specifically identify this agent; diagnostic laboratories often characterize mycoplasmas only to the level of the genus based on results of mycoplasma culture. Because other mycoplasma such as *Mycoplasma bovirhinis*, *Mycoplasma dispar*, and *Mycoplasma alkalescens* can also be isolated from the respiratory tract of cattle with pneumonia, a report of "*Mycoplasma* spp." is not equivalent to a diagnosis of *M. bovis*. Species-specific identification of *M. bovis* is most commonly made by PCR testing, which is available on request at many veterinary diagnostic laboratories. MALDI-TOFMS can also be used to identify bacterial species once colonies are isolated by culture. Although either mycoplasma culture followed by PCR or direct PCR (without mycoplasma culture first) can be used to identify *M. bovis*, the agreement between both tests used in the same animal may not be strong.[101] One recent report found culture to be more likely positive than PCR when nasal swabs were tested, whereas PCR was more likely positive than culture when milk was tested.[113] Although available data suggest that *M. bovis* is less commonly isolated from healthy cattle than are other mycoplasmas, because the organism can be found in nasal swabs and lung tissue of apparently normal animals, isolation of the bacteria in the absence of evidence of disease is of uncertain significance.

Serologic assays have been used to identify seroconversion in epidemiologic studies or to identify evidence of recent or past infection, but the tests are not widely available, and their results have not been shown to reliably indicate active infection.[114] Serology is most commonly used to determine whether *M. bovis* is a likely cause of mastitis in dairy herds; the value of serology in the diagnosis of respiratory disease is not well established. A review article discussing the diagnosis of mycoplasmas in cattle in detail was recently published and should be consulted for more information.[115]

Treatment and Prevention Several antimicrobials, including tulathromycin (Draxxin [Pfizer Animal Health, Parsippany, N.J.]), florfenicol (Nuflor Gold [Merck, Madison, N.J.]), enrofloxacin (Baytril 100 [Bayer Healthcare LLC, Pittsburgh, Pa.]), and gamithromycin (Zactran [Boehringer Ingelheim, Ingelheim am Rhein, Germany]), are currently labeled for treatment of disease due to *M. bovis*. However, multiple authors report that cattle with pneumonia caused by *M. bovis* respond poorly to antimicrobial therapy.[80,81,114] Because *M. bovis* can be seen in association with foci of coagulation necrosis in lungs of affected cattle,[82,98] it may be that antimicrobials are not maximally effective in this environment, or it may be that insufficient duration of treatment is carried out in at least some cases. Controlled trials indicating the duration of antimicrobial therapy needed for effective treatment of pneumonia caused by *M. bovis* are lacking, but anecdotal reports suggest that early treatment is critical for success[77,116] and that treatment should be continued for at least 10 to 14 days. Failure of antimicrobials that are predicted to be efficacious against *M. bovis* may also be related to an inability of the immune response to effectively clear the organism due to immunosuppressive mechanisms described previously. Some veterinarians report that outbreaks of *M. bovis* cannot be stopped with any treatment but that outbreaks eventually terminate when chronically affected animals die or are shipped to slaughter.

Recently, multiple European reports have described increasing rates of antimicrobial resistance based on in vitro assessment

VetBooks.ir

of *M. bovis* isolates.[117] Although clinical trials under conditions typical of U.S. and Canadian cattle operations that confirm the efficacy of treatment in a field setting are lacking, antimicrobial resistance may begin to make treatment of cattle with disease due to *M. bovis* even more problematic.

Research indicates that vaccination can theoretically afford some protection against experimental challenge with *M. bovis*.[118,119] Vaccines for control of disease due to *M. bovis* vaccines are licensed for sale in the United States; for vaccines to be fully licensed, they must show evidence of safety and efficacy in experimental challenge studies. However, properly designed field trials provide better evidence of usefulness of vaccines in the field, and reports of field trials to test the efficacy of currently licensed *M. bovis* vaccines are sparse. Results from two trials testing the effect of *M. bovis* vaccines on respiratory disease in dairy or veal calves have been reported.[120,121] In one trial there was no difference in respiratory morbidity or mortality in the first 90 days of life for vaccinated calves, as compared to unvaccinated controls.[47] In the second trial, which evaluated the effect of two different commercially available *M. bovis* vaccines on lung lesions at harvest of veal calves at approximately 145 days of age, lung lesions were decreased in one vaccine group but not in the other group, as compared to unvaccinated controls.[48] Autogenous vaccines have been used for years, but no reports with large numbers of animals and appropriate controls are available to provide information about efficacy. More properly designed field trials are needed to determine the value of *M. bovis* vaccination as used in the field in different types of cattle populations. Issues contributing to the lack of an unequivocally effective vaccine to prevent disease due to *M. bovis* have recently been reviewed.[122]

Definition and Etiology

Mycoplasma mycoides subsp. *capri*

Caprine pneumonias that are not contagious among adults can be caused by several species of *Mycoplasma*. However, *M. mycoides* subsp. *capri* (Mmc; formerly *M. mycoides* subsp. *mycoides* Large Colony type) can be a very serious cause of mortality among goat kids, and it is so in North America.[123,124] *Mycoplasma mycoides* subsp. *mycoides* Small Colony type (MmmSC), which is related to Mmc, is the causative agent of contagious bovine pleuropneumonia, a serious cause of sickness and death in cattle in Africa. MmmSC has been eradicated from North America.

Clinical Signs In herds with Mmc infections, goat kids usually appear clinically normal until 2 to 8 weeks of age, when the following three clinical syndromes occur:

1. A peracute illness characterized by high fevers (41.1° to 42.2° C [105.8° to 107.9° F]) and death within 12 to 24 hours;
2. A central nervous system syndrome with opisthotonos and death within 24 to 72 hours; and/or
3. An acute to subacute syndrome with high fevers, multiple hot swollen joints, and pneumonia.

The most common manifestations are swollen joints, lameness, and recumbency. About one half of affected kids have increased lung sounds on expiration and elevated respiratory rates. During an outbreak, 80% to 90% of kids die or are euthanized because of permanent recumbency. Mmc infection in adult is also life threatening.[125]

Necropsy Findings The most common necropsy finding in goat kids that die of Mmc infections is a fibrinopurulent polyarthritis. Approximately half of field cases have pneumonia. One or more lung lobes have areas of patchy to diffuse red consolidation that is sometimes covered with a fibrinous exudate. Clear, golden-yellow to serosanguineous fluid is found in the thorax in half of the cases. In some patients there are fibrinous adhesions between the lungs and thoracic wall. Affected lungs have microscopic evidence of bronchopneumonia or interstitial pneumonia. Other common lesions include pericarditis, peritonitis, and enlargement of the kidneys, liver, and spleen.

Diagnosis The definitive diagnosis of Mmc infection in individuals requires isolation of the agent from milk, joint fluid, blood, urine, or tissue. Infected goat herds can be readily identified by culturing bulk tank milk, because infected does shed up to 10^{10} Mmc organisms per milliliter of milk. Inapparent carriers can be identified by milk culturing, but false-negative results are a risk because organisms are shed intermittently. Goats can carry Mmc in their external ear canal, and PCR of auricular swabs has been shown to be a sensitive means of diagnosis of chronic carriers.[126]

Treatment and Prevention Conventional antibiotic therapy for goats with Mmc infections is almost always unsuccessful. Tylosin or tetracyclines have been used; newer-generation antibiotics effective against *Mycoplasma bovis* could also be tried, although this would be an extralabel use of these drugs. A low percentage of kids make a clinical recovery from the septicemic illness but often have arthritis by the time they freshen. Does that recover from mastitis become chronic carriers.

Prevention is based on maintaining herds free of Mmc infection. Purchased does should originate only from herds that have no history of mortality in kids from arthritis and pneumonia and that have negative bulk tank cultures for Mmc. Purchased individuals should be held separate from the milking herd until they have an Mmc-negative milk culture result; treatment for ear mites may also be prudent. A vaccine is not commercially available.

Control of Mmc outbreaks centers on prevention of the systemic infection in kids and mastitis in milking does. Rapid prevention of new cases in kids can be expected from a program of feeding heat-treated goat colostrum (56° C [132.4° F] for 1 hour) or cow colostrum at birth, pasteurized milk up to 1 month of age, and pasteurized milk or a high-quality milk replacer from 1 month to weaning. All kids with swollen joints should be culled. Milking hygiene should be improved to prevent transmission of infection during milking. Milk samples from all does in the milking herd should be cultured to identify carrier does. Infected does should be kept in a separate string and milked last, or culled. Colostrum of dry does should be cultured as they freshen, and the does should be hand-milked separately until their milk is found to be free of Mmc. Monthly cultures of the bulk tank milk from the noninfected string should be performed to ensure that it is free of Mmc infection. The goal of control procedures is eradication of Mmc from the herd.

Other Mycoplasmas

Mycoplasmas are isolated, usually in combination with other pathogens, from 50% to 90% of beef and dairy cattle pneumonias.[44,127-129] Mycoplasmas have been associated with peribronchial and peribronchiolar lymphoid hyperplasia, which is sometimes referred to as a "cuffing pneumonia," a common lesion in calves that die or are euthanized because of pneumonia.[130,131]

Mycoplasmas have also been recovered from lesions of acute and chronic bronchopneumonia in which a cuffing pneumonia was not apparent.

Other than *Mycoplasma bovis*, the species of mycoplasmas (see Box 31.4) prevalent in North America are generally considered to be mild respiratory pathogens, mainly causing subclinical infections unless coupled with environmental stresses or infections by other pathogens. Tracheobronchial aspiration performed on dairy calves at random found that calves with

VetBooks.ir

both *Mycoplasma* spp. and *Pasteurella* spp. present in the aspirate were at significantly greater risk of developing pneumonia than calves with only one organism or no organisms. A study of feedlot cattle found seroconversion to *M. alkalescens* to be significantly associated with undifferentiated fever, a clinical definition similar to undifferentiated respiratory disease.[16] Effects such as immunosuppression and inhibition of the mucociliary transport mechanism, which can be mediated by mycoplasmas, suggest that they may play an important contributory role in the pathogenesis of bovine pneumonia. *Mycoplasma ovipneumoniae* is often isolated from pneumonic lungs of sheep and goats, usually accompanied by *M. haemolytica*. On its own, *M. ovipneumoniae* is capable of causing mild, subacute to chronic bronchiolitis or bronchopneumonia that probably predisposes to *M. haemolytica* infections.

Bibersteiniia trehalosi

Bibersteinia trehalosi causes pneumonia or systemic disease with multiorgan infection in sheep. *B. trehalosi* has also been reported in association with severe peracute to acute bronchopneumonia in cattle and recently weaned calves.[132] Affected cattle died before they were noticed to be ill, and antimicrobial therapy did not seem to be very effective despite the fact that *B. trehalosi* isolates were susceptible to many antimicrobials in vitro. However, an effort to induce disease by experimental challenge of calves was not successful,[133] making it unclear whether the bacteria alone can be assumed to be the primary cause of respiratory disease in field cases. In cases where *B. trehalosi* appears to be contributing to disease, therapy with antimicrobial drugs effective against *M. haemolytica* should be attempted. Vaccines against *Mannheimia haemolytica* may help limit the problem.[134] At this time it is not known what factors increase the risk of pneumonia due to *B. trehalosi* in cattle or domestic sheep.

Trueperella pyogenes

Trueperella pyogenes (formerly *Arcanobacterium pyogenes*) is a gram-positive rod-shaped species of bacteria that is a common cause of internal or SC abscesses in ruminants. *T. pyogenes* is occasionally isolated from the lungs of ruminants with pneumonia, typically from animals that have chronic pneumonia, possibly from grossly visible abscesses. This species is viewed as an opportunist that contributes to respiratory disease as a secondary or possibly "tertiary" invader after viral pathogens and other bacterial respiratory pathogens have become established. *T. pyogenes* has a variety of virulence factors, including a cytolytic toxin called *pyolysin*, as well as several molecules that aid in adherence to host cells.[135] Diagnosis of this pathogen is usually made as an incidental finding at necropsy of an animal with significant respiratory disease from other primary causes. Finding *T. pyogenes* during a respiratory necropsy should not induce efforts to directly treat or prevent this pathogen but rather should induce efforts to prevent other primary or secondary causes of pneumonia and to treat animals in a timely manner with appropriate therapy for an adequate duration in order to prevent chronic pneumonia.

Chlamydial Agents (*Chlamydophila* Species)

Chlamydial agents, most commonly *Chlamydophila abortus*, *Chlamydia psittaci*, and *Chlamydophila pecorum*, have been associated with a variety of disease syndromes in cattle and small ruminants, including abortion and infertility, conjunctivitis, polyarthritis, encephalomyelitis, and enteritis.[136] These agents are also occasionally identified in pneumonic ruminant lungs. Because chlamydial agents can also be identified in ruminants with no signs of disease and because seroprevalence is high, the importance of chlamydial agents in ruminant respiratory disease has been debated. Although experimental infection of calves with high numbers of *C. psittaci* via a route that bypasses the upper respiratory tract can lead to clinically evident respiratory disease that may be severe,[137] in the natural setting these agents are most likely to participate as one of mutiple factors necessary to induce important ruminant respiratory disease. Research indicates that calves are infected with chlamydial agents relatively early in life and that crowding enhances the likelihood of a high proportion of animals being infected.[138]

Approach to Diagnosis and Treatment of Respiratory Disease of Undetermined Cause (Undifferentiated Ruminant Respiratory Disease)*

Amelia R. Woolums

Information regarding diagnosis and treatment of individual infectious agents that can cause ruminant respiratory disease was presented earlier. However, it is common for more than one of these agents to be involved when a group of cattle, sheep, or goats has an outbreak of respiratory disease. Moreover, when a veterinarian is called to make an initial evaluation of a group of ruminants with respiratory disease, the etiologic agent or agents involved are not known, and efforts to diagnose the microbial agents involved may not in fact be necessary. The term *undifferentiated respiratory disease* has been applied to respiratory disease of uncertain cause. Thinking of an outbreak as "undifferentiated respiratory disease" before a causative diagnosis is confirmed is helpful to ensure that the veterinarian considers all possible infectious agents and management factors that may be contributing to disease in the animals in question.

History Successful treatment of one or more ruminants with respiratory disease will require identification and alteration of the risk factors associated with ocurrence of the disease; this is particularly true when multiple animals are affected in an outbreak or when endemic disease occurs at an unacceptable rate. Evaluation of the problem begins with collection of a thorough history and is followed by examination of affected animals and the environment. The history questions are directed at management practices that predispose to respiratory disease. It is important for the veterinarian to directly observe as many management practices as possible to ensure that what is described is actually occurring. Examination of the environment includes evaluation of animal housing to determine whether poor ventilation, crowded or dirty housing, or temperature extremes are likely increasing the disease susceptibility of animals. The nutrition program should be assessed to determine whether nutritional deficiencies are likely contributing to disease susceptibility.

Clinical Signs Once a thorough history is collected, several animals involved in the outbreak should be examined. The degree of fever and severity of abnormal lung sounds were correlated with risk for retreatement for respiratory disease in feeedlot cattle[1]; thus clinical examination may be important not only for accurate identification of sick cattle but also for improving estimates of outcome for cattle with respiratory disease. Scoring systems have been developed to aid in the assessment of clinically evident respiratory disease in individual dairy calves and in groups of dairy calves.[2,3] These scoring systems are suitable for use by laypersons trained to assess calves periodically, to facilitate timely diagnosis. A limitation is that the scoring systems do not differentiate between upper

*Previous contributions by John C. Baker, Trevor R. Ames, and Steven E. Wikse are acknowledged.

VetBooks.ir

and lower respiratory tract disease. A veterinarian or trained technician can address this limitation by using transthoracic ultrasound evaluation (see the Thoracic Ultrasonography and Radiography section later) to determine whether lung lesions are present in calves with a clincial score indicating respiratory disease.

Ruminants affected by bronchopneumonia exhibit signs of respiratory tract inflammation and sometimes systemic inflammatory response. In early stages, animals stand off by themselves and do not readily approach feed. They hold their heads and ears lower than normal, appear depressed, and move more slowly than normal. As disease progresses, respirations become rapid and shallow, there may be frequent licking of the muzzle, and a moist cough is often present. Animals may have a fever of 40° to 41° C (104° to 105.8° F), and as the disease progresses they appear gaunt, have deep labored respirations, and may hold the head extended. Dyspnea may be both inspiratory and expiratory. Ocular and nasal discharges progress from serous to mucopurulent. The heavy chest wall of larger cattle may make it difficult to hear normal airway sounds. Auscultable lung changes may include increased harshness or loudness of inspiratory sounds ("large airway sounds" or "bronchial tones"). Auscultation may reveal crackles and wheezes. When ventral consolidation occurs, harsh breathing is still audible ventrally, but percussion reveals ventral dullness. Percussion is best accomplished on young calves and goats of any age. Recently shorn sheep can be readily percussed, but heavy wool makes percussion difficult. Animals in which a fibrinous pleuritis develops are reluctant to move because of pain, have shallow respirations, and sometimes have pleural friction rubs detectable on auscultation.

Nasal discharge, dyspnea, abnormal lung sounds, cough, and high fevers are cardinal signs of bronchopneumonia. Other respiratory tract conditions that must be considered as differential diagnoses include interstitial pneumonia, pulmonary edema, pleuritis, laryngitis, tracheitis, and lungworms. Rare conditions include thoracic neoplasia and diaphragmatic hernia. Nonrespiratory diseases that may result in abnormal respiratory signs include septicemia, heart failure, acid-base imbalances, and poisonings such as nitrate toxicity. In sheep and goats, ovine progressive pneumonia (OPP), caprine arthritis and encephalitis (CAE), and lung or mediastinal abscesses caused by *C. pseudotuberculosis* are additional differential diagnoses.

Because ruminants are often housed in groups and are often not acclimated to individual handling, signs of respiratory disease in one or more individuals are often first noticed from a distance rather than from "hands-on" examination. Early signs of bronchopneumonia include mildly depressed attitude and appetite; thus caretakers may first identify animals with bronchopneumonia when they are offered feed, at which time affected animals fail to come forward to consume feed with normal enthusiasm. A standardized system to improve recognition of sick calves can be used to enhance detection of calves with respiratory disease in group pens.[4]

Groups at particularly high risk for respiratory disease, such as animals that have been recently weaned and/or transported by truck or trailer, should be evaluated no less than once per day for at least the first week or two after weaning or transport to facilitate timely identification of new cases. Frequent evaluation of animals at high risk is important because the early signs of respiratory disease are nonspecific and subtle, and severe bronchopneumonia can advance rapidly, sometimes leading to death that is sudden and unexpected in as little as a few hours. For this reason, it is preferable to feed groups of ruminants at high risk for bronchopneumonia frequently, providing only what they will consume in 12 to 24 hours, rather than providing enough feed for several days in a self-feeder or via large amounts of hay. It is important to remember that once obvious signs of bronchopneumonia (such as coughing, profuse mucopurulent nasal discharge, and dyspnea) are evident from a distance, disease is often advanced and animals are less likely to respond well to therapy.

Diagnostic Evaluation of Undifferentiated Ruminant Respiratory Disease

If clinical examination of an individual or group of cattle, sheep, or goats indicates that respiratory disease is present, it is not always necessary to pursue diagnostic testing. Occasional outbreaks of respiratory disease occur in groups of ruminants, and such occasional outbreaks can often be managed successfully with administrative symptomatic therapy alone. Similarly, individuals with a first-time clinical diagnosis of bronchopneumonia may respond completely to presumptive therapy in the absence of any diagnosis. However, if recurrent outbreaks occur or if animals do not respond appropriately to symptomatic therapy, then diagnostic tests are warranted to better characterize the nature of the problem and to help determine the reason for treatment failure. In such situations a careful evaluation of management practices and facility design is also warranted to ensure that all practices possible are in place to maximize the ability of animals to resist respiratory infection. Management practices important to minimizing respiratory infection are described in the Prevention and Control of Undifferentiated Ruminant Respiratory Disease section later.

THORACIC ULTRASONOGRAPHY AND RADIOGRAPHY. The use of transthoracic ultrasound to identify evidence of lung consolidation, pleural effusion or fibrin deposition, and other abnormalities consistent with bronchopneumonia is feasible and helpful if an ultrasound machine is available for use by an individual properly trained in ultrasonographic evaluation and if animals can be restrained for assessment. An ultrasound machine used for pregnacy diagnosis, one with a transrectal probe, is well suited for on-farm transthoracic evaluation. Seventy percent isopropyl alcohol can be used as a transducing agent; it is not necessary to clip the hair unless excessive mud is present. On-farm use of ultrasonography has been evaluated for the diagnosis of bronchopneumonia in feedlot cattle and dairy calves. The procedure is feasible in dairy calves, where evaluation of the tenth through first intercostal spaces on the right side of the thorax and the tenth through second intercostal spaces on the left side of the thorax is possible, and with some practice it allows the practitioner to assess all regions where lesions consistent with bronchopneumonia are likely to occur. While transthoracic ultrasonography can be used to identify lesions of bronchopneumnonia in feedlot cattle and other older animals, due to heavy forelimb musculature it is often not possible to evalute the first and second intercostal spaces, thus some disease is more likely to be missed. Chutes that are necessary to restrain beef cattle also make ultrasonography more logistically difficult, as the chute may obstruct sites where the probe must be placed and puts the operator at more risk of injury. The sensitivity of transthoracic ultrasound evaluation for the diagnosis of lung consolidation consistent with bronchopneumonia in dairy calves has been estimated to range from 66% to 94%, and the specificity ranges from 88% to 100%.[5,6] The reader is referred to a detailed review for more information regarding on-farm use of transthroacic ultrasonography for the diagnosis of lower respiratory tract disease in calves.[6]

When used in conjunction with clinical scoring systems, transthoracic ultrasonography allows identification and discrimination of calves with clinical disease limited to the upper respiratory tract, clinical disease including lung disease, or subclinical lung disease. In one study, the presence of lung consolidation identified by transthoracic ultrasonography in dairy heifers in the first 8 weeks of life was associated with a 525-kg decrease in their first lactation milk production.[7]

VetBooks.ir

Although the value of ultrasonography for the diagnosis of bronchopneumonia in sheep and goats has not been extensively assessed, the technique should also be feasible for use in these species, assuming that the probe can be placed into contact with skin overlying intercostal spaces. This may be difficult for sheep in full fleece but should not be a problem for goats or sheep with little or no wool.

Thoracic radiography is useful for confirmation of pulomonary changes consistent with bronchopneumonia when suitable radiographic equipment is avaiable. For larger cattle this means that radiography is only possible in referral hospitals. On-farm radiography may be feasible for calves and sheep and goats, by use of portable equipment; however, it does carry the risk of radiation exposure to personnel and is likely only cost-effective for valuable individuals.

Clinical Pathology and Assessment of Passive Immunity Complete blood cell counts or serum biochemical analyses are rarely of much value in diagnosis of respiratory disease in ruminants. Some viral infections may cause leukopenia, but when bacterial pneumonia is superimposed the WBC count may be elevated. Animals with bacterial pneumonia may have an inflammatory leukogram characterized by a leukocytosis with a mature neutrophilia, possibly with a left shift; hyperfibrinogenemia is likely to occur. Animals with chronic pneumonia may have a normal WBC count even when there is significant pulmonary pathology.

Failure of passive transfer is a major risk factor for pneumonia in calves,[8,9] so investigation of respiratory disease outbreaks in calves should include an evaluation of passive transfer status by measurement of immunoglobulins or total solids in the serum of a subset of calves 1 to 7 days of age. Measurement of serum total solids with an optical, digital, or Brix refractometer is a practical, satisfactory procedure for estimation of serum immunoglobulin concentrations in groups of calves.

Necropsy Findings The value of necropsy findings to confirm the cause of death, particularly in animals that die unexpectedly, cannot be overemphasized. Much valuable information may be gained before a disease outbreak causes excessive mortality if early cases that die are subjected to timely necropsy. On a herd level, establishing a practice of subjecting all animals that die to at least gross necropsy can aid greatly in maintaining management practices that limit animal disease and death; this is because the actual cause of death identified at necropsy can sometimes be unexpected. For example, if an animal is assumed to have died of pneumonia, but it actually died of acute enterocolitis, then inappropriate control measures may be undertaken.

The cost of having animals sent to the local diagnostic laboratory for full necropsy may dissuade some owners from allowing necropsies. However, useful information can be gained simply by gross necropsy evaluation performed on the farm by the local veterinarian or, on larger operations, by staff members trained by the supervising veterinarian. With some practice veterinarians can develop confidence in identifying the major differentiating gross features of common diseases, and they can thus ensure that management is aimed at control of disease of the correct organ system. Moreover, there are some identifiable characteristics typical of the major infectious causes of bronchopneumonia. Gross necropsy can help the veterinarian make a more accurate list of differential diagnoses for outbreaks of bronchopneumonia, allowing the development of a more appropriate plan for treatment and prevention. Gross pathologic features of disease caused by infectious respiratory agents are described elsewhere in this chapter and are summarized briefly below. A review of the pathology of common pulmonary diseases of cattle is available for additional information.[10]

A respiratory necropsy should include assessment of the upper airways and trachea. Fibrinopurulent material in the larynx is evident in cattle with necrotic laryngitis. Infection with BHV-1 (infectious bovine rhinotracheitis virus [IBRV]) causes generalized reddening (congestion) and small raised, red or pale plaques on the mucosa of the nasal passages and trachea; more severe cases have dark red, hemorrhagic changes, possibly with yellow-brown exudate adherent to the mucosa (fibrinopurulent tracheitis) (see Color Plate 31.2).

Bronchopneumonia in recently transported cattle (shipping fever pneumonia) is most commonly a fibrinopurulent bronchopneumonia. The cranioventral areas of affected lungs are dark red to gray-brown in color, firm, and heavy. Bronchial lymph nodes are swollen, wet, and dark red. The inflamed lung and parietal pleura are sometimes covered with variable amounts of yellow fibrin, and the pleural cavity may contain straw-colored fluid. Fibrinous pleuritis usually indicates the presence of *M. haemolytica* or *H. somni*, or possibly *B. trehalosi.* These species can also cause necrosis of lung, which will be firm and brown to gray, and which may contain dark red, wedge-shaped lesions (infarcts) that are caused by thrombosis of an artery supplying the region. Large amounts of straw-colored exudate are often present in the pleural space. Chronic cases have multiple abscesses and pleural adhesions. As much as 60% to 80% of the lung tissue is often involved in fatal cases of severe bacterial pneumonia. In severe cases the dorsal regions of the caudal lobes often are mottled by interspersed patches of inflammation and normal parenchyma. In some cases, forced respirations result in vesicular to bullous pockets of emphysema in the dorsal areas of the caudal lobe (see Color Plate 31.3). These changes can also be seen with primary BRSV infections or with AIP. Focal or multifocal areas of firm white to yellow material that look like abscesses may actually be caseous necrosis caused by *M. bovis* (see Color Plates 31.6 and 31.7). Abscesses containing caseous or liquid purulent material may also be caused by *T. pyogenes* or anaerobic bacteria; these findings indicate chronicity.

Bronchopneumonia in housed dairy calves is less often fibrinous, but rather is characterized by the presence of firm, collapsed, dark red lobules in the cranioventral and possibly the caudal ventral lung (Color Plate 31.8); in severe cases, whole lobes of the lung may be affected. Firm, dark red lobules without fibrin on the pleura are common in pneumonia caused by *P. multocida*, *M. bovis*, or other mycoplasmas. Infection with BRSV and PIV-3 can also cause lobular consolidation of the ventral lung. *M. haemolytica* or *H. somni* may also be isolated from such lesions even in the absence of fibrinous pleuritis.

Animals that die after chronic persistent coughing, dyspnea, and weight loss often exhibit lesions of chronic suppurative pneumonia. Bronchi and bronchioles are filled with purulent exudate, there are multiple mature lung abscesses, and greatly dilated bronchioles contain malodorous exudate. When bronchiectasis is severe, the lung lobes have a nodular appearance.

Although gross necropsy alone can be very helpful in generating an accurate list of differential diagnoses, histopathologic and microbiologic findings may add valuable information, particularly in situations where symptomatic treatment has failed. Gross necropsy findings alone are not always definitive; for example, in one study of AIP in feedlot cattle, only 67% of the cases that were diagnosed with AIP based on clinical and gross pathologic findings were confirmed by histopathology.[11] Therefore in outbreaks with relatively high mortality or in cases in which therapy is not yielding expected results, the cost of full necropsy of two or three typical cases is likely to be well worth the expense.

If full necropsy at a local diagnostic laboratory is to be undertaken, two or more animals showing signs that are typical of the early stages of the disease outbreak should be sent for

VetBooks.ir

euthanasia and necropsy. Although the producer may be reluctant to euthanize animals that may recover and would rather send animals with chronic, nonresponsive disease, the chronic cases are unlikely to yield information relevant to the primary problem.

Microbiologic Tests

Samples for identification of viral and bacterial pathogens associated with cases of respiratory disease can be collected antemortem from live animals or at necropsy of animals that have died or been euthanized. It is important to remember that administration of modified live viral or live bacterial vaccines, particularly intranasal vaccines, in the 4 to 8 weeks preceding diagnosis may complicate interpretation of test results, as efforts to diagnose wild-type agents presumably contributing to disease may instead identify vaccine strains of virus or bacteria that are likely to be shed for some time after vaccination. Remember also that recent vaccination may induce seroconversion and can complicate the use of serologic testing to diagnose the cause of a respiratory disease outbreak.

Appropriate samples to collect from live animals include nasal swabs, guarded nasopharyngeal swabs, TTA, or BAL. Each of these samples has benefits and drawbacks. Nasal swabs are usually collected with a 6-inch (13.5-cm) swab that is not guarded (protected) from contamination. After sampling, the swab is put into transport medium that may come with the swab or may be obtained from a veterinary diagnostic laboratory. Guarded nasopharyngeal swabs are usually collected using a longer swab guarded by an outer sheath, such as is used for mare or cow uterine culture. While these swabs are unwieldy for sampling young calves, they allow the swab to be protected from contamination by commensal bacteria in the outer nasal passage, providing a theoretically more representative sample of viruses and bacteria in the nasopharynx that are more likely contributing to respiratory disease.

Although respiratory viruses can be shed by cattle without signs of respiratory disease, if viruses are identified in animals with respiratory disease they should be considered contributing factors. Identification of bacterial respiratory pathogens such as *M. haemolytica*, *P. multocida*, *H. somni*, or *M. bovis* from nasal or guarded nasopharyngeal swabs requires some interpetation. Because these bacteria are considered part of the normal flora of the upper respiratory tract, their identification in cattle without signs of respiratory disease is not significant. However, in calves with clinical signs of bronchopneumonia, identification of these agents on nasal or guarded nasopharyngeal swabs has been shown to agree moderately to strongly with the results of culture of materials from the lower respiratory tract, such as TTA, BAL, or materials collected at necropsy.[12-14] Guarded nasopharyngeal swabs are considered by many to be superior for the identification of bacterial pathogens because they are less likely to result in cultures that are overgown by contaminants. Others have suggested that BAL is superior to guarded nasopharyngeal swabs for identification of bacterial pathogens[15]; however, BAL is technically more demanding and time consuming. Overall, for sampling multiple individuals in a group of calves with respiratory disease, guarded nasopharyngeal swabs provide a reasonably good representation of the agents causing disease in the respiratory tract. However, for valuable individuals, TTA or BAL is the preferred method of sampling to identify infectious agents causing bronchopneumonia.

Proper handling and transport of the specimens collected from live animals or at necropsy is critical to maximize the chance of an accurate diagnosis. The veterinarian is encouraged to contact the diagnostic laboratory if he or she is uncertain about the proper methods of sample collection and transport; most laboratories now post this information on their websites, making it easy to find for those with internet access. See Table 31.14 for guidelines for identifying common infectious respiratory pathogens.

Viruses

A specific viral diagnosis requires laboratory confirmation. Most laboratories direct their diagnostic efforts toward the viruses for which vaccines are available. Diagnosis of other respiratory viruses may require the assistance of specialized laboratories.

VIRUS ISOLATION. Virus isolation is time consuming and expensive, but it can be a sensitive method for identifying some viruses. Virus isolation is performed in cell culture, with subsequent use of PCR, immunofluorescence, or IHC to identify the specific virus isolated. A variety of specimens can be tested, including nasal, nasopharyngeal, conjunctival, and tracheal swabs; TTA; BAL; and a variety of respiratory tract tissues that can be obtained at postmortem examination. Fluids, tissues, and swabs may be frozen; however, freezing may kill some of the virus in the sample. Alternatively, swabs and tissue specimens may be placed in a viral transport medium and kept refrigerated or on ice packs until arrival at the diagnostic laboratory, preferably within 24 hours. In general, better success at virus isolation is obtained when specimens are collected in the acute phase of disease.

DETECTION OF VIRAL ANTIGENS. Immunofluorescent antibody (IFA) staining is a rapid method for identifying specific respiratory viruses. Antemortem identification can be made in cells in material obtained from nasal, nasopharyngeal, or conjunctival swabs or from cells obtained by TTA or BAL. Postmortem identification can be made from frozen tissue sections prepared from a variety of respiratory tract tissues. IHC can also be used to test cells from swabs or fixed tissue. This is a useful procedure that allows histologic examination of tissues in conjunction with specific identification of the causative agent.

Antigen capture enzyme immunoassay (EIA) provides a rapid means for detecting certain viruses. These tests can be performed on fluids or homogenates of tissues obtained from the respiratory tract. Commercially available antigen capture EIAs are available for diagnosis of HRSV infections in infants and young children; these are also capable of detecting BRSV[16] and are used in some veterinary diagnostic laboratories. The same technique has been developed for the detection of BVDV and is in use for screening serum samples to detect cattle persistently infected with BVDV.

DETECTION OF VIRAL NUCLEIC ACIDS. Testing material from swabs, fluids, or tissues for viral nucleic acid by PCR (for DNA viruses) or RT-PCR (for RNA viruses) is widely available at veterinary diagnostic laboratories. One benefit of using nucleic acid detection to identify pathogens is that the pathogen does not have to be viable to be identified; this can be a particular benefit for relatively labile viruses such as BRSV.

SEROLOGIC DIAGNOSIS. Retrospective diagnosis of viral infections can be made by determining antibody titers in paired sera from individual animals. The first sample is collected in the acute phase of the disease (the "acute" sample), and the second is collected 2 to 4 weeks later (the "convalescent" sample). In a respiratory disease outbreak, multiple animals should be tested to achieve a serologic diagnosis; it is typical for seroconversion to be identified in only a subset of animals tested in any outbreak. Serologic diagnosis is made by demonstrating at least a fourfold increase (i.e., at least two dilutions) in antibody titer in the convalescent sample as compared with the acute sample; a fourfold fall in titer from the acute to the convalescent sample also indicates recent infection. Because day-to-day variation in results of tests used for serologic

VetBooks.ir

diagnosis is typical, the acute and convalescent samples should be run by the laboratory on the same day. Thus the acute serum samples should be processed and stored in the freezer by the local veterinarian and later shipped together with the convalescent samples. Because infections in young ruminants can occur in the presence of passively derived antibodies, seroconversion may not always occur during outbreaks of bronchopneumonia involving young animals.

A variety of serologic tests are available for antibody determinations, but most laboratories use a serum neutralization (SN) test (also known as a virus neutralization [VN] test) for identification of antibodies to viruses. It is important to remember that SN tests take several days to run. Some laboratories use more rapid procedures such as ELISA or IFA for determination of virus-specific serum antibody titers. A hemagglutination-inhibition test can also be used for PIV-3, influenza D virus, and respiratory coronavirus.

Bacteria

A variety of bacteria have been isolated by aerobic culture of materials collected from the respiratory tract of ruminants with respiratory disease. However, the most frequent and important isolates are *M. haemolytica*, *P. multocida*, *H. somni*, and *M. bovis*. Other mycoplasmas such as *M. dispar* or *M. ovipneumoniae* may be important in some cases. The isolation of *T. pyogenes*, coliforms, or anaerobic bacteria often is indicative of chronic pneumonia or aspiration pneumonia and may be associated with lung abscessation.

Before bacterial culture is attempted, the status of any recent antibacterial therapy should be determined. If possible, specimens from untreated cattle should be collected. It is important to remember that *M. haemolytica*, *P. multocida*, *H. somni*, and mycoplasmas are normal inhabitants of the nasal passages of cattle and may be cultured from respiratory tissue in the absence of respiratory disease. Special culture methods are required to identify *H. somni* and mycoplasmas, and many diagnostic labs will not test for these organisms unless testing is specifically requested. Moreover, most laboratories will not identify the species of mycoplasmas cultured unless that is requested; thus an isolate may be identified only as "*Mycoplasma* spp." If involvement with *M. bovis* is to be confirmed, the veterinarian will likely need to specifically request species identification for any mycoplasmas isolated. Specific identification of *M. bovis* is most often done by IFA, IHC, or PCR. Some mycoplasmas are more hardy or easier to grow than others; for example, it is not unusual for *M. bovis* to overgrow *M. dispar* when both are present in the same sample. Culture of mycoplasmas typically takes at least 1 week, and laboratories often call a sample negative only after it has been subcultured at least once, which usually requires at least an additional week. Thus it takes longer to get the final results of mycoplasma testing than testing for other bacteria.

When sampling lung tissue for bacterial infection at necropsy, contamination of the sample with environmental agents can best be prevented by first searing the lung surface with a heated spatula or knife, then making an incision with a sterile scalpel, followed by sampling with a swab through the incision. However, it may not be practical to sear the surface of the lung in the field setting. Alternatively, sections of lung and other tissue samples can be sent in sterile, sealed containers on ice to the diagnostic laboratory for appropriate sampling for bacteria.

DETECTION OF BACTERIAL ANTIGENS OR NUCLEIC ACIDS. It is common for diagnostic laboratories to use IHC for identification of bacteria in formalin-fixed tissues. This technique offers many advantages, including correlation of the pathogenic organism with the lesion and detection of pathogens not found on bacterial culture because of overgrowth of other organisms such as *T. pyogenes* or *P. multocida*. The use of PCR for identification of bacterial agents in a variety of samples is also increasingly available, and this may be more sensitive than culture.[17] The veterinarian is encouraged to contact the diagnostic bacteriologist at the local diagnostic laboratory or check the laboratory website for information regarding which tests are available. MALDI-TOFMS is used by many diagnostic laboratories for rapid identification of bacteria once they have been isolated by culture.

SEROLOGIC TESTING FOR BACTERIAL PATHOGENS. Diagnosis of infection with bacterial pathogens can be attempted retrospectively through the use of serologic testing as described earlier for viral pathogens. However, the use of serologic tests for identification of infection by bacterial respiratory pathogens has mostly been limited to use in research. Thus these tests are not likely to be widely available in veterinary diagnostic laboratories.

OTHER APPROACHES TO DIAGNOSIS OF RESPIRATORY DISEASE. The use of a computer-aided electronic stethoscope has been shown to have relatively good sensitivity and specificity, compared to pen checking, for identification of respiratory disease in feedlot cattle.[18]

Remote assessment of feeding and drinking behavior, infrared thermography, and remote detection of fever by rumen boluses or ear tags have all been used in research settings to identify cattle that have signs of illness typical of BRD. At present these approaches are not yet practical, reliable, and cost-effective for the routine diagnosis of respiratory disease. However, they will likely be the focus of continued research, and one or more of these methods may eventually become applicable for routine use in the future.

Treatment of Undifferentiated Ruminant Respiratory Disease*

Amelia R. Woolums

ANTIMICROBIAL THERAPY. The basic principles of antimicrobial therapy for bacterial bronchopneumonia are to treat early enough, treat long enough, and treat with the appropriate antimicrobial agent. Because there are currently many effective antimicrobials marketed for the treatment of important bacterial respiratory pathogens in cattle (see Table 31.15), failure to treat early enough is more likely an important cause of treatment failure than failure to choose the correct antibiotic. If lung lesions becomes too advanced before treatment is initiated, it may not be possible to reverse lung pathology with a practicable course of any antimicrobial.

Treating early enough requires timely identification of animals with clinical signs of respiratory disease. Because individual ruminants in production agriculture settings often receive their first treatment for undifferentiated respiratory disease from a layperson caretaker and not from a veterinarian, it is appropriate for caretakers to be taught by the supervising veterinarian to recognize signs of respiratory disease. Caretakers should be trained to watch for these signs whenever they are in contact with ruminants in their care; clinical scoring systems have been developed for identification of respiratory disease in dairy calves.[2,3] Similarly, in cattle feedlots clinical signs are assessed by lay caretakers, including the pen riders who evaluate cattle in the feedlot pens and the "hospital crew" who examine individual cattle "pulled" or removed from feedlot pens by the pen riders and sent to a treatment area for individual assessment

*Previous contributions of John C. Baker, Trevor R. Ames, and Steven E. Wikse are acknowledged.

VetBooks.ir

and treatment by the hospital crew. It is imperative that lay caretakers evaluating animals for clinical signs of disease receive training from the supervising veterinarian and that training be reviewed regularly so disease identification and treatment is as accurate and timely as possible. In addition, treatment of affected animals by lay caretakers should be based on written protocols established by the supervising veterinarian and maintained for easy review on the farm or feedlot.

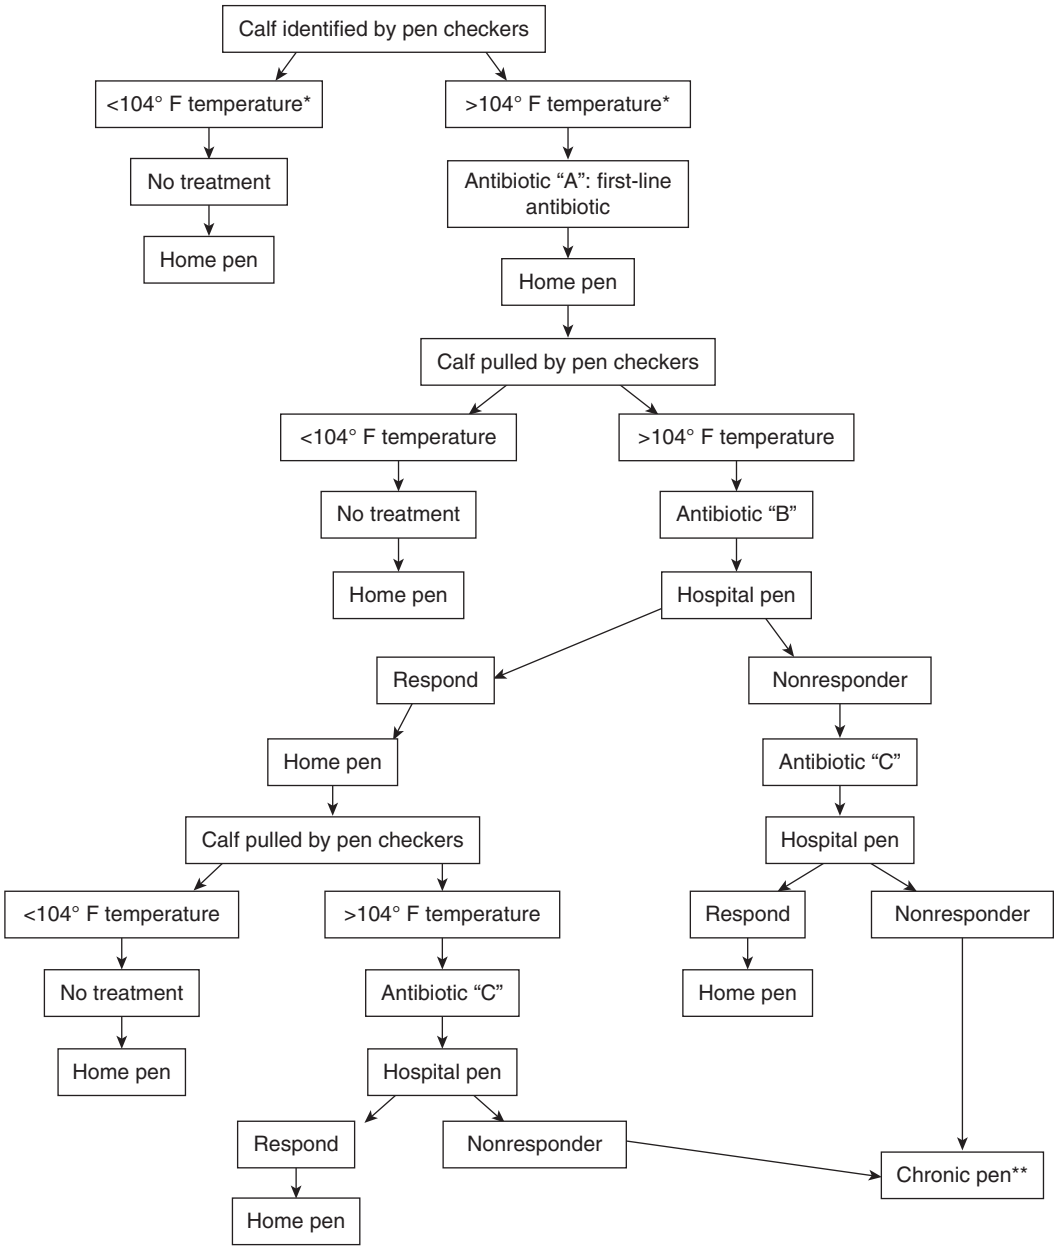
Ruminants with undifferentiated bronchopneumonia are often identified and treated presumptively based on clinical signs, without diagnostic testing to identify specific viral or bacterial etiologic agents. However, if animals fail to respond as expected to nonspecific therapy, diagnotic tests are warranted, as they may reveal an unexpected pathogen, a bacterial pathogen with unexpected antimicrobial resistance pattern, or another underlying disease that must be addressed.

Since bacteria often contribute to bronchopneumonia in ruminants, appropriate presumptive treatment includes an antimicrobial effective against the most common causes of bacterial bronchopneumonia. Selection of the appropriate antimicrobial tends to be what most veterinarians focus on when treating respiratory disease because this is the aspect of therapy over which they have the greatest control. Factors such as cost, route of administration, treatment interval, drug label restrictions, necessity of extralabel doses, and withholding times may exclude a number of antimicrobials, leaving a short list of suitable alternatives for use as a first-line antimicrobial agent. Only antimicrobials that are licensed and effective at label doses should be considered for routine use in food animals. Table 31.15 lists antimicrobials currently approved in the United States for the treatment of respiratory disease in cattle, sheep, and goats. If data regarding the MIC of bacteria isolated from untreated animals are available, the dose or duration of therapy can be rationally modified, but it is imperative that proper withdrawal times be observed when antimicrobials are used in an extralabel fashion. At the time of this writing, the Food Animal Residue Avoidance Databank (FARAD; www.farad.org or 1-888-USFARAD) is an invaluable resource for veterinarians who need to identify withdrawal times for drugs administered to food animals in an extralabel manner. The use of MIC data requires some understanding of the pharmacokinetics and pharmacodynamics of the drugs to be considered; published information is available regarding interpretation of MIC data, or veterinarians can contact FARAD, the diagnostic bacteriologist at their local diagnostic laboratory, or a veterinary clinical pharmacologist for assistance.

A decision regarding which antimicrobial to use to treat bronchopneumonia may be based on the results of antimicrobial susceptibility testing or MIC data for bacteria isolated antemortem or postmortem from animals in the group. However, such results must be interpreted carefully. The most relevant information is gained from testing samples collected from diseased lung at postmortem from animals that have not yet received any antimicrobial therapy. However, because animals are often treated presumptively before they die or are euthanized, it may be difficult to test animals that have not already been treated. Once an animal has been treated, bacteria isolated may be resistant to multiple antimicrobials.[19,20] However, bacteria isolated from the lungs of cattle that have been treated with antimicrobials are not always resistant to these drugs.[21] Currently, evidence-based guidelines for management of cattle with bronchopneumonia attributed to MDR bacteria are lacking; anecdotally it has been reported that cattle can recover despite the presence of *M. haemolytica* resistant to the antimicrobial with which they are treated. This may indicate that the host response can resolve infection and repair pathology in at least some cases of MDR infection. Management of cattle with respiratory disease associated with MDR bacteria is an active area of research.

The choice of which antimicrobial to use can also be based on records of efficacy for animals treated in the past. Producers who keep accurate records of drugs used, with results of treatment responses, relapses, and the proportion of treated animals that become chronic cases, may select first-line antimicrobials based on historical performance of a drug. This may be the best approach to antimicrobial selection. Guidelines for response to antimicrobial therapy for feedlot cattle with respiratory disease have been suggested: 70% to 80% of animals should respond to the first treatment they are given, the case fatality rate should be between 4% and 7%, and the ratio of chronic cases to cases that die should be 0.5 to 1.0.[22]

A final method of choosing a first-line antimicrobial drug is reliance on published treatment trials. Published trials give comparisons between responses for various antibiotics in cattle with naturally occurring bacterial bronchopneumonia. The outcomes of these trials are often expressed as both health and production values. When evaluating published treatment trials that use cases of naturally occurring bacterial bronchopneumonia, it is important to realize that the results may not be applicable to cattle and pathogens outside the operation where the trial was carried out. The highest-quality information comes from meta-analyses or systematic reviews, which incorporate information from multiple trials. Recent meta-analyses provide estimates of the relative efficacy of many of the antimicrobials currently labeled for treatment or control of bovine respiratory disease.[23-25]



Mass medication of an entire group of cattle during an outbreak can curtail the daily number of new cases and improve outcomes. In the acute stages of an outbreak, whatever drug is chosen should be given by injection; therapeutic levels are not likely to be reliably maintained by administering drugs in feed or water because of suppressed feed intake by sick cattle. It is important to base a decision to mass-medicate on measurable criteria. Some feedlot veterinarians implement mass medication when the pull rate of sick animals is 10% on each of 3 consecutive days or 25% on a single day.[26]

Although little research has been undertaken to determine optimal duration of therapy for undifferentiated respiratory diease of ruminants, a general recommendation is that therapy should be continued for at least 48 hours after clinical signs of fever, dyspnea, and systemic inflammatory response have abated. Many of the antimicrobial drugs labeled for use in the treatment of pneumonia in cattle provide multiple days of therapeutic drug concentrations in lung tissue after only a single injection. These products decrease the time and stress associated with daily treatment; in feedlots, they also make it easier for caretakers to return animals to home pens rather than keeping them in hospital pens, which may be associated with poorer responses by treated animals. Although a 3-day course of antimicrobial therapy for undifferentiated bronchopneumonia was in the past considered adequate, the view is increasingly held that treatment for a longer duration may be more appropriate. This is particularly true for pneumonia caused by *M. bovis* in dairy calves or feedlot cattle, which may respond better to treatment for at least 7 to 10 days.[27,28] Although treatment for 7 to 10 days would be extralabel for some antibiotics, multiple drugs currently marketed have been shown to provide therapeutic drug levels for at least 7 days when used at dosages recommended on the label (see Table 31.15).

In some cases clinical signs of bronchopneumonia do not resolve following treatment with the first-line antimicrobial. In such cases, veterinarians must decide when to give a new drug and which drug to choose for second-line therapy. In the past, a standard recommendation was to administer a second antimicrobial if the animal was still febrile 72 hours after treatment with the first-line antimicrobial. However, recent research has suggested that, for cattle given a long-acting antibiotic as a first-line treatment, it may be acceptable to wait longer than 72

hours before administering a second antibiotic. For example, it has been recommended that cattle not responding to treatment with long-acting (200 mg/mL) oxytetracycline should be treated with a second drug after 2 to 3 days, whereas cattle treated with ceftiofur crystalline free acid (Excede® [Pfizer Animal Health, Parsippany, N.J.]) should be treated with a second drug if not responding after 5 to 7 days, and cattle treated with tulathromycin (Draxxin® [Pfizer Animal Health, Parsippany, N.J.]) should be treated with a second drug if not responding after 7 to 14 days.[29] It can be difficult for a veterinarian to withhold treatment with a second or even third drug if cattle are not improving quickly, but administering a different long-acting product every 3 days may not improve outcomes, although the practice will increase the cost of treatment and may also increase opportunities for the development of bacteria resistant to the antimicrobials. More research is needed to provide evidence-based guidelines regarding when a second or third drug should be given to nonresponding cattle. At this time, veterinarians often make recommendations based on past experience. A typical decision tree for treating feedlot cattle with antibiotics is shown in Fig. 31.67, but protocols such as these may be modified as more information about the use of long-acting antimicrobials is obtained from field research.

The same principles of therapy described previously apply to the treatment of sheep and goats. Unfortunately, fewer drugs are labeled for the treatment of sheep and goats as compared with products used for cattle. Drugs labeled for use in sheep and goats are listed in Table 31.15. Note that whereas tilmicosin (Micotil 300 [Elanco Animal Health, Greenfield, Ind.]) is labeled for use in sheep, fatal reactions have occurred in goats treated

*Temperature at which cattle are treated can vary from 103.5° to 104.5°F ; cutoff is selected at discretion of supervising veterinarian.
**Calves in chronic pen should be monitored for weight gain, suffering, and withholding times, so that appropriate action can be taken (i.e., euthanize, sell, continue feeding).

FIG. 31.67 Decision tree for antibiotic treatment of feedlot cattle. *(Input contributed by Dr. Robert A. Smith.)*

VetBooks.ir

with this drug. Goats should not be treated with tilmicosin. It is imperative to ensure that producers are given an appropriate meat and milk withdrawal time when antimicrobials are administered to sheep and goats at extralabel dosages; this is a particular concern in feedlot lambs or goats and in lactating dairy sheep or goats, from which products may enter the food chain in a relatively short time after treatment.

ANTIINFLAMMATORY THERAPY. Viral or bacterial infection that leads to bronchopneumonia can cause significant tissue injury and inflammation. Moreover, many of the bacteria that cause bronchopneumonia are gram-negative bacteria that produce endotoxin, which can cause a systemic inflammatory response that can be harmful and even fatal. Treatment with NSAIDs could mitigate these effects; treatment should also decrease fever and discomfort, which should lead to improved feed intake and improved growth or milk production. A review of the published evidence for the use of NSAIDs in treatment of BRD is available.[30] Although NSAIDs often decrease fever and improve clinical appearance in cattle with BRD in the first few days after administration, a positive impact of NSAID treatment on other outcomes has not been as consistent. For example, average daily gain was improved for cattle with BRD given an NSAID as well as an antimicrobial in one study[31] but not in another.[32] Mortality was not decreased by NSAID treatment,[32,33] but lung consolidation at slaughter or necropsy was decreased in cattle receiving certain NSAIDs.[31,33] Therapy with NSAIDs might be justified on the grounds that they should improve animal comfort and therefore animal welfare, but the degree to which they actually improve comfort and welfare has not been quantified. It has also not been well established that NSAIDs are cost-effective; this will likely vary in different settings depending on the number of animals to be treated and the cost of the drug administered. If NSAIDs are to be used for treatment of BRD, in the United States and Canada flunixin meglumine (Banamine® [Merck Animal Health, Madison, N.J.]) is approved for control of pyrexia associated with BRD (1.1 to 2.2 mg/kg IV either as a single dose or divided into two doses at 12-hour intervals for up to 3 days). It is important to remember that flunixin meglumine is labeled only for IV use; administration via the IM or SC route can result in violative residues in tissues if longer withdrawal times are not observed. Phenylbutazone, which has been used in the past for antiinflammatory effect in ruminants, is now illegal to use in lactating dairy cattle in the United States, and because of prolonged tissue levels found in treated cattle its use is discouraged in all food animals. Recently meloxicam has received significant attention in North America for the control of pain and inflammation in cattle (1 mg/kg PO[34] or 0.5 mg/kg IM[35]). At the time of this writing, meloxicam is not specifically approved for the treatment of BRD in the United States or Canada; it is approved in Canada for treatment of calves with diarrhea or for pain control associated with disbudding. At the time of this writing, no NSAID is labeled in the United States or Canada for the treatment of respiratory disease in sheep or goats.

Because NSAIDs can be nephrotoxic and because nephrotoxicity is exacerbated by dehydration, dehydrated animals should be rehydrated before administration of these drugs. Care should also be taken not to overdose NSAIDs or use them for prolonged periods because they may also result in abomasal ulceration.

While corticosteroids have potent antiinflammatory effect and are sometimes used for treatment of severe inflammation associated with an infectious disease, they should not be used indiscriminately in the treatment of respiratory disease because of the potential for immunosuppression. Corticosteroids may have a place in treatment of respiratory diseases such as necrotic laryngitis or tracheal edema syndrome of feedlot cattle because edema of the larynx or trachea can cause life-threatening airway narrowing. The dose for dexamethasone in cattle is 0.05 to 0.2 mg/kg IM or IV, and the dose for isoflupredone acetate is 10 to 20 mg IM. Treatment with corticosteroids may cause recrudescence of BHV-1 infections.

There has been little research to support the use of antihistamines as an ancillary treatment for bovine respiratory disease. Tripelennamine HCl is labeled for cattle at a dose of 1.1 mg/kg, which can be repeated in 6 to 12 hours.

ANTIVIRAL AND IMMUNOMODULATING THERAPY. Although antiviral drugs could be of theoretical benefit for treating ruminants with undifferentiated bronchopneumonia, they are not routinely used. Levamisole and isoprinosine have been used in attempts to stimulate the bovine immune system with equivocal success.[36] It is important to recognize that the immunostimulatory benefits of levamisole occur at doses in the 2 to 3 mg/kg range, compared with the anthelmintic dose of 6 mg/kg. A decreased immune response has been observed after an 8 mg/kg dose of levamisole. A DNA immunostimulant (Zelnate [Bayer Healthcare LLC, Pittsburgh, Pa.]) is available for use to aid in the treatment of BRD associated with *M. haemolytica* infection. Treatment with this immunostimulant decreased the percent of abnormal lung in calves experimentally exposed to *M. haemolytica*[37] and decreased mortality due to BRD in high-risk cattle.[38]

SUPPORTIVE THERAPY. Supportive treatment may foster recovery of patients with respiratory disease. Sick animals should be provided with shelter that protects them from rain, cold, wind, and hot sun. They should not be crowded or housed in areas with excess mud and manure, and good-quality feed and clean water should be easily accessible. Mineral and vitamin deficiencies should be corrected with the use of injections or oral preparations if necessary.

Epidemiology of Undifferentiated Ruminant Respiratory Disease*

Amelia R. Woolums

RESPIRATORY DISEASE IN DAIRY CALVES. Respiratory disease in dairy calves has been described to occur both in epizootics (outbreaks) and in an endemic (enzootic) pattern ("enzootic calf pneumonia"). At the farm level, the occurrence of producer-identified calf respiratory disease is skewed, with few or no calves being identified with respiratory disease on many farms and many calves being identified with respiratory disease on a few farms. The median (and range of) incidence for producer-identified respiratory disease in the first 90 days of life was 3% to 22% (0% to 52%).[39,40] Case fatality rates for respiratory disease in dairy calves have been reported to range from 2.6% to 9.4%.[40,41] Respiratory disease accounts for a significant proportion of the total mortality (proportionate mortality) in calves raised on dairy farms, with proportionate mortality rates of 24% to 52% reported.[41-43] Respiratory disease in dairy calves can be identified as early as the first week of life.[44,45] In reports describing dairy calf respiratory disease in the first 90 to 120 days of life, the median age at which calves were first identified by producers to have respiratory disease was between 27 and 37 days,[45,46] and the age at which the highest percentage of calves are treated ranged from 35 to 70 days[41,47,48] (5 to 10 weeks). In an assessment of calves in three Canadian dairies, weekly transthoroacic ultrasound in the first weeks of life indicated that 57% of calves were found to have lung consolidation on at least one examination.[7] In a

*Previous contributions by John C. Baker and Trevor R. Ames are acknowledged.

VetBooks.ir

cross-sectional study of 39 dairies in which calves were examined by transthoracic ultrasonography once in the winter and once in the summer, the median calf-level prevalence of respiratory disease as defined by lung consolidation was 8% in winter and 15% in summer.[49]

The agreement between producers and veterinarians in identification of dairy calf respiratory disease was evaluated in two studies. Van Donkersgoed and colleagues[46] found that the risk of respiratory disease in Saskatchewan dairy calves was 39% as diagnosed by the farmer and 29% as diagnosed by the veterinarian. Virtala and colleagues[42] found that the risk of respiratory disease was 11% in New York dairy calves when diagnosed by producers and 26% when diagnosed by a veterinarian. In both sudies the agreement between veterinarian and producer diagnosis was poor at the level of the individual calf but moderate at the level of the herd. For calves subjected to necropsy, and using necropsy as the gold standard, the antemortem diagnosis of respiratory disease by producers was determined to have a sensitivity of 56% and a specificity of 100%.

Respiratory disease in dairy calves has a negative impact on their subsequent growth and productivity. In one study, calves treated for respiratory disease in the first 90 days of life were 2.5 times more likely to die before weaning than calves that were not treated.[50] Multiple investigators have shown that calfhood respiratory disease decreases calf growth.[51-53] Dairy heifers treated for respiratory disease weighed 10.6 kg less at 6 months of age than untreated calves.[51] Calves with signs of respiratory disease in the first 3 to 4 months of life are more likely to leave the herd before calving, calve later, and produce less milk in their first lactation compared to calves without respiratory disease.

RESPIRATORY DISEASE IN PREWEANING BEEF CALVES. Respiratory disease was reported to be the leading cause of preweaning death for beef calves 3 weeks of age or older on U.S. cow-calf operations.[54] Sixteen percent of deaths in beef calves born alive are attributed to BRD.[55] Two reports described the pattern of respiratory disease occurring over several years in beef calves still nursing their dams in a single large herd.[56,57] In 110,412 calves over 20 years, the annual incidence of preweaning calf BRD in the herd varied from 3% to 24%, with an average annual incidence of 11%. Annual mortality among calves with preweaning respiratory disease varied from 7% to 17%, with an annual average of 13%. In some years the incidence of preweaning BRD was higher than the incidence of respiratory disease after calves were weaned and transferred to the feedlot. Calves identified with preweaning respiratory disease weighed 7.7 kg less at birth than calves not identified with preweaning respiratory disease. A mail survey of cow-calf producers in Quebec found that 16% of respondents with fewer than 40 cows recognized calves with BRD, as compared to 36% of respondents with 40 cows or more.[58] In a mail survey of producers in six U.S. states, 21% of operations reported observing one or more calves with preweaning respiratory disease. Of these, 89% treated one or more calves, and 46% reported one or more calf deaths attributed to preweaning respiratory disease.[59]

RESPIRATORY DISEASE IN FEEDLOT AND STOCKER CATTLE. In U.S. and Canadian cattle production systems, weaned beef calves are typically transported from the farm where they are born (cow-calf operation) to feedlots where they are fed and managed until they have reached the appropriate weight for harvest. Calves may enter feedlots by direct delivery from their cow-calf operation of origin or through purchase at local or regional auction markets by an "order buyer" acquiring calves for feedlots. Alternatively, calves may not enter a feedlot directly but instead may be sent for temporary management to a "backgrounding" (also known as "conditioning") operation, where they may receive vaccinations or other treatments such as anthelmintics and growth implants, with dehorning and/or castration if necessary. At the backgrounding operation calves may be reassorted based on their size, breed type, and/or gender into new groups before being sent to feedlots. Similarly, after sale, weaned calves are sometimes transported to "stocker" operations, where they are housed or "stocked" on pasture for weeks to months with supplemental feed given as needed, along with vaccinations and other treatments, before being transported to a feedlot at a later date.

Undifferentiated bovine respiratory disease is the most common cause of morbidity and mortality in feedlot and stocker cattle. The disease is also known as "shipping fever" because it commonly occurs after cattle have been transported. The pattern of BRD in North American feedlot cattle has been well characterized.[60,61] In a study by Alexander and colleagues,[61] data from 17,696 cattle in a single feedlot were evaluated, and factors related to respiratory disease morbidity were also evaluated. Respiratory disease was the cause of treatment for 50% of the cattle treated, with 58% of BRD cases developing in the first 40 days on feed. In a study by Ribble and colleagues,[60] data were collected on all 58,885 spring-born calves entering a single western Canadian feedlot over a 4-year period. Across the 4 years of the study, total (crude) mortality was fairly consistent, ranging from 2.4% to 4.8%, whereas the mortality caused specifically by BRD varied more than tenfold (0.25% to 2.73%). Across years, proportionate mortality caused by BRD ranged from 10% to 57%. Epidemic curves constructed for each of the 4 years showed that peak mortality occurred approximately 16 days after arrival at the feedlot and that at least 50% of BRD mortalities occurred within 3 weeks of arrival. Similar results were found in the Alexander study, where 58% of BRD cases were found to develop in the first 40 days on feed. The consistent onset of fatal disease in cattle within days of their arrival at the feedlot indicates that the disease process is often underway in affected animals before feedlot entry. Ribble and colleagues demonstrated that when the incidence of fatal BRD was high (greater than 2%), the disease clustered within truckload groups of calves and also, in 1 year, within pens.

Another study evaluated patterns of BRD in the first 100 days after feedlot entry in lots (cohorts) of cattle entering 10 U.S. feedlots over 8 years.[62] For 1.2 million cattle in 7553 lots, the cumulative within-lot BRD morbidity ranged from 0.3% to 84.3%, with a median of 4.2% and a mean of 8.8%. This study demonstrated that the pattern of BRD occurrence in the first 100 days on feed can vary greatly among lots of cattle. In some lots 80% of BRD cases occurred within the first 10 days on feed, whereas in other lots 80% of BRD cases had not occurred until the cattle had been on feed for more than 90 days. In some lots the proportion of cattle treated for BRD increased rapidly over relatively few days, and in others the proportion treated increased slowly over several weeks. In some lots a rapid increase in the proportion of cattle treated for BRD occurred relatively late, between 60 and 100 days on feed. The reasons for the different patterns of BRD occurrence that were observed in different lots of cattle were not determined, but they are likely related to a combination of factors related to the cattle and their environment.

Feedlot BRD has a significant negative impact on productivity of cattle. Numerous reports have demonstrated that BRD can decrease average daily gain, final weight at slaughter, and carcass quality, with these impacts decreasing producer profit.[63-67] Feedlot BRD has been shown to decrease average daily gain during the entire feeding period by 0.06 to 0.08 kg.[65,66] In one

*Previous contributions by John C. Baker, Trevor R. Ames, and Steven E. Wikse are acknowledged.

VetBooks.ir

study, cattle treated once, twice, or three times for BRD yielded $41, $58, or $292 less, respectively, than cattle not treated for BRD.[63] Another study evaluating data from more than 212,000 cattle entering Midwestern U.S. feedlots over a 5-year period similarly showed that increasing number of BRD treatments led to decreasing financial return; net returns for fall-delivered cattle treated three or more times were $72 less than cattle not treated.[68] Although the negative impacts of BRD are well established, affected cattle sometimes exhibit compensatory growth in the later phase of feeding period, so that cattle with BRD do not always perform more poorly than unaffected cattle when the entire feeding period is considered.[67] Therefore the exact impact of BRD on the performance and profit returned by a group of feedlot cattle will vary substantially depending on numerous variables, including the specific risk factors the cattle have encountered; the management of health and nutrition in the feedlot; the cost of feed, medications, and labor; and the value of the cattle at the time they are purchased and marketed.

The epidemiology of BRD in stocker cattle is similar to that described for feedlot cattle, although morbidity and mortality rates may be higher because cattle defined to be at "high risk" for BRD make up a large proportion of many stocker cattle groups. In high-risk cattle kept on native Texas range over 3 years, BRD morbidity ranged from 31% to 49%. Net returns for steers and bulls treated for BRD were decreased from 10% to 21%, and heifers treated twice or more for BRD had 19% lower conception rates at first breeding than unaffected heifers.[69] Many reports indicate that BRD is the leading cause of disease in stocker cattle.[69-71] And although Pinchak and colleagues reported death rates of less than 1% in stocker cattle on grass, anecdotal reports indicate that BRD mortality rates in high-risk stocker cattle can be alarmingly high, sometimes approaching 10% to 20%. In trials testing health practices designed to improve health outcomes for high-risk stocker cattle over a 28- to 84-day receiving period, BRD morbidity rates ranged from 62% to 72% and BRD mortality ranged from 0% to 13%.[72,73]

RESPIRATORY DISEASE IN ADULT DAIRY OR BEEF CATTLE. Although anecdotal reports indicate that adult beef or dairy cows can experience outbreaks of respiratory disease with high morbidity and an important impact on milk production in dairy herds, the epidemiology of respiratory disease in adult cows has not been well characterized. Surveys of U.S. producers indicated that respiratory disease is the cause of 3.4% of the deaths that occur in adult beef cattle[54] and 11.3% of deaths that occur in adult dairy cattle.[74] The lack of data regarding respiratory disease in adult cows is likely due to the fact that other diseases that affect reproductive performance and milk yield are of greater economic significance in this class of cattle. However, the few published descriptions of respiratory disease outbreaks confirm that the problem can on occasion be of major importance to individual herds.

RESPIRATORY DISEASE IN SHEEP AND GOATS. Little information is available regarding the epidemiology of respiratory disease in sheep and goats in North America. A survey of U.S. producers indicated that 7% of death in adult sheep is due to respiratory disease, whereas 12% of lamb deaths are due to respiratory disease.[75] Feedlots reported that shipping fever pneumonia accounted for 13% of feedlot lamb deaths, and other respiratory disorders accounted for 29% of lamb deaths.[35]

Host and Environmental Risk Factors for Undifferentiated Ruminant Respiratory Disease*

Amelia R. Woolums

In general, risk factors for respiratory disease in all ruminants are related to (1) factors that impair the host physiologic and immunologic responses that defend against respiratory infection, and (2) characteristics of the environment that overwhelm the ability of these physiologic and immunologic responses to prevent respiratory infection. More specifically, host risk factors are related to (1) mechanical respiratory defense by the anatomic features of the upper respiratory tract and the mucociliary elevator; (2) innate immune defense provided by soluble factors such as lysozyme and defensins and by cells such as granulocytes, macrophages, and natural killer cells; and (3) acquired immune defense provided by antibodies on mucosal surfaces and in serum and by cells such as T-helper lymphocytes and T-cytotoxic lymphocytes. Characteristics of the host that can impair these mechanisms include other concurrent disease, nutritional deficiency, genetics, pronounced or chronic stress related to events such as mixing animals from various sources, crowding, and/or long-distance transport. In young animals, failure of transfer of passive immunity is a cause of transient immunodeficiency that may contribute to respiratory disease.

Environmental factors can also contribute to the development of respiratory disease in ruminants. High concentrations of airborne particulates, infectious agents, or noxious gases impair the function of host respiratory defense mechanisms or enhance the transmission of infectious respiratory pathogens. Inadequate housing can lead to cold or heat stress, which may increase nutritional requirements beyond what is available and lead to increased disease susceptibility. Crowding or mixing animals of different sources and/or age-groups can increase opportunities for transmission of infectious respiratory pathogens. Long-distance transport is well known to predispose animals to respiratory disease; this is due to close contact with other animals, which enhances transmission of infectious agents, as well as to inhalation of particulates and noxious gases in truck exhaust. Mixing animals from multiple sources, such as occurs when animals are sold through livestock auctions, increases risk for respiratory disease by increasing opportunities for exposure to respiratory and other pathogens; psychological stress associated with the establishment of new social hierarchies may also contribute to immune suppression and increased rates of disease.

When respiratory disease occurs in any group of ruminants, a systematic evaluation of host and environmental factors that may increase risk of respiratory disease should be undertaken. The purpose of this evaluation is to identify modifications in management and husbandry that should help limit ongoing respiratory disease and should decrease risk of future respiratory disease. Although this approach is logical, there is unfortunately little research that confirms that management modifications decrease respiratory disease in ruminants; it is to be hoped that future work will address this knowledge gap. Specific risk factors relevant to various classes of ruminants are discussed below.

DAIRY CALVES. In young calves, adequate transfer of passively acquired antibody and possibly also maternal cells from colostrum are very important for defense against respiratory and other infections. Nutritional deficiency, stress associated with weaning, mixing of calves from different sources, castration and/or dehorning, concurrent disease, and temperature extremes may all affect host defense mechanisms. Environmental risk facrtors are related to (1) air quality, including humidity and the concentration of bacteria, other particulates, and noxious gases in air; (2) ambient temperature extremes; and (3) opportunities for exposure of calves to respiratory pathogens through new introductions, mixing animals from different locations or age-groups on the same farm, or contact with older animals on the same farm. When dairy calves are affected by either epizootic respiratory disease (outbreaks) or enzootic calf pneumonia, careful evaluation of management practices that influence both host and environmental risk factors may help prevent future disease.

VetBooks.ir

Specific risk factors for respiratory morbidity and mortalitiy in dairy calves have been evaluated in many studies.[39-42,44,46,47,76-78] It is noteworthy that factors significantly associated with respiratory morbidity and/or mortality in some studies are not always associated with disease in other studies; this is likely because of differences in the populations studied or in methods of collection or analysis of data. Factors identified as signficant in more than one study may be relatively more important. Knowledge of factors associated with dairy calf respiratory disease can help veterinarians focus efforts to modify management to limit or prevent respiratory disease in herds where calf respiratory disease is a problem. Calf-level and farm-level factors that have been found to be significantly associated with dairy calf respiratory disease (morbidity or mortality) are presented in Box 31.5.

PREWEANING BEEF CALVES. As compared to dairy calf respiratory disease, less is known about factors that increase risk for respiratory disease in preweaning beef calves. Calf-level factors associated with preweaning respiratory disease over several years in a large U.S. herd included the year of the calf's birth, the location of the calf's group on the operation, whether or not the calf experienced dystocia requiring major assistance, the calf's sex (with male calves being at greater risk), and the age of the calf's dam (with calves born to heifers being at greater risk).[57]

BOX 31.5

Factors Associated With Respiratory Disease in Dairy Calves

Risk Factors Associated With Increased Respiratory Disease Morbidity in Dairy Calves

Calf-Level Factors

Having diarrhea[39]
Serum total IgG ≤1200 mg/dL[9] or serum total protein <5.7 g/dL[8]
Calfhood in fall or winter[39,42,47]
Being fed mastitic colostrum[9]
Certain sires[47]
Having the navel dipped[8,40]

Farm-Level Factors

Shared housing with cows[9,77]
Diarrhea occurring in calves[40,77]
Larger herd size[42,44,77]
Group housing of calves prior to weaning from milk[40]
More than 8-week age range among calves in same pen[77]
Leaving calves with dams for more than 24 hours after birth[77]
Manual (versus automatic) control of temperature in calf housing[8]

Risk Factors Associated With Decreased Respiratory Disease Morbidity in Dairy Calves

Calf-Level Factors

Being housed individually in outdoor hutch (versus any other housing)[40]
Having supervised calving[76]
Serum total IgG >800 mg/dL[46]
Receiving antibiotic preventatively[40]
Receiving supplemental antibody product to prevent diarrhea[8]

Farm-Level Factors

Decreased total bacterial counts in calf pen air[91]
Solid barriers between individual calf pens[91]
Bedding deep enough for calves to nest[91]
Antibiotics in feed or milk replacer[40]

IgG, Immunoglobulin G.

A survey of cow-calf producers in Quebec[58] found that farms with fewer than 40 cows were less likely to report a problem with preweaning calf pneumonia than farms with 40 or more cows (16% versus 36% of producers recognizing nursing calf pneumonia). The rate of preweaning calf pneumonia was associated with calving season length, with a longer calving season being associated with more cases of calf pneumonia. Another study in Quebec found that the incidence of preweaning calf respiratory disease in the first month of life was decreased if the herd vaccinated cows for respiratory viruses, with a 13% incidence in herds not vaccinating cows versus a 6% incidence in herds vaccinating cows.[79]

More recent research has evaluated herd-level risk factors for preweaning calf respiratory disease in U.S. cow-calf herds. An analysis of U.S. Department of Agriculture National Animal Health Monitoring System (NAHMS) data collected by producer survey found that introduction of steers from outside sources, herd breed makeup, number of visits to the herd by outsiders, administration of antibiotics in feed to prevent calf respiratory disease, and the herd being the primary source of income for the producer were factors associated with preweaning calf respiratory disease treatment rate.[80] A mail survey of cow-calf producers in three eastern U.S. states and three Plains states found that the occurrence of preweaning calf respiratory disease was significantly associated with larger herd size, respiratory disease in cows, and diarrhea in calves.[59] Calving season length was associated with calf respiratory disease in Plains but not eastern herds. Cumulative treatment incidence was associated with winter calving, bringing calves into the herd from outside sources, giving calves supplemental feed, and use of a heat synchronization program. A case-control study of herd-level risk factors for respiratory disease in preweaning beef calves in three U.S. states found that herd size, use of an estrus synchronization program, and use of intensive grazing were associated with treatment of at least 5% of calves for respiratory disease.[81] Taken together, the available evidence suggests that factors that increase opportunities for introduction of respiratory pathogens new to the herd and factors that increase opportunities for close contact between calves, and among cows and calves, are important risk factors for respiratory disease in preweaning beef calves.

FEEDLOT AND STOCKER CATTLE. Risk factors for BRD in feedlot and stocker cattle include factors related to events on the cow-calf operation where cattle originate, events that occur while cattle are in transit, and events that occur at arrival. On the cow-calf operation of origin, factors such as poor nutrition and uncontrolled parasitism are suspected to affect later BRD risk in the feedlot or stocker operation, but data confirming this are currently sparse. Cattle breed has been related to BRD risk.[82] Fetal programming, which refers to epigenetic effects driven by maternal experiences while the cow is pregnant but that affect the health of the calf long after it is born, is an active area of research; this may lead to clearer information about the relationship between events on the farm of origin and later BRD in stocker and feedlot cattle.

The mere fact that feedlot and stocker cattle are subjected to transport from the farm of origin increases their risk for BRD. Other factors related to increased rates of respiratory disease include sale through auction markets and prolonged time in market channels (sales barns, transport vehicles). Excessive dehydration or "shrink" from transport has been shown to account for significant morbidity and mortality in the feedlot. Movement through multiple auctions greatly increases the risk of respiratory disease. Several studies have confirmed that mixing cattle from multiple sources prior to or at feedlot entry is an important risk factor for feedlot respiratory disease.[61,83,84] Shipment for longer distances prior to feedlot entry has been associated with increased rates of

VetBooks.ir

respiratory disease in some studies[83,85] but not others.[86] Changes in weather have been associated with respiratory disease; Alexander and colleagues[61] found that a wide range between the high and low environmental temperatures in the first 2 weeks after feedlot entry was associated with increased respiratory disease. Cernicchiaro and colleagues[87] found that several weather-related variables such as maximum wind speed, mean wind chill, and temperature range were significantly associated with BRD risk, although the effect of weather was dependent on various characteristics of the cattle such as their average weight, risk category, and month of arrival and the number of cattle in the group. Heavier weight at entry has been shown to decrease feedlot BRD risk.[82,83] Castration at arrival has been shown in numerous studies to increase morbidity and mortality in feedlot and stocker cattle; it is preferable for male calves to be castrated or banded early in life to prevent the need for castration postweaning. Placement of water troughs so that cattle in adjoining pens shared them markedly increased risk for BRD in one study; the odds of BRD occurring was more than four times greated for cattle that shared water with cattle in adjacent pens compared to cattle that did not.[88] Metaphylactic antibiotic administration at arrival has been shown repeatedly to decrease risk for subsequent respiratory disease (see more discussion of metaphylaxis in the Metaphylactic Antimicrobial Therapy section later).

Calves that arrive in the feedlot with moderate concentrations of serum antibodies against respiratory viruses have sometimes been shown to have a decreased incidence of BRD, indicating that natural exposure or vaccination prior to arrival can be protective. Starting calves on diets containing 75% concentrate or greater or feeding corn silage as a major dietary component during the first month is associated with higher mortality and morbidity rates, possibly because of inhibition of certain immune functions by systemic acidosis. Feeding of nonprotein nitrogen, such as urea, is associated with increased rates of BRD.

Smith and Gill[89] have presented a helpful summary of risk classification of cattle in stocker and backgrounding operations. Stocker and backgrounding cattle can be grouped into one of three categories: (1) high risk, exposed: cattle with little or no history of vaccination, adaptation to hay or concentrate diet, and other preventative health management and with a history of mixing with cattle from multiple sources; (2) high risk, not exposed: as for high risk, exposed, but with no history of mixing with cattle from multiple sources; and (3) low risk: cattle that have been vaccinated, weaned, and turned out for a period before shipment. By nature most stocker and backgrounding cattle are in categories 1 or 2 and are thus at high risk for respiratory disease due to a variety of factors, including inadequate immunity, stress of recent weaning, and recent transport. Cattle may require dehorning and/or castration when entering the facility, which will further affect their health and productivity. Respiratory disease in high-risk, not exposed calves often peaks at 2 weeks post entry because these calves are not mixed with calves from other sources before they reach the stocker and backgrounding operation.

ADULT DAIRY AND BEEF CATTLE. Studies confirming risk factors for respiratory disease of adult dairy and beef cattle in modern North American production systems are lacking, but it is assumed that factors are similar to those described previously for calves and for cattle entering stocker operations and feedlots.

SHEEP AND GOATS. Many of the risk factors that have been found to predispose sheep and goats to undifferentiated respiratory disease are similar to those affecting cattle. Respiratory disease is more common in younger animals, after shipping or storms, and in crowded conditions. In addition, cold stress is an important risk factor for respiratory disase in young lambs and recently shorn adult sheep and goats. In contrast, heat stress may predispose to respiratory disease in unshorn sheep that do not have access to shade. Respiratory disease is also associated with semiconfinement or total confinement of sheep in poorly ventilated barns.

Prevention and Control of Undifferentiated Ruminant Respiratory Disease*

Amelia R. Woolums

Vaccines are available to prevent or limit disease due to several respiratory pathogens, and proper use of vaccines is an important component of any management effort to minimize ruminant respiratory disease. Information on the use of vaccines for ruminant respiratory pathogens is presented in the sections describing individual viral or bacterial agents.

MANAGEMENT PRACTICES TO MINIMIZE DAIRY CALF RESPIRATORY DISEASE. Efforts to minimize respiratory disease in calves should begin with assessment of factors that may be impairing host defense mechanisms, which were outlined above. Ensuring adequate transfer of maternal antibodies to newborn calves by appropriate colostrum handling and administration is one of the practices most important to ensuring calf health. On farms with high rates of calf respiratory disease, particulary in calves in the first month or two of life, efforts to address respiratory disease should include assessment of transfer of passive immunity in calves within the first week of life. If rates of failure of transfer of passive immunity are unacceptably high, management practices should be corrected to address the problem.

Although transfer of passive immunity is important to ensure calf health, groups of dairy calves with adequate transfer of passive immunity can still have high rates of respiratory disease. Thus other risk factors must also be assessed on dairies with unacceptable rates of calf respiratory disease. The method of calf housing has an important impact on risk for respiratory disease. Commonly used dairy calf housing includes individual calf hutches outdoors, super hutches for small groups of calves outdoors, individual calf pens inside a building, and group calf pens inside a building. Respiratory disease is less common in calves housed in individual hutches outdoors as compared to calves housed in individual pens indoors or in group pens indoors.[9,40] In spite of this, many producers house calves in individual pens or group pens indoors because of the negative impact of weather extremes on calves housed outdoors in hutches and on their caretakers. Group pen housing also facilitates the use of automatic self-feeders to allow calves to nurse milk more frequently, and group pen housing allows calves to interact socially with other calves. These benefits of group pen housing must be weighed against the likelihood of increased rates of respiratory disease for group-housed calves. If calves are housed in group pens, respiratory disease is less common when the pens contain smaller numbers of calves (nine or fewer per pen).[76,90]

Standards for ventilation of calf housing have been reported (see Box 31.5). A study evaluating respiratory disease prevalence in calves housed in individual pens in naturally ventilated barns[91] found that respiratory disease prevalence was decreased on farms where pens had lower total airborne bacterial counts, solid barriers between calves, and bedding that was deep enough for calves to nestle into (so that their legs could not be seen when they were lying down). Because having four or more solid partitions around a calf increased total bacterial counts in pen air, solid partitions should be placed between calves

*Previous contributions of John C. Baker, Trevor R. Ames, and Steven E. Wikse are acknowledged.

VetBooks.ir

but on no more than three sides; on the front, back, and top of calf pens, mesh barriers should be used.

Calf housing with stocking densities that are too high may result in increased transmission of pathogens, especially if there is mixing of calves of a wide age range. Overcrowding also puts additional stress on the building ventilation through buildup of noxious gases and pathogens. Cleaning of calf crates with high-pressure water sprayers is associated with new cases of pneumonia several days later. Bates and Anderson[92] have recommended standards for ventilation, including building location, fan capacity and location, intake location and design, temperature regulation, air space needed and airflow directions, and acceptable humidity levels. Sivula and colleagues[41] found that 80% of calf barns provided housing that failed to meet adequate standards of ventilation and housing regardless of whether calves were housed individually or in groups. In addition, calf housing in which calves shared the same air space as adults never met the adequate standards of ventilation and housing. A much higher percentage of calf housing that used calf hutches met these adequate standards of ventilation and housing, and virtually 100% would have been adequate housing if the hutches had been positioned correctly. Calves raised in inadequate housing have significantly poorer growth rates than do calves raised in housing that is considered adequate, which emphasizes the importance of adequate housing. A review of factors relevant to adequate ventilation of calf housing is available.[93] Ambient temperature is an important factor affecting dairy calf health. Calves must be protected from excessively cold, hot, wet, or humid conditions.

Nutritional problems that can predispose calves to disease include deficiencies of energy, protein, vitamins, or minerals necessary for the immune response. Deficiencies of copper, selenium, zinc, manganese, iron, and vitamins A and E are of special concern. Dairy managers sometimes create energy and protein deficiencies by feeding calves a low volume of milk during the first few weeks of life to minimize the incidence of neonatal diarrhea. Therefore it is important to evaluate feeding practices to correct factors that may be contributing to nutrient deficiency when attempting to limit dairy calf respiratory disease.

Veal calves are at great risk for respiratory disease because they are often reared in rooms that are filled to a high stocking rate with calves from multiple dairies that may put minimal effort into ensuring that the calves are fed adequate amounts of good-quality colostrum. Similar problems can occur on calf-rearing facilities where hundreds to thousands of very young dairy calves are raised until they are old enough to be returned to dairies to become lactating cows or sent on to feedlots. A high proportion of calves that enter calf-rearing facilities may have failure of transfer of passive immunity unless the operation managers uphold standards for passive immunity in calves they receive. Also, the accumulation of a large number of calves with a variety of histories and from a variety of sources causes problems similar to those encountered with older animals in feedlots.

MANAGEMENT PRACTICES TO MINIMIZE PREWEANING BEEF CALF RESPIRATORY DISEASE. Relative to dairy calves, less is known about management practices that should prevent preweaning respiratory disease in beef calves. Risk factors identified include a longer calving season, concurrent neonatal calf diarrhea, and practices that increase opportunities for introduction of respiratory pathogens to the herd or that increase opportunities for close contact among calves and between cows, older calves, and younger calves. Thus in herds where preweaning calf respiratory disease is a problem, it may be helpful to decrease or prevent situations where preweaning calves and/or cows are brought together in close proximity. Improving immunity of preweaning calves by addressing factors that can lead to failure of transfer of immunity from colostrum (such as dystocia and hypothermia) may help mitigate preweaning calf respiratory disease, particularly in herds with a high incidence of respiratory disease in calves in the first month or two of life, when maternal antibodies should be most protective. Because occurrence of calf diarrhea has been associated with preweaning calf respiratory disease, efforts to control calf diarrhea, which usually precedes respiratory disease, should be undertaken in herds with both problems.

Administration of vaccines for viral and bacterial respiratory pathogens to preweaning beef calves may help decrease respiratory disease. Anecdotally, cow-calf operations with a history of perennial outbreaks of preweaning calf respiratory disease have reported decreased rates of disease when respiratory vaccines are administered to calves prior to the time that outbreaks are expected. Vaccination of beef calves still nursing their dams can be logistically challenging and may not have a favorable cost-to-benefit ratio on all farms. However, the perceived value of calf vaccination to decrease outbreaks of preweaning respiratory disease has led to adoption of the practice on some operations where the syndrome has been a problem.

Once an outbreak is underway, anecdotal reports suggest that vaccination with intranasal or injectable modified live vaccines containing IBRV, PIV-3, and/or BRSV may be helpful to shorten the outbreak, but this is not yet confirmed by controlled research. Moreover, BRSV vaccination in the face of a BRSV outbreak has been associated with apparent disease enhancement,[94] thus it is possible that administration of BRSV vacccine could make an outbreak of undifferentiated calf respiratory disease worse if BRSV is the cause of the outbreak.

Vaccination to prevent bovine respiratory disease is discussed in detail in Chapter 48.

MANAGEMENT PRACTICES TO MINIMIZE FEEDLOT AND STOCKER RESPIRATORY DISEASE

Preconditioning. Preconditioning of calves is a practice undertaken to limit the impact of risk factors that influence the occurrence of BRD in feedlot cattle. Preconditioned calves are weaned well in advance of shipment to feedlots. They are trained to eat some grain from feed bunks and drink water from tanks; this is especially important for calves raised on rangeland where feed bunks or water tank may not be seen. Calves are castrated and dehorned, treated for internal and external parasites, and vaccinated against respiratory pathogens, with priming and booster vaccine administration timed to allow a full response to vaccination before calves are shipped to the feedlot. The exact details of a preconditioning program can be tailored to the needs and characteristics of the individual herd of cattle. A variety of preconditioning protocols have been described, and most of the major companies that sell vaccines have recommended standardized preconditioning programs. Also, in many areas of the United States and Canada, state, provincial, or regional groups may offer a standardized preconditioning program for local cattle producers. Typically some sort of validation that calves have received preconditioning is available through these organizations. Some of these groups also help the participating producers market the preconditioned calves in large, relatively uniform groups, which may help the calves bring better prices. In some cases, producers can retain ownership of their cattle after they enter the feedlot and receive data regarding health and performance of their animals throughout the feeding period and at slaughter. Information about local preconditioning programs usually can be obtained from agricultural extension agents or from faculty members who specialize in beef cattle management and health at colleges of animal science or veterinary medicine.

The value of preconditioning has been debated over decades. A summary of eight studies comparing the health of preconditioned calves with that of control calves indicated that, on

VetBooks.ir

average, preconditioning reduced the morbidity rate by 23% and the mortality rate by 50% in the feedlot.[95] However, preconditioned cattle do not always escape disease once they enter feedlots, and they sometimes experience outbreaks of high morbidity and mortality not unlike those seen in high-risk calves that are not preconditioned. Moreover, even when preconditioned calves experience less disease, their performance in the feedlot is not always better than that of nonpreconditioned calves,[96] or they may not always perform well enough that a profit that is greater than the cost of preconditioning is returned.[97] An evaluation of data collected over 8 years by the Texas A&M Ranch to Rail program showed that preconditioned cattle returned on average $90 more per head than nonpreconditioned cattle. However, in some years the return was better for preconditioned cattle than in other years. These data emphasize that preconditioning is likely to be cost-effective in the long run, but it may not always be cost-effective for an individual group of cattle in a single year. Also, while cattle that develop BRD in the feedlot often have decreased weight gain and/or feed efficiency and reduced carcass quality at slaughter,[64-66] they sometimes exhibit compensatory gain after they recover from BRD, which allows them to "catch up" to cattle that do not develop BRD.[67] For this reason, some feedlot operators elect not to specifically purchase preconditioned cattle, which can cost more to purchase and may not consistently yield higher profits. Because of year-to-year uncertainty in the economic advantage of preconditioned cattle, producers who sell preconditioned calves may not always be able to sell calves at a price that provides a profit over the cost of preconditioning. If an individual producer or producer organization develops a good reputation for generating reliably healthy preconditioned calves, marketing these calves directly to cattle buyers may be the best way for the producer to realize a profit from preconditioned calves. Retaining ownership of calves sent to feedlots may also allow the producer to realize better profits, but this requires a relationship with a feedlot that will manage the calves in ways that will continue to optimize health once the calves enter the feedlot. It has also been shown that preconditionning can help the producer net greater returns simply because preconditioned calves weigh more when they are sold.[98]

Backgrounding. Another practice similar to preconditioning is the practice of backgrounding. In backgrounding, weaned beef calves from a variety of sources (often purchased from multiple sale barns) are accumulated and processed in a manner similar to that carried out for high-risk calves at feedlot entry. Calves are then sorted by size and type and sold to feedlots, usually within a few days of arriving at the backgrounding operations. Backgrounding operations are sometimes referred to as "conditioning" operations. A variation of the backgrounding operation is the stocker operation; in stocker operations calves are processed and then "stocked" onto pastures, often with supplemental concentrate feeding, to graze and grow for a few weeks to months before shipment to feedlots. The difference between preconditioning and backgrounding is that preconditioning occurs on the farm where the calf is born or at least before the calf is mixed with other calves from different sources, with some aspects of treatment such as the first dose of vaccines ideally being administered before weaning. Calves that enter backgrounding or stocker operations often have uncertain health histories, they often have been weaned immediately before purchase, and when they arrive they have been mixed with calves with similar uncertain backgrounds from a variety of sources. Because of this, disease outbreaks of high morbidity and mortality are not uncommon on backgrounding and stocker operations, and respiratory disease is the leading cause of morbidity and mortality.[89] The backgrounding or stocker operator is thus taking on some of the risk of high-risk calves and is theoretically providing the feedlot with animals more likely to grow well with minimal disease than if the cattle entered the feedlot straight from the auction market.

Management at Feedlot Entry. It is not surprising that preconditioning does not always influence the occurrence of respiratory disease in cattle after they enter the feedlot because it has no effect on many risk factors active during transit and in the feedlot. Therefore optimal control of feedlot respiratory disease should begin with preconditioning and continue with avoidance of auction yards, minimization of transport time to the feedlot, limited mixing of calves from different sources, limited number of calves per pen, and careful diet management in the feedlot. Correction of vitamin and/or mineral deficiencies if known or detected, using vitamin injections in entering calves, may be helpful to decrease disease associated with immunodeficiencies of nutritional origin.

Processing procedures on arrival at the feedlot can affect the incidence of BRD. General recommendations for handling incoming cattle (the "receiving program") that are appropriate for any category of animals can be made.[26,89,99] In a receiving program, rest, rehydration, and ruminal restoration need to be addressed because cattle are physically and psychologically stressed by the marketing and transportation processes. It is recommended that these cattle be rested for 12 to 24 hours and that in the summer they be processed before the hottest part of the day. Prolonged holding before processing is associated with increased illness, and holding times over 48 hours should be avoided. Holding pens should be clean and dry or have dry bedding because this allows all cattle to lie down and rest. Shelter from wind, sun, rain, and dust should also be provided in the receiving pen.

It is important that incoming cattle have access to clean, fresh water. Raised spigots have been suggested as a way to teach incoming cattle to drink out of automatic watering devices because cattle that may not be familiar with water tanks will be attracted to the sound of splashing water. Incoming cattle should also be offered good-quality, long-stem grass hay on arrival. Hay is the best foodstuff for restoring or refilling the rumen. Hay can be put in the feed bunks as well as in feeders in the pen as a way of teaching cattle to eat out of bunks. Hay feeders may also be put along the pen perimeter to decrease walking the fence line and encourage eating. The starter ration is an important source of energy and should be highly palatable. The proportion of the starter ration dry matter that is forage is not usually less than 50% to prevent problems of acidosis. Starter rations often contain a coccidiostat because coccidiosis can occur in calves after commingling.

Processing protocols may be tailored to the category of the incoming cattle. Pharmaceutical processing options can include vaccination (respiratory and other), vitamin injections, growth hormone implanting, treatment for internal and external parasites, long-acting antibiotic therapy, drugs for aborting pregnant heifers, and probiotic administration. Management procedures for processing include ear tagging, branding, tail trimming, castration, and tip dehorning. Some management procedures such as castration and dehorning could be left for a later time—for example, at reimplanting at 70 to 90 days on feed (if cattle are expected to be on feed for more than 150 days). Taking the rectal temperature of cattle at initial processing may be helpful in identifying sick cattle.

Although vaccination of cattle to prevent respiratory disease when they are first received by feedlot or backgrounding and stocker operations is a common practice, research has not found the practice to be consistently associated with decreased BRD risk.[83,100] In a recent study, delayed administration of multivalent modified live viral respiratory vaccine, in contrast to administration at arrival, was associated with a decreased rate of second treatment for BRD.[38] Failure of vaccination at arrival to protect cattle against later respiratory disease may be because cattle are already infected at the time of vaccination

Examples of Processing Protocols for High-Risk and Low-Risk Cattle Entering Feedlots

Processing Protocol for High-Risk Cattle: Recently Weaned Cattle Purchased Through Auction Markets

1. Modified live BHV-1 (IBRV), BVDV1, BVDV2, BRSV, and PIV-3 vaccines[a]
2. Eight-way clostridial bacterin[a]
3. Antiparasitic
4. *Mannheimia haemolytica* ± *Pasteurella multocida* vaccine
5. *Histophilus somni* vaccine (if significant problem in past)
6. Growth implant
7. Ear tag identification
8. Bulls castrated (if needed)
9. Tip dehorning (if needed)
10. Metaphylactic antimicrobial treatment

Processing Protocol for Low-Risk Cattle: Healthy Yearlings Previously Fed in Backgrounding Operations

1. Modified live BHV-1 (IBRV), BVDV1, BVDV2, BRSV, and PIV-3 vaccines
2. Eight-way clostridial vaccine
3. Antiparasitic
4. Growth implant
5. Ear tag identification

[a]Experts are currently debating whether vaccines should be given to high-risk cattle at arrival or be delayed for some time.

BHV-1, Bovine herpesvirus type 1; *BRSV*, bovine respiratory syncytial virus; *BVDV*, bovine viral diarrhea virus; *IBRV*, infectious bovine rhinotracheitis virus; *PIV-3*, bovine parainfluenza virus type 3

because they are not capable of mounting an adequately protective immune response in time, or because disease is caused by agents not included in the vaccines that are administered. Following on-arrival vaccination, cattle are sometimes given a second dose of respiratory vaccine 7 to 21 days after the initial dose at feedlot entry; it is not clear whether this is consistently beneficial. See examples of processing protocols for high-risk and low-risk cattle in Box 31.6.

Metaphylactic Antimicrobial Therapy. The term *metaphylaxis* refers to the administration of an antimicrobial to a group of animals that may be in the early stages of bacterial pneumonia or that are at significant risk of developing bacterial pneumonia. Thus the antimicrobial drug administered may have either therapeutic or prophylactic effect, depending on the state of each animal treated. Metaphylactic administration of antibiotics on arrival has been shown in many studies to decrease morbidity and mortality in groups of high-risk cattle.[101,102] Long-acting antibiotics have been reported to significantly alter the number of calves from which *M. haemolytica* can be cultured.[103,104] An additional rationale for metaphylaxis on arrival is based on the epidemic curve of fatal disease onset for bacterial bronchopneumonia, which shows that feedlot calves dying from fatal fibrinous pneumonia are already sick on arrival or become ill within days of arrival. Although metaphylaxis through feed and water was used in the past, it is currently recommended that metaphylaxis be administered by use of injectable antimicrobial agents. The ability of these drugs to reach therapeutic levels quickly in all animals gives them a clear advantage given the previously discussed rationale for bacterial bronchopneumonia metaphylaxis.

A number of trials that examine various antimicrobial agents and their effectiveness for bacterial bronchopneumonia metaphylaxis have been published. Most of these studies have examined both health and production values, and a variety of products have been shown to be efficacious in decreasing respiratory morbidity and mortality and sometimes in improving production parameters. Recent meta-analyses provide estimates of the relative efficacy of many of the antimicrobials currently labeled for treatment or control of bovine respiratory disease.[23-25] At the time of this writing, several antimicrobials are approved for administration to control BRD (metaphylaxis; see Table 31.15).

Similar use of long-acting antimicrobials in dairy calves may also be of value. The disease process does not have the same narrow windows of therapeutic intervention that occur in calves entering the feedlot. Dairy calves properly managed in maternity facilities and raised in hutches rarely experience any respiratory disease until they are moved to postweaning housing. Injectable mass medication is often used at the time calves are moved as a means of controlling postweaning BRD.[52]

Although metaphylactic antimicrobial administration has clearly been effective in decreasing BRD morbidity in high-risk beef cattle, recent reports have described a high prevalence of *M. haemolytica* resistant to multiple classes of antimicrobials on nasopharyngeal swabs collected from stocker cattle after metaphylactic antimicrobial administration.[105] The degree to which MDR *M. haemolytica* negatively affect outcome in cattle colonized by these bacteria is not yet clear, but dissemination of MDR *M. haemolytica* in cattle populations may begin to decrease the benefit of metaphylaxis.

MANAGEMENT PRACTICES FOR PREVENTING RESPIRATORY DISEASE IN SHEEP AND GOATS. Prevention of pneumonia in sheep and goats is also based on altering the risk factors that predispose to pneumonia. Minimizing cold and heat stress, providing properly ventilated housing, avoiding overcrowding, and avoiding long transport in adverse weather aid in prevention. Mass medication can be used to control outbreaks of pneumonia in flocks. Injectable long-acting oxytetracycline is often used; tilmicosin can also be used for mass medication therapy for sheep, but it should never be administered to goats, as it can result in fatal reactions. Feedlot lambs are sometimes administered metaphylactic therapy (long-acting oxytetracycline) on arrival. See Table 31.15 for a list of antimicrobials approved for adminstration to sheep and goats.

The Interstitial Pneumonias*

Amelia R. Woolums

Understanding of the interstitial pneumonias of ruminants has evolved considerably over several decades. Unfortunately, lack of clarity still exists, particularly with regard to terminology. Terms such as *acute bovine pulmonary emphysema*, *atypical interstitial pneumonia* (AIP), *fog fever*, *pulmonary adenomatosis*, *farmer's lung*, and *acute respiratory distress syndrome* (ARDS) have been used interchangeably for all of the conditions that follow. This text uses a classification presented by Breeze,[1] which places the interstitial pneumonias into four groups: (1) ARDS, (2) hypersensitivity diseases, (3) chronic conditions that may be sequelae of ARDS or hypersensitivity diseases, and (4) parasitic diseases. BRSV infection can also cause AIP; this disease was discussed in relation to the respiratory disease complex of cattle, sheep, and goats in The Bronchopneumonias (Respiratory Disease Complex of Cattle, Sheep, and Goats) section earlier in this chapter.

*Previous contributions by Daniel L. Grooms and John A. Smith are acknowledged.

Acute Respiratory Distress Syndromes

An ARDS is any respiratory condition characterized clinically by a sudden onset of (usually severe) dyspnea (Fig. 31.68) with gross and histopathologic findings consistent with AIP. The characteristic gross findings of AIP are lungs that fail to collapse when the thorax is opened (Color Plate 31.9) and that are heavy and have a firm, rubbery texture on palpation. Interlobular or bullous emphysema is usually present (see Color Plate 31.3), and sometimes the cut surface of the lung has a shiny or wet appearance because of edema. In some cases affected lobules, which are dark red to purple or sometimes grayish, are interspersed with normal-looking lobules, giving the lung a "patchwork" appearance. Although the gross findings are suggestive and often characteristic, other lung diseases can cause similar changes, so a diagnosis of AIP can be confirmed only by histopathologic evaluation. The histopathologic changes that confirm a diagnosis of AIP include alveolar hyaline membrane formation and fibrin deposition, alveolar and interstitial edema, and type 2 pneumocyte proliferation. Hemorrhage, emphysema, and interstitial inflammatory cell infiltrate can also be seen.

The term *atypical interstitial pneumonia* has often been applied to describe the changes characteristic of AIP, but it has been pointed out that the clinical and pathologic changes in affected cattle are not "atypical" but rather are "typical" of acute lung injury (ALI).[1,2] Use of the term *acute interstitial pneumonia* to describe the characteristic pathologic changes and of the term *acute respiratory distress syndrome* to describe the clinical picture in an animal with AIP of as-yet undetermined cause is both accurate and all-encompassing. A diagnosis of AIP should be understood as a pathologic diagnosis rather than an etiologic diagnosis because a variety of insults can lead to the same lung lesion of AIP.

Definition and Etiology

Acute Bovine Pulmonary Edema and Emphysema

Acute bovine pulmonary edema and emphysema (ABPEE), classically known as *fog fever*, is an ARDS of adult (over 2 years old) cattle that occurs when these animals are changed from dry, sparse forages to lush, green pastures. It is caused by the conversion of L-tryptophan ingested in the lush forages to a pneumotoxic compound (3-methylindole [3-MI]), which leads to the development of pulmonary edema, alveolar epithelial hyperplasia, hyaline membranes, and emphysema.

FIG. 31.68 Heifer exhibiting respiratory distress typical of acute respiratory distress syndrome (ARDS). Note the extended head, frothing at mouth, and wide-set front legs. *(Courtesy Dr. Amelia Woolums, Mississippi State University, Starkville, Miss.)*

Clinical Signs

Adult brood cows are most commonly affected because this is the type of animal most likely to be subjected to the abrupt pasture change required to produce the condition. No breed is resistant. The type of pasture appears to be unimportant, as long as it is lush; ABPEE has been reported on a wide variety of grasses, alfalfa, rape, kale, and turnip tops.[3] Signs usually occur within 2 weeks of the pasture change. In severe cases there is an acute onset of very severe dyspnea with a loud expiratory grunt, frothing at the mouth, mouth breathing, and tachypnea. The animals are obviously distressed (as opposed to exhibiting the typical depression that occurs with infectious respiratory diseases) and stand with the head and neck extended and elevated and the nostrils dilated. Temperature and heart rate may be elevated secondary to the severe dyspnea and hypoxia. On auscultation the breath sounds are usually surprisingly soft in view of the gross dyspnea and tachypnea; a few crackles may be heard. Even mild exercise increases the dyspnea and may precipitate collapse and death. As many as 30% of severely affected patients may die, usually within 2 days. Those that survive typically show a dramatic improvement after 3 days. Recovering patients and those that are less severely affected exhibit tachypnea, harsh breath sounds, and crackles and wheezes, particularly in the caudal lung fields. Subcutaneous emphysema may develop. The demeanor of the entire group tends to become more tranquil. In cattle that have repeated episodes of nonfatal ABPEE, a chronic respiratory condition characterized by diffuse pulmonary fibrosis and alveolitis may develop.[4] For purposes of differential diagnosis, it is important to note that coughing is not prominent in the individual or the group. The main differential diagnoses are those diseases that cause ARDS in pastured adult cattle, usually in outbreak form. The association of ABPEE with typical management conditions (e.g., changes of pasture) and the absence of coughing, signs of sepsis, and adventitious lung sounds in early cases is also very important. Primary considerations should include the other plant toxicities (moldy sweet potatoes, perilla mint, and possibly others) that can be differentiated only by identifying the source. An outbreak of BRSV infection or parasitic bronchitis could cause similar clinical signs and pathology, but these are characterized by more coughing, signs of depression, and more prominent adventitious sounds; fever is common in animals with acute BRSV infection.

Pathophysiology

L-Tryptophan in lush forages is converted by ruminal microorganisms to indole-3-acetic acid and eventually to 3-MI, which is rapidly absorbed from the rumen into the blood. Metabolism of 3-MI by the cytochrome P450 mixed function oxidase system in the nonciliated bronchiolar epithelial (Clara) cells and type 1 pneumocytes results in one or more highly reactive intermediates that bind to intracellular proteins or other macromolecules and thus lead to damage or death of the cells. These intermediates are detoxified by conjugation with glutathione.[5] Cellular damage results in degeneration, necrosis, exfoliation of type 1 pneumocytes and Clara cells, and edema. These lesions in turn cause hyaline membrane formation, proliferation of type 2 pneumocytes, and to a lesser extent, proliferation of Clara cells.[6] The proliferation of type 2 cells is also known as *adenomatosis*.

Epidemiology

As indicated, ABPEE is consistently related to management practices in which hungry adult cattle are suddenly moved from sparse, dry grazing to lush green pastures. The British name "fog fever" arose from the association of the disease with "fog" pastures, which are the lush, green regrowth pastures that occur after hay or silage has been cut.

VetBooks.ir

The problem usually occurs in the fall. In the typical pattern in the western United States, cattle are moved from dry summer range onto irrigated or fertilized aftermath pastures. The disease usually appears as a herd outbreak, but individuals may be affected to widely varying degrees[7]; the morbidity rate commonly approaches 50%, with a case fatality rate as high as 30%.[8] Nursing calves typically are not affected.

Necropsy Findings In animals that die of ABPEE, ecchymotic to petechial hemorrhages occur in the larynx, trachea, and bronchi, and frothy fluid is present in the airways. The gross and histopathologic lung lesions are consistent with AIP. Congestion, edema, and hyaline membranes cause deep red-to-purple coloration of the cranial lung lobes and a smooth, glistening appearance to the cut surface. Interstitial emphysema with large bullae and gelatinous yellow interlobular edema is common. Histologically, eosinophilic hyaline membranes line alveoli and alveolar ducts, and there edema and proliferation of type 2 alveolar epithelial cells are present. In animals that are killed after 3 to 4 days, emphysema and edema are less obvious, and the lungs tend to be light brown, firm, heavy, and rubbery. There is severe diffuse alveolar epithelial hyperplasia ("adenomatosis"), and large mononuclear cells, multinucleated giant cells, and hyaline membranes are present in alveolar spaces. Edema, eosinophils, and inflammatory cells occupy the septa.

Diagnosis Diagnosis is usually presumptive based on the history of recent exposure to lush green forage, typical clinical signs, and gross pathology and histopathology in fatal cases. Measurement of metabolites of 3-MI in blood or urine can be diagnostic, but this test is typically reserved for research applications.[9] Thoracic radiographs could be used to identify changes consistent with interstitial pneumonia in valuable individual animals. The results of TTA or BAL cytology have not been reported for cattle with ABPEE, but a nonseptic mixed inflammatory cell response would be expected. There are no unique hematologic or biochemical changes. A stress leukogram may be seen.

Treatment and Prevention The stress of handling cattle can precipitate further deaths; because there is no specific treatment for ABPEE, moving cattle to attempt treatment may cause more deaths than it prevents. Some authors maintain that most cases in an outbreak occur within 4 days, that removing the herd from the pasture does not prevent additional cases, and that leaving the herd on the pasture does not result in additional cases; consequently the recommendation has been to handle severely affected cattle only if necessary to remove them to shade or to slaughter. Others recommend careful removal from the offending pasture. Antihistamines, corticosteroids, epinephrine, atropine, diethylcarbamazine, and diuretics are alleged to be of palliative value, but none of these has been confirmed to be effective in a properly designed trial. Recovery often occurs without therapy in less severe cases. In view of the dangers of handling affected cattle, the questionable efficacy of medical treatment, the probable irreversible nature of severe lesions, and the probability of spontaneous recovery in less severe cases, the best treatment may be no treatment. If treatment must be attempted, affected cattle should be handled very cautiously, and furosemide (0.5 to 1 mg/kg IM or IV once or twice daily) and flunixin meglumine (1.1 to 2.2 mg/kg IV daily or divided twice daily) or steroids (dexamethasone, 0.05 to 0.2 mg/kg IM or IV once daily) may be given. Most fatalities occur in the first 2 days. Severely affected animals that survive may develop chronic emphysema or heart failure secondary to cor pulmonale. Moderate to mild cases often show marked improvement after day 3, with recovery over about 10 days; relapses do not typically occur.

Prevention is based on modification of management and prophylactic drugs. Management strategies that have been recommended to prevent the exposure of susceptible cattle to potentially toxic pastures include the following[5-8,10]:

1. Place the cattle in a dry lot, feed palatable hay for several days, and turn them onto the lush pasture for 2 hours on the first day. Gradually decrease the amount of hay fed and increase the time on pasture over a period of 10 to 12 days.
2. Delay use of lush pastures until after a hard frost.
3. Mow and windrow the pasture before turning cattle out.
4. Use the pasture for young stock (younger than 15 months old) or sheep or other livestock; turn adult cattle out only after the pasture has been thoroughly grazed over.
5. Use the pasture before it becomes particularly lush.
6. Use continuous strip-grazing.

Because such management changes are frequently not feasible, prophylactic medication is a useful alternative. Monensin or lasalocid at 200 mg/head/day PO reduces the conversion of tryptophan to 3-MI.[3] Treatment with monensin should be started at least 1 day before pasture change and should be continued for an additional 10 days, whereas lasalocid requires a longer pretreatment period of 6 days.[11] Monensin or lasalocid is not expected to be beneficial after the onset of signs. Future possibilities include blockers of the mixed function oxidase system and enhancers of intracellular glutathione levels.

Definition and Etiology
Feedlot Acute Interstitial Pneumonia

In feedlot cattle an ARDS that is commonly referred to as *feedlot AIP* occurs. The exact cause of this syndrome is unknown, and it is probably multifactorial. Feedlot management practices typically do not include exposure of cattle to lush forages similar to those that cause ABPEE, and the feeding of moldy sweet potatoes has not been associated with feedlot AIP.[12] A variety of causes have been proposed[13,14]; unfortunately, the amount of research done to confirm or refute the various hypotheses ranges from small to nonexistent. The most commonly suggested possible causes or predisposing factors are (1) feed-associated pneumotoxins such as 3-MI[9,15,16] or dietary factors related to protein metabolism,[17] (2) chronic bacterial pneumonia,[18,19] (3) gender[9,15] and hormonal influences,[20,21] (4) chronic small airway injury,[18,19,22] (5) BRSV infection,[19,23] (6) heat or dust exposure,[22,24] and (7) hypersensitivity reactions.[22,25,26] These possible causes could also work together in various combinations to cause feedlot AIP.

Support for 3-MI as a cause of feedlot AIP comes from research that showed that levels of a stable metabolite of 3-MI, 3-methyleneindolenine (3-MEIN), were significantly higher in the blood of cattle with AIP than in control cattle.[9,15] Increased levels of 3-MEIN may be a result of decreased clearance of the toxin. Loneragan and colleagues also found that 3-MEIN levels were higher in lung tissue of AIP cases as compared with animals without lung disease, but they were not higher than 3-MEIN levels in the lung tissue of cattle with bronchopneumonia; this suggested that 3-MI may contribute to the pathogenesis of both AIP and bronchopneumonia.[9] The mechanism by which 3-MI is generated and leads to lung damage was discussed in the Acute Bovine Pulmonary Edema and Emphysema section earlier. If 3-MI does contribute to the pathogenesis of feedlot AIP, it is not clear what about the feedlot diet predisposes cattle to produce high levels of 3-MI. Normal cattle produce some 3-MI through metabolism of dietary proteins. It may be that the protein composition (e.g., the tryptophan concentration) of foodstuffs sometimes added to feedlot rations can lead to spikes in 3-MI production. Cattle with feedlot AIP have been found to have higher ruminal pH

VetBooks.ir

values than expected for cattle adapted to a high-concentrate diet. Ruminal pH in AIP cases ranged from 5.6 to 7.2 in one study[19] and from 4.9 to 7.4 in another,[27] whereas the ruminal pH of cattle adapted to a high-concentrate diet is typically about 5.5 to 5.6.[28] Many proteins are relatively basic; therefore the high ruminal pH could be related to abnormal protein metabolism. However, the relatively high ruminal pH could also be caused by anorexia. The concept that abnormal ruminal protein metabolism could contribute to feedlot AIP was also supported by a small study that found increased ammonia levels in the ruminal gas cap of cattle with AIP.[29] An interaction between digestive health and AIP was also suggested by the finding that in feedlot pens in which at least one animal had died from digestive disease, the incidence of AIP was approximately 70% greater than in pens in which digestive disease deaths did not occur.[17]

The hypothesis that bacterial bronchopneumonia contributes to feedlot AIP is supported by the finding by multiple authors that cattle with AIP frequently have superimposed gross and histopathologic lesions consistent with bacterial bronchopneumonia.[18,19,30] In a study evaluating the bacteria isolated from the lungs of cattle with feedlot AIP that had not received antimicrobial therapy, *P. multocida* and *Mycoplasma* spp. were significantly more likely to be isolated from the lungs of cattle with AIP than from the lungs of normal penmates.[19] An earlier study found that bacterial respiratory pathogens were not more likely to be isolated from cases of AIP as compared with controls, but the samples in this study were collected at necropsy of animals that received antimicrobial treatment before death in at least some cases.[31] It should be noted that no study has yet been able to confirm whether in cases with both lesions the bacterial bronchopneumonia was present before AIP occurred or the bacterial bronchopneumonia developed after the animals had AIP. If bacterial bronchopneumonia leads to the development of AIP, it is not clear how this happens. In humans with ARDS, bacterial infection is often a predisposing factor that appears to lead to ARDS through the induction of high local or systemic levels of proinflammatory cytokines.[32] The role of proinflammatory cytokines in cattle with feedlot AIP has not been investigated.

A role for gender and/or hormonal influences in the pathogenesis of feedlot AIP is related to the frequent (although not inevitable)[18] finding that the majority of affected animals are heifers.[15,17,19] Feeding of melengestrol acetate (MGA), which is fed to heifers to control estrus, has been suggested to contribute to AIP by some authors,[20] but others have not found evidence of any association between MGA and AIP.[33] Although one research study indicated that MGA could exacerbate experimentally induced AIP in sheep,[20] a well-controlled experimental study to determine the effect of MGA on AIP in cattle in the field is needed to clarify the involvement of MGA in AIP. It has also been suggested that growth hormone implants may contribute to development of feedlot AIP, although a survey of feedlot managers did not find data to support this.[33]

Infection with BRSV was linked to feedlot AIP in an early study.[23] Because BRSV infection can sometimes cause AIP, the possibility that a ruminant with lesions of AIP is simply a case of BRSV infection must always be considered. However, cattle with feedlot AIP do not always have a fever,[19] which is expected in animals with acute BRSV infection. Moreover, feedlot AIP can occur in outbreaks, but cases often occur sporadically, which would be less consistent with BRSV infection. Neither Sorden and colleagues nor Loneragan and colleagues found BRSV significantly more often in animals with feedlot AIP than in controls.[18,31] In another study the difference in frequency of identification of BRSV in feedlot AIP cases as compared with normal penmates approached significance ($P = .07$).[19] Although AIP is by definition "acute," it is interesting that several authors have reported histopathologic evidence of chronic airway injury (particularly, bronchiolitis fibrosa obliterans) in the lungs of animals with AIP.[18,19,22] In one study, the presence of bronchiolitis fibrosa obliterans was identified significantly more often in cattle with AIP than in penmates with no history of treatment for respiratory disease; this was in spite of the fact that AIP cases in the study also had no history of previous treatment for respiratory disease.[19] It is not known how past airway injury is related to the development of AIP, although chronic airway injury could be linked to the occurrence of chronic bacterial pneumonia, which has also been associated with feedlot AIP, as described previously. It may be that the chronic airway injury is related to dust exposure, although it is not clear why animals with AIP would be more likely to have airway injury caused by dust exposure than other penmates. Dust exposure has been anecdotally related to AIP,[22,24] and feedlot managers often report that efforts to control dust, such as spraying water lightly onto the surface of pens, decreases AIP occurrence when the disease is a problem. However, repeated exposure to feedlot dust or to fungal organisms from feedlot dust did not induce AIP in sheep or goats in experimental studies.[34,35] One study of the effect of dust on feedlot respiratory disease found only a weak association between airborne dust particles and respiratory disease.[36]

High ambient temperatures are thought to contribute to feedlot AIP because several investigators have found that the majority of cases occur in the summer,[17,22] but no mechanism by which hot weather might exacerbate AIP has been researched. Hypersensitivity reactions are often suggested to cause AIP. It is true that anaphylaxis can cause pulmonary edema, hemorrhage, and emphysema, with microscopic evidence of hyaline membrane formation.[37] However, animals that survive longer than a few hours after an episode of anaphylaxis do not have lung changes consistent with AIP, such as type 2 pneumocytic proliferation and interstitial inflammatory cell infiltrate.[38] Therefore an anaphylactic reaction may cause an occasional case of sudden death with lung changes typical of AIP, but anaphylaxis does not explain the majority of feedlot AIP cases. Other types of hypersensitivity-mediated lung disease have pathology that is unlike that seen in feedlot AIP, also making other types of hypersensitivity an unlikely cause of the majority of feedlot AIP cases.[1]

In summary, the cause of feedlot AIP is unknown, but the strongest support currently exists for some role for (1) factors related to feed, or ruminal metabolism, including 3-MI; (2) infectious respiratory disease, especially chronic bacterial pneumonia and possibly BRSV; (3) gender and/or other hormonal influences; and (4) chronic airway injury, which may be related to infectious respiratory disease. It seems likely that multiple factors can contribute to the development of feedlot AIP, and the factors may act in some as-yet unidentified combination in at least some cases. It is also possible that some causes predominate in some feedlots or individual cases, whereas other causes predominate in other feedlots or individual cases. A study evaluating the occurrence of bacterial respiratory pathogens in cattle with feedlot AIP found bacterial respiratory pathogens in the lungs of the majority of cases in one feedlot and in almost none of the cases in a second feedlot,[19] suggesting that bacterial infection played a role in the development of AIP cases in the first feedlot but not the second.

Clinical Signs Feedlot cattle with AIP may be found dead in the pen. Clinical presentation includes rapid onset of expiratory dyspnea and tachypnea, although if the respiratory effort is great, the actual respiratory rate may not be greatly elevated. Cattle typically stand with their heads extended and front legs spread apart and exhibit open-mouth breathing (see Fig. 31.68). Frothing from the mouth may also be observed. Rectal temperatures are variable, ranging from normal to elevated.[19] Physical examination may reveal cyanosis,

VetBooks.ir

tachycardia, and subcutaneous emphysema that extends from the cervical to dorsal thoracic area. Auscultation of lungs reveals dull areas throughout the lungs, along with some crackles. Differential diagnoses of bronchopneumonia, tracheal edema, tracheal obstruction, and hypersensitivity pneumonitis should be considered.

Pathogenesis Because the cause of feedlot AIP is unknown, the pathogenesis is also uncertain. If feed-related pneumotoxins cause at least a subset of cases with AIP, the pathogenesis will be similar to that described for ABPEE, 4-ipomeanol toxicity, and perilla ketone toxicity. If bacterial infection is a cause of some cases of feedlot AIP, as is true for some human cases of ARDS, then proinflammatory cytokine production and the resultant inflammatory cascades they initiate are likely involved. More research is necessary to determine the cause and the pathogenesis of feedlot AIP.

Epidemiology In the 1999 NAHMS survey of feedlots, AIP was identified as the second leading cause of feedlot mortality, behind bronchopneumonia (shipping fever).[39] Mortality rates resulting from AIP of 0.03% to 0.15% have been reported.[17,22,30,33] An important feature of AIP is the tendency of the disease to occur most often in cattle on feed more than 60 days,[15,19,22,31] as opposed to shipping fever, in which mortality peaks by 45 days after feedlot entry. This means that losses due to AIP deaths are amplified by the fact that relatively more resources in feed and labor have been invested in cattle that die of AIP, as compared with cattle that die of shipping fever. Most cases of feedlot AIP occur in the summer,[17,33] but the disease can occur in any season of the year, and most studies report that heifers are disproportionately affected.[15,17,19] One survey found that the odds of an animal with AIP being a heifer were 3.1 times greater than the odds of the animal being a steer.[17] In feedlot pens in which an animal died from a digestive disorder, the relative risk of AIP occurring was about 1.7, indicating that pens with a digestive disorder death were about 70% more likely to also have an AIP death, as compared with pens with no digestive disorder deaths.

Necropsy Findings The gross pathology of feedlot AIP is essentially the same as that described for ABPEE. If there is concurrent bacterial bronchopneumonia, there may be cranioventral consolidation, with fibrin deposition on the pleura, but in cases with no concurrent bacterial pneumonia, the pleura is free of fibrin. Grossly it is common to see a "patchwork" appearance of dark and light-colored lobules interspersed, and the lobules are freely movable (see Color Plate 31.9). Histologically, the most acute cases will have only hyaline membrane formation and alveolar edema, possibly with hemorrhage in the alveoli or interstitium; cases that have been going on longer will have proliferation of type 2 alveolar epithelial cells and inflammatory cell infiltrate into the interstitial space (septa). It is not unusual to find evidence of chronic airway injury, such as peribronchiolar lymphoid cuffing, peribronchiolar vascular fibrosis, and bronchiolitis fibrosa obliterans.[18,19] Whether the chronic airway injury is related to the pathogenesis of AIP or is an incidental finding is unknown.

Diagnosis Diagnosis of feedlot AIP can be confirmed only by histopathologic evaluation of lung from animals that die or are euthanized because of the disease. Clinical signs and even gross pathology are not definitive; only 65% to 80% of cases identified based on clinical signs were confirmed by histopathologic evaluation to have AIP in two studies.[6,15]

Treatment and Prevention Recommended treatments are similar to those recommended for ABPEE. However, feeding monensin does not preclude development of feedlot AIP, as cattle that die of AIP are often consuming feed including monensin when they contract AIP.[15] Treatment is supportive and typically includes administration of antiinflammatory drugs such as steroids (dexamethasone, 0.05 to 0.2 mg/kg once or twice) or flunixin meglumine (1.1 to 2.2 mg/kg IV q24h) and diuretics such as furosemide (1 mg/kg IM or IV q12-24h). Antimicrobial drugs are appropriate given that cases often have superimposed bacterial pneumonia (see Table 31.15). There are no studies evaluating the response of cattle with AIP to any treatment, and such studies would be difficult because there is no perfect method of making an antemortem diagnosis of the disease. However, anecdotal reports indicate that the prognosis is guarded even with treatment. It is important to note that simply moving cattle out of the pen could lead to death from severe respiratory compromise. Because of the risks and uncertainties of treatment and the expected high case fatality rate, immediate salvage slaughter may be the most economic course to take; if salvage slaughter is attempted, remember to observe proper drug withdrawal times.

Because the cause of feedlot AIP is unknown, it is difficult to recommend control measures. Administration of aspirin and of vitamin E have been suggested as rational preventative strategies to counteract inflammatory pathways suspected to be involved in feedlot AIP; however, two trials showed no clear effect of these therapies on levels of 3-MI in treated cattle.[40,41] No cattle in these trials developed AIP, so an effect on disease could not be identified. The risk factors identified suggest that management strategies to minimize abrupt dietary changes and to control infectious respiratory disease may be helpful; anecdotal reports also suggest that efforts to control feedlot dust may be helpful.

Definition and Etiology
4-Ipomeanol (Moldy Sweet Potato) Toxicity

Moldy sweet potato toxicity is caused by the ingestion of a furanoterpenoid toxin produced by sweet potatoes *(Ipomoea batatas)* in response to infestation with the fungus *Fusarium solani (javanicum)*. It should be emphasized that this disease is an intoxication and not an allergic response to the fungus.

Clinical Signs There is an acute onset of tachypnea, tachycardia, hyperpnea, and dyspnea, with loud expiratory grunting, frothing at the mouth, extension of the head and neck, flaring of the nostrils, and frequent deep coughing. Crackles and harsh bronchial sounds are heard on auscultation. Signs usually occur within 1 day of exposure, and deaths may occur 2 to 5 days later. Differential diagnoses are as for ABPEE (see earlier discussion), which this condition closely resembles, except for the history of exposure and the more prominent cough and adventitious lung sounds.

Pathogenesis When *F. solani* (or closely related species) grows on sweet potatoes, the potato produces several 3-substituted furans, including 4-hydroxymyoporone, which is hepatotoxic. This is converted by the fungus to a series of pneumotoxins, the most abundant of which is 4-ipomeanol. When ingested by cattle in sufficient amounts, this toxin is absorbed, carried to the lungs in the blood, and converted to a highly reactive metabolite by a cytochrome P450–dependent mixed function oxidase system. From this point the pathogenesis is similar to that of ABPEE—that is, the toxin binds to intracellular macromolecules in the cell, causing cellular damage, particularly in Clara cells, type I pneumocytes, and endothelium; edema, hemorrhage, cellular necrosis, hyaline membrane formation, and proliferation of cuboidal epithelium result, with secondary emphysema.

Epidemiology The disease usually occurs in outbreak form when groups of cattle are fed damaged sweet potatoes.

Morbidity and case fatality rates are high. Calves nursing affected cows are unaffected.[42]

Necropsy Findings The lungs are wet, firm, and large and fail to collapse. Hemorrhages, yellow gelatinous edema fluid, and emphysema with bullae occur throughout. Lobules are dark-red and firm. Microscopic lesions include edema, emphysema, hyaline membranes, hemorrhage, mixed interstitial infiltrates, alveolar epithelial hyperplasia, peribronchiolar fibrosis, and bronchiolitis obliterans.

Diagnosis Diagnosis is made based on a history of feeding sweet potatoes and identification of clinical signs and pathology consistent with AIP. Other diagnostic tests as described for ABPEE could also be attempted in valuable individual animals.

Treatment and Prevention Treatment has not been investigated. Because the pathophysiologic mechanisms are similar to those of ABPEE, similar recommendations are suggested: handle affected animals with extreme care; if treatment is attempted, furosemide (0.5 to 1 mg/kg IM or IV q12-24h) and flunixin meglumine (1.1 to 2.2 mg/kg IV daily or divided twice daily) or dexamethasone (0.05 to 0.2 mg/kg IV or IM q24h) may be given. The prognosis for moderate to severe cases is grave, regardless of management. Because toxicity is difficult to predict and is usually severe and irreversible when it occurs, the feeding of mold-damaged sweet potatoes should be strictly prevented.

Definition and Etiology

Perilla Ketone (*Perilla frutescens*) Toxicity

Perilla ketone toxicity is an ARDS caused by ingestion of a pneumotoxin found in the leaves and seeds of *Perilla frutescens*, a common weed in the southeastern United States. This plant is also known as purple mint, perilla mint, wild coleus, and beefsteak plant.[43] It is an erect herbaceous annual about 2 m high, with characteristic square stems, an aromatic odor, and opposite, coarsely serrated ovate leaves 5 to 10 cm long and 4 to 8 cm wide with a purplish tint at maturity. The seed and flower stage, which occurs in August to October, appears to be most toxic. The flowers are small, white to purple blooms on a long raceme. The plant prefers semishade, such as damp, open wooded areas.

Clinical Signs Animals are often found dead.[43] Signs observed include a sudden onset of moderate to severe dyspnea, wheezing, frothing at the mouth, and an expiratory heave or grunt. In less severe cases the cow may pant. Exertion worsens the signs and may precipitate death. Mature cows are most often affected, but deaths have been reported in yearlings and calves. Death occurs in 3 to 7 days in experimental toxicity.[43] Differential diagnoses are as for ABPEE, which this condition closely resembles and from which it can be differentiated only by history of exposure.

Pathogenesis The volatile oils of *P. frutescens* contain a number of 3-substituted furans that are chemically similar to 4-ipomeanol, the moldy sweet potato toxin. One of these, perilla ketone, predominates in the later growing season (when most toxicities occur) and has been shown to be pneumotoxic when given parenterally to mice, hamsters, goats, calves, and sheep.[43] The toxin is absorbed from the rumen, carried to the lungs through the blood, and probably metabolized to the toxic form by the mixed function oxidase system, as for 4-ipomeanol and 3-MI. The pathogenesis from this point parallels that of ABPEE or moldy sweet potato toxicity.

Epidemiology *P. frutescens* seems to thrive in late summer, when pastures in the southeastern United States are frequently dry and dormant. This also corresponds with the more toxic stage of the plant. Cattle normally avoid the plant when other pasture is available but may be forced to consume it during this critical period. However, under experimental conditions calves were noted to prefer the mint.[43] The preseed stage appears to be of relatively low toxicity; the green seed–stage plant is most toxic, especially the seed parts; dried hay from seed–stage plants is less toxic than green plants but is still potentially lethal; and frosted plants appear to have relatively low toxicity.[43] The exact toxic dose is unknown, but 2.3 kg of green seed–stage plant and 11.2 kg of hay were lethal for cattle in one trial.[43]

Necropsy Findings The lungs are distended (often bearing the impressions of the ribs), fail to collapse, and are moist, heavy, edematous, and emphysematous. There are often bullae, pleural effusions, and froth in the airways. Histologic characteristics are edema, extensive alveolar epithelial hyperplasia, emphysema, and congestion.

Diagnosis Diagnosis is based on history of exposure to perilla mint and characteristic clinical signs and lung pathology. Other diagnostic tests as described for ABPEE could also be attempted in valuable individual animals.

Treatment and Control Treatment has not been investigated. On the basis of the similar pathophysiologic mechanisms, the recommendations for ABPEE should be followed. The prognosis for severe cases is grave, regardless of management. Cattle should be provided with sufficient forage that they do not seek out perilla mint; once they have begun to eat it, they should be fenced away from stands of the plant, and other forage should be provided.

Other Toxic Plants

Brassica spp. (rape, kale, turnip tops) are currently regarded as one of the types of pasture that can precipitate 3-MI–associated disease. The possibility that other specific toxins may be identified in these species has not been excluded. Morbidity and mortality rates appear to be much higher on *Brassica* spp. pastures than on other lush forages.[1] The hepatotoxic effects of pyrrolizine alkaloids are well known, but they also cause lung lesions. Lung lesions develop only in animals with chronic liver lesions, and the minimum dose necessary to produce lung lesions is never less than that which is hepatotoxic; therefore signs of liver disease usually predominate. *Crotalaria* and *Trichoderma* spp. are the most common offenders; to a lesser extent, *Senecio* spp. are a cause. Horses, sheep, cattle, and pigs have been affected. Pulmonary lesions include edema, congestion, hemorrhage, proliferation of bronchiolar and alveolar epithelial cells with megalocytosis, and interstitial fibrosis and cellular infiltration. As with 3-MI, 4-ipomeanol, and perilla ketone, the toxicity of the pyrrolizine alkaloids depends on activation by the mixed function oxidase system; in this case, however, the toxin is probably formed in the liver and spills over into the blood to reach the lungs. Vascular endothelium is probably the primary target for injury (versus the Clara cells and type 1 pneumocytes in the other ARDS).

Toxic Gases

Ruminants may be exposed to a variety of toxic gases in the environment. The most important are ammonia, hydrogen sulfide, carbon dioxide, and methane from excreta and respiration; these can be especially important when excreta is collected in pits or tanks. Other gases include nitrogen dioxide from silos; carbon monoxide from machinery exhausts and heaters; zinc oxide from welding of galvanized metal in barns; chlorine, formaldehyde, insecticides, and other fumes from agricultural chemicals and cleaners; and smoke from fires. In most cases

VetBooks.ir

concentrations usually remain below overtly toxic levels, and effects are very subtle. Such chronic low-level exposure may result in decreased disease resistance and depression of growth rates. Slightly higher levels of chronic exposure may cause clinically vague syndromes of lethargy, mild dyspnea, anorexia, depressed growth, excessive lacrimation and salivation, low incidence of sudden deaths over weeks or months, and stillbirths. Acute, severe outbreaks usually occur in tightly enclosed facilities and are related to accidents, power outages, agitation or pumping of manure pits, or other combinations of unusual circumstances. Such outbreaks are characterized by an ARDS of variable morbidity and frequently a high case fatality rate.

NITROGEN DIOXIDE. Nitrogen dioxide (NO_2) is a yellow-orange to brown gas with an acrid odor that is produced by anaerobic fermentation of green plant material. It is a major component of "silo gas." Acute exposure of farm workers to high concentrations of NO_2 causes a respiratory condition known as "silo-filler's disease," characterized by severe acute edema and congestion and followed by bronchiolitis obliterans and progressive interstitial pulmonary fibrosis. A similar condition has been induced experimentally in cattle,[44] and apparent spontaneous field cases have been reported.[45,46] Clinical signs in experimental and apparent field cases include cough, tachycardia, tachypnea, respiratory grunting, depression, anorexia, hypogalactia, extension of the head, open-mouth breathing, fever, salivation, lacrimation, and subcutaneous emphysema. Auscultation reveals decreased breath sounds and crackles. The primary differential diagnoses should include other ARDS of housed cattle that occur in outbreak form, especially exposure to other toxic gases (manure pit gases, zinc oxide, chlorine, carbon monoxide), and hypersensitivity pneumonitis from moldy hay. Nitrate toxicity should also be considered. Clinical pathologic evaluation is of limited benefit. Leukocyte counts remained normal in experimental cases; methemoglobin levels increased to a peak at 30 minutes after exposure and returned to normal in 12 to 24 hours.[44] The pathophysiologic mechanism probably involves the dissolution of the NO_2 in the water of the respiratory tract to form nitric acid. Nitrates and nitrites are also formed; these are irritating, and the nitrites cause methemoglobinemia. Nitrogen dioxide is also an oxidant itself and may contribute directly to the injury. The disease occurs as an outbreak, usually in housed cattle in proximity to a silo chute in a tight or poorly ventilated barn.[45,46] Nitrogen dioxide is heavier than air and layers on top of silage or spills out around the bottom of the silo. Corn silage produces more gas than hay, and a high nitrate content increases the danger. The levels are highest in the first 48 hours after filling the silo but may remain dangerous for 2 to 3 weeks.

Necropsy findings in experimental disease include hyperemia of the upper airways; hemorrhages, fibrinous membranes, and froth in the trachea; distended, noncollapsing lungs with rib imprints; a mottled appearance caused by consolidated lobules alternating with emphysematous lobules; and bullae. Microscopic lesions include alveolar epithelial hyperplasia, large foamy alveolar macrophages, hyaline membranes, hyperemia, hemorrhage, and edema.

Treatment involves the establishment of adequate ventilation; cows should be completely removed from closed buildings if necessary. Corticosteroids have apparently been beneficial in field cases, but no controlled studies have been performed to confirm efficacy. Because of the obvious differences in pathophysiologic characteristics, it would be unwise to extrapolate treatment regimens from those of ABPEE. Suggested empiric therapy might include corticosteroids (dexamethasone, 0.05 to 0.2 mg/kg IM or IV daily), furosemide (0.5 to 1.1 mg/kg IM or IV daily or twice daily), and appropriate antibiotics to prevent secondary bacterial infections.

ZINC OXIDE. Zinc oxide (ZnO) fumes have been associated with an ARDS in cattle.[47] Oxyacetylene cutting or arc welding of galvanized pipe results in production of white fumes of zinc oxide containing colloidal particles 0.3 to 0.4 mm in diameter, which can reach the terminal alveoli when inhaled. Construction activities in closed barns containing animals may result in toxicity in animals in close proximity to or in the path of ventilation. All ages may be affected.

Clinical signs in severe cases include acute onset of anorexia, frothing at the mouth, anxiety, extension of the head and neck, mouth breathing, expiratory grunting, tachypnea, tachycardia, mild fever, subcutaneous emphysema, and crackles on auscultation of the lungs. Death may occur within 12 hours. Less severely affected animals exhibit depression, mild fever, and tachypnea. Differential diagnoses include other ARDS of housed cattle that occur in outbreak form, such as exposure to other toxic gases (nitrogen dioxide, manure pit gases) or hypersensitivity pneumonitis. The pathophysiologic process presumably involves direct damage to cells by the ZnO and its products dissolved in the fluid lining the respiratory tract. Necropsy findings include purulent conjunctivitis; subcutaneous emphysema; congestion of the airways; tracheal hemorrhages; stiff, noncollapsing lungs; and pulmonary congestion, edema, and emphysema with bullae. Histologic lesions include pulmonary congestion, emphysema, edema, and mixed cellular infiltrates with a prominent eosinophil component. Treatment of severe cases with epinephrine, antihistamine, atropine, and corticosteroids had no effect in one outbreak, whereas mild cases recover spontaneously. Suggested empiric therapy could include ventilation of the area, dexamethasone (0.05 to 0.2 mg/kg IM or IV daily), furosemide (0.5 to 1.1 mg/kg IM or IV daily or twice), and appropriate antibiotics to control secondary bacterial invaders.

CHLORINE. Chlorine is a greenish-yellow gas widely used in manufacturing. Animal exposure is usually the result of industrial accidents. Exposed animals may be found dead. Signs include depression, profuse nasal discharge, lacrimation, and dyspnea; crackles may be heard on auscultation.[48] The toxic effects are the result of the formation of hydrochloric and hypochlorous acids; the latter breaks down to hydrochloric acid and oxygen, both of which are toxic to tissues. Necropsy findings include congestion of the nasal mucosa, tracheitis, and pulmonary edema, hemorrhage, and emphysema. Histologic lung lesions include edema, emphysema, hemorrhage, atelectasis, hyaline membrane formation, and lymphocytic bronchitis. Treatment is empiric; suggestions include corticosteroids (dexamethasone, 0.05 to 0.2 mg/kg IM or IV daily), furosemide (0.5 to 1.1 mg/kg IM or IV daily to twice daily), and appropriate antibiotics to prevent secondary bacterial infection.

MANURE GASES. Manure gases include mixtures of hydrogen sulfide, ammonia, carbon dioxide, methane, and carbon monoxide.[1] Accumulation of these gases can result in asphyxiation of animals in enclosed barns over manure pits.

SMOKE INHALATION. Smoke inhalation injury may occur in animals that survive barn fires. Many clinical changes may not become evident for 24 to 48 hours after the fire. It is important to assess the degree of damage as early as possible and to attempt to anticipate sequelae so that early aggressive therapy can be instituted.[49] Common problems to check for include oral burns, conjunctivitis, and laryngospasm. Hoarseness, expiratory wheezes, and carbonaceous sputum indicate potentially serious sequelae. Crackles and wheezes on auscultation may occur very early or may be delayed for hours. Cough, stridor, and tachypnea may also occur. Bright red mucous membranes may indicate carbon monoxide poisoning or burns and may mask cyanosis. Carboxyhemoglobin determinations

VetBooks.ir

VetBooks.ir

on iced venous blood (often available at human hospitals), serial arterial blood gas determinations, transtracheal wash, and bronchoscopy are useful in delineating the extent of damage and prognosis.

The pathophysiology of smoke inhalation is complex and involves two main mechanisms: carbon monoxide toxicity and smoke toxicity. Carbon monoxide toxicity results in tissue hypoxia in all organs, especially the brain; oxygen consumption in the fire and the pulmonary effects of smoke may aggravate this hypoxia. Heat damage in animals is usually limited to the upper airways. Smoke toxicity is related to the inhalation of soot, superheated particles, and a variety of noxious gases (e.g., aldehydes, oxides of sulfur and nitrogen, benzene from plastics), which results in the formation of dissolved acids, alkaloids, and other direct irritants in pulmonary fluids. These mechanisms eventually (usually 2 to 24 hours after inhalation) result in alveolar damage, interstitial edema, hypoxia, and secondary bronchopneumonia.

Treatment involves establishing a patent airway with intubation or tracheostomy if necessary. Oxygen, up to 100% for short periods, is indicated; care must be exercised because 100% oxygen can also cause pulmonary damage. IV fluids should be given, with careful monitoring for pulmonary edema. The use of corticosteroids is controversial. Antibiotics are indicated to prevent secondary bronchopneumonia. Bronchodilators such as aminophylline at 6 to 10 mg/kg IV or PO three times daily may help relieve soot-induced bronchospasm.

Hypersensitivity Pneumonitis

Definition and Etiology Hypersensitivity pneumonitis, also known as *extrinsic allergic alveolitis* (EAA) or "bovine farmer's lung," is an allergic respiratory disease caused by inhalation of organic dusts. Several such conditions are recognized in humans, differing only in the nature of the antigen and the circumstances under which exposure occurs. The classic example, of which the bovine disease is probably the counterpart, is "farmer's lung." EAA is caused by exposure to the dust from moldy hay, grain, or other plant matter containing spores and products of thermophilic actinomycetes such as *S. rectivirgula* (formerly *M. faeni*) and *T. vulgaris*.[50,51] Other unidentified forms of hypersensitivity pneumonitis probably occur in cattle.

Clinical Signs EAA is a disease of confined adult cattle; consequently it is more common in dairy breeds than in beef breeds. Typically a succession of acute cases occurs during the winter housing period, so the clinician is presented with a group problem in which animals are in varying stages of the disease. The acute form is indicative of recent exposure and is characterized by a sudden onset of dullness, decreased appetite, hypogalactia, coughing, expiratory tachypnea, dyspnea, and cranial-ventral crackles on auscultation of the lungs.[50-52] There is a moderate transient fever, which is frequently missed. The chronic form is insidious at onset and may not be detected until there is considerable fibrosis. Animals with the chronic disease may have acute exacerbations as a result of heavy antigen exposure; some may not be detected until turned out in the spring, when increased exercise causes an acute crisis. There is a history of weight loss and coughing for several winters, with remission in the grazing season. Chronic signs include hypogalactia, weight loss, productive coughing, tachypnea, obvious hyperpnea, and widespread crackles and wheezes on auscultation of the lungs, especially in the rostral-ventral areas. Differential diagnoses should include respiratory diseases affecting groups of housed adult cattle in winter. Infectious diseases (viral and bacterial pneumonias) can usually be differentiated from farmer's lung by careful evaluation of factors such as clinical signs of fever and pulmonary consolidation. Therefore the main differential diagnoses are the toxic gases. It should be emphasized that hypersensitivity pneumonitis is not considered an ARDS and that no evidence exists for the involvement of hypersensitivity in the pathogenesis of the ARDS described previously. However, severe cases of EAA with prominent dyspnea and moderate, nonfatal cases of gas intoxication may appear clinically similar. If the group outbreak aspect of EAA is ignored, the clinician who examines one individual may be unable to distinguish this condition from fibrosing alveolitis.

Pathogenesis The spores of the thermophilic actinomycetes are 0.7 to 1.3 mm in diameter and can easily reach the alveoli, where they induce both humoral (precipitating) and cellular immune responses. It is thought that repeated exposure results in the activation of a number of immunologically specific and nonspecific cellular and humoral effector mechanisms at the alveolar level, which results in tissue damage.

Epidemiology EAA is a problem in areas with wet summers and severe winters, a situation characterized by the combination of moldy hay and housing of cattle in winter. In North America, EAA occurs primarily in the Great Lakes region of the United States and the eastern provinces of Canada.[3] Baling and stacking of hay with a high moisture content (over 30%) results in overheating of the stacks. Thermophilic molds become dominant and produce billions of spores, which are released when the hay is distributed for feeding. A similar situation can occur in stored grains. Affected hay is usually dry, friable, discolored, and dusty; however, it is not necessary for hay to be grossly dusty and poor in quality to release large numbers of spores.

Necropsy Findings In acute cases the lungs are superficially grossly normal. Closer inspection reveals small gray spots in many lobules, which represent interstitial and peribronchiolar accumulations of lymphocytes. Other lobules exhibit dark red centers of atelectasis surrounded by pale pink raised edges of trapped air that are caused by narrowing of airways with lymphocytic infiltrates. Histologic evaluation confirms the presence of these lymphocytic infiltrates and aggregations, as well as epithelial granulomas, bronchiolitis, and bronchiolitis obliterans. The gross appearance in chronic cases is similar, with the addition of focal areas of interalveolar fibrosis and epithelial hyperplasia; epithelioid granulomas are absent unless a recent acute exposure has occurred.

Diagnosis Precipitating antibodies to *M. faeni* are found in the serum in most cases. However, two precautions are necessary. First, the presence of precipitating antibodies only indicates exposure to the antigen; many normal animals also have antibodies. Second, it is possible that other as-yet unidentified antigens may cause allergic respiratory disease in cattle. The presence or absence of titers is therefore not necessarily diagnostic of the clinical status of the animal, and the magnitude of the titer does not reflect the extent of disease.

Treatment and Prevention Treatment and control center around removing the offending antigen, which is frequently difficult from an economic and management standpoint. Corticosteroids (dexamethasone, 0.05 to 0.2 mg/kg IV or IM daily) may be beneficial in acute cases. Suggestions to decrease the molding of hay or degree of exposure include making silage instead of hay, ensuring proper drying before baling, and feeding hay outside. If the condition can be arrested before significant fibrosis occurs, the prognosis is good.

Anaphylaxis

In ruminants the lung is the major target organ in immediate (type I) hypersensitivity reactions. Precipitating antigens include

VetBooks.ir

vaccines, drugs, blood, *Hypoderma bovis* or *Hypoderma lineatum* larvae, insect bites, and bee stings. Signs of anaphylaxis usually develop in 10 to 20 minutes and include severe acute dyspnea, with flaring of the nostrils, extension of the head and neck, open-mouth breathing, frothing of the mouth, hyperpnea, and abduction of the elbows. Pharyngeal and laryngeal edema cause stertor and inspiratory dyspnea. Urticaria may occur in some cases, such as milk allergy in Jersey cows. Shivering, salivation, lacrimation, pruritus, diarrhea, fever, edema (eyes, muzzle, anus, and vulva), collapse, nystagmus, cyanosis, and discharge of froth from the nostrils also may occur. On auscultation there are harsh breath sounds, large airway sounds, and crackles. The primary differential diagnosis is peracute interstitial pneumonia. The pathogenesis involves an initial exposure to the antigen, which results in a genetically determined production of IgE. This antibody attaches to receptors on mast cells and basophils. On subsequent exposure to the antigen, bridging of the Fab parts of the antibody on these cells results in degranulation, with release of a variety of mediators such as histamine, bradykinin, 5-hydroxytryptamine, serotonin, slow-reacting substance of anaphylaxis (SRS-A), eosinophil chemotactic factor A, platelet activating factor, kinins, and prostaglandins. These mediators result in a cascade of vascular events, notably increased vascular permeability, which in turn results in acute severe edema. Pulmonary venous constriction, pulmonary artery hypertension, splanchnic pooling, increased mucus secretion, and bronchospasm also occur. Ruminants that die of anaphylaxis have severe pulmonary congestion and edema, laryngeal edema, and froth in the airways. Lung lesions of ARDS may be present.

The treatment of choice is epinephrine, 4 to 8 mg (4 to 8 mL of 1:1000 solution) IV or SC or 1 to 5 mg IV for an average 500-kg cow and 1 to 3 mg IV or SC for an average adult sheep or goat. Epinephrine has a short half-life, and animals should be observed closely for relapse. Ancillary therapy includes corticosteroids (dexamethasone, 0.1 mg/kg IM or IV; prednisolone, 2.2 mg/kg IM or IV daily). Other supportive therapies include shock doses of IV fluids (40 mL/kg/h), aminophylline, diuretics such as furosemide, oxygen therapy, and tracheostomy if necessary.

Miscellaneous Chronic Pneumonias

At least two chronic interstitial pneumonias of uncertain cause have been identified in cattle: fibrosing alveolitis and bronchiolitis obliterans. These are typically chronic diseases of individual animals.

Fibrosing Alveolitis

Fibrosing alveolitis is by definition a chronic disease of unknown and possibly multiple causes, characterized by diffuse inflammation of the lung beyond the terminal bronchiole. Approximately 50% of cases produce positive results for precipitating antibody to *M. faeni*, and it is possible that these cases represent chronic farmer's lung, whereas others (that have negative *M. faeni* results) may be the chronic stage of hypersensitivity to other unidentified antigens.[1] Field investigations have failed to substantiate any connection between fibrosing alveolitis and repeated episodes of ARDS such as ABPEE. Furthermore, recovery from a single dose of 3-MI does not result in lesions typical of fibrosing alveolitis. However, repeated doses of 3-MI at weekly intervals experimentally cause fibrosing alveolitis–like lesions. Fibrosing alveolitis occurs in individual adult cattle (usually over 6 years of age) in both housing and pasture conditions. The history is usually that of a chronic progressive respiratory disease several weeks to 2 years in duration. Affected cattle remain bright and alert and continue to eat until the terminal stages of cor pulmonale and heart failure intervene. Signs include marked weight loss; consistent coughing; tachypnea; very marked hyperpnea, even at rest; and dyspnea after mild exertion. Auscultation may reveal crackles in the rostral-ventral lung field and widespread wheezes. Fever is not apparent. The primary differential diagnoses to consider are other chronic respiratory conditions of individual adult cattle. Chronic suppurative pneumonia and metastatic pneumonia can usually be differentiated from fibrosing alveolitis by careful physical examination and detection of depression, anorexia, shallow respiration, thoracic pain, and hemoptysis. ARDS caused by feed-associated pneumotoxins and lungworms are typically group problems, with at least some severe cases in the group. Differentiation from EAA may be impossible if the group outbreak nature of farmer's lung is not apparent; in fact, at least some cases of fibrosing alveolitis may represent chronic farmer's lung. At necropsy the lungs are very pale, firm, and heavy throughout. Scattered lobules are gray-red, slightly collapsed, and edematous. Thick mucus may be found in the airways, and there is frequently right ventricular hypertrophy as a result of cor pulmonale. Histologic changes are diffuse and include interalveolar fibrosis and infiltration with plasma cells, lymphocytes, mast cells, and interstitial cells; obliteration of alveolar spaces; mononuclear exudates in alveoli; alveolar epithelial hyperplasia; bronchitis; and bronchiolitis. The epithelioid granulomas characteristic of acute farmer's lung are absent. No treatment exists, and the lesions are irreversible.

Bronchiolitis Obliterans

Bronchiolitis obliterans is a chronic respiratory condition of yearling or young adult cattle characterized by a deep infrequent cough, tachypnea, hyperpnea, and an exaggerated expiratory effort. There is no fever. The cause is unknown; the condition is speculated to be a sequela to viruses (BRSV, PIV-3, IBR), parasites such as *Dictyocaulus viviparus*, or hypersensitivity pneumonitis. The lungs appear grossly normal at necropsy, except that they do not collapse. Histologic examination reveals extensive bronchiolitis and bronchiolitis obliterans, with epithelium-covered polyps with a connective tissue core projecting into and obstructing the lumen.[1]

Chronic Progressive Pneumonias of Sheep and Goats

Jeanne Lofstedt • Emily John

Chronic progressive pneumonias are diagnosed with some frequency in mature small ruminants. In sheep, ovine progressive pneumonia (OPP) and *Corynebacterium pseudotuberculosis*–induced mediastinal lymph node and lung abscesses are the chief causes of chronic progressive pneumonia. Chronic progressive pneumonia in goats has been associated with the pneumonic form of caseous lymphadenitis (CLA) and occasionally with caprine arthritis encephalitis virus (CAEV)–induced lung lesions. Additional differential diagnoses that should be entertained in small ruminants that exhibit signs of chronic pneumonia include ovine pulmonary adenomatosis (OPA) in sheep and chronic bacterial pneumonia, verminous pneumonia, mycotic pneumonia, tuberculosis, and pulmonary neoplasia in sheep and goats.

Ovine Progressive Pneumonia (Maedi-Visna)

Definition and Etiology *OPP* and *maedi-visna* (MV) are North American and European terms, respectively, for multisystemic diseases of adult sheep characterized by chronic, progressive, debilitating pneumonia; wasting; indurative mastitis; arthritis; and occasionally neurologic signs.[1-5] Synonyms are *Marsh progressive pneumonia*, *Montana sheep disease*, *zwoegerziekte*, *la bouhite*, and *Graafff-Reinet disease*.[2,4] The OPP virus (OPPV) and MV virus (MVV) are nononcogenic exogenous retroviruses

VetBooks.ir

that belong to the genus *Lentivirus*, which includes the human, simian, feline, and bovine immunodeficiency viruses; equine infectious anemia (EIA) virus; and CAEV.[4,5] These enveloped, single-stranded RNA viruses contain the enzyme RNA-dependent DNA polymerase or reverse transcriptase (RT). With this enzyme the viruses use cellular machinery to transcribe a segment of DNA from a template of single-stranded viral RNA; the DNA strand or provirus is then incorporated into the host genome. Close similarity of causal viruses, clinical signs, and lesions produced in tissues permits discussion of OPP and MV as a single disease entity.[3] Extensive mutation of the gene encoding for envelope glycoproteins occurs in all lentiviral infections; this allows the mutated virus to escape elimination by the host immune response. Antigenic variation in the MVV has been documented.[4] The ovine lentiviruses (OvLVs) are closely related to the CAEV of goats, and cross-species transmission is possible through feeding of infected milk and colostrum.[5] These two viruses are now often referred to as *small ruminant lentiviruses* (SRLVs).[4,5]

Clinical Signs and Differential Diagnosis The incubation period of OvLV infections is prolonged, and most infections are subclinical.[4,5] Approximately 25% to 30% of infected sheep eventually exhibit clinical symptoms.[1] Clinical disease is usually not evident until at least 50% of a flock is seropositive.[1] Conditions in sheep attributed to infection with OvLV include progressive emaciation ("thin ewe syndrome"), progressive respiratory failure, indurative lymphocytic mastitis ("hard bag"), posterior paresis, and chronic nonsuppurative arthritis.[1,4,5]

In North America, progressive pneumonia and aseptic indurative mastitis are the most common clinical manifestations of OvLV infections.[3] Clinical signs of disease are usually first observed in 2- to 3-year-old sheep, but most affected animals are 4 or 5 years old before they exhibit signs.[3,6,7] Emaciation, despite a good appetite, is one of the earliest symptoms. Tachypnea and respiratory distress develop gradually and initially are evident only on exertion.[3-5] Flared nostrils, neck extension, and open-mouth breathing are seen in advanced cases. Thoracic auscultation may reveal increased breath sounds, but crackles and wheezes are typically absent.[3] Pyrexia and purulent nasal discharge are uncommon and, if present, usually indicate concurrent secondary bacterial pneumonia.[5] Wool loss may be seen in advanced cases.[4] Affected ewes may give birth to small, weak lambs.[5] Death from anoxia or secondary bacterial infection ensues within 6 to 12 months of first appearance of clinical signs. In some flocks the disease appears to persist virtually unrecognized, whereas in flocks kept under harsh environmental conditions, mortality rates are quite high.[4]

The neurologic form of OPP is accompanied by weight loss and neurologic signs such as hindlimb ataxia, stumbling, and proprioceptive deficits, which progress over a period of months to paralysis or occasionally quadriplegia[3,5] (see Chapter 35). This form of the disease is encountered sporadically in heavily infected flocks and may occur separately or concurrently in sheep with respiratory distress.[4,5] Indurative mastitis is often encountered in heavily infected flocks. The somatic cell count (SCC) in affected ewes is increased, but the milk is grossly normal; a firm udder may be detected with careful palpation.[4] The main consequence is poor weight gains in lambs suckling affected ewes, particularly if there are twins or triplets.[4] Arthritis, primarily affecting the carpal joints, is a rare manifestation of OvLV infection.[4,5]

Chronic pneumonias of sheep that have to be differentiated from OPP include chronic bronchopneumonia caused by *Mannheimia (Pasteurella) haemolytica*, OPA, verminous pneumonia, and pulmonary and thoracic lymph node abscesses caused by *C. pseudotuberculosis*.[1,2] Thoracic radiographs, culture of tracheal wash material, and fecal examination by the Baermann technique are useful for antemortem differentiation. Gross and histopathologic evaluations of pulmonary tissues obtained at necropsy are helpful for diagnosing a flock problem.

Clinical Pathology and Diagnosis Hematologic changes in sheep with OPP are nonspecific and may include lymphocytosis early in the course of disease and mild hypochromic anemia and hypergammaglobulinemia in advanced cases.[3,7] A presumptive diagnosis of OPP can be made based on clinical signs of progressive weight loss and chronic pneumonia or, in rare cases, neurologic disease in adult sheep,[4,5] but the diagnosis is often overlooked if mildly affected sheep are culled for other reasons.[4] The majority of sheep infected with OvLV do not show obvious clinical signs and are essentially asymptomatic virus carriers serving as a reservoir of virus for other sheep in the flock.[4,5] For disease control purposes it is important to identify such animals as soon as possible after infection. Several tests, based on detection of antibodies or virus, have been used to identify subclinically infected sheep.

Serologic tests include the agar gel immunodiffusion (AGID) test, several ELISAs, and the Western blot assay.[3,4] The period from infection to seroconversion typically ranges from 3 weeks to several months but can take up to a year.[4] Some infected sheep never seroconvert, whereas others with advanced disease become transiently seronegative.[5] The AGID test has been the preferred serologic test for many years. It has good specificity but has gradually been replaced by a variety of ELISAs.[4,5] ELISAs are more sensitive than the AGID test and are useful when large numbers of samples need to be screened.[3-5] The use of ELISAs to detect antibodies in milk offers the option of low-cost screening in milking sheep flocks.[4] The Western blot test is used on occasion to confirm ELISA results.[5]

Tests for virus include virus isolation in cell culture or viral genome detection by PCR.[5,8,9] These tests are usually reserved for select cases—for example, when infection is suspected in a seronegative animal or in young lambs that have received colostrum from seropositive ewes.[5] Milk or lung lavage samples are useful substrates for this purpose. Virus isolation, which is time consuming and expensive, is accomplished by coculture of infected fresh or frozen tissue with indicator cell lines. In culture, retroviruses form characteristic multinucleated syncytia.[7] Viral antigens can be detected in these syncytia by use of immunofluorescent staining.[7] PCR testing is more cost-effective than virus isolation.[3,4]

Pathophysiology OvLVs gain access to the body via ingestion of milk or colostrum or through inhalation of aerosolized infectious particles. Infection is then established in the monocyte or macrophage cell line and spreads via these infected cells to the lungs, lymph nodes, choroid plexus, spleen, bone marrow, mammary glands, and kidneys.[7] The virus is able to persist in the face of humoral and cellular immunity through (1) latent infection of host cells by DNA provirus, (2) long-term nonproductive infection of blood monocytes (virus replicates only on differentiation of monocytes into macrophages), and (3) virus mutation with emergence of new antigenic variants that are not neutralized by preexisting antibody.[7] Because of the interaction of the virus with the macrophage monocyte series, a progressive multisystem chronic inflammatory process is initiated, primarily but not exclusively in the lungs and mammary gland.[4] Variations in genetic susceptibility, virus genotype, and the immune response of individual sheep influence target organ involvement and disease progression.[4]

Epidemiology OPP and MV are present in many sheep-rearing countries but have not been diagnosed in Australia or New Zealand.[5] The seroprevalence of OPP in cull ewes in the United States has ranged widely and increases with advancing age.[2] With the exception of West Texas, which has an infection

rate of 0.5%, serologic surveys in cull ewes in other states have revealed infection rates of 30% to 67%. The low seroprevalence in Texas has been attributed to the hot, dry climate and extensive grazing practices.[7] Risk factors for increasing within-flock seroprevalence in North America include large flock size, purchase of more than 50 sheep, and maintaining flocks on nonfenced range.[10,11] Limited studies in large mixed-breed flocks have provided evidence that some sheep breeds may be more resistant to infection than other breeds are.[2] Additional research is required before a particular breed or line of sheep can be viewed as resistant to OvLV infection. The lung and mammary gland are believed to be the main sources of excreted virus.[2] Studies conducted in Europe and Iceland have shown that transmission from the ewe to her lambs commonly occurs through the ingestion of infected colostrum and milk.[2] In other studies, close confinement of diseased or seropositive sheep with healthy or seronegative sheep resulted in disease or seroconversion in the previously healthy or seronegative animals; these infections were presumed to have occurred via the respiratory route.[2] Concurrent OPA is believed to have a synergistic effect on disease transmission via the respiratory route.[4] OvLV transmission has been shown to occur through fecal contamination of drinking water.[2] Blood-contaminated placentas, contaminated milking equipment, and poor biosecurity practices have also been implicated as playing a role in the spread of infection.[2,4] Transmission through the uterine wall or via germ cells can occur but is of minor importance compared with other routes.[2,4]

Necropsy Findings Lesions may develop in any or all of the following tissues of OPPV-infected sheep: lungs and regional lymph nodes, brain, joints, mammary glands, and blood vessels.[4] Changes are most obvious in the lungs, which do not collapse on opening of the thorax.[4,5,7] Vertical rib impressions may be seen on the exterior lung surface. Affected lungs are heavy and, after removal of any visible trachea, weigh more than 1 kg (normal lung weight is up to 500 g) and have a mottled to uniform pink-brown to gray-blue discoloration.[5] Secondary bacterial pneumonia may cause anterior-ventral pulmonary consolidation. Tracheobronchial and mediastinal lymph nodes are markedly enlarged (up to 10 times normal size), bulge on cut surfaces, and are homogeneous gray-white throughout.[4,5] Histologic examination reveals a diffuse lymphoproliferative pneumonia characterized by prominent lymphoid follicle formation adjacent to bronchioles and small vessels; discrete nodules of lymphocytes, unrelated to vessels or airways, are also found in the lung parenchyma.[7] Lymphocytes, plasma cells, and macrophages infiltrate into interalveolar septa, and hyperplasia of alveolar epithelium and terminal bronchial smooth muscle may be seen.[4] A recent study has shown that proviral load of OPPV is correlated with histologic severity of tissue lesions in naturally infected sheep.[12] In some flocks uncomplicated OPP is the norm. In other flocks it may occur as a mixed infection with lungworm, bacterial bronchopneumonia, or pulmonary adenomatosis, which may result in the OPP lesions being overlooked on routine necropsy.[4]

Treatment and Prevention OPP is not treatable. Antimicrobials can be used to control secondary bacterial pneumonia, but most sheep die within a year of first exhibiting clinical signs.[2,6] No effective vaccines are presently available for control of the disease. There is some evidence that vaccinating lambs born to seronegative ewes early in life may delay the onset of seroconversion when these lambs are maintained in an infected herd.[13]

OPPV is difficult to eradicate from a flock once infection has been established. Uninfected flocks should maintain strict biosecurity measures to avoid introduction of the disease. This may include not sharing rams, not mixing sheep with other flocks, and maintaining segregation at shows.[4] Breeding stock should be purchased from known OPP-free herds and quarantined and tested to ensure that they are seronegative before being introduced into the flock. Control methods that may be economically feasible for purebred flocks with a low seroprevalence rate include (1) a "test-and-cull" practice and (2) isolation of infected adults and artificial rearing of their offspring.[3] With the first method, all sheep are tested annually for antibody, and seropositive animals and their progeny younger than 1 year of age are culled or isolated from the negative flock; culling is preferred because of the risk of cross-contamination. New additions should be seronegative and originate from seronegative flocks. Annual testing should be performed until two consecutive negative test results are obtained to be reasonably confident that the flock is virus free. With the second approach, progeny are removed from their dams before they nurse and are fed cow's colostrum or colostrum from seronegative ewes and raised in isolation. The clean herd should be kept isolated from infected sheep and goats and from humans and equipment in contact with infected sheep. Herd additions and annual testing should be handled as described for method 1. In flocks with well-established infections and a high seroprevalence rate, control options are limited.[4] The test-and-cull procedure and removal of lambs are impractical under commercial conditions. Increasing the flock replacement rate by strict culling of suspect cases and not keeping ewes beyond 4 to 5 years of age will assist in keeping the flock seroprevalence down and in reducing the incidence of clinical disease.[4]

Recent research has demonstrated that variation in the gene encoding transmembrane protein 154 (TMEM154) results in decreased susceptibility of sheep to infection with SRLVs.[14] Three main haplotypes of the TMEM154 gene have been identified: haplotype 3, the ancestral variant; haplotype 1, with a single amino acid substitution E35K; and haplotype 2, with a different single amino acid substitution N70I. Under natural exposure conditions, sheep possessing at least one copy of haplotypes 2 or 3 were 2.85 times more likely (95% CI 2.36–3.43) to be seropositive for OPPV than sheep possessing two copies of haplotype 1.[15] This suggests that marker-assisted selection of genetically resistant sheep may help decrease prevalence of OPPV infection within flocks.

Ovine Pulmonary Adenocarcinoma

Definition and Etiology OPA, also known as jaagsiekte (South Africa), sheep pulmonary adenomatosis (United Kingdom), or pulmonary carcinoma (United States),[16] is a naturally occurring, retrovirus-induced bronchioloalveolar carcinoma of sheep and, in rare cases, goats that has been associated etiologically with a betaretrovirus called jaagsiekte retrovirus (JSRV).[17,18] OvLVs and herpesviruses have been isolated from OPA tumors; however, they are not consistently present and do not induce OPA when inoculated experimentally.[19] One theory is that these viruses may act as cofactors in tumor induction. Defining the role of JSRV in OPA has been complicated by the presence of 15 to 20 endogenous jaagsiekte retroviruses (enJSRVs) that are stably integrated into the genomes of sheep and goats.[20,21] Recent research has indicated that exogenous JSRV is likely not of endogenous origin. There has been speculation that the endogenous viruses may modify the genome of exogenous JSRV, either by inducing the expression of an oncogene or by inactivating a tumor suppressor gene.[18] Sequence analyses of exogenous JSRV and enJSRV suggest that endogenous viruses do not directly contribute to the pathogenesis of OPA through large-scale recombination events, but small-scale recombination or complementation of gene function has not been definitively excluded.[20] There has been speculation that expression of enJSRV in the fetal or

VetBooks.ir

neonatal period may influence expression of OPA through induction of immunologic tolerance.[17,20] Endogenous JSRVs appear able to exert a protective effect on the host by blocking cellular entry of JSRV via receptor interference as well as by preventing proper cellular trafficking and, ultimately, release of virus particles.[22]

Clinical Signs and Differential Diagnosis Symptoms normally appear in mature sheep between 2 and 4 years of age, although lambs as young as 3 months of age and sheep as old as 11 years have occasionally been diagnosed with OPA.[16] Signs include exercise intolerance, weight loss despite a good appetite, tachypnea, dyspnea, occasional cough, and high-pitched crackles on thoracic auscultation. A characteristic feature of OPA is the accumulation of abundant fluid in the respiratory tract that is frothy, clear, milky, or at times pink-tinged and may flow from the nostrils of affected sheep when the rear limbs are raised and the head is lowered ("wheelbarrow test").[16-18] Up to 400 mL of nasal secretions may be collected in a day, although 10 to 40 mL/day is more usual. Rectal temperature is usually normal unless secondary bacterial infection is present. Sheep with OPA typically succumb within a few weeks to months after first exhibiting clinical signs.

Chronic pneumonias of sheep that must be differentiated from OPA include chronic bronchopneumonia caused by *M. haemolytica*, OPP, verminous pneumonia, and pulmonary and thoracic lymph node abscesses caused by *C. pseudotuberculosis*.[1,2] Thoracic radiographs, culture of tracheal wash material, and fecal examination by the Baermann technique are useful for antemortem differentiation. Gross and histopathologic evaluations of pulmonary tissues obtained at necropsy are helpful for diagnosing a flock problem.

Clinical Pathology and Diagnosis The only reported clinical pathologic abnormality in sheep with OPA is hypergammaglobulinemia. Advanced clinical cases in mature sheep can be presumptively diagnosed based on clinical signs of weight loss and respiratory distress accompanied by copious nasal secretions, but in many cases the disease is subclinical.[16,17] To date, sensitive and specific tests for identifying apparently healthy animals that may be infectious are lacking. The absence of JSRV-specific antibodies in infected sheep have precluded the use of serologic tests for diagnosing infection.[17,18] PCR tests, capable of demonstrating viral nucleic acids of endogenous JSRV tissues in OPA-infected animals, have been developed but have a high false-negative rate and are not useful for identifying individual animals for eradication purposes.[17] The most successful approach for early diagnosis of OPA is PCR testing of bronchoalveolar fluid collected from live animals, but this is impractical for widespread testing, and saliva and nasal secretions of infected sheep often test negative for JRSV.[17] Recently, rapid transthoracic ultrasound has shown high sensitivity and specificity for antemortem identification of sheep with lung lesions consistent with OPA at postmortem examination, making this imaging modality potentially useful for flock-level screening for OPA.[23]

Epidemiology OPA has been reported in sheep-rearing countries throughout the world but not in Australia, New Zealand, or the Falkland Islands.[17,18] Iceland is currently free of OPA as a consequence of implementing an aggressive slaughter policy in endemic areas in the 1950s.[17] The prevalence of OPA varies among countries in which the infection occurs; it is endemic in Scotland, Peru, and South Africa, where annual losses range from 2% to 10%. In contrast, OPA is infrequently diagnosed in the United States and Canada, where totals of 11 and 43 cases, respectively, have been reported.[18]

OPA has been reproduced experimentally by intratracheal inoculation of lung homogenates or pulmonary lavage fluids obtained from infected animals.[24] Lambs between birth and 5 weeks of age have been shown to be more susceptible to experimental infection than 10-week-old lambs.[24] This age-related susceptibility to OPA suggests that natural virus transmission occurs in the neonatal period.[17] Aerosol transmission and contamination of feed and water by respiratory secretions are likely methods of disease spread, particularly in confined sheep. Provision of diets deficient in selenium had no effect on development or progression of pulmonary tumors when compared to sufficient dietary selenium intake.[25]

Necropsy Findings OPA lesions in the lungs are categorized as classical OPA or atypical OPA based on their appearance.[16,17] In classical OPA the lungs are heavy (two to three times normal weight) and exude clear fluid from the cut surface.[16-18] The trachea and bronchi often contain clear, foamy fluid. Large, firm, gray masses are commonly encountered in the cranioventral regions of one or both lungs. Smaller (1- to 2-cm) nodules are occasionally visualized in the caudodorsal lung regions. In atypical OPA the tumors consist of solitary or aggregated hard, white nodules that are clearly demarcated from normal lung tissue and have a dry cut surface.[16,17]

Metastasis to regional lymph nodes occurs in approximately 10% of cases, resulting in pulmonary lymph node enlargement.[16,17,26] Metastases to cardiac and skeletal muscles are infrequently reported.[16,17,26] Metastasis to solid abdominal organs as well as to the digestive tract and skin is also possible, although rare.[27] Secondary bacterial pneumonia caused by *M. haemolytica* may mask the lesions of OPA.[17]

OPA is classified by the World Health Organization (WHO) as a bronchioloalveolar carcinoma arising from alveolar type II pneumocytes or nonciliated bronchiolar cells.[26] Histologic lesions in the lungs consist of columnar or cuboidal cells arranged in an acinar or papillary pattern and are similar for classical or atypical OPA but with an exaggerated inflammatory response and fibrosis in the atypical form of the disease.[16]

Treatment, Prevention, and Prognosis There are no known treatments for this disease. Antibiotics may prolong the life of OPA-affected sheep through control of secondary bacterial pneumonia.[18] There are no vaccines for OPA at this time.[17] Prompt culling of ewes suspected to be infected, as well as their offspring, has been used to decrease disease prevalence in endemic flocks.[16,17] OPA was eradicated from Iceland by slaughtering all sheep in endemic areas.[16-18] Contaminated areas where infected sheep were held should be left vacant for 2 months.[17] OPA has reportedly been eliminated from two flocks by removing the lambs at birth, depriving them of maternal colostrum, and raising them in isolation or by using embryo transfer.[16,17] This approach is impractical for commercial flocks. Until reliable diagnostic tests for subclinically affected sheep are developed, control will remain problematic.

Caprine Arthritis and Encephalitis

CAE is a persistent lentiviral infection of goats with four possible clinical presentations: leukoencephalomyelitis in kids 2 to 6 months of age and chronic, hyperplastic polysynovitis, indurative mastitis, and interstitial pneumonia in mature goats.[28-30] Mild interstitial pneumonia, which is silent clinically, is a common postmortem finding in goat kids infected with CAEV.[31] Occasional kids with leukoencephalomyelitis may have diffuse involvement of one or more lung lobes.[30] In one study, 60% of adult goats serologically positive for CAEV had lesions of severe chronic interstitial pneumonia at slaughter.[31] In addition, chronic interstitial pneumonia, accompanied by exercise intolerance and dyspnea, was described in dairy goats originating from herds

VetBooks.ir

that had clinical cases of arthritis and leukoencephalomyelitis.[32] The lung lesions in these goats resembled those of OPP and MV and were positive for CAEV.[32,33] However, CAEV has been recovered from the lungs of goats with advanced arthritis but without interstitial pneumonia. In addition, goats inoculated intratracheally with purified CAEV did not develop pulmonary lesions.[32] This may indicate that there is no causal relationship between CAEV and interstitial pneumonia in goats or that an additional agent such as a helper virus is required for the lesions to develop.[30] The first signs of chronic progressive pneumonia associated with CAEV infection appear at times of stress such as kidding and include exercise intolerance, dyspnea, weight loss, and occasionally a cough.[30] Enlarged carpi may be present in some of the affected goats.[30] Radiographs in advanced cases demonstrate large areas of lung consolidation and sometimes bullous emphysema in the cranioventral or caudal lung lobes.[32] Histopathologic examination of lung biopsy samples may assist with an antemortem diagnosis.[30] Serologic testing is of no diagnostic value other than identifying the presence of CAE in the herd of origin. Lesions in the lungs at postmortem are as for sheep with the pneumonic form of OPP.[30] CAE is discussed in detail in Chapter 38.

Caseous Lymphadenitis

CLA, caused by *C. pseudotuberculosis* (previously known as *C. ovis*), is a chronic disease of sheep and goats characterized by the development of pyogranulomatous abscesses in lymph nodes and internal organs.[34-39] The disease affects small ruminants worldwide.[39] CLA most commonly presents as an external form characterized by abscesses in superficial lymph nodes.[37,39] The internal, or visceral, form of CLA manifests as internal abscesses in the mediastinal and mesenteric lymph nodes as well as internal organs, primarily the lungs, but also in the liver, kidneys, and central nervous system.[39] Small ruminants with the visceral form of the disease rarely have concurrent abscessation of external lymph nodes.[38] Goats are more commonly afflicted with external abscesses, whereas the visceral form of CLA appears to be more common in sheep.[34] Visceral CLA may be asymptomatic but is typically associated with progressive weight loss.[34,38,39] Specific clinical signs that may implicate visceral CLA of the lungs and associated lymph nodes include exercise intolerance, tachypnea, dyspnea, and chronic cough. Because of the encapsulated nature of pulmonary abscesses and the lack of exudate in airways, pulmonary crackles are rarely auscultated.[38,39] Nonspecific laboratory findings in sheep and goats with CLA include leukocytosis, hyperfibrinogenemia, hyperproteinemia, and hypergammaglobulinemia; however, laboratory findings are frequently normal in animals with chronic abscesses.[36,37] A definitive diagnosis of visceral CLA with pulmonary involvement may be achieved by thoracic radiographic and ultrasonographic findings of abscesses in the lungs and mediastinal lymph nodes or by isolating *C. pseudotuberculosis* from a transtracheal aspirate (TTA).[34,38] Failure to isolate the organism from tracheal wash fluid, however, does not rule out CLA as the cause of pulmonary disease. Characteristic postmortem findings of the respiratory form of CLA are one or more thick-walled, laminated, encapsulated, caseopurulent abscesses in the bronchial lymph nodes, mediastinal lymph nodes, and/or lung parenchyma.[36] Serologic tests have been developed for the detection of asymptomatically affected animals or those with internal abscess. They include the synergistic hemolysis inhibition (SHI) test and several ELISAs.[36,37] Most serologic tests are not specific enough to justify their use in culling programs. However, an ELISA developed in the Netherlands for disease eradication purposes has recently been improved to increase sensitivity (94%) and specificity (98%).[40] CLA is discussed in more detail in relation to the hemolymphatic system (see Chapter 37).

Parasitic Bronchitis and Pneumonia*

Dwight D. Bowman

There is only a single lungworm, *Dictyocaulus viviparus*, that matures to the adult stage within the lungs of cattle. In sheep, the three main lungworms that may occur are *Dictyocaulus filaria*, *Muellerius capillaris*, and *Protostrongylus rufescens;* some other species mature in the lungs of sheep and goats around the world, but they are fairly rare compared to these other species. *Toxocara vitulorum* of cattle larvae undergo a liver to lung migration on their way to the intestine after infective eggs are ingested, and they can induce a transient pneumonitis during lung passage. In cattle, *Ascaris suum* of pigs can also cause signs similar to larval toxocariasis if cattle ingest large numbers of eggs; these infections do not develop to patency. In sheep and goats, *Toxocara canis* and perhaps other species from carnivores can cause transient pneumonitis as the larvae migrate through the liver and lungs on their way to arrest as larvae in other tissues such as muscle and nervous tissues.

Lungworms of Cattle: *Dictyocaulus viviparus*

Definition and Etiology

Dictyocaulus viviparus is a trichostrongylid nematode that is found in the bovine trachea and bronchi. These are robust white worms that can reach lengths of 8 cm; the slightly smaller males have very dark brown, stubby spicules that can often be visualized within the body of the worm just anterior to the copulatory bursa. The life cycle of *D. viviparus* is direct. The female produces larvated eggs that hatch in the lungs, and the larvae make their way up the respiratory tract, are coughed up, and are swallowed to be passed in the feces. The larvae on pasture ultimately develop to an infective third stage without feeding and can develop in the laboratory in aerated water into doubly sheathed infective stages. The larvae take 5 days or longer, depending on environmental conditions, to develop to the infective stage on pasture. The larvae then migrate to grass, where they are ingested by the feeding cattle. After ingestion, the larvae migrate through the intestinal wall and make their way into the mesenteric lymph nodes, where they molt to the fourth stage. It is the fourth-stage larvae that make their way to the lungs via the blood and lymph systems and initially are found in the terminal capillaries of the ventral parts of the caudal lobes. At about 7 days after ingestion, the fourth-stage larvae enter the alveoli and then molt to the immature adult stage. The adults develop and mate, and eggs first appear in the bronchi, and subsequently larvae appear in the feces, some 3 to 4 weeks after the animal was initially infected. Clinically evident infection with *D. viviparus* typically occurs in young, nonimmune stock (younger than 12 months old) or in previously unexposed yearling or adult cattle. A reinfection syndrome can also occur when previously infected (and therefore immune) adults are subjected to massive challenge with infective larvae.[1,2]

Clinical Signs and Differential Diagnosis

Primary infection with *D. viviparus* can be broken down clinically into a prepatent phase, a patent phase, and a postpatent phase.[3] No signs are associated with the initial penetration of larvae until they reach the alveoli, where they provoke an eosinophilic exudate that blocks small airways. During the prepatent phase (approximately 7 to 25 days after ingestion) there is a gradual onset of coughing and tachypnea (35 to 60 breaths/min), which

*Previous contributions by Anne Zajac are acknowledged.

VetBooks.ir

becomes increasingly apparent from day 14 to day 25. The severity of signs in this stage is proportional to the number of larvae ingested, the rate of ingestion, and the proportion of larvae reaching the lungs. Severe illness and death can occur in cases of heavy infection. In the patent phase (approximately 25 to 55 days after ingestion) a parasitic pneumonia with consolidation develops in the ventral areas of the caudal lung lobes as a result of aspiration of eggs and larvae into these areas. Tracheitis and bronchitis associated with the adult worms also develop. Clinical signs vary in severity and range from intermittent to marked coughing, tachypnea (respiratory rate may increase to more than 70 breaths/min), dyspnea, anorexia, and weight loss. Fever may develop with secondary bacterial infection. Auscultation reveals harsh breath sounds and widespread crackles and wheezes. In severe cases animals may exhibit open-mouth breathing, extended head and neck, protrusion of the tongue, and an expiratory grunt. Death is common in untreated, heavily infected animals.[2,3]

Recovery begins in the late patent phase, and the signs gradually resolve, sometimes over several months. During the postpatent phase (about days 55 to 90), adult parasites are expelled by a self-cure phenomenon. In approximately 25% of severe cases the postpatent phase is characterized by a sudden exacerbation of dyspnea at days 45 to 60 that is often fatal, after secondary bacterial infection or alveolar epithelialization.[1,3] The reinfection syndrome occurs 14 to 16 days after adult cattle are placed on heavily contaminated pastures. Signs include acute hypogalactia; severe, frequent coughing; marked tachypnea; and depression. Auscultation reveals only harsh breath sounds with no crackles or wheezes.[1,3]

Relative to *D. viviparus*, an ancillary finding occurred as part of a 3-year study in Sweden that examined the effects of different parasite control strategies administered to cattle during their first grazing season on their weight gain in the three second grazing seasons when they were all handled equivalently.[4] Basically, during the second season of grazing, deficits acquired within each management group in the first year were maintained during the second year, but the first season of treatment had no effect on weight gain in the second season. During the second and third second-season grazing periods, *D. viviparus* entered the groups when additional contaminated pastureland was added to the grazing area in the final 2 years. The work then clearly showed that the presence of *D. viviparus* had a detrimental effect on all animals in both seasons and that during the second such season, signs of dictyocauliasis appeared in August and the cattle underwent dramatic weight loss (the trial precluded treatment without more serious signs of induced disease). Thus it was fairly clear that the larvae had overwintered on pasture, increased in number within the herd, and were there in sufficient numbers to cause significant effects in the second year.

Differential diagnosis should be straightforward if both clinical signs and epidemiologic characteristics of the disease are taken into account, especially in endemic areas. This is a disease of groups of cattle at pasture, typically in late summer or fall in northern temperate climates; the situation thus resembles ABPEE, which differs in clinical signs (i.e., less coughing and fewer adventitious lung sounds). The signs associated with lungworm infection are reminiscent of those of farmer's lung, which occurs in quite different circumstances. In typically nonendemic areas, outbreaks associated with climatic changes are frequently mistaken for acute bacterial bronchopneumonia.[1]

Diagnosis

Classically, diagnosis has been through the detection of the characteristic larvae passed in the feces. In cattle, this is the only nematode parasite routinely producing larvae found in the feces, and thus if the fecal sample is fresh, the finding of larvae is fairly diagnostic. Rectal fecal samples are preferred for parasite examination because samples picked up off the ground may contain free-living nematodes that can be difficult to differentiate from lungworm larvae. Recovery of larvae from fecal samples is substantially diminished if the sample is stored at room temperature for more than a few hours. The larvae are best detected by the Baermann test[5] and may be seen on a transtracheal wash. The larvae themselves are large (390 to 450 μm × 25 μm), have a somewhat pointed tail (compared to *Dictyocaulus filaria* of the sheep), and have an intestine filled with dark granules. The esophagus appears clear compared to the intestine under the microscope and is about one fourth of the total length of the larva. If the Baermann test cannot be set up soon after fecal collection, the sample can be safely refrigerated for 24 to 48 hours without serious larval loss.[6] No larvae are detected in the reinfection syndrome. In some European countries, ELISAs are used within various diagnostic laboratories to detect antibodies in cattle that have been exposed to infection.[7] An increase in eosinophils in the peripheral blood may also occur approximately 2 weeks after infection, peaking at 4 to 7 weeks after infection.[8] It has been suggested that with an average herd size of 73 (19 heifers and 54 cows), 9 heifers and 15 cows need to be sampled using the Baermann methods and 6 heifers and 10 cows need to be sampled when using the serum ELISA to be 95% confident that one test is positive if *D. viviparus* is present in the herd.[9]

In Europe, ELISA technology that is based on an antigen that is a recombinant product representing a major sperm protein of the adult male has now been developed to detect antibody in the milk and serum of cattle.[9-11] Examination in experimentally infected dairy cows revealed that the ELISA detected antibodies in the serum and milk some 30 to 32 days after infection and remained elevated for 112 to 138 days post exposure even though the cows had been treated for their infections with eprinomectin 49 days after infection and had ceased larval shedding.[11] However, if the cattle were treated during the prepatent period, larvae were never shed in the feces, and the animals remained antibody negative. This technique has now been adapted to determine the presence of antibodies in bulk milk and has been used to collect epidemiologic data. Of 810 dairy farms in Germany that were tested in January, September, and November, some 18% were positive on one occasion, and most positive samples were detected in January.[9] It was not known what percentage of zero-grazing herds were included in the bulk milk samples.

Pathophysiology

Once the fourth-stage larvae enter the alveoli, they incite an eosinophilic exudate that blocks small bronchi and bronchioles, resulting in atelectasis and causing the cough and tachypnea of the prepatent phase. As these larvae mature and migrate up the airways, these lesions may resolve. However, the adult worms produce an inflammatory response in the larger airways, and aspirated eggs and larvae cause a marked macrophage and giant cell response, with consolidation of the ventral caudal lobes; these lesions are the cause of the signs in the patent phase. At any point in the pathogenesis (prepatent, patent, or postpatent stage), complications may occur that account for acute exacerbation and death. These complications are as follows:

- Development of pulmonary edema caused either by heart failure or by extensive alveolar epithelial damage and hyaline membrane formation
- Severe interstitial emphysema from the severe dyspnea
- Alveolar epithelial hyperplasia
- Secondary bacterial infection, which is relatively uncommon

In the reinfection syndrome, the immune response cannot completely overcome a massive challenge, and a small number of larvae reach the lungs. The signs are caused by the immune reaction to the migrating larvae. Lymphoid nodules develop around dead larvae in the bronchioles.[1-3]

VetBooks.ir

Epidemiology Parasitic bronchitis and pneumonia in cattle occur most often in temperate areas with high rainfall or intense irrigation. In the United States, lungworm infection is widely distributed, but disease outbreaks are uncommon, probably because periods of dry summer weather limit larval survival and accumulation on pasture.[2] In the southern United States, lungworm transmission is probably greatest in the cool winter months,[12] whereas autumn is probably the season of most intense transmission in the northern United States.[13,14]

Dictyocaulus infections have been studied extensively in Europe, where the parasite is an important pathogen. Disease outbreaks occur most frequently in first season grazing animals. If large numbers of larvae are present on pasture at spring turnout of calves, disease may develop at that time. Often, however, levels of pasture larvae are too low to cause disease but lead to low-level primary infections in calves that result in the accumulation of additional larvae on pasture. This second wave of infection may lead to clinical lungworm disease when the primary infection did not produce adequate levels of immunity. If infection levels remain low, disease may not be observed until a third generation of parasites occurs. Immunity develops beginning about 10 days after heavy infection, and patent infections usually persist for only a few months. In the absence of continued exposure to parasites, immunity to reinfection will begin to decline after several months.[2,15]

Older animals without immunity also develop lungworm disease when exposed to high levels of pasture contamination with larvae. This can occur when animals from a nonendemic area are moved to an endemic area. In recent years outbreaks of primary parasitic bronchitis have become an important cause of respiratory disease in adult dairy cows in Europe. The increased prevalence of disease in this older age-group is likely the result of decreased levels of immunity after the widespread use of powerful suppressive anthelmintic regimens in first and second season grazing animals. Other management factors, such as isolation of calves from adult carrier animals and increased movement of livestock, may also contribute to a decline in levels of immunity.[7,16] Beef animals are less often affected than dairy cattle because management practices are more extensive and levels of infective larvae on pastures are generally lower.[2] The reinfection syndrome occurs in immune adult animals when, for example, immune cows are placed on a pasture previously contaminated very heavily by calves with patent disease.[1,2]

In northern temperate climates, the infection is carried from year to year by overwintering of larvae on pasture in some areas, by spreading of manure from infected housed calves in the spring, and by carrier cattle. Lungworm larvae also may be inhibited in the lungs of calves in winter (as with *Ostertagia* species in the abomasum) and mature in the spring.[1,3] It appears that over the last decade the disease is becoming more common in the more northern parts of the United Kingdom.[17]

Necropsy Findings In the prepatent phase the lungs are largely normal, with a few atelectatic lobules in the ventral caudal lobes; adult worms are not present until late in this phase, but larvae may be detectable by microscopic examination of smears of bronchial exudate. In the patent phase there is usually bilaterally symmetric red consolidation of the ventral caudal lobes. Adult worms can be recognized on necropsy by their relatively large size and location in the trachea and bronchi. The lesions of the postpatent phase are similar, but no adult worms or larvae are present. In those patients that die of an acute exacerbation, there is extensive pulmonary edema and emphysema, with hyaline membranes and alveolar epithelial hyperplasia.

In the reinfection syndrome the pulmonary lymphoid nodules may be 3 to 4 mm in diameter and thus grossly visible as raised, gray-red to greenish-yellow nodules under the pleura. Initially these are composed of a core of eosinophilic parasitic debris surrounded by macrophages, multinucleated giant cells, hyperplastic bronchiolar epithelium, eosinophils, and plasma cells. The lesions eventually mature to lymphoreticular nodules with a germinal center. There is also greenish mucus in the airways and a greenish discoloration to the tissues, both caused by eosinophil infiltration. There is no edema or emphysema, and the rare lungworms that may be found are small and stunted.[1]

Treatment, Prognosis, Prevention, and Control *D. viviparus* infection can be treated with a number of bovine anthelmintics available in the United States and other countries (Table 31.16). Macrocyclic lactone products also have residual efficacy against *D. viviparus*, and there is now an extended-release eprinomectin compound that will provide protection for 150 days.[18,19] Animals with only cough and tachypnea respond well, whereas those with dyspnea, fever, anorexia, and depression have a more guarded prognosis; some of these animals can be expected to die or remain chronically unthrifty.[1] Control (see also Chapter 49) involves appropriate pasture management and the strategic use of anthelmintics to prevent buildup of infection in the herd and on pastures. Several strategic deworming programs that effectively suppress lungworm infection throughout the grazing season have been developed in Europe. These programs include use of ivermectin at 3, 8, and 13 weeks after turnout and use of doramectin or eprinomectin at 0 and 8 weeks. Use of an oxfendazole pulse release bolus (not available in the United States) also provides strategic treatments. Alternatively, use of a continuous-release ivermectin

Table 31.16

Anthelmintics Approved for Treatment of *Dictyocaulus viviparus* in the United States

Anthelmintic	Formulation	Efficacy of a Single Treatment	Approved for Dairy Cattle of Breeding Age
Levamisole	Drench, bolus, injection		
Fenbendazole	Paste, suspension, medicated feed, mineral		+
Oxfendazole	Suspension		
Albendazole	Paste, suspension		
Ivermectin	Injection, pour-on	28 days	
Eprinomectin	Pour-on	21 days	+
Eprinomectin	Injection	150 days	
Doramectin	Injection, pour-on	28 days	
Moxidectin	Pour-on, injection	42 days	+ Pour-on only

VetBooks.ir

or fenbendazole bolus (not available in the United States) will prevent development of lungworm infection during its period of efficacy.[16] A long-acting moxidectin injection product that provides protection from lungworm infection for 120 days is also now available in some countries.[20] Anthelmintic treatment with moxidectin or fenbendazole followed by movement of calves to safe pasture 9 weeks after turnout was also effective in controlling lungworm.[21] None of these control programs has been extensively tested under the variety of grazing conditions found in the United States.

Despite concern that suppressive programs may limit exposure to larvae and interfere with the development of immunity to lungworm, several studies conducted in Europe have shown that stimulation of the immune response still occurs, although relative levels of immunity may vary with different management systems and annual variation in the intensity of lungworm challenge.[7,22-24] In Europe, methods of control also include an effective irradiated larval vaccine.

Delay of spring turnout is an adjunct to control but should not be relied on as the sole means of control.[23] A targeted selective deworming program was successful in controlling lungworm infection in a dairy herd in Sweden. Only cattle testing positive for lungworm by the commercial ELISA were treated at each sampling date.[25] In an attempt to eradicate *D. viviparous* from two farms in the Netherlands that had had lungworm-associated disease outbreaks, both herds were mass treated with eprinomectin at turnout.[26] From August to November of the first year after treatment, all first-year heifers remained lungworm negative as determined both by fecal examination and by monitoring for *D. viviparus*–specific antibodies. However, in the second year after treatment, one of the herds developed signs of parasitic bronchitis that was confirmed serologically. The other herd remained negative until at least the fourth year after treatment, but then signs of parasitic bronchitis were observed and the cattle were treated. The authors of this report believed that in both cases the *D. viviparous* was reintroduced into the herd from an outside source or perhaps that the reuse of pastures that may have lain fallow for an extended period provided the source of the new infections.

TOXOCARA VITULORUM. This parasite seems to be reemerging in prevalence within the developed world; there have been recent reports from a bison herd in western Canada, suckling beef calves in the Netherlands, and suckling Simmental cattle in the United Kingdom. In a closed cow-calf beef operation in north-central Florida, 17.6% of 105 calves under 3 months of age were found to be infected, and on a beef farm in Iowa, 40% of 34 calves were found to be infected after a calf died due to an ascarid intestinal impaction.[27-30] Infections in neonatal calves are acquired by fairly large larvae (0.75 to 1.5 mm in length) that are passed from cow to calf in the milk. In cows that ingest eggs, the larvae undergo a liver-lung migration before they make their way to the various tissues of the cow, where they are known to persist for at least 5 months.[31] There typically do not appear to be any signs associated with the lung migration of the larvae, but repeated passage of the larvae through the lungs on contaminated pasture could perhaps produce respiratory signs in older calves or adult animals.

ASCARIS SUUM. Cattle exposed to large numbers of *A. suum* eggs in areas contaminated by swine may have an interstitial pneumonia. Animals are typically affected approximately 10 days after exposure. Signs include depression, anorexia, fever, tachycardia, tachypnea, dyspnea with an expiratory grunt, variable coughing, ruminal stasis, and bloat. Auscultation of the lungs reveals increased breath sounds without adventitious sounds. Some deaths may occur. Differential diagnosis is difficult. Differentiation from the other interstitial pneumonias depends more on history of exposure to the causative agents (e.g., lush pastures, sweet potatoes moldy with *Fusarium solani*, wild mint, *Perilla frutescens*, toxic gases, moldy hay). Differentiation from viral pneumonia (such as that caused by BRSV) and *D. viviparus* reinfection syndrome requires necropsy and demonstration of larvae. Ascarid larvae have characteristic lateral alae in histologic sections. Patent *D. viviparus* infection can be differentiated by Baermann examination of the feces. In fatal cases the lung lobes are firm and mottled blue, red, and gray. The cut surface oozes thin yellow exudate. There is emphysema in the dorsal diaphragmatic lobes and subpleural hemorrhage with neutrophil infiltration and necrosis of bronchiolar and alveolar epithelium. In chronic cases the cellular infiltrate is lymphocytic, and there is proliferation of bronchiolar epithelium and peribronchial fibrosis. Recommended treatments include corticosteroids (dexamethasone, 0.04 mg/kg IM or IV or prednisolone, 1 mg/kg IM or IV daily) and antibiotics to control secondary bacterial infection.[32] Clinical signs resolved after treatment with oxfendazole in one outbreak of suspected *A. suum* migration.[33] Cattle should not be exposed to areas heavily contaminated by swine.

Lungworms of Sheep and Goats

Three species of lungworms are of primary importance in sheep and goats: *D. filaria* and the two metastrongylid nematodes, *M. capillaris* and *P. rufescens*. Other genera of metastrongylid lungworms of minor pathogenic importance in sheep and goats include *Cystocaulus*, *Spiculocaulus*, and *Neostrongylus*. These parasites are rare or absent in North America.[34]

DICTYOCAULUS FILARIA. *D. filaria* has a life cycle essentially identical to that of *D. viviparus;* the time from ingestion to the appearance of larvae in the feces is about 4 weeks. Mainly young animals are affected, but disease can also occur in adults. Dyspnea, tachypnea and coughing, and loss of condition occur in clinical cases.[32,33] Differential diagnosis includes the progressive viral pneumonias. Diagnosis is made by finding larvae in fresh feces by the Baermann test.[5] Samples should be tested soon after collection because larval recovery is significantly reduced in stored samples.[6] Larvae of *D. filaria* are similar in size and appearance to those of *D. viviparus* but also have a distinctive knob on the anterior end. The pathogenesis is similar to that of *D. viviparus* (see earlier discussion). The adults are found largely in the dorsal-caudal regions of the diaphragmatic lobes. Bronchitis and peribronchitis, along with cone-shaped areas of pneumonia and atelectasis, and emphysema are present. Secondary bacterial infections may also occur.[34,35] Levamisole (8 mg/kg), fenbendazole (5 to 10 mg/kg), ivermectin (0.2 mg/kg PO),[33] and moxidectin (0.2 mg/kg PO or SC)[36-38] can be used for treatment. When outbreaks occur, all animals should be treated and moved to fresh pasture when possible. Clinical *D. filaria* infections seem to occur most frequently in areas with warm climates. In temperate areas the parasite overwinters either as arrested larvae in ewes or as larvae on pasture.[34]

MUELLERIUS CAPILLARIS. *M. capillaris* is probably the most common of the lungworms of sheep and goats. Infection is more pathogenic in goats than in sheep. Surveys in Maryland and Georgia detected the parasite in 64% and 68% of goats, respectively.[39,40] The life cycle is indirect. First-stage larvae are coughed up, swallowed, and passed in the feces. These larvae are relatively resistant and may survive for several months in the environment. After penetration of an appropriate molluscan intermediate host, the infective third stage develops in a minimum of about 12 days, is ingested with the snail, and passes to the mesenteric lymph nodes. The fourth-stage larvae proceed to the lungs, where adults develop in the alveoli. The prepatent period of *M. capillaris* infection is about 6 weeks.[41] Although

VetBooks.ir

many infections are subclinical, clinical disease may develop. Goats appear to be more likely than sheep to develop unthriftiness, coughing, and dyspnea. Infection may also predispose to secondary bacterial infection.[40] The difference in clinical signs between sheep and goats probably results from a difference in the pathogenesis of infection. The adult worms live in the pulmonary parenchyma, particularly the subpleural tissue. In sheep they produce grayish nodules typically 2 to 3 mm in diameter. On palpation at necropsy, these nodules have been described as feeling like "lead shot."[40] Each nodule contains a worm and necrotic leukocytes and pulmonary tissue surrounded by a connective tissue wall and giant cells.[34] They may calcify or become secondarily infected with bacteria. Reports of lesions in goats indicate that *M. capillaris* causes an interstitial pneumonia. The lungs are resilient and firm, fail to collapse, and have tan, yellow, or gray patches located especially in the dorsal diaphragmatic lobes. The histologic lesion in goats is a diffuse thickening of alveolar septa, with a mononuclear cell infiltrate and alveolar epithelial hyperplasia that extends far beyond the area immediately around the parasite. The local reaction around the worm is quite variable and does not appear to produce the nodules seen in sheep.[42] Diagnosis is made by Baermann examination of the feces. The larvae are smaller than those of *D. filaria* and have a kink at the end of the tail with a characteristic subterminal accessory spine.[5]

Several anthelmintics have been used in the treatment of *M. capillaris* infections. Moxidectin (0.2 mg/kg in oral or injectable formulation) is effective in treating sheep infected with *M. capillaris* and other small lungworms (*Cystocaulus ocreatus*, *Neostrongylus linearis*, and *P. rufescens*) and may be equally effective in goats.[43] Although larvae may initially disappear in the feces after treatment, they often reappear in fecal samples again after 1 to 2 months because anthelmintics are ineffective against immature worms and/or because inhibited larvae resume development.[5] Treatments that appear to eliminate adult parasites in goats include fenbendazole (15 to 30 mg/kg),[41,42,44-47] albendazole (10 mg/kg),[562] oxfendazole (7.5 to 10 mg/kg),[563] and ivermectin (0.3 mg/kg).[44,48] *M. capillaris* is largely resistant to levamisole.[35] Better control of immature or inhibited larvae with fenbendazole was achieved by administering the drug (1.25 to 5 mg/kg) for 7 to 14 days, although a regimen of 1 week on/1 week off/1 week on appeared to provide the most effective treatment. Albendazole (1 mg/kg PO daily for 7 to 14 days) was also effective.[46] Possible teratogenic effects of extended benzimidazole treatment in goats have not been thoroughly investigated, and albendazole should be used cautiously in the first 35 days of pregnancy.[44] Administration of ivermectin (0.3 mg/kg) or fenbendazole (15 mg/kg) two or three times at 35-day intervals has also been suggested for treatment.[35] Control methods include avoiding wet pastures and treating animals before the start of the grazing season to reduce infection levels in the intermediate host.[35]

PROTOSTRONGYLUS RUFESCENS. *P. rufescens* also uses molluscan intermediate hosts, and adults develop in the small bronchioles of sheep and goats.[41] Most infections are probably subclinical or produce only mild signs of chronic bronchitis or bronchopneumonia with nasal discharge and cough. Occasionally *P. rufescens* may produce severe or even fatal disease.[47] The diagnosis of *Protostrongylus* spp. infection is made by finding larvae in the feces with the Baermann technique. The larvae are similar to those of *Muellerius* except that *Protostrongylus* larvae lack the subterminal accessory spine on the tail.[5] Fenbendazole, levamisole,[49] and moxidectin[43] can be used for treatment at the dosages used for *Dictyocaulus*. Other macrocyclic lactone products also may be effective but have not been tested. Control strategies are identical to those for *M. capillaris*. Few cases of infection have been reported in the United States, but nonspecific clinical signs, presence of subclinical carriers, and need for a special diagnostic technique may produce an underestimation of the prevalence of *P. rufescens* infection in sheep and goats.[49]

LARVAL TOXOCARIASIS. The dog ascaridoid *Toxocara canis* will infect and persist in the tissues of sheep and goats following the ingestion of infective eggs from pasture.[50-52] Migration of the larvae through the lungs does result in diffuse pulmonary inflammation, but there do not seem to be any clinical pulmonary signs accompanying the experimental infections.[53,54] Examination of sheep serologically using antibody detection tests has revealed that the prevalence of infection increases with age, with overall prevalences being 50% or more in the older animals sampled in Wales and Brazil.[55,56] More recent reports have found high levels of antibodies to *T. canis* in sheep from Brazil, Mexico, and Greece, and the report from Greece indicated that the seroprevalence in sheep was 7.71-fold higher than that found in goats from the same area.[57-59]

Bovine Tuberculosis

W. Ray Waters

Definition, Etiology, and Epidemiology Tuberculosis (TB) in animals and humans may result from exposure to bacilli within the *Mycobacterium tuberculosis* complex (i.e., *M. tuberculosis*, *M. bovis*, *M. africanum*, *M. pinnipedii*, *M. microti*, *M. caprae*, or *M. canetti*). *Mycobacterium bovis* is the species most often isolated from tuberculous cattle, and it is infectious to humans (zoonotic). Within the United States, bovine TB is nearly eradicated in cattle; however, sporadic cases are detected primarily due to ongoing importation of tuberculous cattle from Mexico, spillover from a wildlife reservoir host (i.e., white-tailed deer, *Odocoileus virginianus*) in the northeast region of the lower peninsula of Michigan, transmission from captive cervids infected with *M. bovis*, and herd-to-herd transmission in the United States. From 1998 to March 2017, there were 144 TB-affected herds within the United States (60.4% beef, 29.9% dairy, 0.7% bison, 1.4% mixed, and 7.6% captive cervid). In Great Britain the prevalence of bovine TB has been steadily rising despite continuous compulsory testing, with 10% of cattle herds in England (22.7% in the South West region) under movement restriction and nearly 25,000 cattle slaughtered at a cost of £91 million.[1] This dramatic and steady rise in TB prevalence is most likely due to the failure of the tuberculin skin test and slaughter strategy as applied in Great Britain and the presence of a wildlife reservoir (Eurasian badgers, *Meles meles*).[1] Wildlife reservoirs also hinder eradication efforts in New Zealand and Spain, with continual spillover from brushtail possums *(Trichosurus vulpecula)* and wild boar *(Sus scrofa)*/red deer *(Cervus elaphus)*, respectively.[2,3] In Latin American and Caribbean countries, bovine TB is relatively common, with estimates of 70% of cattle being held in regions with *M. bovis* prevalence rates greater than 1%.[4] In underdeveloped regions of Africa and Asia, bovine TB is endemic, causing significant economic losses for producers and public health concerns due to the close contact of humans and animals and the frequent consumption of unpasteurized milk. Bovine TB in African free-ranging species (e.g., African buffalo *[Syncerus caffer]* and lions *[Panthera leo]*) threatens wildlife conservation efforts and ecotourism, affecting the balance of entire ecosystems.[5] Tuberculosis in goats and sheep, primarily due to *M. caprae* or *M. bovis*, is uncommon in the United States but may occur in other regions of the world (e.g., Spain, Italy, New Zealand, Ireland, United Kingdom, Sudan, and Africa).[6,7]

In most countries with active control programs, affected cattle herds contain few infected animals suggestive of low rates of cattle-to-cattle transmission and a slowly progressive

VetBooks.ir

course of disease.[8] Transmission is generally by direct contact with TB-infected animals, as the organism may occur in exhaled droplets, saliva, feces, milk, urine, vaginal discharges, semen, or exudate from tuberculous lesions (e.g., lymph nodes with draining tracts that communicate to the exterior). Infection of the upper respiratory tract, pharyngeal area, and GI tract may also result from ingestion of infected feeds.[9] Housing (e.g., milking parlors, cattle sheds) and crowding increase the contact of naive animals with infected animals and enhance the spread of this disease. *M. bovis* is also transmitted by indirect contact through contaminated feed and water, feeding and watering equipment, cleaning equipment, or movements of personnel (i.e., anything that mechanically transfers the organism between locations). Movement of infected animals resulting from transfer of ownership, sharing of breeding animals, and fence-line contact with other herds is a common means of transferring the disease between herds and regions. In addition, global trade agreements are increasingly being implemented to promote international trade of livestock, thereby significantly increasing risks for interregional spread and distribution of TB over great distances.

Primary control strategies for bovine TB include diagnosis via tuberculin skin test and/or interferon-gamma release assays, isolation of affected herds, subisolation of infected animals within affected herds (i.e., Bang method), slaughter of infected animals, slaughter surveillance, and movement or border testing policies.[10] In addition to these traditional methods, antibody-based tests have recently emerged to detect *M. tuberculosis*–infected elephants,[11,12] *M. bovis*–infected captive cervids,[13] and on occasion *M. bovis*-infected cattle.[14] Also, molecular-based tools such as mycobacterial interspersed repetitive-unit–variable-number tandem-repeat (MIRU-VNTR), spoligotyping, and restriction fragment length polymorphism (RFLP) analysis of mycobacterial DNA are used to characterize mycobacterial isolates for epidemiologic investigations to determine potential links between new cases and prior outbreaks as well as the likely origin of infection. Most recently, high-throughput whole genome sequencing and rapid sequence analysis tools have been developed for a more thorough comparison of relatedness between *M. tuberculosis* complex isolates obtained from livestock, wildlife, humans, and zoo species; this technology is rapidly replacing MIRU-VNTR, spoligotyping, and RFLP for determining relatedness of *M. tuberculosis* complex strains from livestock and wildlife.[15]

Clinical Signs and Antemortem Diagnosis

In most animals the disease is slowly progressive; however, bovine TB occasionally follows a more rapid, fulminating course with early dissemination. Most animals do not show clinical signs of *M. bovis* infection until late in the course of the disease. Clinical signs, when present, are often nonspecific (e.g., weight loss, inappetence, low-grade fluctuating fever) and vary according to the organs involved. Respiratory signs are generally mild and may include a soft, moist cough more noticeable during cold weather and after exercise. In advanced stages, animals may exhibit obvious dyspnea, emaciation, and respiratory distress. Enlarged lymph nodes may rupture and drain. Enlarged mediastinal lymph nodes may cause bloat. Enlarged retropharyngeal lymph nodes, a frequent sequela in cervids, may cause dysphagia, stridor, and salivation. Enlarged mesenteric lymph nodes may cause intestinal obstructions. Lesions occur less frequently in peripheral lymph nodes, the reproductive tract (causing infertility, abortion, metritis, and vaginitis), and mammary gland. Particularly with chronic cases, tuberculous mastitis may occur with the potential for transfer of *M. bovis* to humans, calves, cats, or other animals through ingestion of unpasteurized dairy products.

The tuberculin skin test remains the primary tool for the diagnosis of bovine TB. Specific applications of the tuberculin skin test, however, vary according to regional and country directives.[10] Primary screening tests may use a single injection of *M. bovis* purified protein derivative (PPD) applied either to the skin fold at the base of the tail (e.g., caudal fold test used in New Zealand, the United States, Canada, and Mexico) or to the skin of the midcervical region (e.g., in many European Union member states). Alternatively, a dual injection of *M. avium* and *M. bovis* PPD may be applied to separate midcervical sites as the primary screening test (in Great Britain, Ireland, and Portugal) or as a confirmatory test (in the United States and Canada). An interferon-gamma release assay (e.g., Bovigam™ [Prionics, Schlieren, Switzerland]; ID-Vet, Montpellier, France) is also used as a confirmatory test in many countries.[10,16] Bovine TB test specificity differs regionally, most likely due to variations in application techniques (including differences in PPD usage), environmental factors, and co-infection (e.g., parasite burden[17]). In particular, it is widely recognized that exposure of cattle to various nontuberculous *Mycobacteria* spp. may confound interpretation of PPD-based tests. The use of dual injection of *M. avium* and *M. bovis* PPDs at separate sites was developed to address this issue, and comparative tests improve test specificity with only a slight loss in test sensitivity when compared to single-injection tests (e.g., caudal fold test). Recently, *M. tuberculosis* complex–specific antigens such as ESAT-6, CFP10, and Rv-3615c have been developed for use with interferon-gamma release assays and skin tests.[18] These antigens are generally not produced by nontuberculous *Mycobacteria* spp., including *M. avium* subsp. *paratuberculosis*[19]; thus they afford greater specificity with only minimal loss in test sensitivity.

Pathophysiology, Necropsy Findings, and Differential Diagnosis

While often viewed as a pulmonary disease in humans, TB is primarily a disease of the lymphatic system. With ruminants, tuberculous lesions are most commonly detected within pulmonary and cranial lymph nodes as well as lungs. In naturally infected cattle, 67% of tuberculous lesions are detected in lungs and pulmonary lymph nodes, 39% in cranial lymph nodes, and 8% in mesenteric lymph nodes.[20] Lesions are most commonly detected in the medial retropharyngeal lymph nodes of tuberculous white-tailed deer[21]; lungs, pulmonary lymph nodes, and pleura are also common sites of lesions in deer. In pigs (i.e., Eurasian wild boar and free-ranging domestic black pigs), tuberculous lesions are most commonly detected in the cranial lymph nodes, and dissemination is common.[22,23] With experimental infection, infectious dose affects disease severity and progression; animals exposed to high doses develop an earlier onset of lesions with greater severity than animals exposed to lower doses. The infectious dose of *M. bovis* for ruminants is quite low. For instance, intratracheal administration of one colony-forming unit (~6 to 10 bacilli) may cause disease.[24]

M. tuberculosis complex bacilli (including *M. bovis*) infect cells primarily of monocyte or macrophage lineage yet may also be found within type II alveolar epithelial cells, dendritic cells, neutrophils, and a few others. The pathognomonic lesion of *M. bovis* infection is the granuloma. Tuberculous granulomas form in response to pathogen virulence factors and chronic antigen stimulation (due to persistent infection). Granulomatous inflammation is thought to limit the spread of tuberculous bacilli within the host by walling off the organism. The combination of the initial site of infection and the regional (i.e., draining this site) lymph node constitutes the primary complex commonly referred to as Ghon's complex with pulmonary *M. tuberculosis* infection in humans. Dissemination from the primary complex occurs via both lymphatic and hematogenous spread. Particularly in cases of prolonged or severe disseminated disease, determination of the primary complex may be impossible, confusing speculation on the initial

VetBooks.ir

route of infection. When infection occurs across mucous membranes, such as the oropharynx or intestine, the initial lesion in the mucous membrane may not be visible. whereas lymph node lesions are generally obvious.[25] From the initial site of entry, the organism invades local lymph nodes, where it causes necrosis surrounded by granulomatous inflammation consisting of primarily mononuclear cells. Localized lesions stimulate development of a fibrous capsule that varies in severity depending on the rate of development and chronicity of infection. Postprimary dissemination may occur, leading to spread of the organism and resulting in discrete nodular lesions in various lymph nodes and organs. Diffuse miliary TB may occur in severe cases. Latency, although a common sequela with *M. tuberculosis* infection of humans, is typically not considered a common stage of disease with *M. bovis* infection of cattle; however, *M. bovis* may be isolated from tissues without visible gross lesions, indicating a potential for "latent" infection.

Postmortem diagnosis is based on (1) gross and microscopic evaluation for tuberculous lesions, (2) detection of the organism by mycobacterial culture within tissues, with follow-up confirmation or characterization using molecular techniques, (3) direct detection of *M. tuberculosis* complex DNA within tuberculous lesions, and (4) detection of *M. tuberculosis* complex–specific DNA by PCR on histologic sections. Often multiple lesions are detectable on examination, although infected cattle may display no grossly visible lesions or only a single visible lesion. Macroscopic lesions appear as firm, encapsulated nodules and vary in size from barely visible to greater than 100 mm in diameter. Lesions may contain thick, white to yellow-orange, creamy to caseous purulent material. Lesions may be calcified. Lymph nodes, organs, and pleural or peritoneal serosa may be riddled with small miliary tubercles, and in the lungs these lesions may coalesce into a suppurative bronchopneumonia. Granulomas along the pleural serosa (i.e., pearl disease) often appear glossy. Chronic lesions are characterized by a discrete, thickened fibrous to calcified capsule, often containing thick caseous material. Lesion cavitation due to *M. bovis* infection in cattle is rare. Microscopically, lesions in lymph nodes or organs are granulomatous, generally consisting of caseous necrosis surrounded by infiltrates of epithelioid macrophages, Langhans-type multinucleated giant cells, and lymphocytes. Lesions with necrotic cores may contain dystrophic calcification. Detection of acid-fast bacilli within granulomatous lesions in tissue sections provides a preliminary diagnosis of mycobacterial infection that must be confirmed by mycobacterial culture and PCR. Acid-fast bacilli are often few in number and most commonly detected within the caseum of the necrotic core. Resolving lesions are thought to be rare. Lesion development can be divided into four different stages primarily based on the level of necrosis, fibrous encapsulation, and mineralization: stage 1 (no necrosis), stage 2 (minimal central necrosis, thin connective tissue capsule), stage 3 (central caseous necrosis with complete fibrous encapsulation), and stage 4 (extensive multicentric caseous necrosis with mineralization). Differentiation between the thickness of the fibrous capsule and the histopathologic stage of development may assist in determining the chronicity of the infection.

Mycobacterial culture is the gold standard for TB diagnosis. *M. bovis* grows slowly, and cultures are generally incubated for 8 weeks; growth usually becomes visible within 3 to 6 weeks. The identity of the organism in cultures may be determined with biochemical tests, colony morphology, and *M. tuberculosis* complex–specific PCR. Potential pathogens for consideration in differential diagnosis include nontuberculous *Mycobacteria* spp., *Nocardia* spp., *Arcanobacterium pyogenes*, *Corynebacterium pseudotuberculosis* (caseous lymphadenitis in goats and sheep), and mycotic infections. In particular, nontuberculous mycobacteria (e.g., *M. avium* subsp. *paratuberculosis*, *M. avium* subsp. *avium*, *M. kansasii*, and many others) are common isolates within tissues obtained from domestic livestock and wildlife. Johne's disease, caused by *M. avium* subsp. *paratuberculosis*, is common in domestic livestock, causing a mild to severe granulomatous enteritis. Other nontuberculous mycobacteria occasionally cause clinical disease resulting in granulomatous lesions in lymph nodes, lungs, and visceral organs.

Treatment, Prevention, and Control Bovine TB is rarely, if ever, treated in domestic livestock. Particularly in developed countries, affected animals are slaughtered to limit potential transmission to other animals and to limit the duration and severity of regulatory restrictions. Antimycobacterial therapy may be indicated for rare or endangered animals or for those considered valuable as zoologic exhibits.[11] Antituberculous first-line chemotherapies include isoniazid, rifampin, pyrazinamide, ethambutol, and streptomycin. These agents have the greatest activity with the least undesirable side effects. Second-line agents include capreomycin, ethionamide, cycloserine, and thiacetazone. The fluoroquinolones (moxifloxacin, ciprofloxacin, levofloxacin, and enrofloxacin), although not considered first-line agents, have significant bactericidal activity against *M. tuberculosis* complex species. Outside of these rare cases, treatment for TB in animals is generally not considered practical on a cost basis.

Many countries have official bovine TB eradication or control programs, including uniform methods and rules for application of the programs. Prevention and control efforts are designed to identify affected herds and remove infected animals or depopulate the entire herd (stamping out). These efforts are generally achieved via routine slaughter surveillance to identify affected herds, targeted testing schemes to remove TB test–positive animals (reactors), movement restriction of affected herds, thorough epidemiologic investigations of reported cases to determine risks for other affected herds, and depopulation of affected herds. In addition, movement testing with certification of a negative TB tests may be required prior to entry of animals into certain countries or regions. In certain instances, entry of animals from known TB-affected regions may not be allowed. Specific regulations and rules concerning bovine TB control are provided within specific country and regional directives.[1,26,27] Due to limitations in the sensitivity of antemortem diagnostic tests for tuberculosis, depopulation of infected herds is thought to be the most effective means to ensure eradication of the disease from the target population. Surveillance and control of *M. bovis* infection in wildlife reservoirs, as well as mitigation efforts to limit spread from wildlife to livestock, are also critical for bovine TB control.

In instances where herds are depopulated and the owner intends to repopulate in the future, it is important to remove or thoroughly clean and disinfect facilities and equipment potentially exposed to the organism. The ability of *M. bovis* to survive for an extended period in the environment, and the ineffectiveness of disinfection of organic materials, necessitates that pastures and fields to be used in repopulation schemes be left vacant for a period prior to use. Instances of infection that are thought to originate from wildlife sources may precipitate changes in facilities, management and feeding practices, or wildlife control to prevent reinfection. Current experience with endemic *M. bovis* infections in wildlife in numerous countries has demonstrated that eradication of TB in free-ranging wildlife is difficult and a long-term proposition. Vaccines are rarely used for the control of bovine TB in regions with official control programs, primarily due to the potential for interference with traditional antemortem testing using PPD as antigen (i.e., tuberculin skin test and interferon-gamma release assays).[28] Bacillus Calmette-Guérin (BCG) is an attenuated *M. bovis* developed by Albert Calmette and Camille Guérin circa 1911 at the Pasteur Institute in Lille, France. Field efficacy trials

performed in the early twentieth century demonstrated the partial effectiveness of BCG for the control of bovine TB.[28] Recent experimental trials with cattle have demonstrated that (1) subunit vaccines may boost immunity elicited by BCG in cattle, (2) BCG is particularly protective when administered to neonates, and (3) differentiation of infected and vaccinated animals is feasible in cattle using in vitro or in vivo methods.[18,28] In regard to wildlife reservoirs, the efficacy of BCG delivered orally has been demonstrated for brushtail possums (in field trials) as well as for Eurasian badgers, wild boar, and white-tailed deer (each in experimental challenge studies). The most practical route of vaccine delivery to wildlife reservoirs of *M. bovis* is via oral-delivered baits, although a parenteral route is being used for badgers in England. Additional research is needed in the areas of diagnostic testing, environmental sampling, vaccine development, and management practices that may decrease the risk of disease spillover from wildlife reservoirs to cattle.

Other Pneumonias*

Amelia R. Woolums

Aspiration Pneumonia

Aspiration pneumonia is caused by inhalation of large amounts of foreign material, often liquids. The most common cause is careless drenching or passage of stomach tubes during administration of milk or liquid medication. It also occurs occasionally in pail-fed calves, animals with pharyngeal paresis, animals with necrotic laryngitis, lambs with nutritional myodegeneration, anesthetized animals, sheep that are dipped, cattle that have parturient paresis, and cattle that ingest crude oils or fuel oils. Meconium aspiration secondary to fetal distress has been recognized as a possible risk factor of neonatal calf mortality.[1]

If large quantities of fluid are aspirated, death may be almost instantaneous, but generally a gangrenous bronchopneumonia develops as a result of infection and the irritating properties of the inhaled material. Affected animals exhibit depression, tachypnea, dyspnea, coughing, and fever and may have putrid breath. Crackles, wheezes, and occasionally pleural friction rubs can be heard on auscultation.

A presumptive diagnosis is based on the history and clinical evidence of bronchopneumonia; definitive diagnosis can be confirmed by gross or histopathologic identification of feed, milk, or other aspirated material in airways. Differential diagnoses include acute bacterial bronchopneumonia and septicemia. Necropsy reveals consolidation of the anterior ventral areas of the lungs. Affected areas are severely hemorrhagic in acute cases and contain suppuration and liquefactive necrosis in subacute cases.

The prognosis is guarded in all cases of aspiration pneumonia, but some animals can be successfully treated. Antibiotics combined with antiinflammatory agents should be promptly administered, and long-term antimicrobial therapy (weeks) is required. Prevention of aspiration pneumonia centers on careful administration of medication and avoidance of other risk factors that may promote inhalation of foreign materials.

Mycotic Pneumonias

Fungal pneumonia is a rare occurrence in ruminants. The clinical presentation is typically one of poor response to antimicrobial therapy. Cases of fungal pneumonia with metritis or placentitis have been reported.[2,3] Diagnosis is confirmed by identification of fungal organisms with an inflammatory reaction in tracheal aspirate or bronchoalveolar lavage, or at postmortem with fungal culture to confirm the identity of the agent. Little information is available regarding successful treatment of ruminants with fungal pneumonia. In other species such as horses, treatment requires weeks to months of therapy with antifungal agents such as ketoconazole or itraconazole; these drugs may be cost prohibitive for many ruminant cases, and their disposition in the rumen has not been described. Therapy with oral potassium iodide is an inexpensive alternative that may be attempted for some cases, but the efficacy of this therapy has not been confirmed. Prognosis for fungal pneumonia in all species is guarded to poor, depending on the severity of disease and the feasibility of treatment. Given these restrictions, treatment of fungal pneumonia in ruminants is likely reserved for valuable individuals. More guidelines regarding treatment for fungal pneumonia are presented in the section on equine respiratory diseases.

Vena Caval Thrombosis and Metastatic Pneumonia

Definition and Etiology Metastatic or embolic pneumonia in cattle, also called *caudal vena caval thrombosis*, *pulmonary thromboembolism*, and *embolic pulmonary aneurysm*, is a distinct syndrome associated with multifocal abscessation of the lungs caused by septic thromboembolism of the pulmonary arterial system. The septic emboli arise from septic thrombi of the caudal vena cava (Fig. 31.69) or, less commonly, the cranial vena cava. Vena cava thrombi are in turn a sequela to various septic conditions such as jugular phlebitis, mastitis, metritis, foot rot, or, most often, liver abscesses secondary to rumenitis.[4] A variety of bacteria may be involved; those most frequently encountered include *F. necrophorum*, *A. pyogenes*, staphylococci, streptococci, and *E. coli*.

Clinical Signs Because of its association with rumenitis, this condition is most commonly seen in feedlot cattle, but any age, breed, sex, and class of cattle may be affected. The problem is unusual in cattle younger than 1 year of age. Cattle with metastatic pneumonia usually exhibit respiratory disturbance or weight loss or occasionally thoracic pain. The clinical signs in affected cattle have been described.[5,6] The classic presentation includes tachycardia, tachypnea, dyspnea, coughing,

FIG. 31.69 Postmortem photograph of thrombus in caudal vena cava, which leads to embolic pneumonia demonstrated in Color Plate 31.10. *(Photograph contributed by Feedlot Health Management Services, Okotoks, AB, Canada.)*

*Previous contributions by Steven E. Wikse are acknowledged.

heart murmurs and pale mucous membranes (caused by anemia), widespread wheezes, epistaxis, and hemoptysis. The duration of signs is quite variable, ranging from acute respiratory distress to a chronic history of weight loss and coughing for weeks to months. Other signs, which are more variable, include fever, thoracic pain on deep palpation of the sternum and intercostal spaces, hepatomegaly (indicated by the ability to palpate the caudal edge of the liver in the right paralumbar fossa), subcutaneous emphysema, froth at the muzzle, and melena caused by coughing up and swallowing blood. Nonspecific accompanying signs include depression, anorexia, ruminal stasis, scant feces, and decreased milk production. In chronic cases, cor pulmonale may lead to signs of right ventricular failure such as jugular distention and brisket edema. The combination of respiratory signs with anemia, widespread wheezes, and especially hemoptysis is generally regarded as pathognomonic for this syndrome. Animals usually deteriorate rapidly once hemoptysis becomes evident, and death despite treatment is typical. Many patients die suddenly with an acute episode of severe intrapulmonary hemorrhage or hemoptysis after a variable course of respiratory disease. Some of these cases in which the respiratory signs were overlooked may account for the reports of sudden death attributed to vena caval thrombosis. Caudal vena caval thrombosis can also lead to hepatomegaly and extensive ascites, but most of these animals also have respiratory signs.[6] Sudden erosion of a large hepatic abscess into the caudal vena cava may also result in a massive embolic shower, with acute respiratory distress and death.

In patients with the pathognomonic signs (the majority of cases), no differential diagnoses need be considered. However, many patients are examined before the onset of hemoptysis, and a few may die without exhibiting these signs. Differential considerations in such cases, which usually manifest as acute dyspnea, should include anaphylaxis, various causes of ARDS, hypersensitivity pneumonitis, lungworms, and acute bronchopneumonia. Patients with right ventricular failure should be differentiated from those with pericarditis, lymphosarcoma, cardiomyopathy, and endocarditis.

Pathogenesis The pathogenesis of this disease begins with the development of rumenitis secondary to lactic acidosis caused by highly fermentable diets such as those used in feedlots, some dairies, and some growing rations. Bacteria such as *F. necrophorum* and *A. pyogenes* are then able to penetrate the damaged ruminal epithelium and are transported to the liver in the portal drainage system, where they are filtered out and result in abscesses. If an abscess is located next to the caudal vena cava (where the vessel is closely applied to the left border of the liver), a septic thrombus may form in the vena cava as a result of infiltration of its wall by the abscess (see Fig. 31.69). Septic emboli detach from the thrombus and reach the lungs through the pulmonary arterial system. Alternatives to this classic pathway are rare; they include thrombosis of the cranial vena cava from primary lesions such as jugular phlebitis, thrombosis of the caudal vena cava from other subdiaphragmatic abscesses, right-sided endocarditis, and emboli arising from other septic foci such as mastitis, metritis, and foot rot. Large emboli may block lobar or larger arteries, causing an acute crisis and death. More typically, smaller emboli lodge in arterioles, where they cause arterial thromboembolism, arteritis, endarteritis, and pulmonary abscesses (Color Plate 31.10). The widespread arterial embolism also results in pulmonary arterial hypertension. Arteritis and endarteritis weaken the vessel walls and, in combination with pulmonary hypertension, lead to the formation of aneurysms. In some cases a perivascular abscess not only erodes an arterial wall to produce an aneurysm but also simultaneously erodes a bronchial wall; when the aneurysm ruptures, the abscess cavity channels the blood into the bronchus, resulting in massive hemoptysis. In other cases, rupture of aneurysms results in large interstitial hematomas. Both processes result in anemia; when coughed-up blood is swallowed, melena may result. Coughing and wheezes are probably caused by blood clots in airways, peribronchial aneurysms and abscesses, and suppurative pneumonia. Pain results from dissecting aneurysms and hematomas.

Epidemiology Metastatic pneumonia accounted for 1.3% of necropsy diagnoses in one large feedlot survey, with a rate varying between 1.6 and 7.3 cases per 100,000 head on feed. Cases occurred year round and during all stages of fattening, although 68% of cases occurred during the first 90 days on feed.[7] The case fatality rate is high.

Necropsy Almost all patients with significant hemoptysis have a thrombus in the posterior vena cava between the liver and the right atrium. There is usually an adjacent hepatic abscess, varying degrees of venous congestion of the liver, and hepatomegaly. The lungs are large, uncollapsed, and firm. Aneurysms may occur in either lung or both. Hematomas associated with ruptured aneurysms are frequently 3 to 10 cm in diameter. Large blood clots may be found in the airways, aspirated blood may be found in the alveoli, and swallowed clots may be found in the rumen. Areas of suppurative pneumonia and multiple abscesses are present (see Color Plate 31.10).

Diagnosis The CBC may reveal anemia and a neutrophilic leukocytosis with a regenerative left shift. Hyperglobulinemia is frequently present. Serum chemical analysis may reflect chronic passive congestion of the liver, with elevation of liver enzymes. Radiographs often reveal only an irregular increase in lung density. Small discrete densities (areas of embolic infarction and collapse); large, discrete, spheric opacities (hematomas); cavitating nodules, sometimes with gas-fluid interfaces (abscesses); bullae; and areas of consolidation may be observed in some cases.

Treatment and Prevention The prognosis is grave, so treatment is rarely indicated, and salvage is the most feasible recommendation. In valuable individuals, antibiotics and supportive therapy may be attempted. Penicillin, oxytetracycline, or florfenicol may be effective; treatment should be administered for extended periods (weeks to months). Supportive therapy for cases with acute severe dyspnea includes furosemide (0.5 to 1 mg/kg IV or IM once or twice daily) and flunixin meglumine (1.1 to 2.2 mg/kg once or divided twice daily). One or two doses of corticosteroids (dexamethasone, 0.05 to 0.2 mg/kg IV or IM q24h) may be helpful in cases with severe respiratory distress.

Based on the assumption that rumenitis and liver abscesses are the first steps in the pathogenesis of most cases, measures to reduce the incidence of these problems are appropriate. Recommendations include slow adaptation of animals to high-energy rations and feeding of antibiotics to reduce the incidence of liver

Diseases of the Thoracic Wall and Cavity*

Amelia R. Woolums

Pleuritis and Pleural Effusions

Definition and Etiology Acute, primary pleuritis is rare in ruminants. It is almost always a secondary condition.

*Previous contributions of John A. Smith are acknowledged.

VetBooks.ir

The most common primary cause is most likely bronchopneumonia caused by *M. haemolytica* or *H. somni*. Other possible causes of pleuritis and pleural effusions include traumatic reticulopericarditis, extension from other causes of peritonitis, tuberculosis, liver abscesses, tumors (especially lymphosarcoma), external trauma, fractured ribs, gunshot, perforating injuries, various septicemic conditions, acorn toxicity and other causes of uremia, uroperitoneum, right ventricular failure, hypoproteinemia, ruptured thoracic duct, and hemothorax from trauma or hemangiosarcoma.

■ ***Clinical Signs*** The signs depend on and may be overshadowed by the primary disease process. Pleuritis is a painful, septic process, whereas the signs associated with nonseptic effusions depend largely on the cause. Signs referable to pleuritis itself include anorexia, depression, fever, weight loss, decreased milk production, progressive dyspnea, and a characteristic stance and respiratory pattern, with the head and neck extended, elbows abducted, restricted excursion of the thorax, abdominal breathing, tachypnea, and a grunting or groaning with respiration. The animal may be reluctant to move. If a cough is present, it is often soft and suppressed because of pain. Jugular distention and pulsation may result from interference with venous return. Auscultation may reveal creaking or rubbing noises in dry pleuritis or a cranial-ventral masking of sounds caused by effusion. Percussion may reveal dullness ventral to the fluid line and may elicit pain. Differential diagnoses for dyspnea with abnormally quiet lung fields may include acute interstitial pneumonia, pneumothorax, and space-occupying lesions such as large abscesses, tumors, and diaphragmatic hernia. Once pleuritis or pleural effusion has been identified, the main differential diagnostic consideration is the determination of the underlying cause, as listed previously.

■ ***Diagnosis*** A CBC helps separate infectious causes from noninfectious causes and distinguish relatively acute conditions (with significant left shifts) from those of a more chronic nature (with mature neutrophilia, hyperglobulinemia, and nonregenerative anemia of chronic disease). Serum chemical determinations and urinalysis identify hypoproteinemia and azotemia. A thoracocentesis should be performed and submitted to cytologic and cultural examination for bacteria, mycoplasma, and chlamydia. Nonseptic transudates indicate conditions such as neoplasia, heart failure, hypoproteinemia, and uremia. Septic exudates high in both cells and protein occur with pleuropneumonia, hardware, peritonitis, abscesses, penetrating trauma, and septicemias. A transtracheal wash is usually indicated because of the common association with pneumonia. Pericardiocentesis, abdominocentesis, and radiographs may indicate the primary source of an infection. Tuberculosis tests, leukemia virus titers, electrocardiography, echocardiographic examinations, ultrasonographic examination of the liver, and exploratory laparotomy may also help detect other primary processes.

■ ***Treatment*** The primary problem should be treated. Effusions should be drained, either periodically or continuously through a Heimlich valve or a suction device fashioned from a syringe with the plunger transfixed with a pin. Effective drainage can be difficult in ruminants because of their propensity for fibrin formation and loculation of the fluid. Intermittent drainage is as effective as continuous drainage and simpler to maintain. Attempts at lavage have rarely been successful because of adhesions. Appropriate antibiotics are indicated in the presence of sepsis. NSAIDs (flunixin meglumine, 1.1 to 2.2 mg/kg IV or divided twice daily) are useful to relieve pain, ease respiration, and improve appetite. Rest and good nursing care are essential. The prognosis obviously depends on the extent and duration of the disease.

Pneumothorax

Pneumothorax is not common in ruminants. Most cases result from the rupture of an emphysematous bulla associated with pneumonia, straining, or coughing or from puncture of the lung by a fractured rib. The bullae that occur in BRSV-induced pneumonia are a common source. Trauma to the pharynx or larynx can also lead to pneumothorax, presumably caused by air traveling from the cranial cervical regions through soft tissues and into the thoracic cavity. Penetration from the exterior is possible but less common. A case has been described in a postparturient cow with no other underlying cause found.[8] A retrospective study of 30 cattle with pneumothorax presented to a referral hospital found that 18 of the cases (60%) were associated with bronchopneumonia, 7 cases were associated with interstitial pneumonia, 3 cases were associated with laryngeal or pharyngeal trauma, and 2 cases were associated with neonatal respiratory distress.[9] Of interest was the finding that 13 of the 18 cases with bronchopneumonia were chronic, based on history and diagnostic findings; an association between pneumothorax and chronic bronchopneumonia had not been previously reported. The rate of survival for cattle with pneumonia and pneumothorax was lower than for cattle presented with pneumonia without pneumothorax, with an overall survival rate of 60% for cattle presented with pneumothorax.

Clinical signs of pneumothorax include inspiratory dyspnea, sometimes severe, with open-mouth breathing sometimes present. One side of the thorax may be relatively collapsed and immobile, with a compensatory increase in the size and excursion of the other side; however, this latter finding is often subtle and difficult to appreciate. Ruminants have a complete mediastinum; thus when pneumothorax occurs it is usually unilateral, and the animal is able to ventilate adequately using the opposite lung. Unless an infectious disease is responsible, affected animals are often alert and anxious. They may attempt to stand with the forefeet elevated. There is a pronounced abdominal component to the respirations. Cyanosis may occur, and airflow may be markedly reduced in severe cases. On auscultation there is an obvious disparity between the two sides; bronchovesicular sounds will be diminished dorsally on the affected side or may be entirely absent. Those lung sounds that are audible have a harsh, high-pitched, large airway character similar to those of a consolidated lung, especially over the carina; these sounds seem to be distant, as if the animal were breathing in a barrel. The point of maximum intensity of the heart may be displaced, and tachycardia is often present. Percussion may reveal an abnormal resonance when compared with that of the normal side, and simultaneous auscultation and percussion may produce a "ping" over the thorax. Subcutaneous emphysema is a fairly common feature, and pleuritis is often a sequela. Differential diagnoses of the inciting cause should include the various causes of ARDS, bronchopneumonia, viral pneumonias (especially BRSV), pleural effusions, diaphragmatic hernia, other space-occupying lesions (large abscesses, tumors), and clostridial infections. Pneumothorax can be diagnosed with radiographs, transthoracic ultrasound, or thoracocentesis; radiographs and ultrasound will also be useful to characterize the extent of any underlying lung disease. Other diagnostic tests to characterize underlying lung disease as described for infectious bronchopneumonia or interstitial pneumonia are appropriate.

If the affected animal shows signs of significant distress, the air in the pleural space should be evacuated. Evacuation can be accomplished by aseptically placing a teat cannula into the thoracic cavity at the dorsal aspect of the thorax at the tenth intercostal space and withdrawing air by use of an extension set, three-way stopcock, and syringe. In some cases this method can be successfully used to intermittently remove air; in other cases, continuous removal with a pleural evacuation

VetBooks.ir

device (Pleur-evac A-8000 [Deknatel Inc., Fall River, Mass.]) has been more effective.[10] If continuous evacuation is attempted, the animal must be adequately restrained; this is likely to be possible only with hospitalized animals. Other treatment includes therapy appropriate for underlying acute or chronic pneumonia as described previously for infectious bronchopneumonia or interstitial pneumonia. External wounds allowing air to enter the thorax should also be closed if present.

Diaphragmatic Hernia

Definition and Etiology Diaphragmatic hernias are uncommon in ruminants. Hernias may be congenital, but most appear to be acquired, including those occurring in neonates. A congenital weakness in the diaphragm may predispose to some cases. Causes include difficult parturition, external trauma, and, by far the most common cause, traumatic reticuloperitonitis (TRP).

Clinical Signs and Differential Diagnosis Affected animals can be asymptomatic for a prolonged period.[11] Most affected cattle are in late gestation or have calved recently. The history may include decreased milk production, weight loss, capricious appetite, difficulty in swallowing or regurgitation, previous signs of abdominal pain (possibly associated with acute TRP), vomiting, and abnormal posturing of the head and neck on swallowing or regurgitation. Respiratory signs are actually fairly uncommon, with the exception of large congenital hernias, in which there is obvious severe dyspnea and abdominal respiration from birth. Occasional cough and dyspnea have been reported, and auscultation may reveal asymmetric sounds, with lack of lung or heart sounds in the affected area, or splashing sounds similar to those heard with pericarditis. GI signs are actually more common and include bloat, signs consistent with TRP, difficulty or pain on passage of a stomach tube, diarrhea, constipation, and ruminal hypomotility. Some cows may retch or vomit on regurgitation. Pain is evidenced by odontoprisis or grunting on regurgitation. The primary differential diagnoses are TRP, pericarditis, esophageal stricture, esophageal foreign body (choke), neoplasia, and abscessation.

Diagnosis Radiographs can be used to confirm the diagnosis. The normal outline of the diaphragm and heart may be obscured, and the honeycombs or foreign objects in the reticulum may be seen in the thorax because this organ is most commonly involved. Oral barium may also aid in the radiographic interpretation, particularly in early small hernias that will be missed on plain films. Pleuritis and other masses such as tumors and abscesses can also mimic hernias on plain films. If TRP is involved, the CBC, pleural effusions, and abdominocentesis may reflect the septic process. In cases not associated with TRP, the pleural effusion may be hemorrhagic in acute cases and normal in chronic cases.

Necropsy The hernial ring is usually located at the junction of the musculotendinous portion of the diaphragm, about 12 cm ventral to the vena cava and slightly lateral to the midline. The ring is usually round to oval, with a diameter of 7 to 20 cm. The reticulum is usually herniated, most frequently to the right side of the chest. The liver, spleen, rumen, omasum, abomasum, intestine, and omentum may also be involved. Extensive adhesions usually develop between the herniated organs and the thoracic organs, and evidence of hardware can often be found.

Treatment and Prognosis Treatment is surgical. A two-stage approach is usually used. First, a standing left flank laparotomy and rumenotomy are performed; the defect is identified, foreign bodies are removed, and the ruminoreticulum is emptied. Because of the complete mediastinum, ventilatory assistance is rarely needed during this stage. Next, the animal is placed under general anesthesia with positive pressure ventilation. Various approaches have been used for this portion, including ventral midline, paramedian, semilunar postxiphoid, paracostal, and transthoracic with rib resection. The hernia is reduced, and the rent is repaired with sutures or mesh grafts. Mesh grafts are contraindicated if infection is present.

Pleural Mesothelioma

Mesotheliomas have been reported in cattle and goats,[12] including a congenital form in calves.[13] Most are peritoneal, but pleural mesotheliomas also occur.[14] Mesotheliomas result in the accumulation of large amounts of fluid in the involved body cavity; signs of pleural mesothelioma are therefore related to pleural effusion. They include dyspnea, tachypnea, decreased lung and heart sounds (sometimes unilateral, with a concomitant increase in sounds on the normal side), dullness on percussion, exercise intolerance, cyanosis, tachycardia, anorexia, weight loss, decreased production, cough, and weak pulses. If peritoneal lesions are also present, as is common but not universal, ascites is also present. Radiographs confirm the pleural effusion, and thoracocentesis yields a serous, sometimes blood-tinged or gelatinous fluid. Cytologic examination may reveal reactive mesothelial cells. At necropsy the pleura is thickened and contains multiple nodules of gray to yellowish-white tissue measuring several millimeters to several centimeters in diameter. Metastasis is uncommon. The tumor can be difficult to diagnose histologically and may resemble inflammation, pleural tuberculosis ("pearl disease"), or metastasis of another tumor.[13] There is no treatment.

Miscellaneous Conditions*

Amelia R. Woolums

Lung Tumors

Lung tumors are uncommon in large animals. Those reported include pulmonary alveolar carcinomas, pulmonary adenomas, pulmonary adenocarcinomas, bronchogenic carcinoma, and pulmonary blastoma.[15,16] Malignant forms metastasize to regional lymph nodes and occasionally to other organs. Lymphosarcoma is the most frequent neoplasm to become metastatic to the lung, and uterine and ovarian adenocarcinoma may undergo metastasis to the lung. Because many lung neoplasms in cattle are incidental findings at slaughter or necropsy, clinical signs are therefore not well documented. The lesions are typically discrete, round, yellow to gray masses distributed throughout the lung tissue. Tumors are most likely to be detected antemortem by radiographic examination. Differential diagnoses in such cases include pulmonary abscesses, mycotic pneumonias, and tuberculosis.

Equine Alimentary System

Samuel L. Jones, *Consulting Editor*

Examination and Imaging of the Equine Alimentary System

Samuel L. Jones • Michelle H. Barton

A thorough physical examination is compulsory, and tests that provide a minimum database (complete blood cell count [CBC], serum chemistry profiles, and urinalysis) are often indicated in horses with suspected alimentary tract disease. Once a differential diagnosis is compiled, a number of ancillary diagnostic tests are available to narrow the possibilities. Each diagnostic test or procedure is limited in the type and extent of information that can be obtained, and therefore the clinician should select the complement of procedures that is most likely to provide the information required to make a proper diagnosis and determine the appropriate therapy.

Rectal Examination A systematic approach to examining the abdominal and retroperitoneal viscera should be established and applied during each examination to ensure that all pertinent regions and structures are examined. When feasible and if required, the patient should be sedated to allow a more thorough examination. In some cases, *N*-butylscopolammonium bromide administration or epidural anesthesia is required to obtain adequate access to structures during rectal examination. The principal goal of a rectal examination is to identify changes in size, texture, shape, or location of visceral organs, peritoneum, mesentery, and vasculature, or to detect objects that are normally not present. Rectal examination is often performed with ultrasonographic examination, and information derived from each must be considered in order to draw conclusions. Ultrasonographic examination is described in a later section of this chapter.

In the pelvic region of the normal horse, the urethra and accessory sex glands (male) or the vaginal vault and cervix (female) can be palpated. The urethra is usually not discernible in the female, but abnormalities such as uroliths may be detected. In the caudal abdominal cavity, the bladder, the uterus in females, and the pelvic flexure and small colon typically should be identified. The pelvic flexure and left ventral and left dorsal portions of the colon are normally located ventrally, on midline, or toward the left side of the abdomen. The small colon, in which formed fecal balls are palpable, courses throughout the caudal abdomen, mostly on the left side. In females the left ovary can be identified in the left dorsal, caudal region of the abdomen. Both ovaries should be palpated in conjunction with palpation of the uterus. The peritoneal surface should be detected along the surface of the abdominal wall and the surfaces of the viscera. It should feel smooth, with no crepitus or irregularities. Farther along the left side of the abdomen, the spleen is palpable as a smooth structure; the caudal border is well-delineated and tapered. The size and location of the spleen are variable because it can extend from the left body wall to the right ventral region of the abdomen. Farther cranially and dorsally, the left kidney can be palpated. The kidney should feel smooth and the renal pelvic fissure should be discernible, although in an overweight horse, extensive perirenal fat may obscure this detail.

From the left kidney, toward midline and extending from the abdominal aorta, the cranial mesenteric and ileocecocolic arteries may be palpated. Fremitus detected in these arteries may be associated with arteritis and thrombus formation secondary to *Strongylus vulgaris* larval migration; however, this association has been very inconsistent. Fremitus is frequently absent when severe arteritis exists, or the arteries may be entirely normal and fremitus felt. Fremitus can often be elicited by compression of the wall of the normal artery, which accelerates flow through the compressed lumen. The mesenteric root of the colon can be palpated ventral to the cranial mesenteric artery. This should feel like a mildly taut band of tissue extending from the dorsal midline ventrally. Excessive tension, displacement, thickening, or masses within the mesentery are abnormalities. It may be possible to palpate an enterolith, a fecalith, or a gravel impaction in the transverse colon, but this may be beyond the reach of the examiner because the transverse colon is cranial and medial to the left kidney.

On the right side of the abdomen, the base and cupola of the cecum can be palpated. The body of the cecum can be followed partially along the medial aspect of the cecum, cranially toward midline. The cecum has a prominent ventral band and

sacculations. Gas, together with ingesta that is soft and mainly of a fluid consistency, can be identified within the cecum. Firm or excessive ingesta suggest an abnormality.

Findings that are different from normal often must be identified as either variations of normal or true abnormalities. Abnormalities of the peritoneal surface are common findings. Crepitus, or a "plastic wrap" texture, is indicative of gas secondary to trauma or infection. An irregular or rough surface may be indicative of fibrin on a visceral surface or neoplasia; with a perforated intestine, ingesta may be adhering to a visceral surface. There are many abnormal presentations of the large colon, most of which are associated with signs of colic. Thickening of the wall of the colon may be appreciated on rectal palpation and is indicative of edema or cellular infiltration of the colon. Abnormal masses palpated in the wall of the colon or in association with the colonic mesentery are indicative of infection, infarction, granulomatous colitis, or neoplasia.

The small intestine is not normally discerned by palpation. On occasion, however, peristaltic contractions may be felt in the small intestine as it courses across midline toward the base of the cecum. In some cases this causes the small bowel to feel firm and tubular. Relaxation of the peristaltic contraction should be discerned in such cases. Distention of the small intestine is abnormal. In some cases the bowel may feel thickened, which can occur with ileal muscular hypertrophy, edema, or inflammatory disorders of the small bowel.

Other abnormal findings that may accompany disorders of the abdominal alimentary system include masses, adhesions, enlarged and thickened mesenteric arteries, and caudal displacement of the spleen (secondary to gastric distention or neoplasia).

Paracentesis Abdominal paracentesis is performed routinely in patients with suspected disorders of the abdominal viscera. Cytologic studies are used to quantitate peritoneal fluid; white blood cell (WBC) and red blood cell (RBC) counts; protein, fibrinogen, serum amyloid A, lactate, phosphate, and glucose concentrations; lactate dehydrogenase, creatine kinase (CK), and alkaline phosphatase (ALP) activity; and pH. The results of peritoneal fluid analysis may help establish a specific diagnosis but, of more importance, may help distinguish inflammatory from noninflammatory conditions, identify vascular obstructions or ischemic injury to the intestine, and determine whether surgical intervention is indicated.

Endoscopy Two basic types of endoscopic equipment are available: equipment based entirely on a fiberoptic system and equipment based on a video system. Many affordable endoscopes are now available, and endoscopic examination of the proximal alimentary tract in horses is now common. A typical endoscope found in many private practices is a fiberoptic endoscope that has an insertion tube that is 100 to 110 cm in length and 10 to 14.5 mm in outer diameter. The larger-diameter tube can be inserted only through the nasal passages of older yearlings and adults and is not suitable for alimentary endoscopy, whereas a tube 10 mm in diameter can be passed through the turbinates of young foals. An insertion tube length of 110 cm is sufficient to reach the stomach of foals up to 40 days of age. A length of 150 to 180 cm is required for weanlings, and 200 cm is usually required for yearlings and adults. An insertion tube length of 200 cm is sufficient to reach the stomach of all adults of warm-blooded breeds, although 280 to 300 cm is required to examine the pylorus in adult horses. A 280- to 300-cm-long insertion tube enables duodenoscopy in adult horses.

Before a gastroscopic examination, suckling foals up to 20 days of age are not routinely kept from nursing for more than 1 hour. Older foals and mature horses, in contrast, should not have solid feed for 6 to 10 hours so that ingesta from the stomach may be adequately emptied. Longer duration of feed deprivation (12 to 18 hours) is desirable to view the antrum and pylorus of horses. Many foals less than 30 days old do not require sedation for gastroscopy, although sedation with xylazine (0.5 mg/kg) may facilitate the procedure. Sedation is required if the foal is to be placed in a recumbent position so that the entire glandular portion of the stomach can be examined. Older foals and horses must be sedated for gastroscopy. Xylazine (0.5 mg/kg given intravenously [IV]) usually provides adequate sedation. For greater sedation, detomidine (0.005 to 0.05 mg/kg IV) or a combination of xylazine and butorphanol (0.01 mg/kg IV) is effective.

After insertion of the endoscope, the stomach is distended with air until the nonglandular and glandular regions of the gastric surface can be observed. Distention with air is tolerated by foals and horses and has been associated only rarely with adverse effects. On occasion, sick neonates with poor intestinal motility have developed distention of the small intestine and experienced discomfort after gastroscopy.

More complete descriptions of techniques of gastroduodenal endoscopy can be found elsewhere.[1,2]

Endoscopy of the rectum and distal small colon can be performed with most flexible endoscopes in use in equine practice and should be preceded, as much as possible, by evacuation and saline lavage of the rectum and distal small colon. The mucosal surface should appear pink to pale red and should have a smooth, velvety appearance. Mucosal edema or thickening, hyperemia, irregularities, defects, tears, and intraluminal masses are abnormal findings. Because of the concern for trauma to the rectum and small colon, horses should be adequately sedated and restrained before preparation and examination of the distal alimentary tract.

Laparoscopy Laparoscopy can offer valuable diagnostic information regarding the abdominal cavity and is only minimally invasive.[3,4] It should always be preceded by a thorough physical examination, including abdominal rectal palpation, and by abdominal ultrasonographic examination, with particular attention to the sites for trocar insertion to ascertain the presence of adherent masses or viscera in the area. If abdominocentesis is to be part of the diagnostic workup, it should be performed before laparoscopy because laparoscopy can affect abdominal fluid values. In experimental animals undergoing diagnostic laparoscopy with carbon dioxide insufflation, both the abdominal WBC count and the abdominal total protein increased.[5]

The indications for laparoscopy include palpable abdominal masses, enlarged viscera, adhesions, acute or chronic colic, weight loss, and the need to obtain visceral biopsy specimens. Contraindications include adherent viscera or masses at the site of laparoscopic trocar insertion, diaphragmatic hernias, or extreme bloating. Horses with acute colic can be safely examined laparoscopically if the trocars and telescopes are inserted carefully.

The basic instruments for laparoscopic examinations include a laparoscopic telescope, laparoscopic cannula and trocar assembly, fiberoptic light source and cable, insufflator, and biopsy and manipulation instruments. Video cameras make visualization easier with less eyestrain but require more powerful light sources. The cost of laparoscopic instrumentation has decreased because laparoscopy has become popular in humans and animals, and the procedure is far more cost effective than in years past.

Horses should fast for 18 to 24 hours before most laparoscopic procedures; water is allowed on an ad libitum basis. Fasting increases intraabdominal visualization and decreases the possibility of penetrating a gas-distended viscus. The animal is restrained in standing stocks if the procedure is to be done while it is standing. Preoperative antibiotics, antiinflammatory drugs, tetanus prophylaxis, and a sedative analgesic combination are administered. It is important to administer the analgesics before abdominal insufflation. The flank areas are prepared for aseptic surgery. Local anesthetic agents are infiltrated subcutaneously (SC) and intramuscularly (IM) in the middle of the paralumbar fossa, slightly above the crus of the internal abdominal oblique muscle, for the insertion of the laparoscopic telescope. It is preferable to begin the laparoscopic procedure

VetBooks.ir

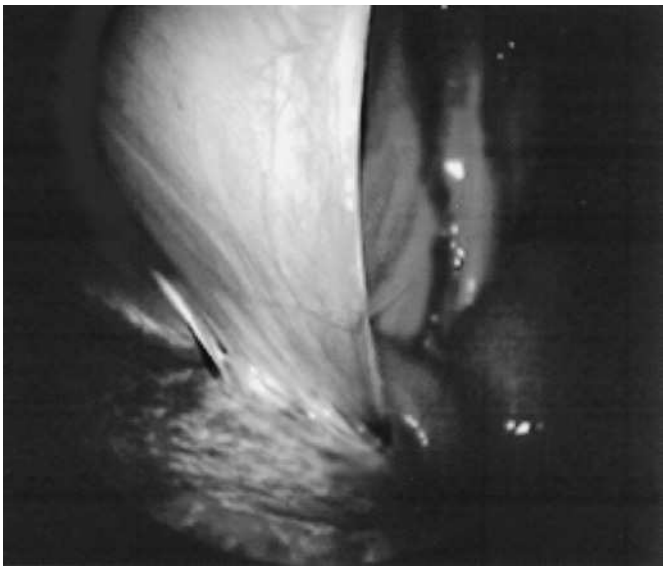

FIG. 32.1 Laparoscopic view of nephrosplenic ligament in a horse.

on the left side of the abdomen to minimize the chance of penetrating the cecal base. Additional ports may be created in the right paralumbar fossa to increase access to intraabdominal and retroperitoneal structures and enable the use of additional instruments. Ports are created with a stab incision, and a laparoscopic cannula and trocar assembly are inserted through the musculature and into the abdominal cavity. The trocar should be oriented toward the opposite coxofemoral joint when it is inserted. The trocar is exchanged for the telescope, and entry into the abdominal cavity is confirmed before insufflation begins. If the abdominal cavity has not been penetrated, a quick thrust with the telescope usually penetrates the peritoneum. Insufflation of the abdomen with CO_2 to 8 to 10 mm Hg is usually sufficient for most examinations.

The abdominal cavity is then examined systematically. On the left side of the abdomen, the spleen, left kidney, nephrosplenic ligament (Fig. 32.1), stomach, left side of the liver, diaphragm, and ventral portion of the colon are visualized cranially. A caudal view includes the root of the mesentery, the isolated small intestinal and small and large colon sections, the urogenital tract, the bladder, and the terminal rectum. The procedure is repeated on the right side of the abdomen. The liver, epiploic foramen, right kidney, descending duodenum, cecal base, and large colon are visualized cranially. The urogenital tract, root of mesentery, and intestinal segments are visualized caudally. Technical innovations have enabled extensive examination of intraabdominal structures. For example, it is possible to examine the entire small intestine via laparoscopy.[6] Depending on the pathologic condition, diagnostic laparoscopy may provide a diagnosis and allow access to surgically resolve the problem. Liver biopsy and right kidney biopsy samples are taken from the right side of the abdomen; left kidney and spleen biopsy samples are taken from the left side. Mesenteric lymph node biopsy samples are usually obtained via the left flank. Biopsy samples of other masses are taken from the more accessible side. At the end of the procedure, the abdomen is deflated, and the skin is closed with skin sutures only. The skin incision should not be closed until examination of both sides is completed, in order to minimize subcutaneous emphysema.

In some horses with ventral or cranial abdominal masses as determined with ultrasonography, the animal can be anesthetized and placed in dorsal recumbency for better characterization of the mass. Biopsy samples may be readily obtained. In horses with acute colic but without obvious signs indicating the necessity for surgery, laparoscopy can guide the decision to continue medical therapy or proceed to surgery. Strangulated sections of small intestine can be visualized, proximal enteritis can be diagnosed, and edema and vascular compromise to the large colon can be seen. No abnormalities may be detected in some animals with very localized lesions, or lesions may be inaccessible, depending on location.

Laparoscopic complications are similar to those of any other abdominal exploratory procedure. A viscus may be penetrated inadvertently; the left kidney may be perforated if the laparoscope is inserted too far dorsally; and the spleen may be penetrated if the laparoscope is inserted too far ventrally or is not aimed toward the opposite coxofemoral joint. The cecum may be perforated when the laparascope enters from the right side. If the horse has fasted and the laparoscopic trocars are inserted carefully, these problems are minimized. Subcutaneous emphysema occurs commonly but has not caused any clinical problems. The peripheral WBC count increased but stayed within normal limits in experimental animals undergoing laparoscopy.[5]

Transcutaneous Ultrasonography of the Mature Equine Alimentary Tract

Michelle Henry Barton

TECHNIQUE. One of the most innovative, practical, affordable, and portable diagnostic tools introduced into the field of equine internal medicine since 2000 is transcutaneous ultrasonography. Although several different types of ultrasound transducers exist, adult equine abdomens are most completely imaged with a 2- to 5-MHz curvilinear array transducer, but a high-frequency (6- to 8.5-MHz) linear array transducer can be used to optimize resolution of superficial intraabdominal structures. Ideally, before the procedure, the patient's hair is clipped, the skin cleaned, and coupling gel applied. If clipping the hair is not an option, debris can be removed with grooming aids and the hair soaked in isopropyl alcohol. Most horses tolerate transabdominal ultrasonography without sedation. In patients sedated with α_2-adrenergic agonists, small intestinal and cecal motility can be transiently reduced, especially in horses that have fasted, and the luminal diameter of the small intestine may appear more dilated than in unsedated patients.[7,8] Likewise, administration of *N*-butylscopolammonium bromide will immediately reduce duodenal, cecal and left ventral colonic contractions for 30 (cecum and colon) to 120 minutes (duodenum).[9]

Detailed review of the physics of ultrasonography is beyond the scope of this section; however, several general principles should be kept in mind when transabdominal ultrasonography is performed. First, to ensure that all structures are properly assessed, the approach for covering the entire area to be evaluated must be consistent and systematic: for example, scanning one side at a time, dorsal to ventral, cranial to caudal. Using seven discrete locations in horses being evaluated for acute abdominal pain, the examiner can complete the fast localized abdominal sonography for horses (FLASH) method in less than 15 minutes; this method is extremely helpful in establishing the correct diagnosis.[10] The seven locations evaluated in the FLASH method are ventral, gastric, splenorenal, left middle third of the abdomen, duodenal, right middle third, and thoracic. Focused technique can be used to consistently identify the cecum, sacculated large intestine, spleen, liver, and right kidney. The left kidney is not always identified, and successful identification of small intestine may require repeated examination.[11]

Second, to ensure correct orientation of the anatomy being imaged, the examiner should be mindful of the position of the transducer and its orientation marker on the patient (Fig. 32.2). Because abdominal ultrasonography is often performed with the transducer over an intercostal space, the transducer should be oriented in a slightly oblique transverse plane (i.e., "slicing" across the long axis of the body). Careful attention should be paid to the spatial relationship of the viscera because this may be the only key feature distinguishing normal from abnormal.[12] Furthermore, the walls of some sections of the gastrointestinal tract appear strikingly similar and cannot be distinguishable unless information is provided about the probe's exact location on the patient.[13]

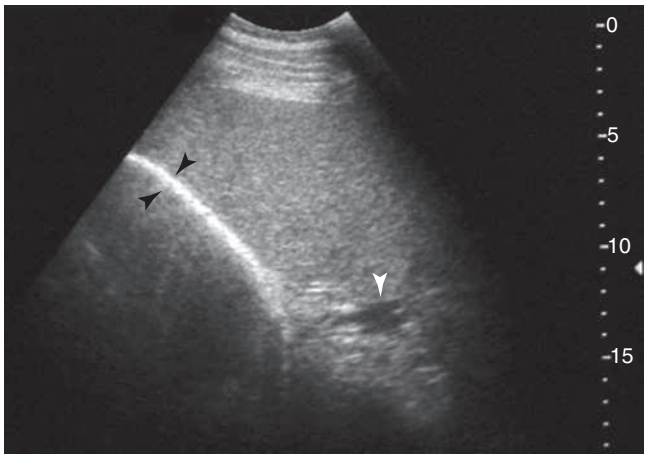

FIG. 32.2 Ultrasound view from the gastric window in the left eleventh intercostal space at the level of the shoulder in a horse. The left side of the image is dorsal. The *black arrowheads* mark the border between the serosal layer and the mucosal-luminal interface of the stomach wall, which appears as a curved hyperechoic line. The spleen is located in the near field between the stomach wall and the body wall. The *white arrow* marks the splenic vein. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 19 cm.

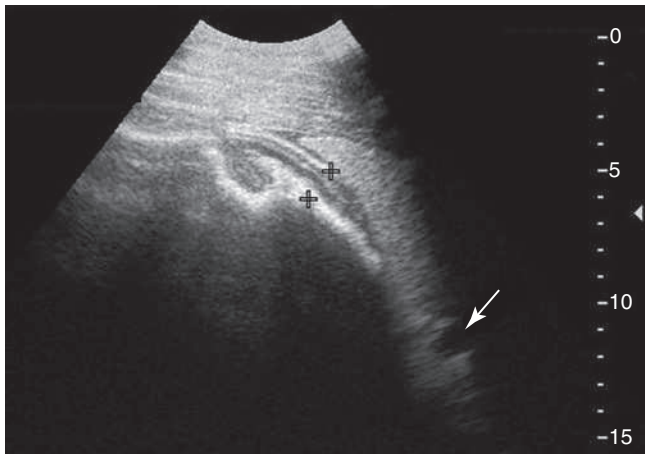

FIG. 32.3 Ultrasound view of the layers of the stomach wall from the gastric window in a horse. The left side of the image is dorsal. The *white arrow* marks the splenic vein. The electronic calipers (represented by *plus signs*) are placed at the border between the serosal layer and the mucosal-luminal layer and mark the stomach wall. The five ultrasonographic layers of the wall are visible, and it is abnormally thickened at 1.34 cm. Follow-up gastroscopy revealed that the horse had severe gastric ulceration.

Third, in any ultrasonographic examination, it is important to be aware of the depth of the field of view. Selecting the appropriate frequency for the transducer is the key to producing high-quality images that are suitable for the depth of display. High-frequency probes provide sharp images, but the resolution is compromised as the depth of the viewing field increases.

A final general and helpful principle of ultrasonography is that more sound waves reflect to the transducer if two adjacent interfaces have markedly different acoustic impedances. The more sound that reflects to the transducer, the "whiter" the interface appears on the monitor; these tissue interfaces are called *echogenic* or *hyperechoic*. In contrast, less dense tissues reflect less sound, appear darker, and are referred to as *anechoic* or *hypoechoic* structures. The acoustic impedance of the soft tissue of the walls of the gastrointestinal tract is several thousand times greater than that of the free gas inside the adjacent lumen.[14] Consequently, the image at this soft tissue–to–gas interface appears as a fuzzy hyperechoic border (see Fig. 32.2). Because most of the sound waves at this interface are reflected and the free gas in the lumen has extremely low impedance, sound is neither penetrating nor reflecting from the lumen, and the rest of the lumen is therefore obscure.

Gas within a large luminal viscus is one of the greatest limitations to gastrointestinal ultrasonography in horses, inasmuch as it impedes visualization of deeper structures. While imaging a patient, the ultrasonographer should remember that gas rises to the nondependent portion of the abdomen, and fluid and heavier structures fall to the dependent locations. When a 3.5- to 5-MHz curvilinear transducer is used, the difference between anatomic layers of the intestinal wall in healthy horses is less distinct; the wall typically appears as a single hyperechoic line. Depending on the surrounding tissue and the contents of the lumen, three to five layers of the gastrointestinal wall may be visible when a high-frequency transducer is used; these five layers are the hyperechoic serosa, hypoechoic muscularis layer, hyperechoic submucosa, hypoechoic mucosa, and the hyperechoic mucosal interface with the lumen (Fig. 32.3).[15]

In the following sections, transabdominal ultrasonography of the gastrointestinal tract is described with a systematic approach of scanning in a cranial-to-caudal direction. For the gastrointestinal tract, the ultrasonographer should be careful to document the following key elements: motility, presence of luminal distention, wall thickness and structure, luminal contents, and viscera position.

ULTRASONOGRAPHY OF THE LEFT SIDE OF THE ABDOMEN

Stomach. When imaging is started on the left rostral side of the abdomen, the stomach should be located deep to the spleen between the ninth and thirteenth intercostal spaces at approximately the level of the shoulder. In this location, the only part of the stomach that can usually be seen is the wall of the greater curvature, which can be reliably identified as a smooth, curved, hyperechoic line adjacent to the spleen and the splenic vein (see Fig. 32.2).[16] The motility of the stomach is sluggish, and the ultrasonographer may get the impression that the greater curvature of the stomach remains stationary.[8] The stomach has the thickest wall in the gastrointestinal tract, measuring approximately 7 mm thick from the serosal layer to the mucosal-luminal interface.[17] When the stomach is empty, the wall measures up to 1 cm thick, ill-defined loops of small intestine may appear between the stomach and the spleen, gastric rugal folds may be visible, and the gastric wall may be found only below the costochondral junction.[8,17]

Gastric Impaction and Ulceration. Because only the dorsal portion of the greater curvature is visible and the lumen generally contains gas at this location, transcutaneous ultrasonography of the stomach is not a sensitive tool for diagnosing gastric ulceration, intramural gastric masses, or gastric impaction. However, if the wall of the greater curvature of the stomach extends beyond the fourteenth intercostal space in a horse that has not recently drunk or eaten, gastric distention should be suspected.[18] Furthermore, if excessive gastric fluid is present ventrally, a distinct hyperechoic gas–fluid interface may be apparent in the lumen (Fig. 32.4). If the stomach wall appears irregular or thickened, follow-up gastroscopy is indicated for a more definitive diagnosis (see Fig. 32.3).

Spleen and Left Kidney. Although the focus of this section is gastrointestinal ultrasonography, the spleen and left kidney warrant brief review because of their proximity to the gastrointestinal tract. Caudad from the stomach, the spleen should be identifiable immediately adjacent to the body wall, from the left ventral eighth intercostal space to the paralumbar fossa. The size and location of the spleen vary greatly: The

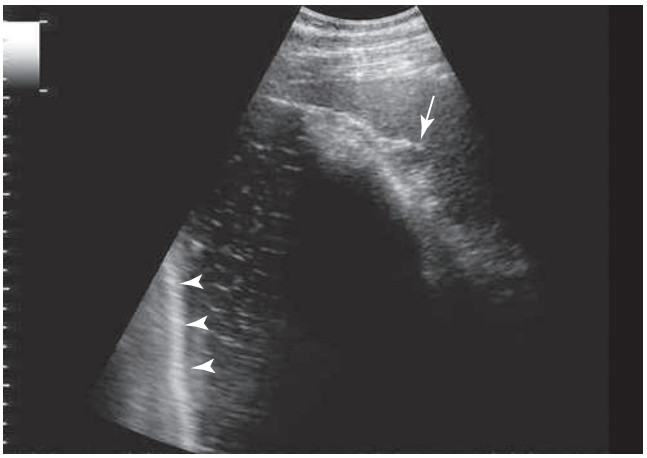

FIG. 32.4 Ultrasound view from the gastric window in a horse. The left side of the image is dorsal. The *white arrow* marks the splenic vein. The *white arrowheads* mark the interface between hyperechoic fluid in the dependent portion of the stomach *(right)* and gas dorsally. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 23 cm.

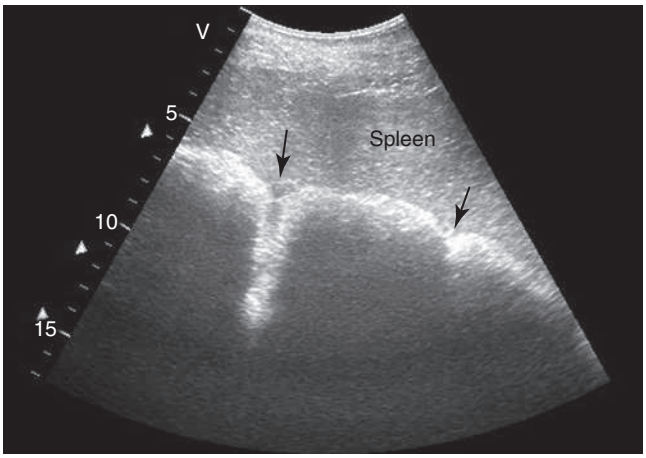

FIG. 32.6 Ultrasound view from the left flank of a horse, showing the spleen adjacent to the left ventral portion of the colon, identifiable by its location and the presence of sacculations *(black arrows)*. The left side of the image is dorsal.

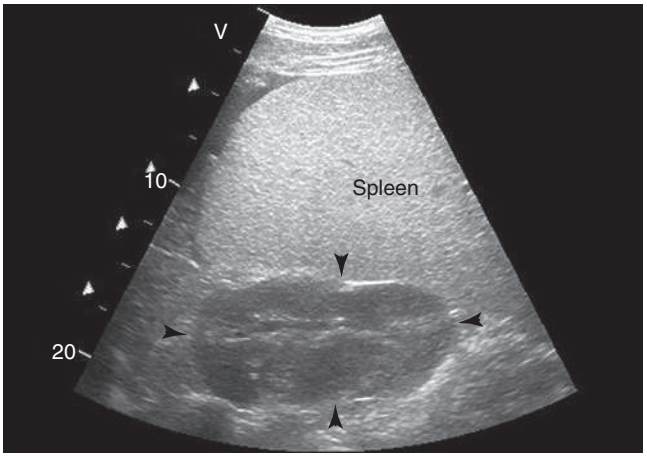

FIG. 32.5 Ultrasound view from the left dorsal fifteenth intercostal space in a horse, showing the normal adjacent orientation of the spleen to the left kidney *(black arrowheads)*. The left side of the image is dorsal. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 21 cm.

spleen can be left of the midline or extend slightly right of the ventral midline. In the rostral ventral left abdomen of some horses, the most rostral aspect of the spleen can appear either lateral or medial to the liver.[12] The spleen's ultrasonographic architecture is usually homogeneous, with vessels that are rarely visible. The echogenicity of the spleen is greater than that of the liver or kidneys.

The left kidney can be found between the fifteenth and seventeenth intercostal spaces and the first to third lumbar vertebrae, medial or deep to the spleen (Fig. 32.5), between the level of the tuber coxae and the tuber ischii.[19,20] In rare cases, the left kidney directly apposes the left body wall.[12] Gas in the small colon, left portion of the colon, or lung can preclude transabdominal viewing of the left kidney, which is normal, although colonic gas obscuring visualization of the left kidney may be adjunct evidence of dorsal displacement of the left portion of the colon.[21] The ultrasonographic dimensions of the left kidney vary according to the location from which the measurements are obtained. The longitudinal axis for craniocaudal length (i.e., the dorsal plane parallel to the spine) is difficult to measure because of interference by the ribs.[20] In Thoroughbred horses, the length of the left kidney varies from 9.6 to 15.6 cm.[19] The dorsoventral height in the slightly oblique transverse plane varies from 3.1 to 8.1 cm, and the lateromedial thickness varies from 6.6 to 9.1 cm.[19] The corticomedullary junction should be distinct, with the cortex being more echogenic. The adrenal glands are not usually identifiable via transabdominal ultrasonography.[12]

Left Portion of Colon. Many disorders of the large colon can be palpable by rectal examination, and thus transabdominal ultrasonography is an ancillary tool. Ventromedial to the spleen, the left ventral portion of the colon can be identified by its sacculated wall (Fig. 32.6) and sluggish but visible motility, normally contracting two to six times per minute.[8,13,15] Precise measurement of the colonic wall can be difficult because of the indistinct mucosal-luminal interface; in general, however, the wall of the colon should be less than 4 mm thick.[13,15,17] The left dorsal portion of the colon is not sacculated and can be dorsal, lateral, medial, or even ventral to the left ventral portion of the colon. Gas in the left ventral portion of the colon often precludes distinct identification of the left dorsal portion of the colon when the latter lies medial or dorsal to the left ventral portion of the colon. Gas in the colon typically generates a hyperechoic wall with an indistinct luminal border and intraluminal acoustic shadowing that precludes identification of the contents and the medial walls.

Colitis. When visualized through ultrasonographic examination of the left portion of the colon, useful diagnostic characteristics include wall thickness and structure, orientation of the colon, and its contents. For example, thickening of colon wall can be caused by inflammation, infiltration by neoplastic cells, hemorrhage, or edema. Inflammation of the colonic wall (i.e., colitis) can result in mural widening, but the mucosal border often appears shredded, undulating, or wavy (Fig. 32.7). These later findings may be particularly helpful in identifying horses in the prodromal phase of colitis, before the onset of diarrhea. The contents of the colon can change from characteristic acoustic shadowing to that of swirling mixed echogenic fluid that may enable visualization of the distal colonic wall. With colitis, colonic motility can be increased or decreased, or it can remain unaffected.

Colonic Volvulus. Colonic edema resulting from a volvulus of the colon also results in uniform hypoechoic mural thickening that is best identified with imaging along the ventral midline behind the xyphoid process. In one study in which colon wall edema was evaluated by transcutaneous ultrasonography through a ventral abdominal window, colon wall thickness of more

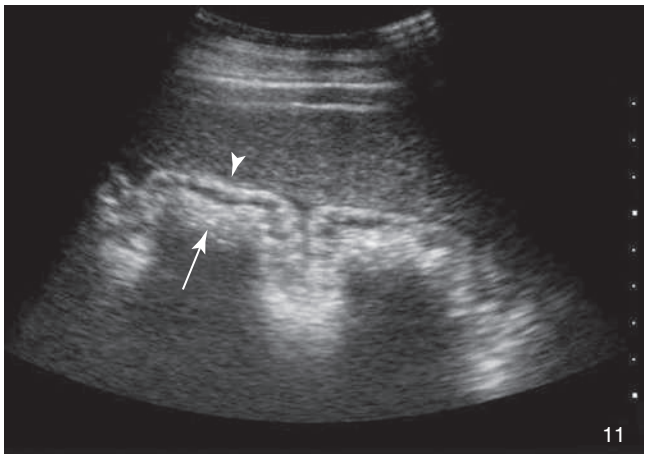

FIG. 32.7 Ultrasound view obtained from the same location as in Fig. 32.6 but from a horse with colitis. The left side of the image is dorsal. The left ventral portion of the colon is identifiable by its location medial to the spleen and by its sacculations. The wall of the colon was thickened to approximately 1 cm with three distinct layers: hyperechoic serosa *(white arrowhead)*, hypoechoic muscularis, and submucosal, hyperechoic mucosal-luminal interface *(white arrow)*. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 11 cm.

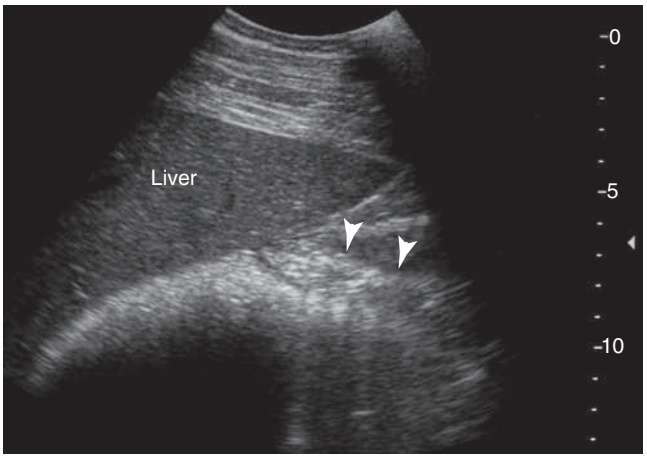

FIG. 32.9 Ultrasound view obtained at the eleventh right intercostal space at approximately the level of the shoulder in a horse. The left side of the image is dorsal. Sand and gravel in the dependent portion of the right dorsal portion of the colon (*white arrowheads* on serosal surface) created reverberation artifacts in the lumen. The colon wall is thickened. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 13 cm. *(Courtesy Science In 3D, Inc., and copyright 2002, University of Georgia Research Foundation, Inc.)*

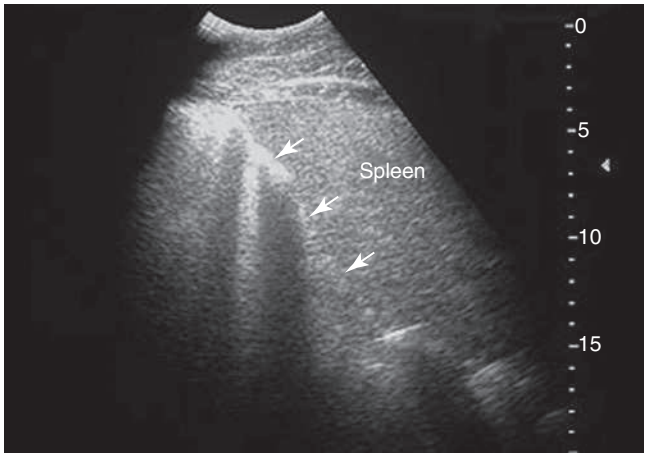

FIG. 32.8 Ultrasound view obtained from the same location as in Fig. 32.5 but in a horse with left dorsal displacement of the colon into the renosplenic space. The left side of the image is dorsal. The gas-distended colon *(arrowheads)* obscures visualization of the left kidney. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 20 cm. *(Courtesy Science In 3D, Inc., and copyright 2002, University of Georgia Research Foundation, Inc.)*

than 9 mm had a sensitivity of 67% and specificity of 100% for colonic volvulus.[22] In addition, in some cases of colonic volvulus, nonsacculated colon tissue replaces sacculated colon tissue in the left ventral abdomen.[23] Furthermore, the blood supply to the ascending colon is located in the mesentery along its medial aspect, and thus major blood vessels are normally not visible ultrasonographically on the lateral surface (adjacent to the body wall) of the ascending colon. The ultrasonographic finding of distended vessels with reduced blood flow in colonic mesentery adjacent to the body wall implies that the colon is rotated along its long axis and is consistent with a diagnosis of displaced colon or a colonic volvulus.[24] Colonic motility is reduced with a volvulus.

Displacement of Left Portion of Colon. On the left side of the abdomen, dorsal displacement of the left portion of the colon over the nephrosplenic ligament may obscure ultrasonographic visualization of the dorsal aspect of the spleen or left kidney, or the colon may appear lateral to the spleen (Fig. 32.8).[21] However, if gas is not present in the entrapped colon, the ultrasonographic diagnosis can be missed. Likewise, gas within the left portion of the colon can obscure the left kidney without entrapment of the colon. When ultrasonographic and other clinical findings support the diagnosis of left dorsal displacement of the colon, serial ultrasonography of the area can be a useful noninvasive method of determining whether the colon has relocated to its ventral position, as evidenced by successful ultrasonographic visualization of the left kidney.

Colonic Impaction. Gas within the colon often precludes accurate ultrasonographic diagnosis of colonic impaction. An impaction should be suspected in the ventral portion of the colon when a hyperechoic border at the mucosal surface casts a strong acoustic shadow and when sacculations are flattened. Sand impactions are best visualized in the ventral abdomen and often compress the mucosal surface, create excessive acoustic shadowing or reverberation artifacts (Fig. 32.9), and significantly reduce visible motility of sacculations.[25]

Small Colon. The small colon is in the left paralumbar fossa, medial or ventral to the spleen. Because of its small diameter, sacculations, and packed serpentine loops that suspend from the dorsal mesocolon, often only small sections of the surfaces are visible ultrasonographically as short, sharply curving, hyperechoic lines (Fig. 32.10). As with the large colon, the motility of the small colon is slow (no more than three contractions per minute), and luminal surface gas typically prevents visualization of the contents and the distal walls.[15] Likewise, the dense contents of fecal balls in the small colon often generate anechoic shadows from the near wall that precludes visualization of the distal wall (see Fig. 32.10).

Impaction in the Small Colon. Impactions or enteroliths obstructing the lumen of the small colon can usually be readily diagnosed by transrectal examination; however, transabdominal ultrasonography may reveal loss of, or enlargement of, sacculations and intense anechoic shadowing (Fig. 32.11).

Small Intestine. The jejunum can be identified in only approximately 10% of fed healthy horses.[8] The examiner must carefully watch for peristaltic activity that creates transient expansion of the lumen from movement of ingesta. Because of its medial location, the ileum cannot be identified distinctly by transcutaneous ultrasonography. The jejunum is most consistently found in the left inguinal area, medial to the spleen and the left ventral portion of the colon (Fig. 32.12). The

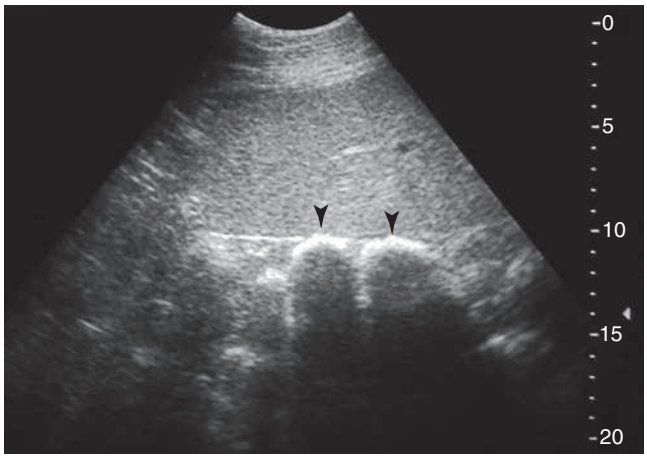

FIG. 32.10 Ultrasound view obtained from the left dorsal paralumbar fossa in a horse. The left side of the image is dorsal. The spleen is in the near field. The serosal surface *(black arrowheads)* of two adjacent loops of small colon are visible. Note the anechoic shadowing that precludes visualization of the distal small colon wall. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 21 cm.

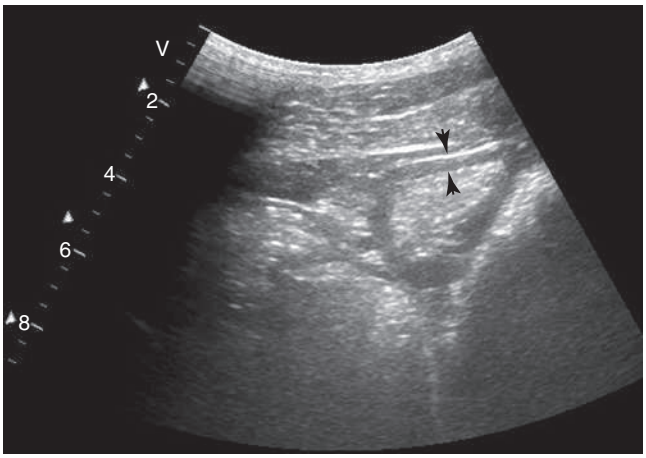

FIG. 32.12 Ultrasound view obtained of the left flank in a healthy, unsedated horse. A single loop of small intestine is visible between the body wall and the left ventral portion of the colon. The serosal to mucosal surfaces are most distinct in the near wall and are marked by the black arrowheads. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 8 cm.

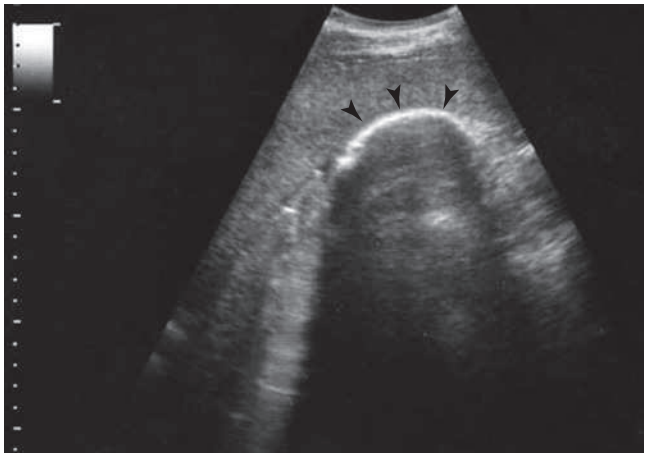

FIG. 32.11 Ultrasound view obtained from the left dorsal paralumbar fossa in a horse. The left side of the image is dorsal. The spleen is in the near field. The serosal surface *(black arrowheads)* of the small colon is visible and is bulging. Note the dramatic anechoic shadowing that was created by an intraluminal enterolith. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 21 cm. *(Courtesy Science In 3D, Inc., and copyright 2002, University of Georgia Research Foundation, Inc.)*

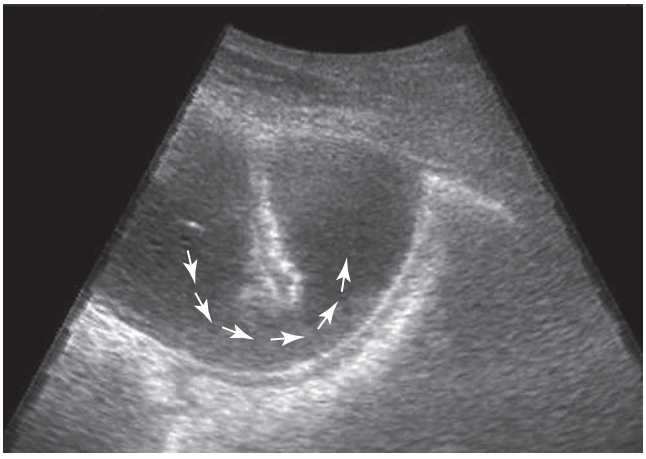

FIG. 32.13 Ultrasound view obtained from the left flank of a horse. A segment of distended small intestine is folding back on itself, creating the appearance of a "U turn" *(arrows)*. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 10 cm.

small intestine has the most visible motility of any part of the gastrointestinal tract; peristaltic waves produce frequent rhythmic contractions. Fluid luminal contents typically enable accurate measurement of the wall (<3 mm) and visualization of the far wall along its long or short axis.[17] In healthy horses, jejunal luminal diameters rarely exceed 3 cm.[17] After complete contraction with peristalsis, a distinct lumen becomes difficult to discern. Fasting or sedation of the horse with an α_2-adrenergic agonist decreases motility of the small intestine, thereby significantly increasing the likelihood of visualization.[7,8]

Distended Loops of the Small Intestine. Distended loops of small intestine often look the same on ultrasonography, despite the underlying cause. As mentioned, normal duodenum and jejunum are difficult to visualize in healthy fed horses; if the small intestine is found easily by ultrasonographic examination, the luminal diameter of small intestine exceeds 3 cm, or peristaltic contractions are notably reduced, the finding should be considered abnormal. Distention of the small intestine can result from paralytic causes, in which motility is reduced without physical luminal blockage or for mechanical reasons, in which a distal luminal or extraluminal obstruction impedes peristalsis. With either paralytic or mechanical ileus, small intestine distention can progress to the point at which the dilated segments of small intestine must fold back on themselves, creating the appearance of turns or curves within the lumen when viewed in long axis (Fig. 32.13). As ileus progresses, denser ingesta settles to the dependent portion of the affected segments (Fig. 32.14). In general, if small intestine distention progressively increases and motility decreases over serial examination, mechanical causes of obstruction that necessitate surgical intervention should be considered.[26,27] Scrutiny of the patient's clinical signs, ancillary diagnostic findings, and some distinguishing ultrasonographic features can be helpful in discriminating paralytic from mechanical causes of small intestine distention. In particular, the ultrasonographer should pay close attention to the small intestinal wall thicknesses and structure, progression of distention, degree of motility, and appearance of the intestinal contents.

Acute Enteritis. The wall of the small intestine can be thicker than normal (i.e., >3 mm) as a result of inflammation, edema,

VetBooks.ir

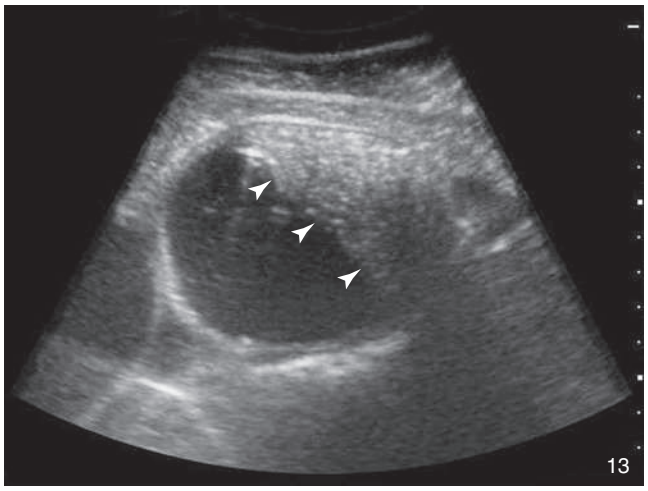

FIG. 32.14 Ultrasound view obtained from the left flank of a horse, showing a segment of distended small intestine in which hyperechoic ingesta settled dependently *(arrowheads)*. The left side of the image is dorsal. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 13 cm.

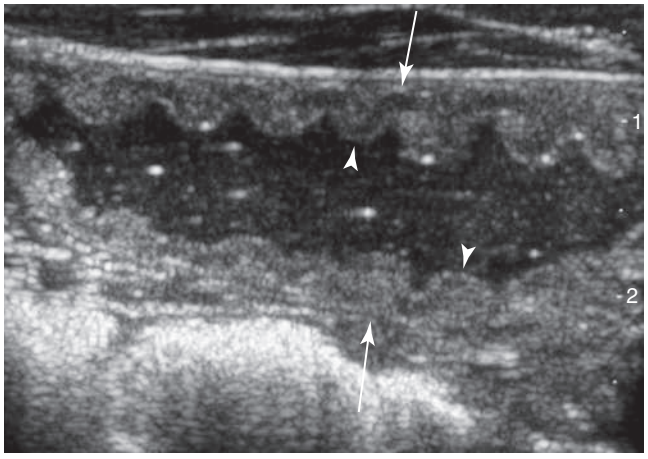

FIG. 32.15 Ultrasound view obtained from the ventral left flank of a horse with enteritis. The small intestinal wall is thickened (up to 6 mm in some areas), and the mucosa has a wavy or corrugated appearance. The *white arrows* mark the serosa, and the *arrowheads* mark the mucosal-luminal interface. This image was obtained with a linear probe set to a depth of 3 cm.

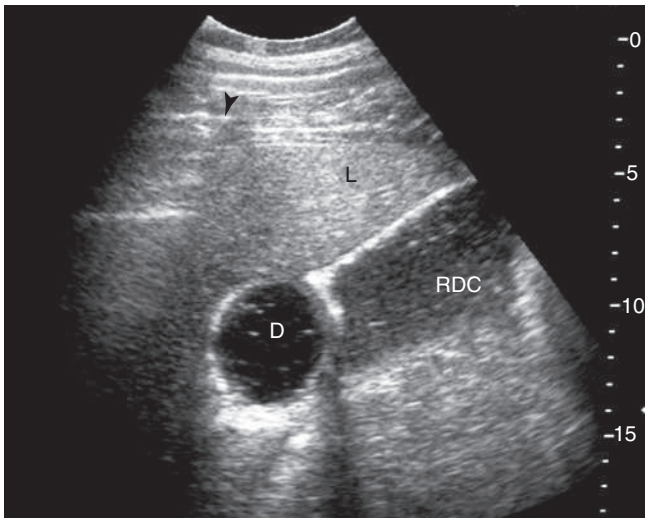

FIG. 32.16 Ultrasound view obtained from the right twelfth intercostal space of a horse with proximal enteritis. The duodenum *(D)* was distended to approximately 4 cm with reduced motility. The duodenal wall was mildly thickened (4 mm). The *black arrowhead* marks the ventral tip of the lung. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 18 cm. *L*, Liver; *RDC*, right dorsal portion of the colon.

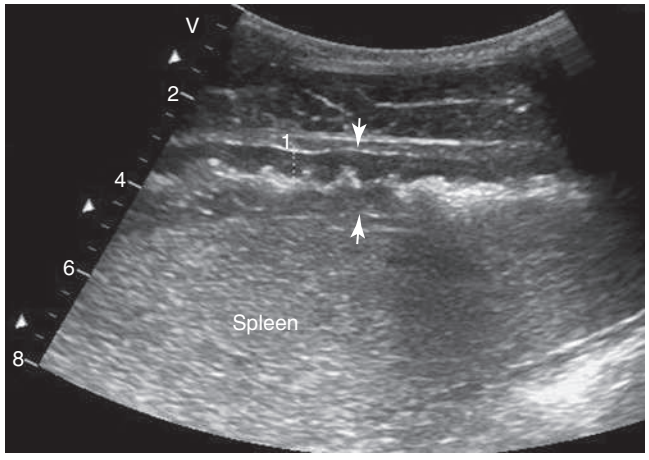

FIG. 32.17 Ultrasound view obtained from the left flank adjacent to the spleen, revealing the thickened and wavy wall of a longitudinally oriented segment of small intestine in a horse with chronic inflammatory bowel disease. The *white arrows* mark the serosal surfaces. The thickened walls are predominantly hypoechoic. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 8 cm.

hypertrophy, or neoplasia. Some causes of inflammation and edema are acute in nature, such as proximal or anterior enteritis, and some causes are chronic or insidious in nature, such as the inflammatory bowel syndromes or idiopathic intestinal hypertrophy. In addition to the clinical signs and other diagnostic features of proximal enteritis (low-grade fever, gastric reflux, inflammatory findings on leukogram, pain followed by depression after gastric decompression), on ultrasonographic examination, the mucosal wall of the small intestine may appear shredded,[17] corrugated, or wavy, resembling the edge of a lasagna noodle (Fig. 32.15). The proximal portions of the small intestine, especially the duodenum (see duodenum subsection later; Fig. 32.16), and the stomach may be distended with fluid. The movement in these loops can vary from apparently absent to hypermotile. For horses with enteritis, the expected response to medical therapy varies, but lessening degrees of luminal distention with progressive improvement in motility are expected. The appearance of hyperechoic gas bubbles within the wall of the small intestine is indicative of either necrosis or anaerobic bacterial infection..

Inflammatory Bowel Disease and Ileal Hypertrophy. If the signs of abdominal pain are more insidious, if an affected horse exhibits weight loss despite a good appetite, or if panhypoproteinemia is present, then symmetric and diffuse or regional thickening of the small intestine may be a sign of infiltrative or hypertrophic disease, such as inflammatory bowel disease, neoplasia (especially lymphosarcoma), or idiopathic ileal hypertrophy.[28] In these circumstances, the wall can be either uniformly or irregularly thickened, often with a narrow or obscure lumen (Fig. 32.17). In a study involving 35 horses with chronic wasting, a 5-mm cutoff value for patients with diffuse small intestinal wall thickness provided the best compromise between sensitivity (50%) and sensitivity (100%) for inflammatory bowel disease; rectal biopsy findings served as the reference standard.[29] Motility is usually preserved, unless mural thickening results in secondary mechanical obstruction. Definitive diagnosis of inflammatory bowel disease or idiopathic hypertrophy requires histopathologic evaluation.

Nonstrangulating Obstructive Lesions of the Small Intestine. Mechanical obstruction of the small intestine in which the adjacent blood supply remains intact—such as an ileal impaction, adhesions, mural hematoma, or that caused by severe chronic infiltrative disease of the intestinal wall—causes variable degrees of luminal distention proximal to the site of obstruction. In general, lack of significant changes in wall thickness or structure are features helpful for distinguishing simple nonstrangulating lesions of the small intestine from strangulating or severe inflammatory lesions. If serial ultrasonography reveals progressive severity of distention and lack of motility (see Fig. 32.17), surgical intervention should be considered.[26,27]

Strangulating Obstructive Lesions of the Small Intestine. Progressive pain with poor response to medical intervention, lack of fever, and the presence of serosanguineous peritoneal fluid with increased or increasing lactate concentrations are clinical features that might help distinguish strangulating lesions of the small intestine from simple obstructions and enteritis. As with nonstrangulating obstructive lesions of the small intestine, ultrasonographically, the intestine proximal to strangulating obstructions is distended with either gas or fluid. The degree of distention and motility varies with the duration of strangulation; preobstruction segments may become turgidly circular and completely amotile loops of small intestine, and this development is highly correlated with mechanically obstructive lesions that necessitate surgical intervention (Fig. 32.18).[26,27]

An important distinguishing feature of strangulated small intestine is the appearance of focally and usually uniformly thickened walls at the site of the strangulation (Fig. 32.19). Thus when regional uniform thickening of the small intestine is identified ultrasonographically, with other evidence of obstruction (hypomotile, hairpin-turn stacks of turgidly round and distended loops of small intestine with dependent ingesta), a strangulating obstruction should be the top consideration. Frequently the strangulated loops are identified in the ventral portions of the abdomen. In one study, the presentation of focal thickening and distention of the small intestine with no motility was 100% sensitive and 100% specific evidence of strangulating lesions of the small intestine.[26] If the affected segments are most readily visualized adjacent to the spleen and stomach on the left side of the abdomen (Fig. 32.20) or between the liver and right dorsal portion of the colon on the right side of the abdomen (Fig. 32.21), these respective locations are areas in which gastrosplenic and epiploic foramen incarcerations are readily found.

Intussusception. Intussusceptions of the small intestine are most common in foals and young horses, and affected segments have a characteristic "bull's-eye" or target appearance in images across the short axis of the small intestine (Fig. 32.22).[30] The intussuscepted intestine tends to fall toward the dependent portion of the abdomen. As in other mechanical obstructive diseases, the proximal small intestine has normal wall thickness but is distended, with reduced motility and hairpin turns, depending on the degree of obstruction.

ULTRASONOGRAPHIC ANATOMY OF THE RIGHT SIDE OF THE ABDOMEN. Right-sided transabdominal ultrasonography is described with a systematic approach of scanning in the direction of cranial to caudal.

Liver and Pancreas. The liver, descending duodenum, and right dorsal portion of the colon have characteristic locations and can be identified in the right rostral abdomen at the level of the shoulder (Fig. 32.23). The liver is located from the sixth to the fourteenth intercostal spaces, between the diaphragm

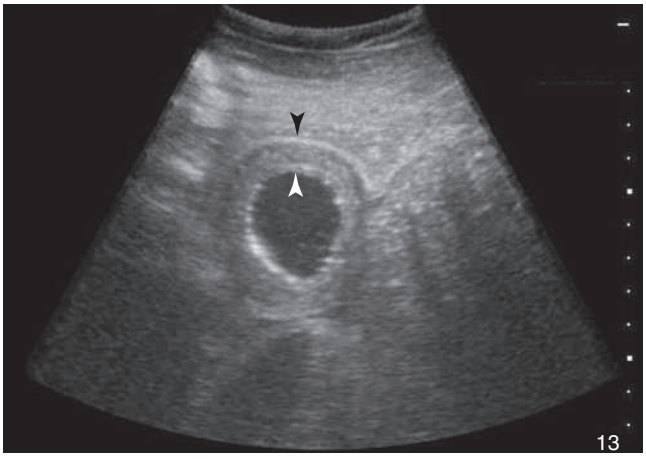

FIG. 32.19 Ultrasound view obtained from the left flank from a horse with a strangulating obstruction. A single distended loop of small intestine exhibits uniform thickening of the wall to approximately 8 mm (between *arrowheads*). In real time, this segment had no discernible motility. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 13 cm.

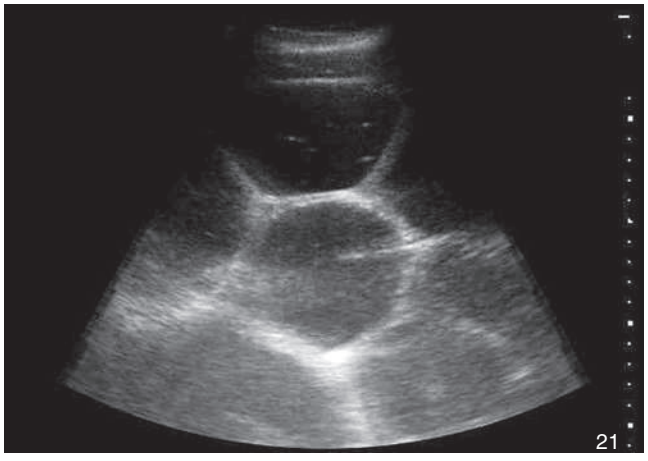

FIG. 32.18 Ultrasound view obtained from the left flank from a horse with a nonstrangulating obstruction that necessitated an exploratory celiotomy for correction. Note the numerous turgidly round and distended loops of small intestine. In real time, these distended loops had no appreciable motility. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 21 cm.

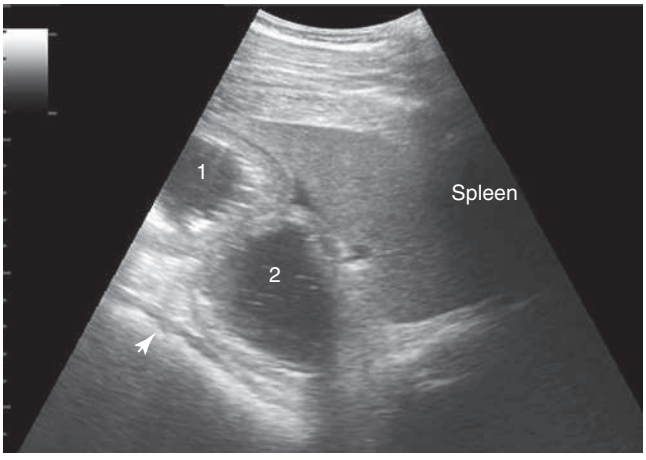

FIG. 32.20 Ultrasound view obtained from the gastric window from a horse with a strangulating gastrosplenic ligament entrapment. The left side of the image is dorsal. Two thickened, distended, and amotile loops of small intestine (labeled *1* and *2*) were found between the spleen and the stomach *(arrowhead)*. This image was obtained with a 3.5-MHz probe set to a depth of 17 cm.

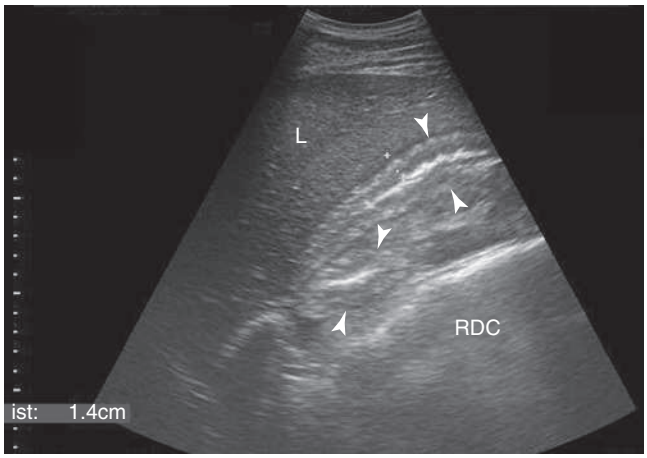

FIG. 32.21 Ultrasound view obtained from the right twelfth intercostal space from a horse with an epiploic foramen entrapment. *Arrowheads* mark the serosal surfaces of two thickened (14-mm wall) and compressed loops of amotile small intestine between the liver *(L)* and the right dorsal portion of the colon *(RDC)*. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 24 cm.

FIG. 32.22 Ultrasound view obtained along the caudal ventral midline in a horse with a jejunojejunal intussusception. The *arrowhead* marks the inner loop telescoped into the outer loop of jejunum *(arrow)*, which created the classic "bull's-eye" appearance. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 10 cm.

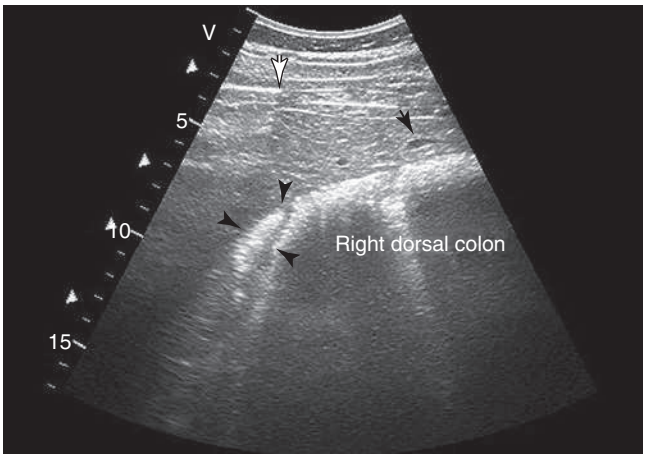

FIG. 32.23 Ultrasound view obtained at the eleventh right intercostal space at approximately the level of the shoulder in a horse. The left side of the image is dorsal. The *white arrow* marks the ventral tip of the lung. The *black arrowheads* mark the serosal surface of the duodenum with a hyperechoic lumen, between the liver and the right dorsal portion of the colon. Short hyperechoic parallel lines in the liver are the walls of portal veins *(black arrow)*. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 17 cm.

and the right dorsal portion of the colon (see Fig. 32.23). Gas in the lung or the right dorsal portion of the colon can obscure identification of the liver dorsally or ventrally, respectively; ultrasonographically, the liver may thus be visible over only a few intercostal spaces. Only a small portion of the right side of the liver can be imaged, so its size is estimated on the basis of its expanse across the intercostal spaces.[12] It is unusual for the liver to be seen beyond the fifteenth intercostal space or in the same transverse plane as the right kidney, except at the most rostral aspect of the kidney. The ventral edges of a normal liver are distinctly sharp. Like that of the spleen, the architecture of the liver is relatively homogeneous, but more vessels are visible in the liver, and the general echogenicity of the liver is less than that of the spleen.[17] Portal veins have more connective tissue in their walls and thus have more echogenic walls than do the hepatic veins.[12] Short segments of smaller portal veins often appear as hyperechoic parallel lines (see Fig. 32.23). In some small horses, the portal vein can be seen entering the hilus deep on the medial side of the image. The common bile duct and its branches within the liver are not normally visible.[12] The pancreas is not usually identifiable via transabdominal ultrasonography.[12]

Duodenum. The position of the duodenum is fixed by its suspending mesoduodenum; thus the duodenum can reliably be found descending the right middle abdomen at approximately the level of the shoulder, between the liver and the right dorsal portion of the colon (see Fig. 32.23), where it can be imaged transversely along its short axis. As with the jejunum, to locate the descending duodenum, the ultrasonographer must wait for a peristaltic contraction to deliver ingesta through the lumen, thereby expanding the lumen; otherwise, the shape of the duodenum typically appears as a hyperechoic flattened or crescent-shaped line to a flattened oval. It is unusual for the duodenal diameter to exceed approximately 3 cm in healthy horses during peristaltic propulsion of ingesta.[31] The duodenum contracts one to four times per minute in fed horses,[31] but contractions are less frequent in anorexic, fasting, or heavily sedated horses. The duodenum can be followed on imaging to the level of the ventral right kidney (Fig. 32.24), where it crosses medially into the abdomen and is no longer distinguishable. The wall of the duodenum is less than 3 mm thick.[17]

Right Portion of Colon. The right dorsal portion of the colon, which has no sacculations, is immediately ventral to the liver and duodenum and is usually found from the right tenth to twelfth intercostal space, although it can extend to the fourteenth intercostal space.[32] The wall of the right dorsal portion of the colon consistently appears as a hyperechoic curved line, adjacent to the liver (see Fig. 32.23). Because of gas contents in the right dorsal portion of the colon, wall thickness is difficult to measure accurately, and although thickness of up to 5.9 mm has been reported in healthy horses, less than 4 mm is typical.[32] The walls of the right dorsal portion of the colon are significantly thinner in ponies and miniature horses than in large breed horses, typically measuring less than 3.2 mm.[33] If the ultrasonographer locates the right dorsal portion of the colon and slides the transducer ventrally, the interface between the right dorsal and right ventral portions of the colon is often identifiable, appearing as an indentation in the wall between the nonsacculated right dorsal portion of the colon dorsally and the sacculated right ventral portion of the colon ventrally. The right ventral portion of the colon has sacculations, and its contractions and wall thickness are similar

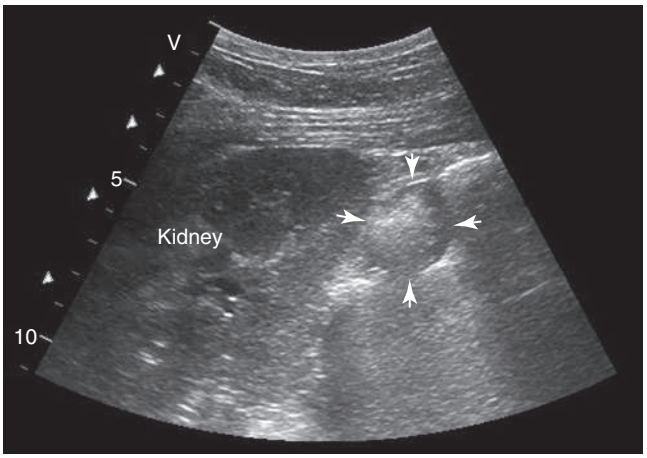

FIG. 32.24 Ultrasound view obtained from the right fifteenth intercostal space in a horse. The left side of the image is dorsal. The duodenum *(arrows)* can be seen ventral to the right kidney. This still image, captured when a peristaltic wave distended the luminal diameter to approximately 2.5 cm, was obtained with 3.5-MHz curvilinear probe set to a depth of 11 cm.

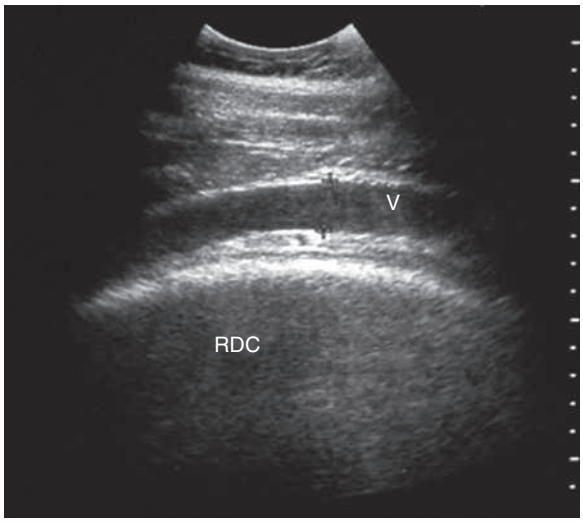

FIG. 32.25 Ultrasound view obtained from the right fifteenth intercostal space in a horse. A distended vein *(V)* is visible lateral to the wall of the right dorsal portion of the colon *(RDC)*. The horse had a colonic volvulus. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 17 cm. *(Courtesy Science In 3D, Inc. and copyright 2002, University of Georgia Research Foundation, Inc.)*

to those of the left portion of the colon, although a wall thickness up to 5.1 mm has been reported in healthy horses.[32] The contents of the different portions of the right portion of the colon and their medial walls are normally obscured by luminal gas. The transverse colon is not usually identifiable via transabdominal ultrasonography.[12]

Right Dorsal Colitis. When diarrhea in a horse is accompanied by panhypoproteinemia and a history of nonsteroidal antiinflammatory drug (NSAID) therapy, transabdominal ultrasonography of the right dorsal portion of the colon can be a useful diagnostic aide.[32] In patients with NSAID-induced right dorsal colitis, the wall of the right dorsal portion of the colon often appears thickened with mixed echogenicity and an irregular mucosal-luminal interface.

Displacement Right Dorsal Portion of Colon. Identification of a large gas-distended viscus in the right caudal abdomen by transrectal palpation with accompanying taut colonic bands is consistent with a diagnosis of right dorsal displacement of the colon. The only major blood vessels normally visible ultrasonographically in the right caudal abdomen are those associated with mesentery of the lateral cecal band.[15] Thus the ultrasonographic finding of distended vessels with reduced blood flow in colonic mesentery adjacent to the body wall implies that the colon is rotated along its long axis and would be consistent with a diagnosis of right dorsally displaced colon or a colonic volvulus (Fig. 32.25).[24]

Cecum. The cecum has a sacculated wall that extends from the right paralumbar fossa to ventral midline, and its motility is similar to that of the different portions of the colon.[8,15] A unique characteristic that can be useful for distinguishing the cecum from the right ventral portion of the colon is that the lateral cecal band is oriented dorsoventrally and contains an associated artery and vein, whereas the lateroventral band of the right ventral portion of the colon is oriented caudocranially and does not have associated vasculature.[15] The cecal wall is less than 4 mm thick, and gas in the lumen precludes imaging the contents and far wall. Most diseases affecting the cecum can be sufficiently identified by transrectal palpation; however, transcutaneous ultrasonography can be helpful in confirmation of the diagnosis.

Typhlitis. With acute inflammatory disease of the cecum, the cecal wall may be thickened, the mucosal surface may appear irregular or wavy, and movement varies from hypomotile to hypermotile. Gas normally present in the body or base of the cecum precludes visualization of its contents and distal wall; however, with typhlitis, the cecum is often distended with fluid that is readily seen swirling inside of the lumen, and the distal wall can be visualized, especially toward the cecal apex.

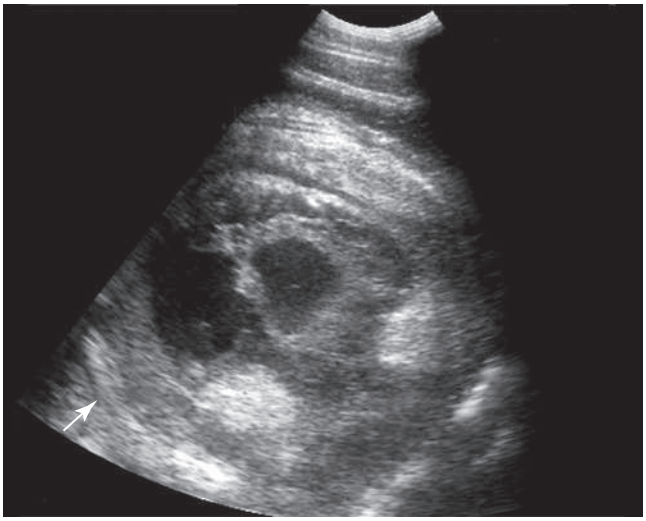

FIG. 32.26 Ultrasound view obtained from the right midflank in a horse with a cecocolic intussusception that appears as a large mass *(arrow)*. The appearance of a "wall within a wall" is most apparent in the near field. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 24 cm.

Cecal Impaction. Transrectal palpation is a better method of diagnosing cecal impactions, but transabdominal ultrasonography of cecal impactions may reveal loss of characteristic sacculations.

Cecocolic and Cecocecal Intussusception. On transrectal evaluation, intussusceptions involving the cecum are often palpable as indistinct large, firm masses in the right or midcaudal portion of the abdomen. As with small intestinal intussusceptions, the characteristic "bull's-eye" can be seen in the wall of the cecal apex or body within the lumen of the cecum or right ventral portion of the colon. In chronic intussusceptions, the walls are very thick and may appear abscessed or mass-like (Fig. 32.26).

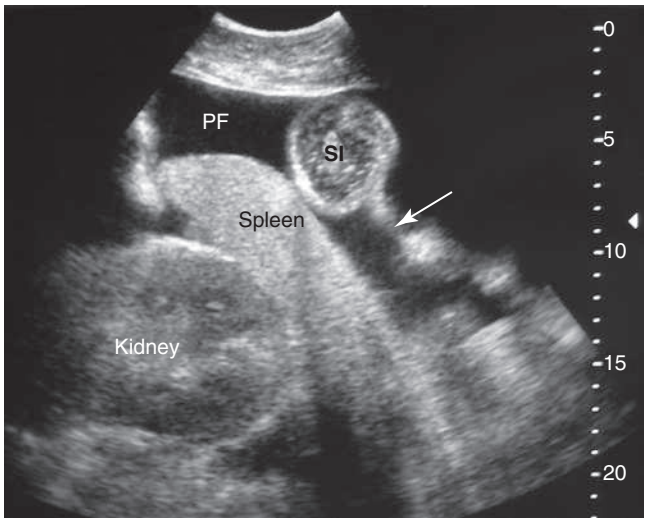

FIG. 32.27 Ultrasound view obtained from the left dorsal sixteenth intercostal space in a horse. The left side of the image is dorsal. Excessive hypoechoic peritoneal fluid *(PF)* has displaced the spleen from the left body wall and enabled distinct visualization of a single loop of small intestine *(SI)* and its supporting mesentery *(arrow)*, appearing as a "balloon on a string." The horse had metastatic mesothelioma. This image was obtained with a 3.5-MHz curvilinear probe.

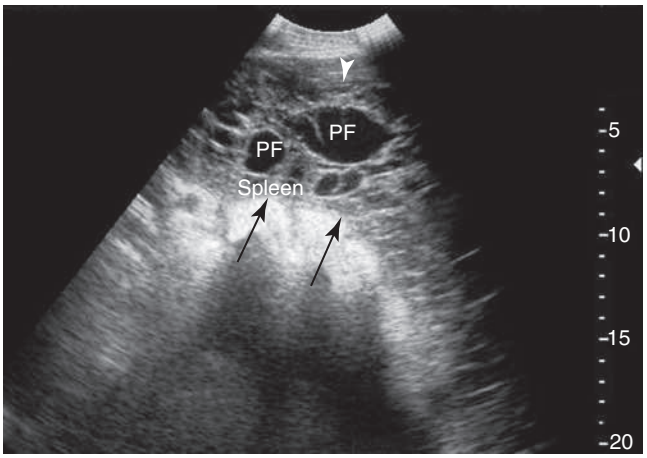

FIG. 32.28 Ultrasound view obtained from the lower right flank in a horse. The left side of the image is dorsal. Numerous hyperechoic fibrinous and fibrous adhesions trapping pockets of hypoechoic peritoneal fluid *(PF)* are present between the body wall *(white arrowhead)* and the serosal surface of the right ventral portion of the colon *(black arrows)*. The horse had septic peritonitis. This image was obtained with a 3.5-MHz probe set to a depth of 21 cm.

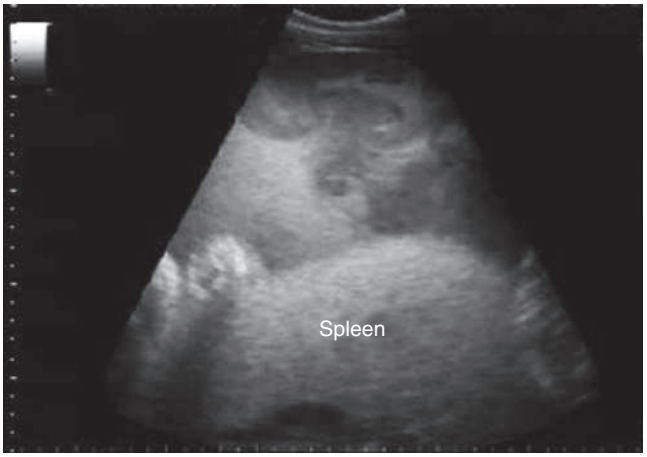

FIG. 32.29 Ultrasound view obtained from the lower left flank of a horse with hemoabdomen. The left side of the image is ventral. Blood displaces the spleen from the left body wall and appears as swirls of mixed echogenicity between the spleen and left body wall. This image was obtained with a 3.5-MHz curvilinear transducer set to a depth of 24 cm.

Right Kidney. Gas in the cecum, right dorsal portion of the colon, or lungs sometimes obscures visualization of the right kidney, which is normally found in the rostral fifteenth to seventeenth intercostal spaces[20] (see Fig. 32.24). In Thoroughbred horses, the right kidney measures 6.5 to 9.1 cm dorsoventrally (the slightly oblique transverse plane), 12.1 to 16.2 cm in length craniocaudally (the dorsal plane), and 6.5 to 8.4 cm lateromedially.[19] The ureters are usually difficult to identify, but the proximal right ureter sometimes appears as a hyperechoic circular structure at the hilus. The architecture of the right kidney is similar to that of the left kidney.

Peritoneal Cavity. In a healthy horse, only minute pockets of peritoneal fluid should be identifiable in the rostroventral area of the abdominal cavity or adjacent to sacculations of the ventral portion of the colon. Excessive peritoneal fluid displaces organs and greatly facilitates visualization of structures not normally seen on ultrasonographic examination, such as the mesentery of the small intestine (Fig. 32.27).

Peritonitis. Peritonitis should be suspected if volume or echogenicity of peritoneal fluid is increased. In some cases, free-floating or adherent fibrin or fibrous tags may be visible (Fig. 32.28). An abdominocentesis is an integral step for further characterizing the cause of peritonitis.

Hemoabdomen. Excessive blood in the peritoneal cavity displaces organs off the body wall. Blood in the peritoneal cavity appears as a mixed echogenic fluid that, in real time, often appears to swirl as it mixes with less echogenic peritoneal fluid (Fig. 32.29).[15] Abdominocentesis confirms the presence of blood.

Intraabdominal Masses. Abscessation, hematoma, and neoplasia are the top potential diagnoses for intraabdominal space-occupying lesions, each of which can be located just about anywhere in the peritoneal cavity, in or attached to bowel, other intraabdominal viscera (i.e., spleen, kidney, liver), or the peritoneum. Space-occupying lesions appear as soft tissue densities of variable shapes and acoustic properties that distort normal sonographic architecture (Fig. 32.30). Although the definitive cause of an intraabdominal mass is often not discernible ultrasonographically, both abscesses and hematomas appear as either uniform echogenic or loculated space-occupying masses of mixed echogenicity. Chronic abscesses may be characterized by the presence of a thick echogenic capsule. Abscesses and hematomas are more commonly confined to a single location, whereas metastatic neoplasia should be considered if space-occupying lesions of varying sizes that distort normal ultrasonographic anatomy are visible in multiple locations. Although the ultrasonographic appearance of a space-occupying lesion may not help determine the cause, ultrasonography can be a useful guide for biopsy or aspiration of the affected tissue.

Other Imaging of the Alimentary Tract

RADIOGRAPHY. In horses the alimentary tract is a dynamic and complex environment to evaluate with any modality. Because of the size of the animal, as well as the distinct difference between air and soft tissue, radiographs are a useful diagnostic tool for evaluating the teeth, pharynx, esophagus, stomach, and intestinal tract. Portable radiographic units with maximal kilovolt peak (kVp) settings of 100 and maximal milliampere-second (mAs) settings of 30 make it possible for ambulatory

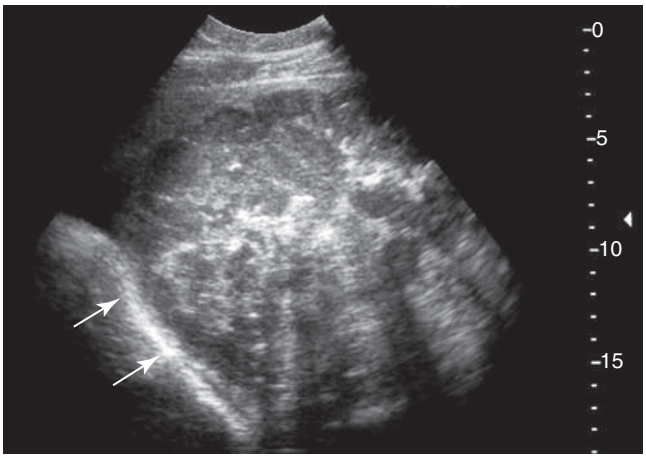

FIG. 32.30 Ultrasound view obtained from the gastrosplenic window in a horse. The left side of the image is dorsal. A large mass of mixed echogenicity occupies the space adjacent to the stomach wall *(arrows)* in the location normally occupied by the spleen. The horse had abdominal lymphosarcoma. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 19 cm.

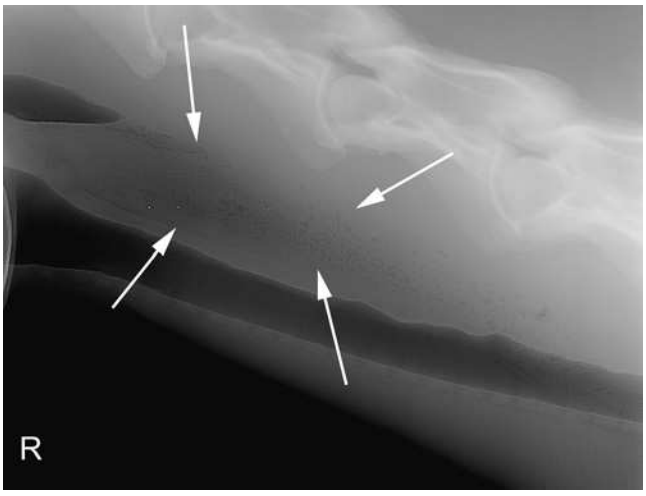

FIG. 32.31 Standing lateral radiograph of a 13-year-old Morgan gelding with an esophageal tear. Note the tubular region of small gas opacities caused by air trapped around the outer border of the esophagus *(arrows)*. An esophageal perforation secondary to an ingested foreign body was confirmed with endoscopy.

practitioners to obtain diagnostic images of the head and cranial portion of the esophagus. However, to obtain images of the thoracic portion of the esophagus and abdomen, a referral clinic with a more powerful radiographic generator is usually required.

For average foals, exposures ranging from 80 to 88 kVp and 20 to 26 mAs have been used in radiography of the abdomen.[34] In adult horses, exposures range from 60 to 140 kVp and 20 to 70 mAs.[35,36] To perform a complete evaluation of the abdomen, it is recommended that the abdomen be divided into four quadrants (cranioventral, midabdominal, caudodorsal, and caudoventral).[35] Large cassettes (35 cm × 43 cm) and fast screens are also needed to ensure that a diagnostic image is obtained. Because of the large amount of scatter radiation produced from the high exposure and thickness of tissue penetrated, an 8:1 to 10:1 grid should be used.[34-38] Alternatively, an air gap technique can be used to prevent image degradation.

The advent of computed radiography and digital radiography has greatly increased the diagnostic capabilities of conventional radiographic examinations. Both systems, available to equine practitioners, are considered indirect imaging modalities in which the x-ray photon interacts with an intensifying screen to convert the x-ray photon to light. This light then interacts with an imaging plate: film, as with a conventional radiographic system; within a photostimulable phosphor, as with computed radiography; or within a flat-panel detector, as with digital radiography. Regardless of the method, these images are considered "indirect" because the x-ray photon is first changed to light and then detected by the imaging medium.[39] The main benefits of computed and digital radiography are the increased latitude of the film. It is possible to change the contrast and grayscale levels after the exposure if the number of photons is adequate. The digital radiography systems also offer a rapid evaluation of the image because the cassette is directly connected to the computer. This allows the portable systems to show radiographic images within 10 seconds after the exposure is made. In contrast, the computed radiography system requires the cassette to be placed into a reader in order to display the image. Finally, because both computed and digital radiography are generally compliant with the Digital Imaging and Communications in Medicine (DICOM) standard, this allows any specialists with standard medical imaging software to view the images via a compact disk or via the Internet.

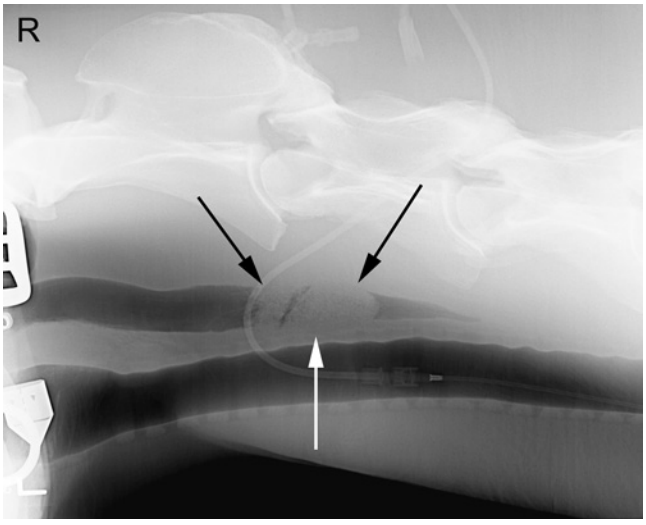

FIG. 32.32 Standing lateral radiograph of a 12-year-old Quarter Horse mare. Note the ovoid mass surrounded by gas just dorsal to the trachea *(arrows)*. This lesion was a mixture of hay and grass.

Survey radiography is generally helpful in evaluating the cervical portion of the esophagus for evidence of rupture, as well as in evaluating the abdomen. Esophageal ruptures secondary to an obstruction or vigorous placement of a nasogastric tube produce a small volume of gas that tracks just dorsal to the trachea (Fig. 32.31). This can be confused with a tracheal laceration; however, with tracheal lacerations, generally the gas accumulates around the trachea, and the volume of gas within the subcutaneous tissues and the cranial mediastinum is extreme. In addition, esophageal obstructions, also called *choke*, can sometimes be identified on survey radiographs, depending on the material that is causing the obstruction and the amount of air or contrast medium that is able to surround the structure (Fig. 32.32). Although the nature of the obstruction cannot be determined, the extent of the abnormality can sometimes be identified.

Abdominal radiography is useful for evaluating the small and large intestines for sand accumulation, enterolithiasis,

FIG. 32.33 Standing lateral radiograph of a 4-year-old Arab mare with a history of colic. Note the large amount of opaque material within the ventral portion of the colon, probably secondary to sand accumulation.

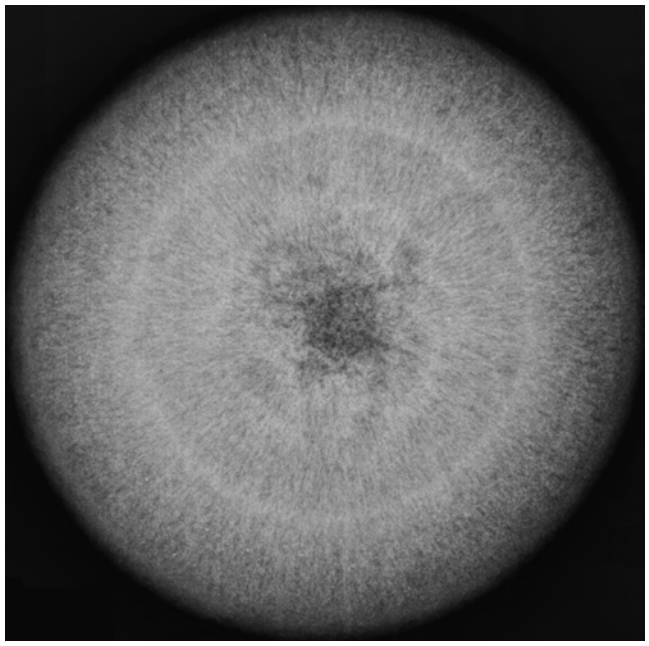

FIG. 32.34 Radiograph of enterolith obtained after surgical removal from the small colon. Note the variation in opacities caused by the various types of minerals that are contained within the enterolith.

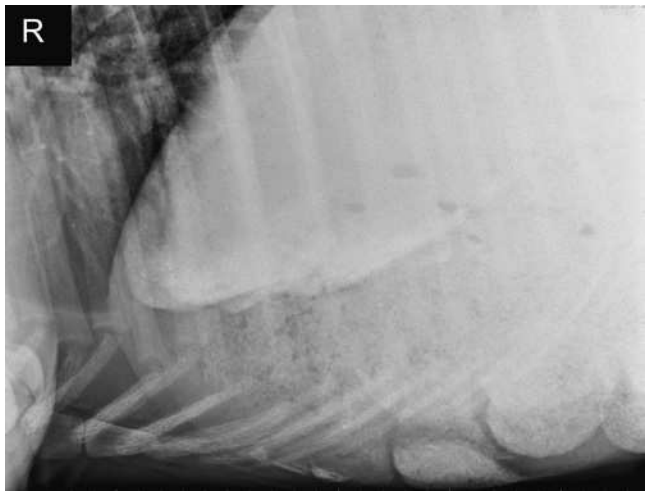

FIG. 32.35 Standing lateral radiograph of a 3-year-old Paint Horse gelding with a pelvic flexure impaction. The radiograph shows the sternal flexure with a large amount of granular material and a small amount of sand accumulation in the ventral portion of the colon.

impactions, or small intestinal disorders in foals. When sand is ingested, it generally accumulates within the large colon along the ventral abdomen[10] (Fig. 32.33). Radiography is useful for monitoring the resolution of sand impactions after medical management; however, sequential examinations are needed to verify that the volume of sand has decreased.[36] If the volume of sand is large enough, it is difficult to determine whether an enterolith is present because of radiographic summation of the two lesions. Enteroliths are solid concretions of mineral that usually form around a nidus, such as a metallic foreign body (Fig. 32.34). The mineral composition is varied, as illustrated by the different opacities within the enterolith. Radiographs have a 96.4% positive predictive value for detecting enteroliths in high-prevalence areas. In one study, enteroliths were generally found to be within the midabdominal radiograph, and 67% of small colonic enteroliths caused large colonic distention, which was also identified on radiographs.[35] Impactions are more difficult to diagnose because radiography usually demonstrates only increased feed accumulation within the abdomen. Although no enterolith or obstruction is identified, granular material can be seen, usually within the ventral portion of the colon near the sternal flexure. This is because pelvic flexure impactions cause the feed material to accumulate orad, causing distention of the left ventral portion of the colon (Fig. 32.35). Intestinal disorders such as functional ileus secondary to enteritis (Fig. 32.36) or obstruction secondary to intussusception or meconium impaction (Fig. 32.37) in foals can also be identified on abdominal radiographs. These images show large dilation of the small intestine, and differentiation between functional and mechanical ileus in foals is generally based on the size of the intestine and the volume of gas that is present.[37] Evaluation of the abdomen with ultrasonography may aid in qualifying the small or large intestinal motility, as well as identifying the source of an obstruction if it cannot be determined on radiographs.

Radiography also allows for the use of contrast medium to further outline the alimentary tract and to evaluate pharyngeal function and esophageal motility.[40-42] Approximately 60 mL of barium sulfate paste or liquid, administered orally via a 60-mL dosing syringe, for radiographs of the laryngeal region and esophagus provides useful information about swallowing and large obstructions. If the barium liquid is identified dorsal to the soft palate, within the larynx or trachea, pharyngeal function is probably abnormal.[40] The barium paste coats the pharynx and esophagus, and this appearance is useful for identifying any ulcerations or irregularities in the mucosal surface. After those procedures have been performed, or if

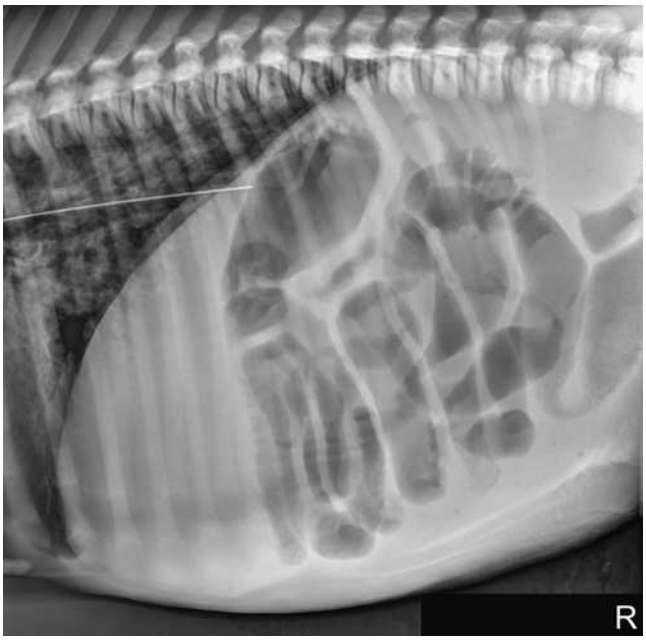

FIG. 32.36 Standing lateral radiograph of a 1-day-old, premature Quarter Horse filly. Note the large amount of gas-distended intestine. Because of the large amount of small intestinal distention, functional ileus was the primary differential diagnosis.

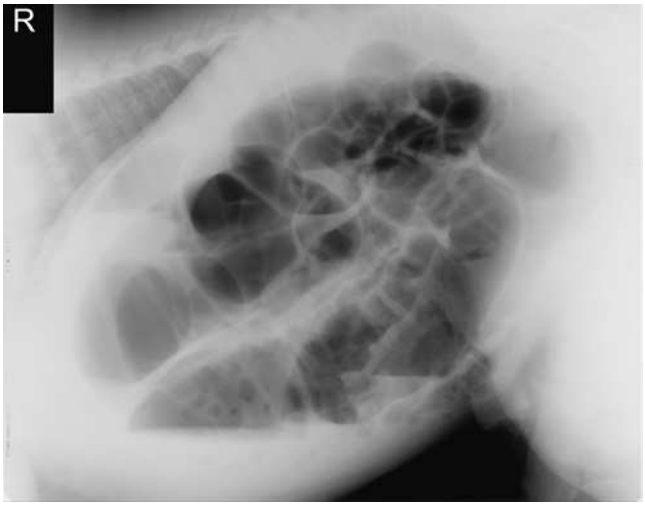

FIG. 32.37 Standing lateral radiograph of a 2-day-old Thoroughbred colt with a meconium impaction. Note the large amount of gas distention of the colon.

there is no evidence of an oropharyngeal dysphagia, esophagography is performed. For this procedure, water is added to approximately 200 to 500 mL of barium sulfate liquid to achieve a concentration of 1:1 or 2:1, which brings the total volume to 500 to 1000 mL. This liquid is administered through a nasogastric tube or cuffed endotracheal tube placed within the cranial portion of the esophagus to the level of C2 to C3. If a cuff is available, the cuff can be inflated with approximately 10 mL of room air. A radiograph is then made to verify that the tube is not within the trachea, and when it has been confirmed to be within the esophagus, the dose of barium is administered with a stomach pump. Toward the end of the dose, while the liquid is still being pumped, radiographs of the cranial, mid, and caudal portion of the esophagus are

FIG. 32.38 Standing lateral radiograph, showing a normal esophagogram with barium liquid. The *arrow* marks the region where the nasogastric tube ends. This is approximately at the level of C3.

obtained (Fig. 32.38). The use of the pump provides distention of the esophagus to help identify strictures or irregularities in the esophageal wall.

Positive (barium sulfate) and negative (room air) contrast media, administered orally, have also been used to evaluate the stomach and intestinal tract radiographically,[34,43,44] and the rectum and colon have been evaluated through retrograde administration of contrast medium.[44] These methods allow for the evaluation of the stomach, intestinal tract, and rectum for regions of obstruction, as well as ulcerations, tumors, motility disorders, and malformations. Although these methods have been described, ultrasonography has virtually eliminated the need to expose personnel and patients to the repetitive, high doses of radiation needed to obtain sequential radiographs of the abdomen.

Computed tomography (CT) and magnetic resonance imaging (MRI) are of little use for evaluation of the alimentary tract (except for the head). This is mainly because of the size of the patient in relation to the size of the gantry and bore in CT and MRI units, respectively. Dental disorders such as abscesses and fractures are clearly visible on CT images, especially on three-dimensional reconstructions (Fig. 32.39), and CT is also useful for detecting pharyngeal and esophageal masses that may not be fully identified with conventional radiographs. CT and MRI can be used in foals that can be placed within the gantry or bore of the magnet; however, because of the motion of the gastrointestinal tract and the long acquisition times used with respiratory gating sequences, MRI has not been used widely to evaluate the thorax or abdomen. A single case report has been published about the use of contrast esophagography and CT to aid in the surgical planning of a persistent right fourth and left sixth aortic arch that caused a vascular ring anomaly in a foal.[45] However, the applications for these technologies have yet to be realized.

SCINTIGRAPHY. Nuclear medicine is used widely for imaging the gastrointestinal tract in humans and animals. Although physical obstruction can be assessed with endoscopy, ultrasonography cannot delineate the pylorus in the normal horse because of the peripheral nature of the colon and colonic gas. Nuclear medicine provides a functional evaluation of the pylorus to determine whether gastric emptying is delayed in comparison with that in normal horses. This modality works better than gastric emptying with barium sulfate because of

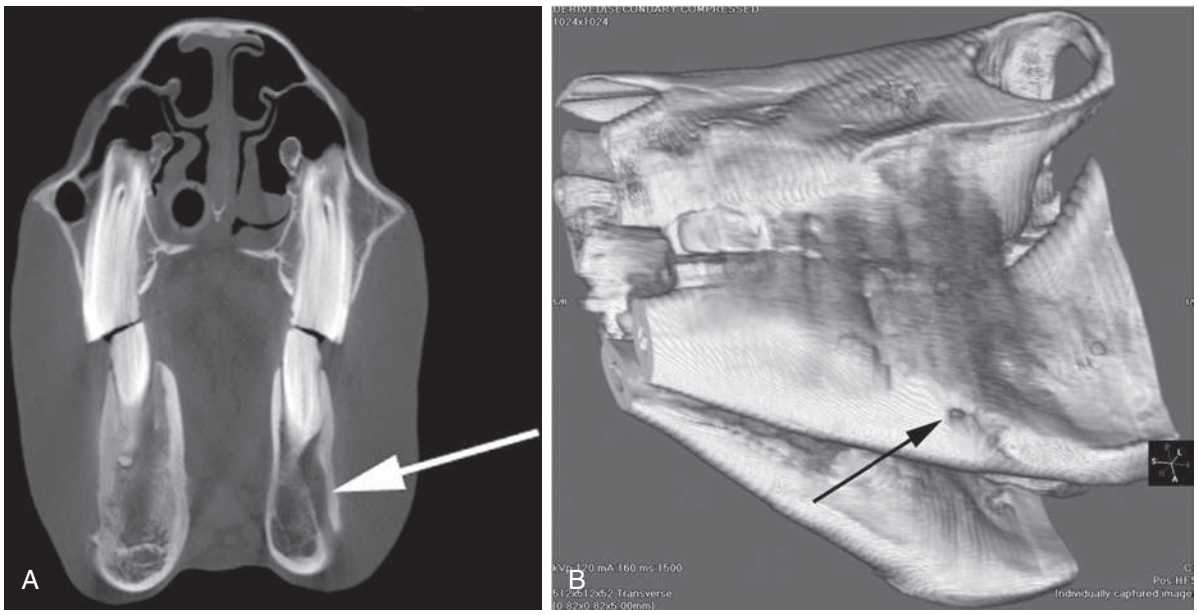

FIG. 32.39 Transverse **(A)** and three-dimensional **(B)** reconstructed computed tomographic images of the head of a 4-year-old pony mare with chronic draining tracts from the mandible. The *arrows* illustrate the tract through the mandible that communicates with the apical portion of the left mandibular first molar (tooth #309).

the minimally invasive nature of the modality and ease of image acquisition. However, because of the need for a gamma camera to generate the images and the licensing requirements to handle radioactive material, this modality is less universally available. The primary use of scintigraphy in evaluating the gastrointestinal tract is to measure gastric emptying time.[46-49] Two protocols have been outlined in the references provided: The first entails the use of the readily available technetium-99m pertechnetate (^{99m}Tc) bound to disofenin or sulfur colloid.[47,50,51] This combination of radioisotope and radiopharmaceutical is fed in a pelleted ration alone or mixed with radiolabeled eggs. The normal range for the $t_{1/2}$ gastric emptying has been reported to be 1.49 ± 0.17 hours[26] and 1.56 ± 1.08 hours.[26] The other method is the breath test involving carbon-13 bound to octanoic acid (^{13}C-OABT). This method was compared with the ^{99m}Tc sulfur colloid method, and the solid-phase gastric emptying $t_{1/2}$ was found to be similar.[45] The main difference is that the ^{13}C-OABT is measured in the exhaled breath of horses and with spectroscopy, rather than with a gamma camera. The rationale for ^{13}C-OABT is that because a gamma camera is not needed, this test may be more portable and useful for field investigations.[50]

Another nuclear medicine procedure in the realm of alimentary tract evaluation involves the use of ^{99m}Tc with hexamethylpropyleneamine oxime (HMPAO). This procedure allows for radiolabeling WBCs in order to determine areas of inflammation.[52,53] The use of ^{99m}Tc is a matter of convenience because it is also used in equine bone imaging. Detection equipment, such as a low-energy, all-purpose collimator, is readily available in many practices. HMPAO is used because it binds to granulocytes and therefore should travel to areas of increased inflammation.[53] HMPAO also associates with the reticuloendothelial system, enabling localization within the lungs, liver, spleen, kidneys, and urinary bladder. The main drawback is that with the HMPAO bound to WBCs, there is a general lack of anatomic information, which can cause lesion localization to be difficult.[53] Although this technique is expensive and labor intensive, the results from the limited studies available appear encouraging.

Biopsy The decision about whether to perform biopsy is often based on the ease of obtaining a sample and the relative value of the evaluation that can be made. Very small samples, such as those obtained with an endoscopy biopsy instrument, are relatively easy to obtain, but they provide limited information. Full-thickness bowel specimens, obtained by means of ventral midline or flank laparotomy, are more difficult to obtain, but they provide much more information. Laparoscopic techniques to safely obtain full-thickness intestinal biopsy samples have been described[54] and may be more practical than laparotomy.

Obtaining a biopsy sample by endoscopy allows the practitioner to choose the biopsy site on the basis of the appearance of the mucosal surface, which most frequently reflects an inflammatory disorder. Conversely, when a biopsy sample is obtained through laparotomy, the serosal surface of the bowel may not reflect a disorder within the bowel wall. In such instances, obtaining several biopsy specimens may be helpful. Rectal mucosal biopsies are easily performed. Many instruments can be used to obtain the biopsy specimen, and a uterine biopsy forceps works well. A fold of mucosa can be pinched readily between two fingers, and a sample of this tissue is obtained this way. The size of such a sample is adequate for histologic or bacteriologic examination.

Fecal Examination Cytologic, biochemical, bacteriologic, immunologic, and electron microscopic evaluations can be performed on fecal samples. In addition, the consistency and color, the presence of foreign material such as sand or gravel, and the presence of parasites should be examined in the examination of the alimentary system. In addition to fecal consistency, fecal particle size can be used to evaluate the efficiency of mastication or the colonic transit time. Increased particle size, with loose or watery stool, is suggestive of decreased colonic transit time.

Cytologic examinations are used primarily to evaluate the parasite burden of the animal. Ova of large and small strongyles, tapeworms, round worms, and *Strongyloides westeri* are most common. Coccidia are observed occasionally, but their presence

VetBooks.ir

is clinically unimportant. Examination of fecal WBCs has been advocated in the evaluation of horses and foals with enterocolitis. Because these cells are very labile, their presence in large numbers indicates that an inflammatory process is present and that the inflammation is in the distal portion of the colon or is associated with decreased transit time.

The presence of fecal occult blood should be determined so as to diagnose gastric ulcers, duodenal ulcers, and other potentially hemorrhagic disorders of the alimentary tract. However, the usefulness of this test has been shown to be quite limited because negative results can be obtained when blood is present in the proximal portion of the gastrointestinal tract.[55] The sensitivity of most commercially available tests is poor; they may yield negative results in the presence of severe gastric bleeding.

Fecal culture is an essential component in the evaluation of many patients. In bacteriologic culture techniques for fecal samples, selective media that are designed to isolate *Salmonella* are routinely used. These media include selenite broth, tetrathionate broth, brilliant green agar, XLD agar, and *Salmonella-Shigella* agar. Less selective media, MacConkey agar, and eosin methylene blue agars are desirable for culture of other potential Gram-negative bacterial pathogens such as *Escherichia coli*, but the mere presence of *E. coli* in the feces does not determine its pathogenicity. Enterotoxigenic *E. coli* strains have been isolated from foals with diarrhea, but special tests, such as polymerase chain reaction (PCR) assays, must be performed to determine whether an isolate produces enterotoxin. Rapid enzyme-linked immunosorbent assays (ELISAs) are available at diagnostic laboratories for detection of enterotoxins of *Clostridium difficile* (*C. difficile* Tox A/B Test, TechLab, Blacksburg, Va.) and *Clostridium perfringens* (*C. perfringens* enterotoxin test, TechLab, Blacksburg, Va.) in fecal specimens.

The presence of rotavirus in a fecal sample can be determined by ELISA or an agglutination test. Both assays test for the presence of viral antigen in the feces. PCR assays are also available to detect rotaviral nucleic acids. ELISA is reported to be more sensitive than the agglutination test but is less specific. Therefore the agglutination test is likely to yield more false-negative results, and the ELISA test is likely to yield more false-positive results. The ELISA test is more time-consuming and inconvenient to perform than the agglutination test. When rotavirus is a concern, particularly as a farm problem, a reasonable approach is to screen fecal samples with the agglutination test and repeat testing of samples that yield negative findings with ELISA or PCR.

Some diagnostic laboratories have developed sensitive and specific multiplex PCR tests for panels of gastrointestinal pathogens (equine coronavirus and rotavirus, *Lawsonia intracellularis*, *Cryptosporidium*, *Rhodococcus equi*, *Neorickettsia risticii*, *Salmonella* spp., coronavirus, rotovirus, and *C. difficile* toxins A and B), that provide relatively rapid diagnostic information that can be used alone or in combination with culture or antigen detection methods.

Absorption and Digestion Tests

Tests of the ability of the equine intestinal tract to digest and absorb nutrients have a more limited clinical application in horses than in human or small animal medicine, but they can be useful in the evaluation of chronic weight loss, suspected small intestinal inflammation or neoplasia, gastric and small intestinal partial obstruction, and postoperative small intestinal malabsorptive disorders. For absorption tests to be diagnostic, the intestinal disorder must either be diffuse or affect the delivery to and transit through the small intestine.

Maldigestion tests are performed to evaluate exocrine pancreatic function and disaccharidase activity at the mucosal brush border of the small intestine. Pancreatic exocrine deficiencies have not been described in horses, probably because equine pancreatic secretions consist primarily of water and bicarbonate and have less enzymatic activity than in monogastric omnivorous species. Maldigestion related to disaccharidase activity at the mucosal brush border is relevant in viral and bacterial enteritides of foals, particularly rotavirus and coronavirus enteritides. As a result of these viral infections, there is loss of the superficial villous epithelial cells of the small intestine, in which the disaccharidases lactase, cellobiase, maltase, sucrase, and trehalase are located.[56] Lactase levels are highest in young suckling foals, and loss of this enzyme activity, secondary to loss of the mucosal villous cells, leads to lactose maldigestion. Lactose tolerance can be tested by administration of a 20% solution of D-lactose at a dose of 0.5 to 1 g/kg. This dose should result in an approximate doubling of the serum glucose level within 60 minutes of administration.[57]

Clinically applicable absorption tests include the D-glucose and D-xylose absorption tests. The glucose absorption test has the advantage of being relatively easy to perform and inexpensive. However, cellular uptake and metabolism of glucose, as well as intestinal absorption, influence the results and thus are undesirable variables. The D-xylose absorption test is therefore advantageous because it more directly measures intestinal absorptive capacity. The results of both tests, however, are affected by gastric emptying rate and small intestinal transit time. In the United States, D-xylose is available only through chemical suppliers and only for research purposes; its availability for clinical diagnostic use is restricted.

The D-glucose and D-xylose tests are performed similarly. After an 18- to 24-hour fast, a 10% solution of D-glucose or D-xylose, 0.5 to 1 g/kg, is administered through a nasogastric tube. For the measurement of glucose, blood is collected in sodium fluoride tubes, and for the measurement of D-xylose, blood is collected in heparinized tubes. Samples are taken immediately and 30, 60, 90, 120, 150, 180, 210, and 240 minutes after administration. Peak levels, which normally range from 20 to 25 mg/dL, are reached 60 to 120 minutes after administration and should decrease thereafter. The normal curve resembles an inverted V. Absorption curves vary as a function of each horse's age and type of feed given.[58] Delay or flattening of the absorption curve may reflect delayed gastric emptying, increased intestinal transit time, or impaired intestinal absorption.[59] Accurate interpretation of the results of these tests depends on the results of other diagnostic evaluations. In addition, different types of diets have been shown to affect the height, although not the shape, of the absorption curves significantly. In general, with diets that have higher digestible energy content, the curve has a lower peak.

Breath Tests

In humans, dogs, and cats, breath tests are used to assess a variety of intestinal disorders. The hydrogen breath test is used in assessments of intestinal bacterial overgrowth and in determination of carbohydrate digestion and absorption in the intestine. In patients with an abnormal intestinal bacterial population or carbohydrate malabsorption, bacterial fermentation of carbohydrate is excessive, one by-product being hydrogen. Because hydrogen is freely diffusible from the bowel into the blood and from the blood into the alveoli, measurement of exhaled hydrogen gas can be used to assess the status of intestinal bacterial fermentation of carbohydrates.

In horses, the hydrogen breath test is most applicable to conditions involving carbohydrate malabsorption and thus increased delivery of soluble carbohydrate to the large intestine for bacterial fermentation to occur. This technique has been used in horses: In one report, different carbohydrate substrates were evaluated in seven ponies,[60] and in another, the hydrogen breath test was used in conjunction with D-xylose absorption in nine horses with a variety of clinical disorders.[61] In the study with ponies, fasting resulted in negligible levels of breath

VetBooks.ir

hydrogen excretion. Sustained increases in breath hydrogen concentration to more than 10 parts per million (ppm) were observed in all ponies after they ingested oats or wheat flour, in three ponies after the administration of glucose and xylose, and in two ponies after the administration of lactulose and lactose. The pattern of breath hydrogen excretion varied among animals after the ingestion of identical test meals. In the clinical study, the diseased horses showed higher fasting breath hydrogen levels (range 7.5 to 61.5 ppm) than did normal horses (range, 0 to 5 ppm). After xylose administration, none of the healthy animals showed an increase in breath hydrogen production, and five of diseased animals showed increases in breath hydrogen. In this group of patients, abnormalities in hydrogen breath measurement were more apparent than abnormalities in D-xylose absorption.

Dentistry and Oral Disease

Jack Easley

The equine species has evolved as a continuously grazing animal, developing its own dental form and function over millions of years. The oral and dental structures provide horses with the ability to detect, prehend, masticate, and begin the digestion of mixed grass forage. As humans have domesticated and confined horses, their diet has been altered to consist of grazing improved pastures with more interval feedings of dry hay, grain, processed forages, and concentrates. Selective breeding and domestication practices have increased the incidence of equine dental and oral disease in modern equine populations.

Anatomy and Function

The structures that horses use in eating include tactile and prehensile lips, hypsodont incisors, premolars and molars, facial bones, muscles of mastication, tongue, hard palate, buccal mucosa, cheeks, olfactory organs, taste buds, salivary glands and ducts, blood vessels, lymphatic vessels, and nerves that support them. The equid oral cavity is long and cylindrical and is the entrance to the alimentary canal. The muscular lips form the entrance to the mouth, which is bound laterally by the cheeks, dorsally by the palate, and ventrally by the body of the mandible and the mylohyoid muscles. The caudal aspect of the mouth is composed of the soft palate, root of the tongue, and epiglottis and is continuous with the oropharynx.[1,2]

The blood supply to the mouth is derived from the maxillary, mandibular, labial, and sphenopalatine arteries. The venous drainage is chiefly through the linguofacial veins. Nerve sensation in the mouth, cheeks, and lateral aspect of the tongue is derived from the mandibular and maxillary branches of the trigeminal nerve (cranial nerve V). Motor function of the sublingual and mandibular salivary glands, lacrimal glands, and facial and labial muscles is activated by the facial nerve (cranial nerve VII). The hard palate has a central raphe, dividing the surfaces into right and left halves. The portion of the palatal mucosa just caudal to the upper incisors may appear swollen in 2- to 5-year-old horses when permanent incisor teeth erupt. Such mucosal enlargement is normal and has historically been referred to as *lampas*. Farther caudal, the hard palate becomes more concave and contains paired transverse ridges that traverse the cavity. These ridges are instrumental in moving a food bolus caudally in a spiral manner as horses masticate forage.

The highly mobile, muscular tongue sits in the bottom of the mouth between the paired hemimandibular rami. It is covered by a tough, specialized squamous epithelium modified to form papillae. The tongue is supported in a sling formed by the mylohyoideus muscles. The root of the tongue is attached to the lateral aspect of the soft palate, pharynx, and hyoid bone. The lingual muscles receive their motor innervation from the hypoglossal nerve (cranial nerve XII) and sensory innervation from the lingual and glossopharyngeal nerves (cranial nerve IX). The rostral portion of the tongue is susceptible to injury from bits and other tack placed in the oral cavity. Injury from penetrating foreign body (usually wire) and neurogenic injury are possible.

The mandible is the largest bone of the face and is formed by the paired hemimandibles, which fuse rostrally at the mandibular symphysis when horses are approximately 2 to 3 months of age. Each hemimandible is composed of a horizontal and a vertical ramus. The horizontal ramus contains the alveoli of the teeth in the lower jaw. The vertical ramus terminates with the coronoid process rostrally and the mandibular condyle caudally. The temporalis muscle inserts on the coronoid process.

Between the incisors and the rostral aspect of the mandibular cheek teeth in the horizontal rami of the mandible is a large diastema: the interdental space or "bars" of the mouth. Canine teeth, if present, are located in this area. In young horses, the ventral border of the mandible is wide and round. Eruption swellings or "bumps" are often seen on the ventral border of the mandible of 2- to 4-year-old horses as the permanent mandibular cheek teeth erupt. With age and as eruption of the mandibular cheek teeth continues, the ventral border of the mandible takes on a sharper, angled appearance.

The paired incisive (premaxillary) bones form the rostral part of the upper jaw and contain the alveoli of the upper incisors. Caudally, the incisive bone becomes thinner and forms the rostral part of the hard palate. The suture line between the incisive bones and the maxillary bones is an anatomically weak area and a common site of facial fractures. The upper canines (if present) are situated just caudal to this suture line.

The paired, large maxillary bones extend from the incisive bone rostrally to the nasal bones dorsally and lacrimal bones caudally. The facial crest is a prominent ridge of bone on the lateral aspects of the maxillae. This crest continues caudally as the zygomatic process and joins the molar and temporal bones to form the zygomatic arch. The ventromedial aspects of the maxillary bones join to form a horizontal shelf that provides rigid support to the majority of the hard palate. The alveoli of the upper canines, premolars, and molars are embedded in the maxillae. The positions of the alveoli of the upper cheek teeth are somewhat variable, but usually the alveoli of the first two cheek teeth lie rostral to the maxillary sinuses. The third and fourth cheek teeth lie within the rostral maxillary sinus in young and middle-aged horses. The caudal two cheek teeth lie within the caudal maxillary sinus. As the teeth continue to erupt with age, the maxillary sinus volume increases. More detailed anatomic relationships of the maxillary cheek teeth and the paranasal sinuses have been explored in horses of various ages with the use of CT.[3] Each alveolus is separated by transverse interalveolar bony septa.

Horses have seven paired paranasal sinuses: ventral conchal, dorsal conchal, frontal, sphenopalatine, caudal maxillary, rostral maxillary, and ethmoidal sinuses. The rostral and caudal maxillary sinuses are contained within the maxillae and are usually separated by a thin bony septum, although this septum often breaks down with sinus disease. The long infraorbital canals (one on each side of the head) traverse longitudinally through the maxillary sinuses, encasing the large paired infraorbital nerves.

Sinusitis can result from disease of the third, fourth, fifth, and sixth upper cheek teeth and classically results in a unilateral, malodorous nasal discharge. In a young horse, virtually the entire maxillary sinuses are occupied by dental alveoli. Therefore as the facial bones grow and reserve crowns of the upper cheek teeth erupt, the cheek teeth move forward and ventral in the sinus compartments. The maxillary sinuses drain into the back of the nasal cavity via a slitlike aperture, the nasomaxillary opening. The medial compartment of the rostral maxillary sinus is called the *ventral conchal sinus*. This compartment has

VetBooks.ir

poor drainage and is a common site in which inspissated pus accumulates. Its secretions must drain dorsally over the infraorbital canal into the lateral compartment of the rostral maxillary sinus. Drainage from these two sinuses courses into the caudal middle meatus adjacent to the drainage angle of the caudal maxillary sinus. The areas rostral to the paranasal sinuses are scrolled sections of the nasal cavities, referred to as the *dorsal* and *ventral nasal conchal bullae*. These structures have been shown to be an area in which inspissated pus accumulates in cases of chronic sinusitis.[4]

The temporomandibular joint is a synovial joint formed by the articulation of the squamous temporal bone and the condylar process of the mandible. The joint lies approximately 15 cm above the level of the occlusal surface of the cheek teeth. The joint cavity is large and divided in two by a cartilaginous intraarticular disk. The joint is bound by a tight capsule and lateral and caudal ligaments. The unique functional anatomy and age-related changes in the normal equine temporomandibular joint were described only as recently as the mid-2010s.[5,6] This joint can make a wide range of lateromedial movements (allowing the medially directed power stroke of mastication) but limited vertical and rostrocaudal movements.[7]

As a result of the wide lateromedial range of motion of the temporomandibular joint associated with the power stroke of chewing, the masseter and pterygoid muscles are the most highly developed muscles of mastication in horses. The powerful masseter muscle originates along the full length of the facial crest and zygomatic arch and has wide insertions along the caudolateral aspect of the mandible. The superficial masseter muscle fibers run almost vertically, whereas the deep fibers course in a ventrocaudal direction. The masseter pulls the jaw to the ipsilateral side and also contributes to closure of the jaw. The medial and lateral pterygoid muscles have origins and insertions similar to those of the masseter, and these lie on the medial aspect of the mandible. The digastricus muscle originates on the occipital bone and attaches to the caudal aspect of the mandible and is small in horses as a result of the minimal effort required to open the jaw with gravity assistance. The temporalis muscle, whose function is jaw closure, is also small and poorly developed in horses because vertical opening of the temporomandibular joint is limited. The muscles of mastication are innervated by the motor branch of the mandibular nerve, which originates from the trigeminal nerve (cranial nerve V).

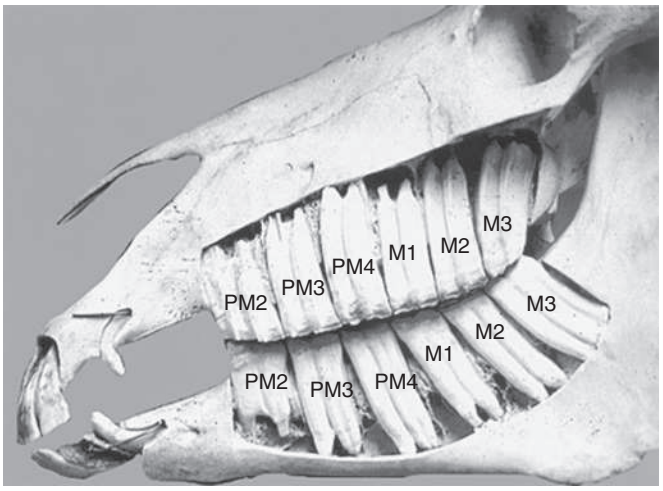

FIG. 32.40 Lateral view of equine cadaver skull. *M*, Molar; *PM*, premolar.

Teeth At approximately 6 months of age, 24 deciduous teeth have erupted in a foal. Development of the cranial and facial bones during the first 2 to 3 years of life allows room for the expansion of the dental formula from 24 deciduous to between 36 and 44 permanent teeth in a mature horse. The mature mouth of a horse contains six incisors each in both the upper and lower jaws, six permanent upper cheek teeth on each side of the mouth, and six lower cheek teeth on each side of the mouth (Fig. 32.40). The rostral three cheek teeth are premolars, and the caudal three cheek teeth are molars. Incisors and premolars have deciduous and permanent sets. Molars erupt at an older age and do not have deciduous counterparts. The cheek teeth of the upper jaw are broad and square, whereas the lower cheek teeth are narrower and rectangular.

The cheek teeth in each quadrant of a horse's mouth are commonly referred to by number, from rostral to caudal (1 to 6). The inconsistent and vestigial first premolar, often referred to as a "wolf tooth," is not included in the 1-to-6 nomenclature. To help avoid confusion, the American Veterinary Dental College has endorsed use of the Modified Triadan System of tooth numbering for horses.[8] This three-digit tooth numbering system is based on a full phenotypic dentition composed of 44 teeth in total. The first digit designates the quadrant and arcade location and whether the dentition is deciduous or permanent. The numbering sequence for permanent teeth starts with 1 for the upper right, 2 for the upper left, 3 for the lower left, and 4 for the lower right. The corresponding deciduous teeth quadrants are numbered 5 to 8, respectively. In each dental quadrant, the first or central incisor is always 01; the other incisors are numbered 02 and 03. The canines, whether present or not, are designated 04 in this formula. The premolars are numbered 05 to 08 and the molars 09 to 11.

The equine incisor and molarized cheek teeth are hypsodont and have long anatomic crowns, which erupt throughout the life of the animal in a dynamic process of periodontal ligament and alveolar bond remodeling. The tooth crown is the enamel-containing portion of the tooth. When these hypsodont teeth first erupt, the occlusal surface is covered with cementum overlying the enamel. As the teeth are subjected to masticatory forces and abrasive forage, the thin layers of occlusal cementum and enamel wear away, exposing the true or functional occlusal surface of the tooth. This process is termed *coming into wear*. The functional occlusal surface of hypsodont teeth is composed of thin, brittle sheets of hard enamel, sandwiched between softer but more stress-resistant layers of cementum and dentin. This three-textured occlusal surface is self-sharpening and very wear- and fracture-resistant. At the time of eruption, there are no true roots, and teeth are divided into apical and coronal regions, but most of the crown (reserve crown) lies within the alveolus. True roots are formed gradually over a period of 2 to 3 years after eruption.

The incisors and upper cheek teeth have enamel crown invaginations termed *infundibulae*. These invaginations partially fill with cementum that receives its blood supply from the occlusal soft tissues covering the tooth before eruption. A shallow infundibulum is present on each incisor tooth and has a wide opening at the occlusal surface referred to as a *cup*. As a tooth wears down over time, the small bottom portion of the infundibulum is exposed at the occlusal surface and is called the *spot*. Each upper cheek tooth has two deeper infundibulae: one rostral (mesial) and one caudal (distal). These extra enamel cones give the central area of these teeth a hard, serrated, but wear-resistant chewing surface. As these teeth develop but before the occlusal surface comes into wear, the infundibulae are supplied by infundibular arteries entering from the occlusal direction. Cementogenesis of the infundibulum starts first at distinct enamel infoldings in the occlusal part of the infundibula and advances in an apical direction.[9] The center of the cement lake that fills the infundibulum contains a hole of variable diameter. This channel is a remnant ("ghost")

of the central blood vessel that supplied nutrition to the now dead infundibular cementum. If the blood supply becomes compromised before cementogenesis is complete, infundibular cemental hypoplasia can develop, which predisposes affected teeth to infundibular caries and midsagittal fractures.

The interior of a tooth is composed primarily of dentine; primary dentine lines the walls of the common pulp chamber of a newly erupted tooth. The pulp chambers of hypsodont teeth are active throughout a horse's life, with primary and secondary dentine continually produced within the pulp cavity. This process of continuous secondary dentine production prevents pulp exposure at the occlusal surface as the tooth wears. The depth of secondary dentine at the occlusal surface of the pulp horns (seen as a brownish area on the occlusal surface of the tooth) varies in horses but is usually 5 to 7 mm thick. No age-related increased thickness of occlusal secondary dentine has been found research, which supports the theory that secondary dentine deposition is at least partially regulated by occlusal stimulation.[10,11] The pulp cavity in the young equine permanent cheek tooth is very large. With increasing age, it divides into smaller pulp chambers (or horns) as dentine deposition increases. From 2 to 4 years after eruption, mandibular cheek teeth have a distinct, apically located, common pulp chamber that communicates with the pulp horns. The number of pulp horns has been well described: Five pulp horns are present in the 07 to 10 teeth, six pulp horns in the 06 teeth, and six or seven pulp horns typically present in the 11 teeth (Fig. 32.41).[12] Two to four years after tooth eruption, the dentine divides the endodontic system of most of the mandibular cheek teeth into two distinct compartments or roots. Each compartment consists of a root canal, a pulp chamber, and two or three pulp horns. The anatomic changes in pulps with age are quite complicated and slightly different between horses; thus endodontic treatments in this species are challenging.[13] The maxillary cheek teeth, as well as the 311 and 411, have three roots: one palatal and two buccal. Because of the continuous production of cementum around the apical or root portion of the tooth and continuous crown wear, old equine teeth wear apically past the infundibular enamel and peripheral enamel infolding that normally prevents crown attrition (senile excavation). When most of the crown enamel has worn away, the softer dentine and cementum are quickly worn away, which leads to a condition known as "senile excavation." As the crown undergoes further wear, the peripheral enamel is lost, and the smooth dentine and cementum become the functional occlusal surface. When this condition involves multiple teeth in an arcade, it is referred to as *smooth mouth*.

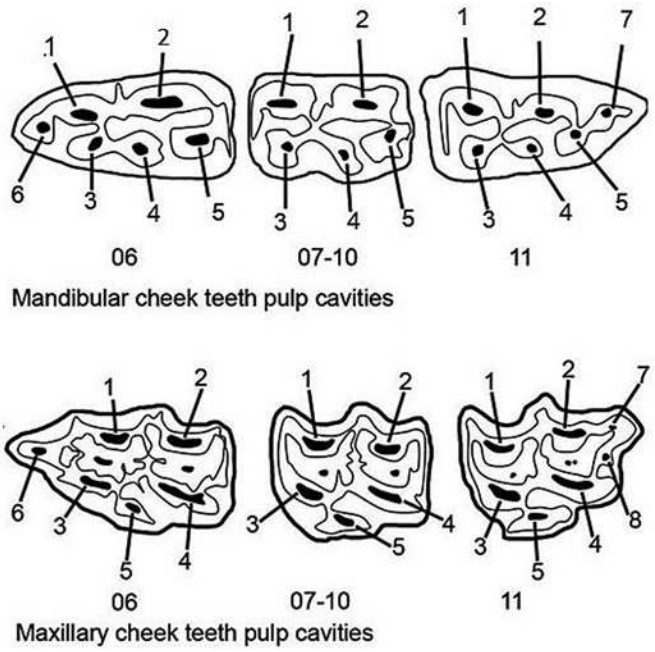

FIG. 32.41 Diagram of the premolar and molar pulp horns, seen as dark areas of secondary dentine on the occlusal surface.

Innervation of the dental structures is supplied by the trigeminal nerve (cranial nerve V), which exits the skull just below the ear. This nerve traverses rostrally and divides into the ophthalmic, maxillary, and mandibular branches. The maxillary nerve lies in the pterygopalatine fossa deep to the subperiorbital fat pad and enters the caudal maxilla ventral to the orbit via the maxillary foramen. It runs through the maxilla in the infraorbital canal, at which point it becomes the infraorbital nerve, and gives off branches to supply the maxillary cheek teeth and incisors. A branch of the infraorbital nerve exits the maxilla at the infraorbital foramen, just rostral and dorsal to the facial crest. The mandibular nerve runs medially along the mandible, becoming the lingual and inferior alveolar nerves, which arise as a common trunk and pass rostrally between the pterygoideus medialis and the ramus of the mandible. The inferior alveolar nerve enters the mandibular canal on the caudomedial aspect of the mandible, innervating the mandibular teeth. The mental nerve exits the mandibular canal via the mental foramen at the rostrolateral aspect of the mandible just rostral to the mandibular cheek teeth and supplies the ipsilateral soft tissues over the incisive portion of the mandible. These nerves and their branches are clinically significant in diagnostic procedures or procedures involving regional anesthesia in horses.[14]

Rudimentary first premolars (wolf teeth) are constant in fetal life in both upper and lower jaws. Many never develop to the point of eruption but instead degenerate and become incorporated in the maxilla or mandible. The upper wolf teeth erupt in 20 to 80% of horses; the lower wolf teeth rarely erupt (in 1% to 5%).

Equine males normally have two upper and two lower canine (bridle) teeth. This type of anatomic discrepancy is referred to as *sexual dimorphism*, inasmuch as as canine teeth are absent or rudimentary in most mares. The upper canine teeth erupt just caudal to the suture between the incisive and maxillary bones. The lower canine teeth lean forward, producing a long lower diastema or interdental space.

The horse is anisognathic: that is, the bottom jaw is narrower (by ≈25%) than the upper jaw. The lateral excursion of the jaw during mastication is conducive to occlusal wear of the buccal aspect of the lower and the lingual aspects of the upper molar arcades. The horse's jaw anatomy and jaw motion have an effect on the angle of the molar tables.[15] Cheek teeth occlusal angles have been found to range from 15 to 20 degrees in normal horses, according to three-dimensional models from CT images.[16] As horses chew, the jaw moves in rotational motion from side to side with some rostral-caudal excursion.[17] The construction of the molars with interdigitations of enamel, cementum, and dentine allows for uneven, continuous wear with a sharp, serrated surface when horses are grazing. The extent of lateral excursion of the mandible during normal mastication is affected by the length of the stem or roughage in a horse's ration. A horse on pasture or hay has a full or wide area of mandibular excursion. However, horses eating pellets or concentrates have a limited range of lateral jaw excursion. Horses with limited lateral jaw excursion have incomplete wear of the molar surfaces, which predisposes the arcades to sharp enamel edges, a vaulted ceiling of occlusion, or the serious problem of shear mouth. Malocclusion of the incisor or molar arcades perpetuates abnormal wear patterns that eventually predispose affected horses to diastema and secondary periodontal disease.[18]

VetBooks.ir

Rostral or caudal molar malocclusions or eruption problems (displaced, deformed, delayed-eruption, missing, or supernumerary teeth) lead to uneven dental wear. Many horses with asymmetry between the upper and lower molar arcades (as a result of mandibular fracture, facial injury, congenital deformities such as brachygnathism [parrot mouth] and prognathism [sow mouth] or a mandible that is abnormally narrow in relation to the maxilla) have abnormal tooth wear in the form of sharp enamel points, dental overgrowths (hooks or ramps), shear mouth, step mouth, or wave mouth.

The dynamic change that takes place in the mature horse's head continues at a slower rate throughout life, with continual eruption and crown wear of the hypsodont premolar, molar, and incisor teeth, which retain their long reserve crowns and slowly-forming, short root structures. With continuous eruption and wear of the equine hypsodont teeth, all horses eventually experience senile attrition and wearing of their teeth "smooth" to the root.

Equine Dental Developmental Abnormalities

Equine dental developmental abnormalities can involve tooth number, structure, or position in the dental arcades. Abnormalities of dental development and eruption are quite common in horses and result in a wide range of clinical conditions. A congenital/developmental problem that manifests at the time of tooth eruption often leads to acquired dental problems as the teeth continue to erupt and wear. Some developmental abnormalities of the teeth of very young horses may not cause it to exhibit clinical signs until middle age. Consequently, several different dental abnormalities with interrelated pathogenesis are often present concomitantly at the time of clinical presentation.[19-21]

SUPERNUMERARY TEETH. Supernumerary teeth are teeth in excess of the normal expected number in any of the dental arcades. This disorder has been referred to as *polydontia* or *hyperdentition*. Supernumerary teeth can be loosely categorized morphologically into two categories: (1) supplemental teeth that resemble teeth of the normal series in crown and root structure but not always in size, and (2) rudimentary or dysmorphic teeth that are abnormally shaped and smaller in size than normal teeth.

In general, these extra teeth are encountered at the caudal aspects of the molar arcades, but supernumerary teeth can also be lingual, buccal, or rostral to the normal arcades. Clinical signs most commonly associated with supernumerary cheek teeth are dental overgrowths and diastemata, which often lead to secondary periodontal disease.

Supernumerary incisors are reported more often in horses than are supernumerary cheek teeth. The main condition included in the differential diagnosis for supernumerary incisors or cheek teeth is retained deciduous teeth. In some cases, it may be clinically difficult to determine whether an extra tooth is a retained deciduous tooth or a supernumerary tooth. Examination with a radiograph that encompasses the entire affected dental arcade is often necessary to diagnose this condition. Radiographic examination of the affected jaw is often indicated to determine the identity of an extra tooth. A retained deciduous tooth has a more mature root and a shorter reserve crown than does the adjacent permanent teeth. Such distinguishing characteristics are visualized with radiographs.

Horses with supernumerary teeth should be managed on a case-by-case basis, but management in general is limited to regular assessment of the dentition, coupled with aggressive dental floating to minimize the opportunity for soft tissue damage by unopposed elongations. Dental elongations place abnormal orthodontic forces on the involved tooth. This can lead to shifting of teeth and diastema formation. In severe long-standing cases, deep periodontal pockets and oroantral fistulas predisposing to forage accumulation in the paranasal sinuses may develop. If complications such as severe periodontal disease or maxillary sinusitis occur, the supernumerary tooth or displaced adjacent tooth should be extracted or appropriate therapy undertaken to manage associated pathology, or both.[18-22]

OLIGODONTIA. Oligodontia is the congenital absence of a tooth germ or retention and inclusion of a tooth within the jaw. It is difficult to differentiate developmental oligodontia from tooth loss caused by damage to, or displacement of, a dental bud from injury. It is possible for permanent tooth germs of a young horse to be damaged, displaced, or removed when deciduous teeth or jaw bones are injured. Absence of a tooth in the dental arcade leads to dental drift or tipping of adjacent teeth. Lack of wear in the antagonist to the missing tooth can lead to dental elongations and abnormal mastication. Radiographic examination is often necessary to confirm a diagnosis of true oligodontia. Oligodontia may be associated with other epidermal defects such as poor development of hair and hooves.[23]

DENTAL DYSPLASIA OR HYPOPLASIA. Dental dysplasia (i.e., abnormal growth or development of a tooth or teeth) may result in an irregularly shaped tooth that does not fit well into a dental row. The poor fit may lead to diastemata, food entrapment and periodontal disease. Enamel hypoplasia has been associated with certain drugs or chemicals administered to the dam during gestation, or it may be idiopathic in origin. Dental dysplasia can involve the abnormal formation of the entire tooth structure or only a single tissue type. Abnormal enamel structure, such as branched pulp horns or abnormally shaped teeth, has been observed. Enamel acts as the scaffolding and template for the deposition of dentine and cementum. These tissues follow the abnormal enamel pattern, and consequently all three calcified tissues are dysplastic. Cemental hypoplasia usually involves the infundibular portion of the tooth, but it can also be a defect of the peripheral, coronal, or reserve crown or root cement.

ABNORMAL DENTAL ERUPTION. Abnormal dental eruption, or maleruption, often results from trauma to developing teeth or surrounding bones, but it has also been reported to be congenital or idiopathic in origin. Cheek teeth can become vertically impacted when dental buds are developing in abnormal or crowded areas in the dental arcades. Teeth may become rotated or otherwise displaced as a result of developmental malpositioning of tooth buds or overcrowding before, during, or after eruption.

Most tooth displacements are developmental in origin as a result of overcrowding of the cheek tooth row at the time of eruption. These malocclusions are seen most often in miniature breeds and ponies and are often bilateral. Tooth displacements are also believed to be caused by abnormal positioning of a dental bud, which may result in impaction and delayed eruption or noneruption of the displaced teeth if they are sufficiently horizontal to the adjacent teeth. Developmental diastemata or abnormal spaces or gaps between cheek teeth are often caused by insufficient angulation of teeth to achieve interdental compression between adjacent teeth. Another cause for diastemata is the development of embryonic teeth too far apart.[21]

Malocclusions of incisors are congenital, developmental, or acquired in origin. Mandibular brachygnathism (parrot mouth) is a congenital incisor malocclusion, the origin of which is unknown but probably genetic. Many horses have some degree of overjet of the premaxillary incisors, but the overjet rarely causes a problem with prehension, unless the premaxillary and mandibular incisors totally lack occlusion. If brachygnathism is discovered when the foal is young, treatment may correct, or at least improve, the functional outcome for the animal.[24]

VetBooks.ir

A main consideration with an incisor overjet in adult horses is the cheek teeth malocclusions that accompany this condition. The maxillary cheek teeth arcades are usually positioned rostral to the mandibular cheek teeth, causing a rostral overgrowth of teeth 106 and 206 and a caudal overgrowth of 311 and 411. Check teeth elongations should be reduced to allow for proper rostrocaudal jaw excursion and mastication. The unopposed incisors can become elongated and limit lateral jaw motion, which can lead to abnormal dental wear and shear mouth.

Prognathism or undershot jaw occurs with less frequency in horses and is most common in miniature or dwarf breeds. Early detection and correction of the malocclusion in the foal may prevent the condition from worsening with age. The cheek teeth should be evaluated for malocclusion caused by overgrowths of teeth 111, 211, 306, and 406 and these should be corrected on a regular basis.

Bony malformations of the head can result in malocclusion of the incisors and cheek teeth. These bony skull curvatures or asymmetries usually result in an offset or diagonal incisor bite. Some bony malformations, such as campylorrhinus lateralis (wry nose) are obvious, and surgical correction may be necessary for a horse to be functional.[25] More subtle changes to the large bony plates in the head can be difficult to recognize and can be managed by correcting dental overgrowths and abnormal wear patterns.[26] Fractures secondary to trauma to the mandible or facial bones can also cause malocclusions and facial asymmetry. Care must be taken with correcting dental overgrowths associated with malocclusions, and they should be corrected gradually to prevent damage to pulp horns (which can lead to apical infection), dysphagia, and pain. Often, incisor malocclusion remains throughout a horse's lifetime, but regular maintenance may prevent it from worsening.

Acquired Dental Disease

Dental disease can be grouped into six basic categories:

1. Dental malocclusions and abnormal occlusal wear
2. Periodontal disease
3. Caries of the infundibulum or peripheral cementum
4. Endodontic disease
5. Tooth resorption and hypercementosis
6. Traumatic dental injuries

These dental disease types are interrelated, and in most clinical cases, affected horses suffer from a combination of varying degrees of different dental disease types.

Alignment of the dental arcades is critical for the normal wear of continually erupting equine dentition, and any malocclusion can lead to abnormal occlusal wear. Historically, abnormal dental wear patterns have been described as dental crown elongations, descriptive terms for which include *hooks*, *ramps*, *waves*, *steps*, and *transverse ridges*. These elongations usually involve a normal tooth that is out of occlusion with an abnormality in the opposite arcade. The opposite diseased, damaged, misplaced, or missing tooth or jaw should be evaluated when elongations are found. Most dental elongations are addressed by reducing the crown height of the long tooth or portion of a tooth with a rasp or grinding instrument. In dental reductions, iatrogenic damage to the tooth, such as pulp horn exposure, thermal injury, or crown fracture, must be avoided. The viable pulp is usually covered by 7 to 10 mm of secondary dentine, but only 2 to 4 mm occlusal secondary dentine covers some pulp horns. Therefore crown reductions should be carried out in stages; no more than 3 to 4 mm of occlusal crown should be reduced in a session. Power grinding dental instruments generate heat that can cause damage to the pulp tissue. Shorter durations of grinding and water cooling have been found to mitigate this heating effect.[27,28] It is important to diagnose and treat the underlying malocclusion or dental disorder in horses with a diagnosis of abnormal dental elongations; otherwise, the elongation of the tooth will recur over time as the tooth erupts.

Periodontal disease is an altered state of the periodontium. The periodontium is the attachment apparatus of the tooth consisting of the gingiva, alveolar bone, periodontal ligament, and cementum. The periodontium is responsible for hypsodontic tooth eruption and for the distribution of masticatory forces from the teeth into the supporting bone. Periodontal disease is often a painful dental condition and is described as the leading cause of "quidding" in horses. Gingivitis is the mildest form of periodontal disease and is often associated with local irritants such as plant awns or bristles, botfly larvae, traumatic injury, or chemical exposure. Oral ulceration can be a reflection of systemic disease, such as vesicular stomatitis, which is a contagious reportable disease. Another mild form of periodontal disease affects primarily young horses 2.5 to 5 years of age when deciduous teeth (caps) are shed and permanent incisors and premolar teeth are erupting. A more progressive form of periodontal disease affects older horses as a result of the chronic effects of diastema or spaces that develop between teeth that are not aligned properly in the arcade. Diastema can form during tooth development when dental buds are spaced too far apart or abnormally angulated so that the teeth in a dental row are not properly compressed, which allows forage to become trapped between teeth. This is usually a progressive condition; left untreated, it becomes worse over time. As food becomes compressed deep between teeth, gingivitis and gingival recession develop. Deeper penetration of food causes periodontal disease to progress to affect all four periodontal tissues, along with proliferation of secondary bacterial infection with multiple species of bacteria that are also found in the normal equine oral cavity. Current molecular bacteriologic techniques help practitioners and scientists better understand this large pool of organisms that cannot be conventionally cultured.[29] Periodontal disease is the primary cause of tooth loss in mammals and is the most common reason for extraction of equine cheek teeth.

Management of periodontal disease involves treating both the cause and the effect of the problem. Diastema with feed trapped in the gingival margin often responds to thorough cleaning with dental picks, irrigation, or both. Reduction of any associated abnormal wear patterns is also indicated. In more refractory cases, it may be necessary to open or widen the diastema with a special burr or a right-angle grinder. This procedure may allow horses' masticatory actions to more easily channel food in and out of the gap, thus preventing or reducing entrapment of feed or stagnations and decay. This procedure is not without risk of pulp exposure and should be performed only by a professional with proper equipment and training.[30]

Some practitioners have had positive results using high-pressure irrigation to clean out periodontal pockets, followed by packing the area with a perioceutic agent such as doxycycline gel or a powdered antibiotic. This technique packs a high concentration of antibiotic in contact with the infected and inflamed tissues and acts as a temporary barrier to recontamination. This form of therapy may need to be repeated on a regular basis (every 4 to 6 months) in order to achieve long-term positive results. Severe periodontal disease that has resulted in bone loss and tooth mobility responds positively only to extraction of the involved teeth.

Dental caries is the macroscopic destruction of calcified dental tissues as a result of pH changes. These changes usually result when microorganisms within the oral cavity metabolize dietary carbohydrates to produce acids, which dissolve the mineral components of teeth. Because the mineral content of cementum (65% inorganic material) is lower than that of enamel (96 to 98% inorganic material), the critical pH required for the demineralization process is higher (less acidic) than that for enamel; a pH of 5.5 is required for enamel, 6.2 for dentine, and 6.7 for cementum. Caries in horses can affect the exposed

VetBooks.ir

crown or infundibulum of the hypsodont teeth, the softer cementum being more commonly involved. Peripheral caries involving the cementum around the erupted tooth crown is poorly understood. This condition usually involves the distal cheek teeth and can progress to involve all three dental tissues. The prevalence is higher in particular regions of the world, and feeding on hay high in water-soluble carbohydrates, feeding on silage with a low pH, and drinking water with a low pH were found to be contributing factors. Equine peripheral caries does appear to be a reversible condition if the etiological agent is removed.[31]

Caries can also involve the infundibular portion of the incisor and maxillary cheek teeth. All infundibulae of incisor and cheek teeth show some evidence of cemental decay in the cup or open portion.[9,32] As the tooth wears, the portion of the infundibulum that is more apical fills with cementum (except for the small central vascular channel) and becomes exposed at the occlusal surface (referred to as the *spot* in the incisor teeth). Feed and other products of mastication can be compressed into a ghost of a vascular canal, and some degree of decay is always present. The infundibulum contains dead cementum and is lined with a layer of enamel. Therefore this decay does not usually lead to an inflammatory response or dental infection, and such superficial decay is innocuous in most cases. True dental disease secondary to infundibular decay can occur only if the protective enamel layer is penetrated. Developmental malformations of the infundibulum may weaken this enamel and predispose affected horses to dentine exposure and pulp disease. In upper cheek teeth with very large vascular channels or deformed infundibula, decay may weaken the tooth and predispose the tooth to excessive crown attrition or midsagittal crown fracture. A shallow infundibulum or senile attrition of the infundibulum can allow central occlusal excavation, which can lead to dental elongations on the opposite occlusal arcades (wave mouth). These abnormal wear patterns need to be reduced on a regular basis. To help strengthen the tooth and delay the progression of infundibular decay, some practitioners advocate cleaning out abnormally enlarged infundibular vascular channels and packing and sealing them with a dental composite material.[33] As advanced diagnostic methods such as CT become more readily available to equine practitioners, these abnormal-appearing infundibula can be better evaluated and treated.

Disease of the dental pulp is referred to as *endodontic disease* and occurs primarily in horses between the ages of 4 and 10 years. This type of dental disease usually manifests as an infection and associated inflammatory changes at the apical region of the tooth. The clinical presentation depends on the structures adjacent to the apex of the affected tooth. Infections of the lower first four cheek teeth can manifest as ventral mandibular swellings with a draining tract. The last two lower cheek teeth are embedded in the portion of the mandible surrounded by the large muscles of mastication. These muscles are often enlarged or swollen, and ultrasound evaluation may reveal exudate accumulating between the mandible and muscle. The upper rostral two or three cheek teeth apices are closely associated with the facial bones and nasal passages. The caudal three or four upper cheek teeth are in the maxillary sinuses and can be associated with secondary sinusitis. Unilateral nasal discharge often occurs when the upper cheek teeth are affected. Because pulp disease compromises the tissue responsible for production of secondary dentine, the pulp horns and root canals on the affected teeth do not fill with secondary dentine as they should. In the later stages of pulp disease, the affected tooth usually shows some degree of pulp horn decay on the occlusal surface. This weakening and decay may predispose the affected tooth to crown fracture.[34,35] Medical therapy has been successful in the management of apical disease in the early stages. Chronic apical infections are usually treated by removal of the tooth and treatment of any associated bone or sinus disease.

Equine cheek teeth have classically been removed by several surgical and nonsurgical methods:

- Extraction via oral approach (with or without tooth sectioning)
- Repulsion via apical or retrograde approach
- Elevation via lateral buccotomy/alveolectomy approach

More recently, minimally invasive procedures involving the use of small radiographically guided pins for repulsion or an oral trocar approach to teeth through the cheek have been developed.[36,37]

A progressive dental condition involving the incisor, canines, and premolars of aged horses has been described as equine odontoclastic tooth resorption and hypercementosis (EOTRH).[38] This disease is characterized by internal and external resorption of dental structures and is sometimes associated with excessive production of irregular cementum on the exterior and interior of the apical or root portion of the tooth. EOTRH is a progressive condition, but the pathophysiologic processes are still under investigation.[39] Clinical signs include sensitivity in the mouth to any manipulation, head shyness, periodic inappetence and weight loss, and decreased use of incisors for grasping or grazing. Oral examination reveals varying degrees of gingival secession, calculus deposition, and firm bulbous enlargement of the incisive bone over incisor reserve crowns. Radiographs are needed to confirm a diagnosis and evaluate the severity of disease. Radiographic changes can include various forms and depths of tooth resorption, cemental thickening, osteosclerosis, osteitis and tooth fracture. This condition can be a painful, progressively debilitating disease of aged horses. No medical or husbandry changes have been identified to slow or change the course of disease. Extraction of painful or fractured unstable teeth appears to be the best method of managing these cases.[40]

Traumatic injuries to facial and dental structures are more common in young horses. Bones that support to teeth are often involved in these injuries, and a good dental alignment in the repair of these fractures is often more important than good bone apposition. Jaw and facial fractures can also involve the deciduous teeth, the developing buds of the permanent teeth, or both. Damage to a deciduous tooth can lead to dental drift and crowding of the eruption pathway for the permanent tooth. Permanent tooth bud damage can result from direct trauma or oral contamination by the damaged deciduous tooth. Facial fractures often lead to bone growth disruption, which predisposes horses to dental malocclusions. Tooth avulsion, subluxation, and total luxation are also observed. Diseased teeth in the fracture line can lead to dental or bone sequestum, delayed union, malunion or nonunion, oronasal or orosinus fistula, and osteomyelitis. Teeth in the fracture site should be preserved in most cases to add to stability of the fracture repair. Problems associated with periodontal or endodontal disease may be observed soon after the fracture has stabilized or may not show up clinically until many years later.

Fractures of the mandible and maxilla involving the teeth can be repaired successfully, but the health of the dental structures must be maintained for good long-term results. Most of the jaw and facial fractures involving the dental bearing bones are best managed by the least invasive approach. Intraoral wiring, alone or combined with a U-bar or acrylic splint, work wells and supports the compression side of the fracture. External fixation with a pinless external fixator provides less stability but is noninvasive and can be combined with oral wiring. Open reduction and internal fixation should be reserved for cases with few other options in stabilizing the fracture. Pins and screws should not be placed in the teeth because this often results in severe pulp damage.[37]

VetBooks.ir

Salivary Glands and Ducts Saliva hydrates and lubricates the oral cavity, facilitates swallowing, prevents tooth demineralization, and regulates the oral flora.[41] Diseases of the salivary glands and ducts, including sialoadenitis, salivary calculi, salivary mucocele, trauma, and neoplasia, are uncommon in horses. During oral examination, the openings of the salivary ducts should be noted. The parotid salivary duct communicates with the oral cavity via a flaplike, dorsally directed papilla, opposite the upper third or fourth check tooth. The mandibular salivary duct opens into the mouth on the lateral aspect of the sublingual caruncle. The sublingual salivary ducts (approximately 30 in number) are small pores in the sublingual recess.

Slobbering or drooling may indicate excessive accumulation of saliva in the mouth (sialism, ptyalism, or dysphagia). Heavy metal toxicity, parasympathomimetic poisoning, cholinesterase-inhibiting insecticides (organophosphates or carbamates), neurologic disease, and stomatitis may cause ptyalism. Slaframine is a cholinergic agonist that can cause "slobbers" in horses consuming forages, mostly commonly clover, contaminated with the fungus *Rhizoctonia leguminicola*. Tests for the presence of slaframine (1-acetoxy-6-amino-octahydroindolizine) are not readily available. Dysphagia can be caused by esophageal obstruction (choke), oral foreign body, rabies, or other neurologic disease.

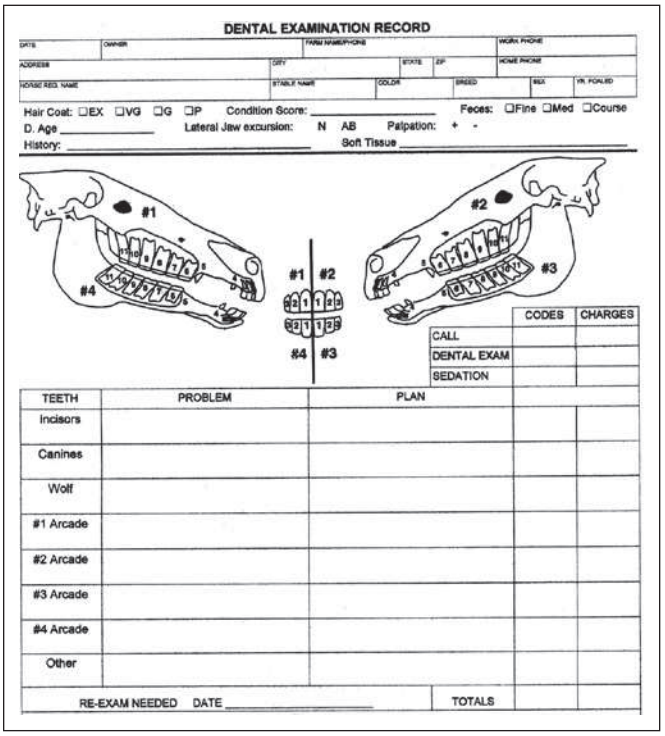
Sialoadenitis may be the result of salivary duct obstruction caused by accumulation of exudate or mucus, by an ingested foreign body, or by a sialolith. Sialoliths develop in the parotid duct and can cause duct obstruction and salivary retention, which can lead to glandular atrophy or acute sialoadenitis, swelling, and rupture. On palpation, sialoliths are usually hard, smooth, and painless enlargements over the course of the parotid duct on the lateral aspect of the jaw. The diagnosis of sialolith is straightforward and differs from that of trauma, tooth abscess, and facial tumor. Surgical removal, usually orally, and primary closure often yield good results.

Salivary mucocele is an accumulation of salivary secretions in a single or multiloculated cavity adjacent to a ruptured salivary duct. A ranula is a type of mucocele that is secondary to obstruction of the sublingual salivary duct. Treatment consists of creating a salivary fistula into the oral cavity or excising the mucocele and associated salivary gland.

Laceration or iatrogenic injury to the salivary ducts can lead to salivary cutaneous fistula. These injuries can be surgically repaired by reapposition of the severed duct and creation of an oral opening for the duct or by resection of the salivary gland. Oblation and sclerosis of the gland has been achieved by flushing of the duct with 1% formalin solution. Wounds involving the salivary glands can usually be handled by cleansing, débridement, and primary skin closure.

Benign mixed tumors, adenocarcinomas, and acinar cell tumors of the salivary glands have been reported in horses. Local invasion of a salivary gland by tumor originating in adjacent tissues and metastasis of melanomas to the parotid salivary gland in older gray horses are more common.

Equine Oral Tumors Equine oral tumors are rare, making up a very small percentage of the facial or mandibular swellings. These tumors can be divided into three basic types: odontogenic, osteogenic, and secondary.[42,43]



Odontogenic tumors are derived from remnants of dental epithelium. Five types have been recorded in the maxillas and mandibles of horses: ameloblastomas, ameloblastic odontomas, complex odontomas, compound odontomas, and cementomas. Because of their rarity, ill-defined biological behavior, and poorly defined radiographic features, diagnosis can be difficult. Histopathologic findings can be confusing because their appearance varies at different sampling sites and because of age-related changes in tumor appearance.

Primary bone tumors are rare in horses and if present, they are usually benign. More than 80% of equine osteosarcomas occur in the head region. As is the case with odontogenic tumors, disagreement remains with regard to histologic classification, terminology, and nature of tumor. In addition to gross and histologic examination, clinicians and pathologists often must find a correlation between the history and clinical, radiologic, and some biochemical findings to establish a diagnosis. Ossifying fibroma can occur in young horses and usually involves the rostral mandible.

Secondary tumors of the head include extensions of oropharyngeal squamous cell carcinoma, lymphosarcoma, papilloma, and melanoma. Squamous cell carcinoma is the most frequently reported oral tumor in horses. In general, these tumors are seen in older horses and have no gender or breed predilection. There are many treatment options and methods of controlling the progression of oral tumors. Radiotherapy, hyperthermia, chemotherapy, cryosurgery, immunotherapy, autogenous vaccines, photodynamic therapy, laser therapy, and surgical resection have been used with variable success.

Dental Examination Biannual dental examination of horses should be part of a routine health maintenance program. Improved eating efficiency and oral hygiene are the most important considerations from a medical standpoint. However, often owners are more enthusiastic about dental care because of its positive effects on a horse's sensitivity to the bit and athletic performance. Written documentation of dental examination findings is necessary to formulate a problem-oriented treatment plan and monitor age-related dental changes and progress after maintenance, treatment, or both (Fig. 32.42). A consistent routine followed by the examiner increases the efficacy and quality of the examination (Box 32.1).[44,45]

Several signs may be noted in the history or observed in a horse suffering from dental problems. A history of abnormal head carriage or head tossing when the horse is being ridden or eating, longer time taken to eat, halitosis, dysphagia, drooling or hypersalivation, dribbling feed (quidding), and eating hay before grain suggest that a dental problem exists. BOX 32.1

Recommended Timetable for Routine Dental Examinations and Common Corrective Procedures

Birth

1. Examine for congenital defects of lips or palate.
2. Assess tongue motion and strength.
3. Identify dental malocclusions.
4. Evaluate all body systems.

Recommended Procedures

1. Provide genetic and orthodontic consultation, and perform corrective surgery if necessary.
2. Look for other problem signs such as underdeveloped carpal or tarsal bones, ruptured extensor tendons, and hernias.

6 to 8 Months of Age

1. Check incisor and premolar occlusions.
2. Check to see that all incisors have erupted.
3. Check for sharp enamel points or hooks.
4. Check tongue and buccal mucosa for ulcers.

Recommended Procedures

1. Provide orthodontic consultation, and float teeth if necessary.

16 to 24 Months of Age

1. Check for expanded eruption of lower wolf teeth.
2. Check points and hooks on premolars.
3. Look for bit lesions.

Recommended Procedures

1. Float teeth and round off rostral corner of premolar 2.
2. Extract wolf teeth.

2 to 3 Years of Age

1. Look for upper and lower wolf teeth.
2. Check corners of mouth and interdental space for bite injuries.
3. Evaluate incisors and molars for eruption and premolars for points and loose or retained deciduous teeth.

Recommended Procedures

1. Float outside of upper and inside of lower cheek teeth.
2. Remove caps if present and ready.
3. Extract wolf teeth.

3 to 4 Years of Age

1. Check corners of mouth and interdental space for bit injuries.
2. Evaluate incisors for retained deciduous teeth or supernumerary teeth.
3. Evaluate molars for eruption and premolars for points and retained or loose deciduous teeth.
4. Evaluate size and shape of lower jaw and percuss sinuses.
5. Check for blind wolf teeth.

Recommended Procedures

1. Remove caps if present and loose.
2. Float teeth.
3. Remove wolf teeth.

4 to 5 Years of Age

1. Check all incisors for eruption and wear occlusion.
2. Check canine teeth for sharp edges or eruption delays.
3. Evaluate entire molar arcade for proper eruption and alignment (third cheek tooth).
4. Visually check upper rostral and lower caudal cheek teeth for hooks from malocclusion.
5. Digitally check for points on sharp edges of cheek teeth.
6. Percuss sinuses.

Recommended Procedures

1. Remove deciduous teeth if loose and ready.
2. Reduce hooks if present.
3. Float teeth.
4. Remove mucosa over canines if gingival cysts are present.

5 Years and Older

1. Examine mouth visually and digitally, especially noting hooks and uneven wear.
2. Evaluate canines for sharp edges and tartar.
3. Percuss sinuses.
4. Use olfactory senses to detect evidence of oral decay or gingivitis.
5. Observe incisors for even wear.
6. Evaluate lateral jaw excursion.

Recommended Procedures

1. Float teeth.
2. Remove hooks.
3. Level or shorten incisors if indicated.

of dental problems in performance horses include tail wringing, headshaking, lunging in or out on the track, and fighting the bit (refusing to collect the head). Chronic colic or choke can result from improper mastication of feed. Reluctance to drink cold water may be a result of dental pain.[19,20,46]

Good dental health is extremely important to the equine digestive system. Proper mechanical digestion of feed allows better carbohydrate absorption in the small intestine and improved fiber fermentation in the cecum and large colon. Improperly masticated roughage and concentrate leads to poor digestibility in the small and large intestine because of large feed particles with decreased surface area per mass. This decreased surface area does not allow proper enzyme degradation or bacterial fermentation. Findings of whole grain or stem particles longer than 5 mm during manure examination indicate improper mastication.

As a routine aspect of the dental examination, a horse's overall condition should be evaluated in view of its use and dietary intake. A body score should be assigned, as this is a more accurate way to subjectively record body condition[47] (Table 32.1). Objective assessment of body condition with the use of a scale, weight tape, or photographs is also beneficial and provides good data to assist in proper documentation and management.

The age of a horse should be considered during evaluation.[48] Different conditions need to be addressed for each stage of the horse's growth, development, and maturity. The use of the horse should be considered during evaluation because dental care for horses that wear a bit might differ from dental care for horses that do not wear a bit. Stable surroundings should be carefully observed for evidence of vices (such as cribbing) or poor eating habits (such as quidding or dribbling grain).

The physical examination begins with observation of the horse's body condition, attitude, and temperament. The horse should be approached from the left side of the shoulder. Body and head conformation should be considered during evaluation of the masticatory system. Horses with small heads have more of an angle in the curve of the mandibular ramus (i.e., curvature

TABLE 32.1

Principles to Guide Health Care Transformation in Canada

Condition	Neck	Withers	Shoulder	Ribs	Loin	Tailhead
1. Poor	Bone structure easily noticeable	Bone structure easily noticeable	Bone structure easily noticeable	Ribs protruding prominently	Spinous processes projecting prominently	Tailhead, pinbones, and hook bones projecting prominently
2. Very thin	Bone structure faintly discernible	Bone structure faintly discernible	Bone structure faintly discernible	Ribs prominent	Slight fat covering over base of spinous processes Transverse processes of lumbar vertebrae feel rounded Spinous processes are prominent	Tailhead prominent
3. Thin	Bone structure accentuated	Bone structure accentuated	Bone structure accentuated	Slight fat cover over ribs Ribs easily discernible	Fat buildup halfway on spinous processes, but easily discernible Traverse processes cannot be palpated	Tailhead prominent, but individual vertebrae cannot be identified visually Hook bones appear rounded but are still easily discernible Pin bones not distinguishable
4. Moderately thin	Neck not obviously thin	Withers not obviously thin	Shoulder not obviously thin	Outline of ribs faintly discernible	Negative crease (peaked appearance) along back	Prominence depends on conformation Fat can be felt; hook bones not discernible
5. Moderate (ideal weight)	Neck blends smoothly into body	Withers rounded over spinous processes	Shoulder blends smoothly into body	Ribs cannot be visually distinguished but can be easily palpated	Back is level	Fat around tailhead beginning to feel soft
6. Moderately fleshy	Fat beginning to be deposited	Fat beginning to be deposited	Fat beginning to be deposited	Fat over ribs feels spongy	May have a slight positive crease ?(a groove) down back	Fat around tailhead feels soft
7. Fleshy	Fat deposited along neck	Fat deposited along withers	Fat deposited behind shoulder	Individual ribs can be felt with pressure, but noticeable fat filling between ribs	Positive crease may be present down the back	Fat around tailhead is soft
8. Fat	Noticeable thickening of neck	Area along withers filled with fat	Area behind shoulder filled in flush with body	Difficult to feel ribs	Positive crease down the back	Fat around tailhead very soft
9. Extremely fat	Bulging fat	Bulging fat	Bulging fat	Patchy fat appearing over ribs	Obvious crease down the back	Bulging fat around tailhead

of Spee) and are predisposed to dental crowding and ramps on the lower dental arcades. The head is observed from both sides and the front, and any asymmetries, protuberances, or swellings should be noted. The tongue is checked for proper movement, abnormal swellings, or signs of trauma or injury; the horse's ability to swallow is checked as well. Lacrimation should be noted, as well as any nasal discharge. Neurologic evaluation should be considered if any cranial nerve deficits are detected. Finally, the examiner assesses the head by palpating the mandibular rami, masticatory muscles, temporomandibular joints, and submandibular lymph nodes to detect enlargements or asymmetry.

VetBooks.ir

The frontal and maxillary sinuses should be percussed with the horse's mouth open. The width between the mandibular ramus should be noted because this is correlated with the room in the mouth for the bit. The sides of the head lateral to the upper dental arcade should be compressed from the orbit, moving forward to the first cheek tooth at the level of the nasal notch; any protuberances, depressions, asymmetry, or evidence of pain should be noted.

The commissures of the lip should be observed and palpated for signs of trauma from sharp teeth or improperly fitting bits. A loose-fitting halter is necessary to properly evaluate the mouth and oral cavity. If the horse is fractious or resists examination, a sedative should be administered before the oral portion of the examination. Sedation should be induced after a medical assessment of the animal (i.e., consideration of temperament, breed, age, body condition, mucous membranes appearance, central reaction time, heart rate and rhythm, and rectal temperature).

The mouth should be rinsed thoroughly with clean water. Impacted or trapped feed in the mouth should be removed manually or with the use of a dental pick and irrigation. Many horses with sharp buccal points on the upper dental arcade resist the full-mouth speculum. Floating the upper arcades before applying the speculum may decrease a horse's resistance. With a full-mouth speculum in place and the head properly restrained, a detailed visual and tactile oral examination can be carried out. A bright light source is necessary to illuminate the entire oral cavity for complete visual inspection. An examiner should manually inspect all hard and soft tissue in the oral cavity. Use of dental mirror, occlusal hook pick, and calibrated periodontal probe is often necessary to see and probe the occlusal surfaces and pockets between the cheek teeth. An oral endoscopic camera can aid in the completeness of the oral examination.[49]

Dental Imaging Diagnostic radiology is a valuable aid in the diagnosis and management of equine dental disease. Because of the excellent contrast among air, bone, soft tissue, and tooth substance, the head is an excellent area for radiologic evaluation. Good-quality films can be obtained with portable x-ray machines and rare-earth intensifying screens without a grid. Digital and computed radiology have improved radiographic image quality and allow for high-quality images to be shared electronically for consultation with colleagues.

Indications for radiographic examination of the head include a suspicion of dental infection, maleruption, diastema, or oral pain of unknown origin. Radiographs should be obtained before, during, and after dental extraction. Any abnormal dental finding, facial swelling, deformity, neoplasm, trauma, or fracture may warrant radiography to aid in diagnosis and management.

Radiographs can be taken in a standing, sedated horse. The technique for acquiring excellent images in the field has been reviewed.[50] The website of the American Veterinary Dental College also has a good example set of dental radiographs that can be viewed for reference (AVDC.com). The head and radiographic cassette can be placed on a stand to decrease motion distortion. A lateral view centered over the rostral edge of the facial crest demonstrates fluid lines, if present, in the sinuses. The lateral view superimposes the dental arcades and should not be relied on to diagnose diseases involving the dental reserve crown and roots. Lesion-oriented oblique films demonstrating the root or apical portion of the upper or lower cheek teeth are helpful in diagnosis of periapical disease. Open-mouth oblique films are beneficial in evaluating the exposed crown of the dental arcades. Special 4-inch × 8-inch (10 cm × 30 cm) flexible dental cassettes can be used to obtain intraoral radiographs of the maxillary dental arcades. Dorsoventral views centered over the tooth in question or area of concern can demonstrate periodontal disease on the buccal aspect of the upper cheek teeth, fractured teeth, or large area of infundibular decay. Intraoral occlusal films are useful in demonstrating incisor lesions or fractures rostral to the bars of the mouth. Other imaging techniques, such as ultrasonography, nuclear scintigraphy, CT, and MRI are useful in the diagnosis of many oral and dental diseases.[51,52]

Treatment A plan for treatment should be based on the results of history, clinical findings, oral examination, and imaging before any dental work is begun. This problem-oriented approach ensures that the owner, the trainer, or both are informed of any abnormalities and are given a plan for treatment, as well as an estimate of the cost, before any corrective procedure is taken.

Therapy must be planned to ensure that all equipment is present to complete the prescribed task. The horse should be properly restrained and adequate help should be present to assist in performing and completing the corrective or surgical procedures. A dental record form should be used to document examination findings, treatment plan, and procedures performed (see Fig. 32.42).

Routine Dental Maintenance

FLOATING (ODONTOPLASTY OF ENAMEL POINTS AND DENTAL CROWN ELONGATIONS). Dental floating is an age-old and routine method of correcting the abnormal wear patterns associated with equine dental eruption and occlusal wear. Floating is also a procedure that allows the sculpting of the teeth to accommodate the bit. The main purpose of molar floating (leveling) is to remove points or sharp edges from the buccal aspect of the upper and lingual aspect of the lower molar arcades. Floating may also entail removing minor hooks or ramps from the rostral or caudal aspect of the arcades or leveling minor elevations on the occlusal surface of the arcades.

Proper equipment is necessary to reach all aspects of the cheek teeth molar surfaces completely, regardless of horse size. Smaller instruments are often needed to access the oral cavity of a miniature horse or pony. Longer, heavier instruments are often used to work in the mouths of large, Warmblood, or draft horse breeds. Sharp float blades made of carbide chips or tungsten carbide planning blades make the work of floating more efficient and less strenuous than in the past. The outward curve of the upper arcade makes the central buccal area involving premolar 3 (PM3) through molar 2 (M2) the easiest to reach with the float. For the area around PM2 and M3, an offset or angled head on the rasps is needed to reach all extremities. In most cases the lower arcade can be floated to remove the lingual enamel points with a flat, long-handled rasp. To correct rostral and caudal hooks, specialized tools such as carbide planing blades or power burrs may be required. The use of all dental equipment requires special training and skill to prevent iatrogenic injury to the horse's mouth.

Use of a full-mouth speculum aids in the oral examination and floating procedures, ensuring that the horse's mouth is kept in an open, safe (for the examiner as well as the animal) position for floating. In horses whose back teeth are slightly ramped back because of a greater curvature of Spee, a mouth speculum and a slightly curved or swivel-head float may be necessary to reach the table of the last molar.

In horses wearing bits, the rounding of the first upper and lower cheek teeth and lowering of the buccal cusps from upper PM2 and PM3 is referred to as a "bit seat" and usually requires an offset float or an S-shaped rasp. In theory, a bit seat is fashioned to prevent the soft tissue of the mouth from pressing against sharp points on the first premolars. To prevent pulp cavity exposure, care should be taken not to "overfloat" the occlusal surface of a tooth when bit seats are formed or overgrowths are corrected because this could lead to a direct pulp horn exposure.[5] Routine floating and other corrective

measures in the mouth may require the added physical restraint of a dental halter and mild chemical sedation.

WOLF TEETH. Wolf teeth are the first premolars to erupt and are present in 20 to 80% of horses. They are most often located in the upper arcade and seldom in the lower arcade. Horses that are worked with a bit in their mouth benefit from having the wolf teeth extracted. Some wolf teeth are naturally exfoliated at approximately 3 years of age when the first cheek teeth (or 06 caps) are shed and the permanent tooth erupts. Although not all wolf teeth cause problems, a loose or sharp wolf tooth can be a distraction or even cause pain of such severity as to lead to bad bitting habits. In some instances, diagnosis of wolf tooth problems is difficult and confusing. Sometimes they do not erupt in a normal downward path, penetrating the gum; rather, they may migrate rostrally under the gum and causing a subgingival enlargement, which in turn, is irritating to affected horses. Such unerupted first premolars have been referred to as "blind" wolf teeth and should be removed. Most wolf teeth are easily elevated with the horse sedated or after a small volume of local anesthetic is instilled around the tooth.

CANINE TEETH. Canine teeth are present in most male horses older than 4 years of age. Because of their unopposed position in the bars of the mouth, they are unlikely to cause problems. Some mares have small or rudimentary canines that do not seem to cause a problem but can become loose or accumulate tartar and must be removed. Long or sharp canines in a stallion or gelding can interfere with bitting, be a nuisance or a danger to the groomer/handler, or become an area of tartar accumulation. Erupting canine teeth in 4- to 6-year-old horses may cause an operculum to form and lead to subgingival pain and bit irritation, which may manifest as headshaking or other bad habits. The thin layer of tender mucosa should be removed over the canine if the gingival operculum is present. Severe calculus accumulation can be present on the lower canines, which predisposes horses to periodontal disease. Scaling calculus and frequent brushing of lower canines can control this problem in most horses.

The canine roots are long and curved, and thus this tooth is extremely difficult to extract in the male. If the canine becomes injured, infected, or involved in painful odontoclastic tooth resorption, surgical removal through a bone flap is indicated.[53]

DENTAL CAPS. As the developing permanent tooth (incisor or premolar) pushes toward the surface, it presses on the roots of the worn-down deciduous tooth, gradually cutting off that tooth's nutrition. The deciduous tooth becomes loose, its blood supply diminishes, the tooth dies, and it is displaced occlusally. The osseous alveolar wall adjusts to these changes by bone production and resorption, thereby providing a new socket for the embedded portion of the newly formed permanent tooth. The remaining cap portion of the deciduous tooth has up to four "legs" (root slivers) that cover the crown of the permanent tooth. If these slivers are broken off and remain subgingivally after the cap has been shed, gingivitis and periodontal disease often result.

The eruption pattern of permanent molarized dentition follows a sequence that predisposes to entrapment of deciduous PM3 and PM4.[54] Delayed shedding of deciduous premolars can predispose horses to gingivitis, periodontal irritation, or apical infection. Retained, split, or displaced deciduous premolars can be distracting in the training process of a young horse and may be a factor in dorsal displacement of the soft palate.

Retained caps can cause displacement or delayed eruption of permanent teeth. Clinically, they manifest as bony enlargements on the ventral mandibular ramus or on the maxilla, rostral to the facial crest. Often, such swellings are benign. However, they can become diseased if eruption is severely inhibited or bloodborne bacteria inhabit the inflamed dental pulp, which leads to anachoretic pulpitis and bony swelling with a draining tract. Caps should be evaluated visually as well as by manual palpation. A crease or indentation can be felt just above the gum line at the juncture of the separating deciduous and permanent tooth. Radiographs may be necessary to diagnose retained deciduous premolars.

Disorders of the Esophagus

Samuel L. Jones • Anthony T. Blikslager

Anatomic and Physiologic Considerations The most cranial aspect of the esophagus is located on the median plane immediately dorsal to the trachea. However, at approximately the midcervical region (C4 to C5), the esophagus typically shifts to the left of the trachea and lies just deep to the external jugular vein.[1,2] It is here that intraluminal obstructions or the tip of a stomach tube may be visualized, and this is the region where trauma can readily result in esophageal perforation. When a stomach tube is passed, it must be palpated to ensure that it is in the esophagus because jugular pulses can be confused with the appearance of the tip of the tube. In addition to its proximity to the external jugular vein, the esophagus is also adjacent to the vagosympathetic trunk and the common carotid artery.[1] The esophagus is innervated by branches of the vagosympathetic trunk, and blood is supplied to the cervical portion of the esophagus by branches of the carotid arteries. The thoracic portion of the esophagus—which lies ventral to the trachea until it reaches the tracheal bifurcation, where it resumes a dorsal position—receives its blood supply from the bronchoesophageal artery. Venous drainage is via the external jugular veins in the cervical portion of the esophagus, and the esophageal vein in the thoracic portion of the esophagus.

The muscular wall of the esophagus increases in thickness as the esophagus courses distally, whereas the lumen shrinks.[1] The esophagus is not covered by a serosa except for a very short segment that traverses the abdominal cavity between the diaphragm and the stomach.[2] Instead, the outer wall of the esophagus is composed of adventitia that is loosely attached to surrounding tissues. This loose connection allows movement of the esophagus during swallowing and during movement of the neck. The cranial two thirds of the esophageal wall consists of skeletal muscle, whereas the distal third of the esophageal wall is composed of smooth muscle. Although the muscular layers, like those in the remainder of the gastrointestinal tract, are composed of an outer and an inner layer, the skeletal muscle layers are oriented obliquely to one another.[1] This, and an abundant submucosa, enables extensive dilation of the esophagus as a bolus of food moves toward the stomach. In addition, the velocity of esophageal contraction is faster in the skeletal muscle segment of the esophagus than in the distal smooth muscle segment.[3] The muscle layers become oriented in more of an outer longitudinal and inner circular configuration in the caudal portion of the esophagus.[1] In the resting collapsed state, redundant esophageal mucosa and submucosa become oriented in longitudinal folds. The mucosa is composed of stratified squamous epithelium that is continuous with the stratified epithelium of the cardiac portion of the stomach.[1]

The cranial portion of the esophageal sphincter is formed by the cricopharyngeus muscle and maintains a resting intraesophageal pressure of approximately 85 mm Hg and a postdeglutition pressure as high as 200 mm Hg. Although the caudal portion of the esophageal sphincter is anatomically indistinct, resting intraesophageal pressure in this region is maintained at approximately 13 mm Hg, and postdeglutition pressure in the caudal portion of the esophagus may be as high as 100 mm Hg. The pressure in the caudal portion of the

esophagus is maintained at approximately 10 mm Hg higher than the intraluminal pressure of the stomach.[3,4] Although the higher pressure in the distal esophagus has been implicated as the cause of the inability of most horses to vomit and for gastric rupture, other factors such as a poorly developed vomiting reflex may be more important.[5]

Diagnostic Considerations Esophageal disease should be part of the differential diagnosis in any horse that demonstrates excessive salivation. Such signs also indicate the need to assess hydration, electrolyte levels, and acid-base status. In a study in which horses had continual loss of saliva via an experimentally placed esophagotomy, abnormalities included hypochloremia, hyponatremia, and hypokalemia.[6] This results from the relatively high levels of these electrolytes in saliva. Furthermore, because horses depend on dietary intake of potassium, hypokalemia would be exacerbated in a horse that was also unable to eat because of esophageal obstruction. Loss of salivary fluid and bicarbonate also results in dehydration and metabolic acidosis. However, metabolic alkalosis subsequently occurs, presumably as a result of renal compensation for loss of electrolytes, particularly chloride.[6]

Further examination of horses with esophageal disease may reveal evidence of swelling or emphysema in the region of the cranial or cervical portion of the esophagus that should prompt a thorough oral examination and further diagnostic studies such as radiography and endoscopy to define the nature of any esophageal abnormalities. If the esophagus has been perforated or ruptured, subcutaneous emphysema is usually evident. The lungs should be carefully auscultated for evidence of aspiration pneumonia. Radiographs of the chest are required for a full pulmonary assessment.

Radiographs of the esophagus should initially include plain films that may reveal evidence of an obstruction or areas of gas opacity within facial planes indicative of esophageal perforation.[7] However, facial and subcutaneous emphysema must be differentiated from other causes, including tracheal perforation.[5] The esophagus is often distended with gas cranial to an obstruction up to the cranial portion of the esophageal sphincter. Plain radiographs may be diagnostic, but contrast radiographs are frequently necessary to fully define the nature of esophageal abnormalities.[7] Administration of barium paste or liquid helps reveal linear opacifications as a result of the linear mucosal folds and may help outline intraluminal obstructions or strictures (Fig. 32.43).[7] A double-contrast study is a useful radiographic technique for defining esophageal wall abnormalities, particularly postobstruction mucosal ulceration. For this study, a cuffed nasogastric tube is placed in the cranial portion of the esophagus, and 300 to 500 mL of liquid barium is injected, followed by a similar volume of air. Care should be taken in evaluation of such radiographs because swallowing can create the false impression that there is a stricture.[8] The incidence of swallowing can be decreased by administration of xylazine or detomidine. Liquid barium is preferable if swallowing function is compromised because it is less harmful to pulmonary tissues than is paste, and water-soluble iodinated contrast material is particularly damaging to the lung because of its hypertonicity.[5] However, if an esophageal perforation is suspected, water-soluble contrast material is preferable.[5]

FIG. 32.43 Barium contrast medium–enhanced esophagogram outlining esophageal luminal structure. *(Courtesy Dr. K.E. Sullins.)*

Ultrasonographic examination of the cervical portion of the esophagus is often helpful to identify the exact location of obstructions and to determine whether abnormalities of the esophagus are present. Perforations can be identified by periesophageal gas patterns. Whereas intraluminal contents often cannot be examined with ultrasonography because of the presence of air, abnormalities of the mucosal or muscularis layers can be identified. Intramural or extramural causes of esophageal problems (particularly obstructions) may be discovered through ultrasonography. The location and characteristics of masses (e.g., neoplasia, granulomas, abscesses) may be evaluated more readily with ultrasonography than with radiography or endoscopy. The thoracic portion of the esophagus, however, cannot be evaluated with ultrasonography.

The esophagus should be evaluated endoscopically as part of a complete evaluation of esophageal injuries and abnormalities. After the patient is sedated, the endoscope should be passed all the way into the stomach before the esophagus is examined; the esophagus is viewed more easily as the endoscope is withdrawn.[7] Inflation of the esophagus must also be performed intermittently because the wall of the esophagus periodically collapses around the end of the endoscope. The longitudinal folds of the esophageal mucosa are readily appreciated and can be flattened out as the esophagus is distended to view the entire circumference of the esophagus more clearly. Swallowing may create artifacts such as the appearance of strictures, so the esophagus should be carefully reinflated after each swallow to carefully evaluate such findings.[8]

The mediastinum, including the thoracic component of the esophagus, may be evaluated via thoracoscopy. Although this procedure caused pneumothorax in one case, a 15-minute period of evaluation allowed observation of numerous structures, including the esophagus.[9] Portals placed at the eighth, tenth, and twelfth intercostal spaces were useful for completion of this procedure and could provide additional information aside from radiographic and endoscopic evaluation of the thoracic portion of the esophagus.

Esophageal Obstruction Esophageal obstruction, either primary (simple choke) or secondary to other disease processes, is the most common esophageal disorder in horses. Although primary obstructions may be caused by foreign bodies (including corncobs, potatoes, apples, carrots, medicinal boluses, stones, riding crops, or wood fragments), primary obstructions are most often caused by roughage, particularly leafy alfalfa hay, coarse grass hay, bedding, and even grass.[10-20] Prior esophageal trauma or poor mastication caused by dental abnormalities may predispose horses to esophageal impaction. Obstructions from roughage may be precipitated by wolfing or gulping food, particularly if an affected horse is exhausted or mildly dehydrated (such as after a long ride) or weakened from chronic debilitation. Secondary impactions are caused by intramural or extramural abnormalities that mechanically impede food passage. Examples of intramural obstructions include tumors (squamous cell carcinomas), strictures, diverticula, cysts, and vascular ring anomalies.[21-27] Mediastinal or

VetBooks.ir

cervical masses (tumors or abscesses) may cause extramural obstructions.

Regardless of whether obstructions are classified as primary or secondary, the associated clinical signs are similar and are rarely specific. Many horses with esophageal obstruction are anxious and stand with the neck extended. Gagging or retching may be noted, particularly with acute proximal obstructions. Bilateral frothy nasal discharge containing saliva and food material, coughing, odynophagia, ptyalism, and dysphagia are usually the primary clinical signs, the severity of which varies with the degree and location of the obstruction. Distention of the cervical portion of the esophagus may be evident at the site of obstruction. Other clinical signs may be observed related to complications stemming from the obstruction, such as dehydration, weight loss, aspiration pneumonia, or esophageal rupture.

Thorough physical examination, including a complete oral examination, must be performed to rule out other causes of hypersalivation, dysphagia, and nasal discharge. Palpation of the jugular furrow may reveal a mass associated with the impaction. In most horses the esophagus is in the left jugular furrow, but it is in the right furrow in some animals. Crepitus or cellulitis may be evident, which suggests rupture of the esophagus. Auscultation of the lungs can determine whether pneumonia or pleural fluid is present because of aspiration or intrathoracic esophageal rupture. Passage of a nasogastric tube is a good way to determine whether and where an obstruction is present, but it provides little information about the nature of the obstruction or the condition of the esophagus.

Ultrasonography of the cervical region is extremely useful not only to confirm the presence of an impaction in the cervical portion of the esophagus but also to provide critical information about the location and extent of the impaction and esophageal wall thickness and integrity. Ultrasonography may also provide information about the cause of the obstruction. Radiography, particularly air or barium contrast studies, are useful for assessing an esophageal impaction but may be more useful for evaluating the esophagus after, rather than before, relief of the impaction to demonstrate stricture, dilation, diverticula, esophageal rupture, or masses.[28,29] Care should be taken in interpretion of radiographic studies in sedated horses, particularly after passage of a nasogastric tube or other esophageal manipulations that may contribute to esophageal dilation.[30] Impacted food material can be detected in the esophagus as a typical granular pattern, and gas is often observed to accumulate proximal to the obstruction. Foreign bodies may be identified by contrast radiographic studies.

Definitive evaluation of esophageal obstructions often necessitates endoscopic examination. Most cases of esophageal obstruction occur at sites of natural narrowing of the esophageal lumen, such as the cervical portion of the esophagus, the thoracic inlet, the base of the heart, or the terminal esophagus; therefore an endoscope longer than 1 m may be required. The endoscope can be used to localize and investigate the nature of the impaction if a foreign body is suspected. Foreign bodies may be retrievable via transendoscopic tethering.[18] Critical diagnostic and prognostic information is obtained after resolution of the impaction to determine whether mucosal ulceration, esophageal rupture, masses, or strictures are present.

The primary goal of treatment for esophageal impaction is to relieve the obstruction. Parenteral administration of acepromazine (0.05 mg/kg IV), xylazine (0.25 to 0.5 mg/kg IV) or detomidine (0.01 to 0.02 mg/kg IV), oxytocin (0.11 to 0.22 IU/kg IM), esophageal instillation of lidocaine (30 to 60 mL of 1% lidocaine), or a combination of these may help reduce esophageal spasms resulting from pain or increased esophageal tone.[15,30-32] However, conclusive studies have revealed that detomidine, acepromazine, or a combination of xylazine and butorphanol had the greatest effect on esophageal motility when evaluated by a monomer in conscious horses.[33] In vitro studies revealed a relaxant effect of oxytocin on esophageal muscle, which suggests it may be useful for relief of esophageal obstruction.[34]

Resolution of an impaction may necessitate physical dispersal of the material. A nasogastric tube can be used to displace the impacted material in conjunction with external massage if the obstruction is in the cervical region. Often it is necessary to carefully flush the esophagus with water via an uncuffed or a cuffed nasogastric tube while the horse's head is lowered to aid in breaking up the impaction. Some clinicians advocate a dual-tube method whereby a tube is placed through each nasal passage into the esophagus for ingress and egress of the lavage fluid. Because of the risk of aspiration of water, food, or both, esophageal lavage is sometimes done with a cuffed nasotracheal tube while the horse is under general anesthesia.

In refractory cases, intravenous administration of isotonic fluid containing 0.9% NaCl and KCl (10 to 20 mEq/L) for 24 hours at a rate of 50 to 100 mL/kg/day, in conjunction with an esophageal relaxant such as oxytocin, may promote hydration and softening of the impaction. Moreover, this helps prevent or alleviate any electrolyte or acid-base imbalances resulting from salivary losses of chloride, sodium, and potassium. Refractory cases may necessitate esophagotomy to relieve the impaction. Restriction of access to food, water, and bedding material must be enforced until the obstruction is resolved and the esophagus has regained function.

Dilation proximal to the site of obstruction, mucosal injury from trauma, and esophagitis are sequelae to esophageal impaction that predispose patients to reobstruction (Color Plates 32.1 and 32.2). The rate of reobstruction may be as high as 37%. Depending on the duration of the obstruction and the degree of trauma or dilation, the risk of reobstruction is high for 24 to 48 hours or longer; therefore food should be withheld for at least 24 to 48 hours after resolution of the obstruction. After 48 to 72 hours or when the esophageal mucosa has recovered as assessed by endoscopy, soft food (moistened pellets and bran mashes) can be fed to the horse. The patient can be returned to a high-quality roughage diet over a period of 7 to 21 days, depending on the degree of esophageal damage induced by the impaction and the nature of any underlying disease. The prognosis for survival is good (78%), but some horses may require permanent dietary modification if persistent chronic obstruction is a problem.[17]

Complications of esophageal impaction include esophageal ulceration, stricture, perforation, aspiration pneumonia, megaesophagus, and metabolic alkalosis from prolonged loss of salivary chloride and sodium. Esophageal endoscopy, ultrasonography, or both should be performed immediately after the impaction is relieved to determine whether any complications of the impaction have developed or whether an inciting cause of the obstruction is present. Endoscopic evaluation is critical to determine the postobstruction treatment and follow-up. Reevaluation should be performed intermittently every 2 to 4 weeks after resolution of the impaction if esophageal dilation or mucosal injury is noted. Additional evaluation with radiography may be warranted to assess motility and transit times.

If the obstruction was present for 48 hours or longer, dehydration, hyponatremia, hypochloremia, and hypokalemia may occur and should be corrected with oral electrolyte solutions or intravenous administration of 0.9% NaCl and KCl (10 to 20 mEq/L). If aspiration is suspected, broad-spectrum antibiotics that are effective against Gram-positive and Gram-negative organisms, including metronidazole for anaerobes, should be administered. Sucralfate (20 mg/kg orally [PO] q6h) may hasten healing if esophageal ulceration is evident, but this is controversial. Some clinicians suggest that administration of an NSAID such as flunixin meglumine (1 mg/kg PO or IV q12h) or phenylbutazone (1.1 mg/kg PO or IV q12h) for 2 to

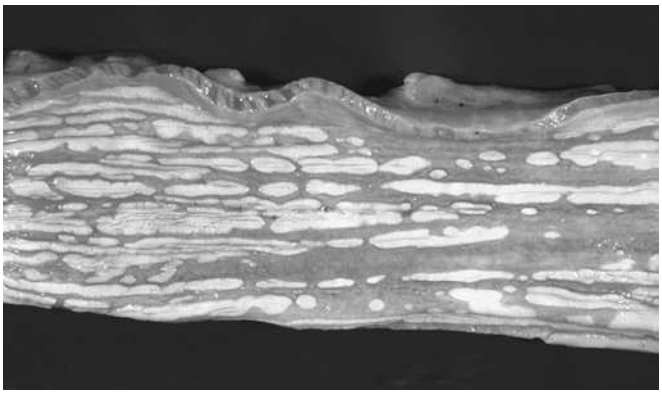

FIG. 32.44 Severe ulceration of the esophagus in a weanling foal that had severe duodenitis and gastric outflow obstruction. *(Courtesy Dr. M.J. Murray.)*

4 weeks after resolution of the impaction may limit the development of strictures.

■ ***Esophagitis*** Inflammation occurs during many conditions of the esophagus. *Esophagitis* refers to a clinical syndrome of esophageal inflammation, which may or may not be ulcerative. Causes of esophagitis in horses include trauma (foreign bodies, nasogastric tube), infection (mural abscesses), and chemical injury (acidic medicines, cantharidin).[35,36] An important category of esophagitis is reflux esophagitis, caused by reflux or delayed clearing of gastric contents into the distal esophagus and subsequent chemical injury to the mucosa (Fig. 32.44). As with ulceration of the squamous portion of the stomach in horses, a major cause of ulcerative esophagitis is epithelial damage resulting from exposure to acid, which is synergistically exacerbated by bile salts.[11,37] The major protective mechanisms of the esophageal mucosa include salivary and food material buffers, normal peristaltic motility, and the barrier formed by the gastroesophageal sphincter. Thus esophagitis may accompany gastric ulcer disease, motility disorders, increased gastric volume from gastric outflow obstructions, gastric paresis, intestinal ileus, or impaired function of the lower portion of the esophageal sphincter.

The clinical signs of esophagitis are nonspecific and similar to those of esophageal obstruction and gastric ulcer disease. In fact, esophagitis may occur concurrently with esophageal obstruction or gastric ulcer disease, so clinical signs may overlap extensively with those of these diseases. Gagging or discomfort when swallowing may be evident, and hypersalivation and bruxism are signs of esophageal pain. Horses with chronic esophagitis may have partial or complete anorexia to such a degree that they exhibit significant weight loss. Motility dysfunction secondary to esophagitis may cause recurrent esophageal impaction. Clinical signs of underlying disease that predisposes horses to esophagitis may predominate or mask the signs of esophagitis. Horses with gastrointestinal motility disorders such as anterior enteritis are at high risk for developing reflux esophagitis because of the presence of both gastric acid and bile salts in the fluid reflux. However, signs attributable to esophagitis secondary to ileus may not be noted because of the profound signs caused by the intestinal disorder. Foals with gastric outflow obstructions commonly have reflux esophagitis.

Diagnosis requires endoscopic examination of the esophagus. Diffuse, patchy, linear, or coalescing erosion or ulcerations may be noted. Significant edema or hyperemia may also be observed. It is important to determine whether underlying disease, such as infection, neoplasia, diverticula, or esophageal stricture is present. In addition, the stomach must be examined because reflux esophagitis is commonly accompanied by gastritis or gastric ulcer disease. If endoscopy is not available to detect esophageal ulceration, contrast radiography may be helpful for assessing esophageal motility and transit time.

The principles of therapy for reflux esophagitis include control of gastric acidity and correction of any underlying disorder that is contributing to gastroesophageal reflux. Thus treatment with histamine-2 (H_2) receptor antagonists such as ranitidine or proton pump antagonists such as omeprazole is important for resolution of the disease. Some clinicians advocate sucralfate administration to aid healing of esophageal ulcers. However, the efficiency with which sucralfate binds to ulcerated mucosa in the squamous epithelium of the gastrointestinal tract has been questioned because low pH is optimal for the sucralfate polymers to bind ulcerated tissues. It is not clear whether reflux esophagitis provides the right pH environment for binding.

Foals with reflux esophagitis secondary to delayed gastric outflow caused by gastroduodenal ulcer disease or gastric paresis may benefit from prokinetic drugs that act on the proximal gastrointestinal tract. Metoclopramide (0.02 to 0.1 mg/kg SC q4-12h) reduces gastroesophageal reflux by increasing tone in the lower portion of the esophageal sphincter and increasing gastric emptying and gastroduodenal coordination. Metoclopramide should be administered to horses with caution because they are prone to extrapyramidal neurologic side effects. Continuous-rate infusion of metoclopramide (0.04 mg/kg/h) is one way to reduce the risk or severity of neurologic side effects. The rate can be reduced if side effects appear. Cholinergic drugs such as bethanechol (0.025 to 0.035 mg/kg SC q4-24h or 0.035 to 0.045 mg/kg PO q6-8h) may improve gastric emptying and are effective for treating reflux esophagitis. For esophagitis from trauma or pressure injury after esophageal impaction, judicious use of NSAIDs may be warranted to reduce esophageal inflammation and pain.

Dietary modification may be necessary in patients with esophagitis, depending on the degree of ulceration or if motility is impaired. Horses with less severe esophagitis should be fed frequent small meals of moistened pellets and fresh grass. Severe esophagitis may necessitate withholding food and complete esophageal rest for several days. Although the prognosis for esophagitis is good in the absence of underlying disease, the risk of stricture formation is high if severe circumferential or coalescing ulcerations are present. Animals with esophagitis caused by severe trauma or infection also may be prone to stricture formation.

■ ***Motility Disorders of the Esophagus*** Esophageal hypomotility is the most common motility dysfunction of the equine esophagus and results in esophageal dilation or megaesophagus. Although megaesophagus in horses is most commonly acquired, there are reports of idiopathic megaesophagus in young horses that is probably congenital (Fig. 32.45 and Color Plate 32.3).[38-43] Congenital megaesophagus appears to be more common in Friesian horses than in other breeds and is associated in some cases with smooth muscle hyertrophuy in the distal esophagus.[39,40]

Acquired megaesophagus in adult horses is usually caused by either primary or secondary esophageal obstruction. Esophageal impactions of relatively short duration cause proximal dilation of the esophagus that is generally reversible. However, if the duration of the obstruction is long, the motility of the esophagus may be permanently impaired. Acquired megaesophagus in foals is often secondary esophagitis resulting from gastric outlet or duodenal obstruction. Other causes of acquired megaesophagus include extraesophageal obstruction by tumors or abscesses, pleuropneumonia, and vascular ring anomalies. In addition, acquired megaesophagus may result from neurologic,

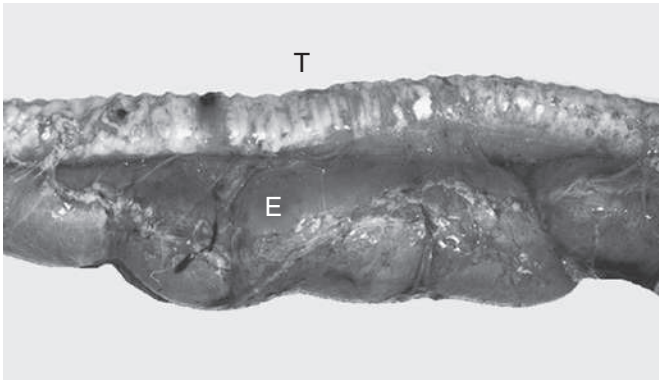

FIG. 32.45 Megaesophagus in a 10-month-old Paint Horse foal that had two duodenal strictures that appeared to have been present for several months. The trachea *(T)* lies dorsal to the dilated esophagus *(E)*. *(Courtesy Dr. M.J. Murray.)*

neuromuscular, or muscular disorders. Neurologic diseases that cause vagal neuropathy, such as equine protozoal myeloencephalitis, equine herpesvirus myeloencephalitis, and idiopathic vagal neuropathy, have been associated with megaesophagus in horses. Pleuropneumonia may accompany vagal neuropathy and thus result in megaesophagus. Megaesophagus is also an early sign of equine dysautonomia[44] and may be noted in patients with botulism. Myasthenia gravis is a well-known cause of megaesophagus in other species but has not been reported in horses. Also in other species, electrolyte disorders, cachexia, primary myopathies, myositis, and Addison disease may affect esophageal motility, but these have not been associated with megaesophagus in horses.

Esophageal inflammation, particularly reflux esophagitis, may affect motility and cause megaesophagus. However, because esophageal hypomotility may predispose to reflux esophagitis, it may be difficult to determine whether the esophagitis or the megaesophagus is the causative disorder (see Color Plate 32.3). Iatrogenic megaesophagus can be induced by the α_2-adrenergic agonist detomidine, but this is transient and reversible.[45] However, the use of this drug may complicate clinical evaluation of esophageal motility. Because esophageal hypomotility represents a functional obstruction, the clinical signs of esophageal hypomotility or megaesophagus are similar to those of esophageal obstruction. These clinical signs include ptyalism, dysphagia, and nasal discharge of saliva and food material. Dilation of the cervical portion of the esophagus may be evident externally. Weight loss is a common sign, and clinical signs attributable to an underlying disease may be evident.

Diagnosis of esophageal hypomotility requires transit studies. Transit time of a bolus from the cervical portion of the esophagus to the stomach can be measured by fluoroscopy or contrast radiography.[7,44] Other signs of esophageal hypomotility and megaesophagus include pooling of contrast material and an absence of peristaltic constrictions. Endoscopy may reveal a dilated esophagus and an absence of peristaltic waves. Evidence of underlying disease causing obstruction or esophageal dilation may be observed. The esophagus should be evaluated for evidence of esophagitis that is either causing esophageal motility dysfunction or is a result of impaired esophageal clearance of gastric fluid. Esophageal manometry may be useful for documenting abnormal postdeglutition contraction pressures, contraction time, and propagation times.[4,38] Other diagnostic tests such as a CBC and chemistry studies help identify an underlying cause. A careful neurologic evaluation should be performed. Signs of neurologic disease and abnormal cerebrospinal fluid analysis suggest an underlying neurologic disorder. Myopathy may be detected by electromyography.

Treatment of esophageal hypomotility or megaesophagus should be aimed at the underlying cause. Dietary modification should be aimed at improving esophageal transit of food. Slurries of pellets should be fed. In addition, it may be beneficial to feed from an elevated position to promote transit. In patients with reflux esophagitis associated with megaesophagus, metoclopramide or bethanechol may be beneficial to increase lower esophageal tone, promote gastric emptying, and reduce gastroesophageal reflux. The prognosis depends on the underlying cause and the degree of dilation. Although many cases of megaesophagus associated with reflux esophagitis respond well to treatment, many other forms of megaesophagus, including congenital megaesophagus, have a poor prognosis.

Congenital Disorders

Congenital disorders of the esophagus are rare. Reported congenital abnormalities include congenital stenosis,[46] persistent right aortic arch, congenital strictures, esophageal duplication cysts,[47,48] and megaesophagus.[39,40,49] In the one report on congenital stenosis, double-contrast radiography revealed concentric narrowing of the thoracic portion of the esophagus in the absence of any vascular abnormalities at the base of the heart. Successful treatment included having the foal stand with the forelimbs elevated off the ground after each feeding.

Persistent right aortic arch is a congenital anomaly in which the right fourth of the aortic arch becomes the definitive aorta instead of the left aortic arch, which results in constriction of the esophagus by the ligamentum arteriosum as it extends between the anomalous right aorta and the left pulmonary artery.[24] Clinical signs may include dysphagia, drooling of saliva, and distention of the cervical portion of the esophagus as a result of partial obstruction of the thoracic portion.[50] Endoscopic examination typically reveals dilation of the esophagus cranial to the obstruction with evidence of diffuse esophagitis. In addition, evaluation of the thorax usually reveals the presence of aspiration pneumonia. Successful surgical treatment of persistent right aortic arch has been reported in one foal.

Esophageal duplication cysts cause typical signs of esophageal obstruction, including salivation, dysphagia, and swelling of the cervical portion of the esophagus as they enlarge. Such signs can make them difficult to differentiate from simple obstruction (choke). However, an aspirate of the mass may aid in the diagnosis by revealing the presence of keratinized squamous cells.[51] Cysts may communicate with the lumen of the esophagus. Surgical treatments have included complete surgical resection and surgical marsupialization. The latter appears to be more successful and to result in fewer complications. Complications of surgical resection have included (1) laryngeal hemiplegia secondary to surgical trauma to the recurrent laryngeal nerve in the region of the esophagus and (2) esophageal fistula formation.

Esophageal Perforation

Perforation typically occurs in the cervical region in response to external trauma or rupture of an esophageal lesion such as an impacted diverticulum. The esophagus is particularly vulnerable to external trauma in the distal third of the neck because it is covered by only a thin layer of muscle at this location.[52] Iatrogenic perforation may occur in response to excessive force with a stomach tube against an obstruction or a compromised region of the esophagus. Esophageal perforations may be open or closed and tend to cause extensive necrosis of tissues surrounding the wound because of drainage of saliva and feed material within fascial planes (Fig. 32.46). This may lead to extensive cellulitis and endotoxemia. Closed perforations of the esophagus are particularly troublesome because wound discharge may migrate all the way to the mediastinum and pleural space via fascial planes and may cause abscessation (Fig. 32.47). In addition, extensive subcutaneous and fascial emphysema frequently develops and is usually evident on cervical radiographs.

VetBooks.ir

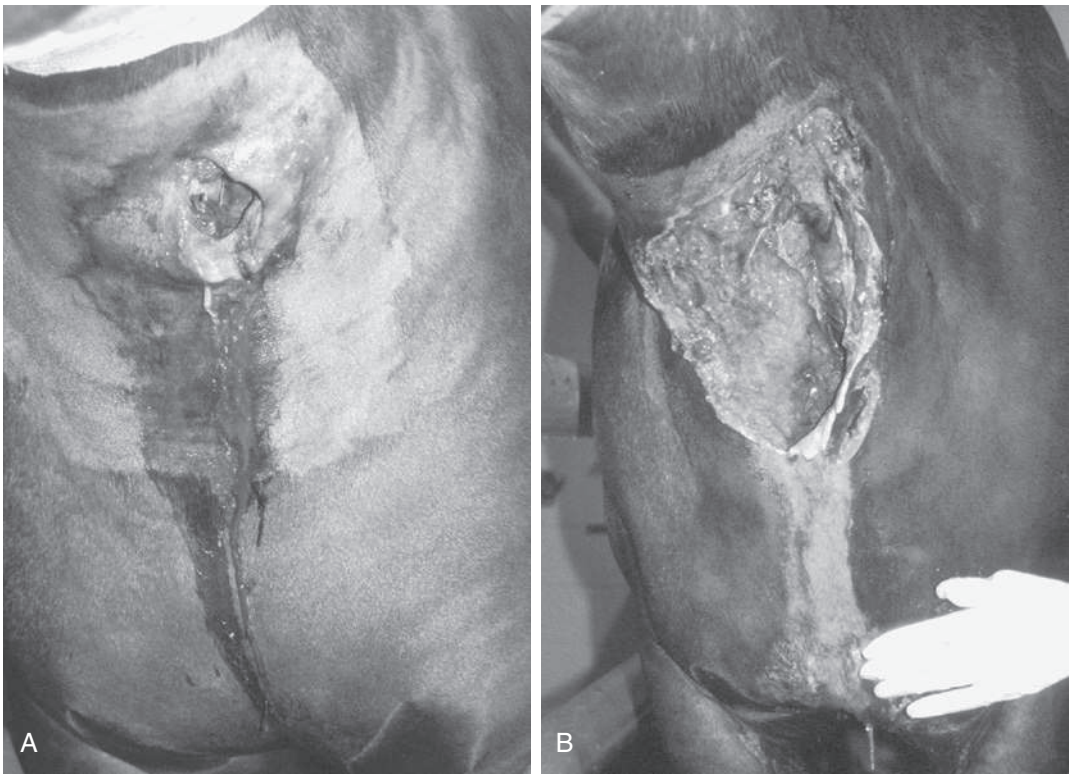

FIG. 32.46 Esophageal perforation in a horse. **A,** An open esophageal laceration was detected on presentation in the midcervical region. The wound was treated by lavage and débridement, and the horse was fed via a tube inserted into the esophagus through the wound. **B,** Approximately 14 days later, dissection of esophageal contents within surrounding fascial planes resulted in extensive sloughing of tissue.

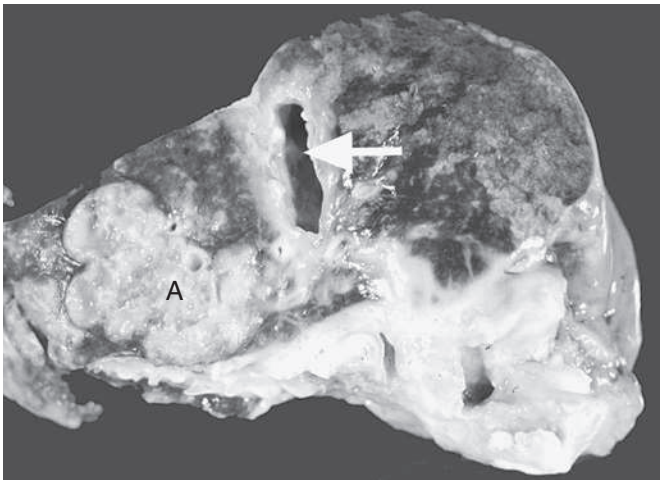

FIG. 32.47 Esophageal abscess *(A)* and cellulitis that developed secondary to an esophageal obstruction. The esophageal lumen is indicated by the *white arrow*. *(Courtesy Dr. M.J. Murray.)*

Treatment should include conversion of closed perforations to open perforations if possible,[53] extensive débridement and lavage of affected tissues, broad-spectrum antibiotics, tetanus prophylaxis, and esophageal rest. The latter may be achieved by placing a feeding tube into the esophagus via the wound. Alternatively, a small (12-French) nasogastric tube should be placed. For open perforations, once the wound has granulated and contracted to a small size, oral feeding may be attempted. Extensive loss of saliva via esophageal wounds may lead to hyponatremia and hypochloremia. In addition, transient metabolic acidosis occurs because of salivary bicarbonate loss, followed by progressive metabolic alkalosis. Although there are reports of esophageal wounds that healed well by second intention, it takes a prolonged period of time.[54] In addition, some perforations never completely heal and form permanent esophagocutaneous fistulas that may necessitate surgical correction. The development of esophageal strictures is not common because wounds are usually linear and not circumferential. However, traction diverticula may develop. Other complications of esophageal wounds include Horner syndrome and left laryngeal hemiplegia.

In a retrospective study on esophageal disorders, only 2 of 11 horses with esophageal perforations survived long term,[17] and in a report on esophageal trauma secondary to nasogastric intubation, 4 of 5 affected horses were euthanized.[55] The prognosis is therefore poor in horses with esophageal perforations, largely because of the extent of cellulitis, tissue necrosis, shock, and local wound complications.

Esophageal Stricture

Strictures most commonly occur as sequelae to esophageal obstructions that result in circumferential erosion or ulceration of the esophageal mucosa; however, they may result from oral administration of corrosive medicinal agents and trauma to the neck.[55] Congenital strictures have also been reported. Strictures that result from mucosal and submucosal trauma are termed *esophageal webs* or *rings*. Strictures may also originate in the muscular layers and adventitia of the esophagus (mural strictures) or in all of the layers of the esophagus (annular stenosis).[56] Horses with these lesions have a presentation similar to that of horses with simple obstructions because strictures result in partial obstruction and accumulation of feed material in the lumen. Esophageal webs or rings can be observed endoscopically, whereas confirming the presence of mural strictures or annular stenosis may require double-contrast esophagography.

FIG. 32.48 Attempted dilation of esophageal stricture with bougienage. In this case, a cuffed Silastic tube (Dow Corning, Midland, Mich.) was passed to the site of stricture under endoscopic guidance, and the cuff was then inflated to distend the site of stricture. *(Courtesy Dr. M.J. Murray.)*

In one study on esophageal stricture after simple obstruction, maximal reduction in esophageal lumen occurred within 30 days of esophageal obstruction. Although surgery has been employed to reduce such strictures, initial medical management is warranted because strictures may resolve with conservative therapy, and the esophagus continues to remodel for up to 60 days after ulceration. In one report, seven horses with esophageal obstruction-induced stricture were treated conservatively by being fed a slurry diet and with antiinflammatory and antimicrobial medications; five of seven were clinically normal within 60 days. One of the five successfully treated horses had a 10-cm area of circumferential ulceration, which suggests extensive mucosal injury may resolve without permanent stricture formation.

If strictures do not resolve within 60 days, other methods to increase esophageal diameter should be investigated. Bougienage has been used successfully in small animal patients and human beings and is increasingly used to dilate strictures in horses. The technique involves passage of a tubular dilatable instrument down the esophagus and stretching of the stricture. Some authors have suggested that this may be accomplished by passing a nasogastric tube with an inflatable cuff (Fig. 32.48).[57] However, the procedure has to be performed frequently to achieve any success and is often not well tolerated by horses. Alternatively, several surgical techniques have been used to resolve strictures, including resection and anastomosis,[58,59] temporary esophagostomy with fenestration of the stricture, esophagomyotomy for strictures of the muscularis layers and adventitia,[60,61] and patch grafting with local musculature.[62] However, such surgeries are fraught with complications, largely because of the propensity for stricture to recur in the traumatized esophagus. The esophagus lacks a serosal layer and does not rapidly form a fibrin seal, as does the remainder of the intestinal tract, and so anastomoses tend to leak. In addition, tension on the esophagus during swallowing and movement of the neck impairs healing of anastomoses.

■ ***Esophageal Diverticula*** There are two types of diverticula: traction (true) diverticula and pulsion (false) diverticula.

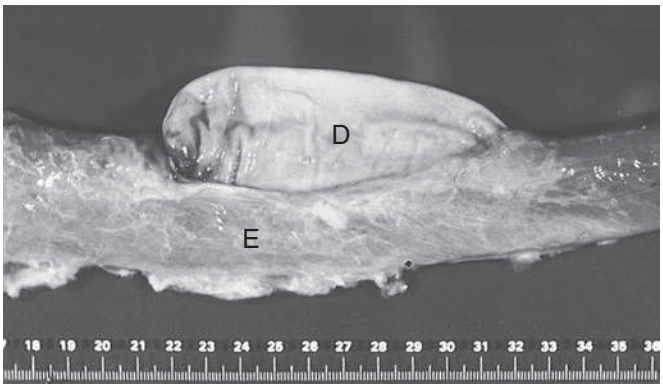

FIG. 32.49 Pulsion diverticulum *(D)* of the esophagus *(E)* in a horse that had intermittent episodes of esophageal obstruction. *(Courtesy Dr. M.J. Murray.)*

Traction diverticula result from wounding and subsequent contraction of periesophageal tissues, with resultant tenting of the wall of the esophagus. Pulsion diverticula arise from protrusion of esophageal mucosa through defects in the muscular wall of the esophagus and usually result from trauma or acute changes in intraluminal pressure (Fig. 32.49). A traction diverticulum appears as a dilation with a broad neck on contrast esophagography, whereas a pulsion diverticulum typically appears as a flask shape with a small neck on an esophagogram.[63] Whereas traction diverticula are usually asymptomatic and of little clinical significance, pulsion diverticula may fill with feed material, ultimately leading to esophageal obstruction.[64] However, a movable mass in the midcervical region may be noticed before onset of complete obstruction.[5] Pulsion diverticula may be surgically corrected by inversion or resection of prolapsed mucosa and closure of the defect in the wall of the esophagus.[26,63,64] Inversion of excessive mucosa may predispose horses to esophageal obstruction and should therefore be reserved for small diverticula.

■ ***Neoplasia*** Neoplasia of the esophagus is rare, but squamous cell carcinoma[65,66] and leiomyosarcoma[67] have reportedly affected the esophagus either as the primary site or in association with a lesion in the squamous portion of the stomach. The predominant clinical signs are weight loss, colic, and recurrent esophageal obstruction. The tumor is typically detected on esophagoscopy and radiography during an affected horse's life, but a definitive diagnosis may necessitate a biopsy during laparotomy.[21,67] When neoplasia affects the lower portion of the esophageal sphincter, gastroesophageal reflux may contribute to ulceration of esophageal mucosa. The prognosis for malignant neoplasia of the esophagus is grave.

Disorders of the Stomach

Gayle D. Hallowell

Various diseases affect the equine stomach and include equine squamous gastric disease (ESGD), equine glandular gastric disease (EGGD), parasitic disease (*Gasterophilus* spp., *Habronema* spp., *Draschia* spp.), gastric impactions, gastric rupture, and squamous cell carcinoma. This section covers these conditions with a particular focus on EGGD, about which a number of reports have been published.

■ ***Equine Squamous Gastric Disease*** Historically, this has been the most prevalent disease identified in the equine stomach. However recent personal communications and anecdotal reports suggest that the prevalence of this condition has fallen since 2005, particularly in sports and leisure horses.[1]

This change in prevalence may be actual, secondary to an understanding of risk factors and subsequent changes in management, or different diseases are diagnosed instead because more veterinarians have longer gastroscopes and thus are able to examine the pylorus and pyloric antrum.

ESGD can be a primary problem or, occasionally, a secondary problem that results from obstruction of gastric outflow with subsequent backflow of acid gastric juices or alkaline biliary secretions. The focus of this section is on primary squamous disease. The management of secondary squamous disease is largely dictated by treatment of the primary disease causing delayed gastric outflow.

PATHOPHYSIOLOGY. ESGD results from increased exposure of the squamous mucosa, which has limited mechanisms of defense against highly acidic gastric contents. Horses constantly secrete gastric acid,[2,3] and hydrochloric acid is primarily responsible for the damage to the squamous mucosa. Damage occurs rapidly; acid injury becomes evident within 30 minutes of exposure in vitro.[4] Horses are constant grazers, and in pasture conditions, the consumption of roughage creates a basketball-sized bolus of feed in the stomach that acts as a buffer to absorb gastric acid and physically prevents the splashing of gastric contents into the dorsal region of the stomach that is lined by squamous mucosa (Fig. 32.50). Any disruption in normal feeding or behavior results in breakdown of this protective mechanism and a resultant increase in the risk for ESGD. Short-chain fatty acids released during fermentation of soluble carbohydrates consumed in the diet are also likely to contribute directly to squamous mucosal injury[5] and disrupt the physical protective effect of a predominantly roughage-based diet. ESGD thus is largely a disease that results from the management changes imposed on horses for a variety of purposes.

CLINICAL SIGNS. Clinical signs reported with ESGD include poor appetite, poor bodily condition, and abdominal discomfort.[6] Other clinical signs loosely associated with ESGD include poor appetite or "picky eating,"[6-9] poor bodily condition or weight loss,[6,7,10] chronic diarrhea,[6,7] poor coat,[8], bruxism,[11] behavioral changes (including aggression and nerviousness),[7,12,13] acute or recurrent abdominal pain,[6,7,8,14-16] and poor performance.[7,8,17-19]

PREVALENCE AND RISK FACTORS. The prevalence of ESGD mirrors exercise intensity: The risk of disease development increases as the intensity of work increases. The highest prevalence of this disease has been reported in Thoroughbred racehorses, of whom more than 70% are affected across a wide range of studies.[8,11,20,21] However, it seems likely that these studies overstate the prevalence of clinically significant disease because many affected animals have only small focal lesions that are likely to be clinically insignificant but, by definition, meet the criteria for diagnosis of ESGD. This overrepresentation has led many clinicians to dismiss ESGD as a normal finding in a performance horse. It is proposed that mild (grade II/IV) ESGD may be an incidental finding and that although it may be associated with clinical signs, horses with grade III-IV/IV ESGD are more likely to have clinical disease.[22] The prevalence and significance of ESGD should be discussed in the context of the relative severity of lesions observed.

The Thoroughbred racehorse is the best studied of horse breeds regarding risk factors and effective treatments. However, ESGD is identified in a wide range of other horse breeds. In a Danish study, ESGD was observed in 69% of horses with varying activities, ranging from horses at pasture to horses in hard work, and there was no association between presence of ESGD and horse use.[23] Similar prevalence of ESGD has been reported in Standardbred (63% to 87%[3,24]), endurance (67% to 93% during competition[25,26]), show (58%[12]), and western performance (40%[27]) horses. The prevalence of ESGD in horses at rest is variable but typically lower and, when observed, tends to be less severe. However, in selected cases, severe (grade III-IV/IV) ESGD can be observed in horses at pasture, and ESGD should not be omitted in the differential diagnosis simply because a horse does not meet the typical risk profile.

The commencement of training, with the multitude of management changes imposed, including exercise[28] and high-concentrate/low-roughage diets,[29] can result in the development of ESGD within 7 days.[30,31] In addition to the overall risk associated with the induction of training, specific risk factors that have been identified for ESGD include fasting,[32] transport,[31] stabling,[3] and time in work.[32] NSAIDs may induce ESGD experimentally; however, because of epidemiologic study results[21] and the lack of a direct link to the pathophysiology of squamous ulceration, it is unlikely that NSAIDs contribute to ESGD in the clinical setting.

TREATMENT. Treatment of ESGD focuses on suppression of acid production and, when possible, changing management practices that may have contributed to the disease (Fig. 32.51). Acid suppression therapy does not contribute directly to healing, but the squamous mucosa has an enormous proliferative capacity,

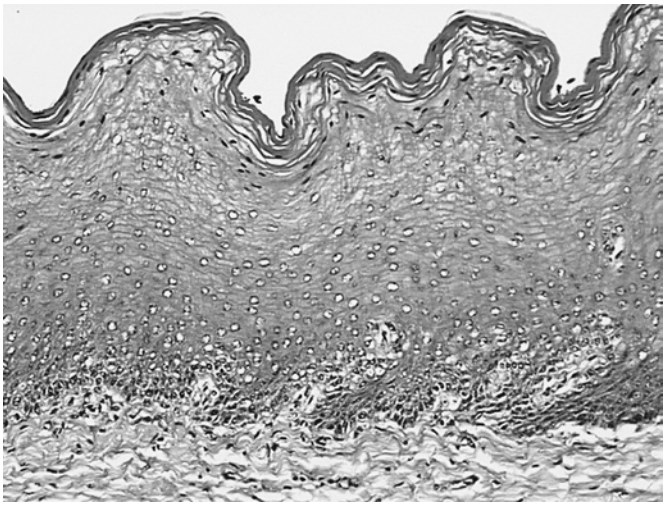

FIG. 32.50 Photomicrograph of equine gastric squamous epithelial mucosa. Multiple layers of epithelium are arranged in parallel with the luminal surface. The most superficial layers of cells are cornified, and superficial to these cells are layers of keratin. (Hematoxylin and eosin stain.)

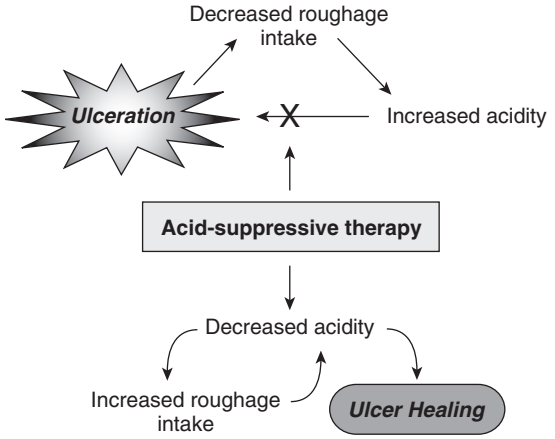

FIG. 32.51 Diagram representing the pathophysiologic process of ulceration in the equine gastric squamous mucosal epithelium and the permissive effect of acid suppression on ulcer healing.

VetBooks.ir

and the removal of ongoing insult is usually sufficient for the tissues to heal. Theoretically, removal of affected horses from the risk factors that caused disease and reestablishment of a normal pH gradient in the stomach should result in healing. However, a reduction in workload is often not possible, and treatment is required in the presence of ongoing exposure to risk factors. Furthermore, even when removal from the risk factors is possible (i.e., resting of an affected horse), acid suppression therapy is often necessary to restore a normal appetite so that enough roughage is consumed to reestablish the pH gradient in the stomach and thereby allow healing to occur. If removal from work is used to manage ESGD, then follow-up gastroscopy 4 to 6 weeks later is indicated to ensure that healing has occurred.

Because the ability to remove risk factors, such as exercise and concentrate diets, can be limited, the use of acid suppression therapy remains a cornerstone in the management of ESGD. Various drugs have been used for this purpose, but oral omeprazole remains the most effective and best studied. Omeprazole inhibits the H^+, K^+–adenosine triphosphatase (proton) pump that secretes hydrochloric acid. Omeprazole is most commonly administered at a dose of 4 mg/kg PO q24h for 28 days, and its efficacy at this dose for treatment of ESGD has been well documented by several clinical trials.[33-37] The use of lower doses has been evaluated and, under certain conditions, doses as low as 1 mg/kg have been shown to be as efficacious as 4 mg/kg in the treatment of ESGD.[38] On the basis of experimental studies,[39-45] it is widely believed that once-daily administration of omeprazole results in 24 hours of acid suppression; however, one study has suggested that the duration of acid suppression after dosing at 4 mg/kg may be as short as 12 hours; thus in nonresponders, administration twice daily may be warranted.[46] As exercise is considered to be the peak risk period for ESGD development,[28] timing of omeprazole administration should be considered before exercise. However, one study revealed no advantage of administration of omeprazole 1 to 4 hours before exercise over administration after exercise.[47]

Reported healing rates at 28 days for horses that stay in work are typically around 70% to 80%.[33,34,37,47] Although the majority of affected animals improve by 28 days,[33,38,47,48] repeated gastroscopic examination is recommended before therapy is terminated to ensure that healing has occurred.

The H_2 receptor antagonists ranitidine and cimetidine are the other drugs that historically have been used for treating ESGD. Both drugs work by competitively blocking the H_2 receptor on the parietal cell, and their efficacy is dependent on maintaining plasma concentrations. Ranitidine, administered most commonly at 6.6 mg/kg PO q8h, has been shown to effectively suppress gastric acidity in experimental studies[2,14,49,50] and provides an alternative option for acid suppression. However, in a direct comparison of the efficacy of ranitidine with that of omeprazole, ranitidine was shown to be inferior,[35] and thus omeprazole remains the treatment of choice. Cimetidine has been poorly studied in this context, and its use is not justified.

For nonresponding patients, which usually is only 10% of animals with ESGD, or those animals to which oral paste cannot be administered, long-acting injectable omeprazole (4 mg/kg IM q5-7 days) should be considered. It can be administered every 5 to 7 days, and studies have shown that it results in effective acid suppression during this period.[51] A small-scale clinical study demonstrated healing in 14 days in 100% of patients.[51] This drug should be administered via deep intramuscular injection into the gluteal mm. Transient swelling has occasionally been reported.[1]

Nonpharmaceutical methods, such as feed supplements and antacids, are popular among owners for the treatment of ESGD because of their low cost and availability. Although antacids can effectively reduce gastric acidity, their effect is short-lived (2 hours)[14,52] and so their use cannot be recommended. Mucosal protectants, such as pectin-lecithin complexes, may play a role in providing a physical barrier between the mucosa and acid, and short-term improvement in clinical signs associated with the use of antacids is often reported. Their use in selected cases may be sufficient for control of ESGD, but they should be considered alongside management changes to prevent recurrence, and alongside omeprazole in the treatment of ESGD, rather than as a primary treatment for ESGD.

PREVENTION OF RECURRENCE. To prevent recurrence of disease, management changes should be recommended. These changes include increased roughage and decreased concentrate in the diet; multiple, smaller feeds; increased turnout; and feeding a small amount of feed, such as a few handfuls of chaff, before exercise to act as a raft to protect the squamous mucosa from acid splash.[22] The use of mucosal protectants such as the pectin-lecithin complexes or administration of sugar beet, which contains pectin, should be recommended in the few months after treatment and may be required longer. Historically omeprazole has been used at 1.0 mg/kg PO q24h for prevention,[31] but 0.5 mg/kg PO q24h has been shown, under specific conditions, to be as effective.[47] Recent data in humans have revealed an association with long-term omeprazole therapy and acute kidney injury[53]; no such studies or association has been performed in horses, but this approach may not be innocuous. Gastric acid is produced for a reason!

Equine Glandular Gastric Disease (EGGD)

It is now widely accepted that EGGD is an entity separate from ESGD.[1] A series of studies have clearly demonstrated that the risk factors for EGGD[32] and response to its treatment[38,47,48,54] differ dramatically from those for ESGD, which is not surprising in view of the differences in the anatomy of the glandular mucosa (Fig. 32.52) and probable pathophysiologic features. EGGD is probably multifactorial in nature in horses.[1] Since 2005, the identification and reported prevalence of this disease have increased. Many authorities believe that this is a true change in disease prevalence; squamous disease is less common as a result of improved management based on risk factors and also is less likely to be diagnosed because of increased awareness of EGGD as an individual entity. Historically, some of the difference in prevalence reported may also relate to endoscopes available; those initially available in the 1990s were only 2.5 m in length, and therefore the pyloric antrum, where the majority of glandular disease occurs,[23,32,38,47,48,54] was rarely observed in clinical cases.

PATHOPHYSIOLOGY. The glandular mucosa differs from the squamous mucosa in that under normal physiologic conditions, it is exposed to highly acidic gastric contents; the pH in the ventral portion of the stomach is relatively stable at between 1 and 3.[46] Whereas ESGD results from exposure of mucosa unaccustomed to acidity, EGGD may result from a breakdown of the normal defense mechanisms that protect the mucosa from acidic gastric contents, which includes bicarbonate and a layer of gastric mucus that is a mixture of glycoproteins, water, electrolytes, lipids, and antibodies.[55]

Lesions of the glandular mucosa are not ulcerative in most situations; they are erosive and inflammatory in nature. They often contain a mixed inflammatory population of lymphocytes, plasmacytes, and neutrophils and should thus be described as glandular gastritis.[56-58] Nodular lesions typically have a lymphocytic, plasmacytic infiltrate. Although lesions that have a fibrinosuppurative cap often have a predominance of neutrophils, their presence does not indicate an infectious cause.[1]

As mentioned, EGGD is probably a multifactorial condition. Different lesion types and location of lesions may have different

VetBooks.ir

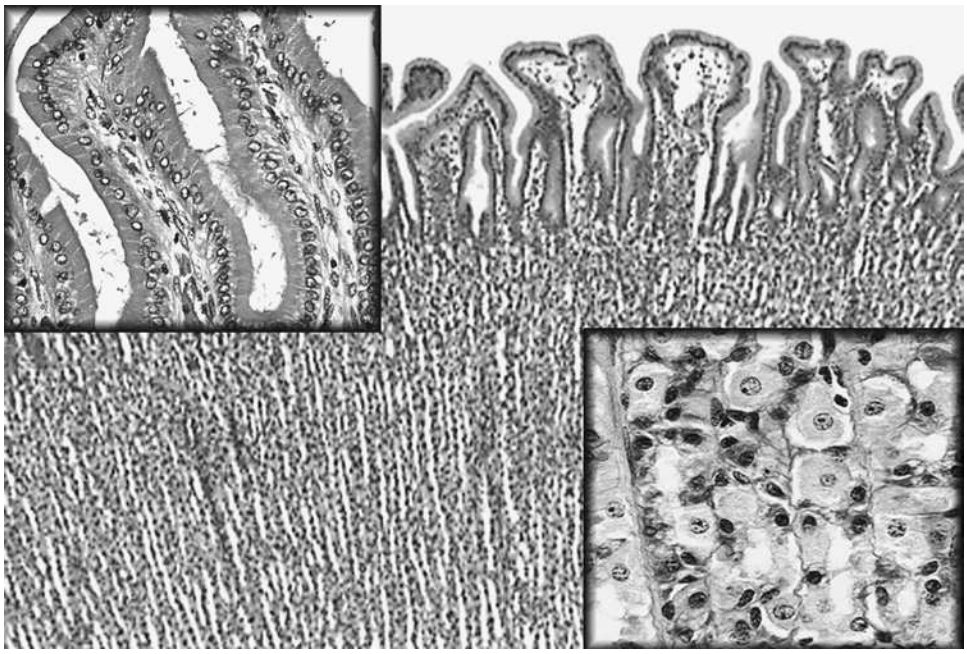

FIG. 32.52 Photomicrographs of equine gastric glandular mucosa. In contrast to the squamous mucosa, the glands are parallel to one another and perpendicular to the luminal surface. There are multiple cell types within the mucosa, with surface epithelial cells and mucus-secreting cells toward the lumen, and parietal cells, chief cells, enterochromaffin-like cells, G cells, and D cells deeper in the mucosa. The *top left insert* is a high-power magnification of cells lining gastric pits on the surface of the epithelium. The *bottom right insert* is a high-power magnification of cells lining the gastric glands deeper in the mucosa. (Hematoxylin and eosin stain.)

causes, and thus responses to treatment may be different. The glandular mucosa in the pyloric, fundic, and cardiac regions differs in anatomy, physiology, and blood flow, which may be why most of the lesions identified in adult horses occur around the pylorus or in the pyloric antrum.[1]

Changes in blood supply may result in breakdown of normal defense mechanisms. Stress may influence gastrin production, reduce blood supply to the glandular mucosa, and thus initiate and perpetuate this condition. Blood supply to different areas of the glandular mucosa is thought to be uneven, and both exercise and feeding could result in initiation or perpetuation of disease.[1]

Acid injury is unlikely to be the initiator of these lesions, but it may perpetuate mucosal damage and prevent mucosal healing.[22]

Because these lesions contain an inflammatory infiltrate, it is entirely possible that some lesions are gastric manifestations of inflammatory bowel disease (IBD) and may necessitate similar treatment and management strategies, including evaluation of the remaining intestinal tract.[1]

CLINICAL SIGNS. Clinical signs of EGGD are often nebulous, which makes assessing clinical significance of lesions challenging. According to a consensus statement,[1] clinical signs that are considered associated with EGGD include changes in temperament, including nervousness and aggression; changes in rideability, including reduced willingness to work and reluctance to go forward; unexplained weight loss, probably concurrently associated with reduced appetite or altered eating patterns; cutaneous sensitivity, manifested as flank-biting or resentment of girthing, leg aids, or rugging; and mild or recurrent abdominal pain.[1] It was deemed unlikely that changes in coat condition, stereotypical behavior, bruxism, and diarrhea were signs associated with EGGD.[1]

Although cutaneous sensitivity seems an implausible clinical sign of gastric disease, data from other species suggests that afferent pathways from abdominal viscera and the sixth to ninth thoracic spinal nerves are pooled, so that afferent signals from the skin may be affected by input and misinterpreted within the brain. In addition, viscerosomatic reflexes can result in pain and sensitivity in segmentally related structures such as the skin.[59]

PREVALENCE AND RISK FACTORS. EGGD prevalences of 47 to 62.5%[20,32] have been reported in Thoroughbred racehorses in Australia. Among a mixed population of horses in Denmark, the overall prevalence of EGGD was 57%[23]; in sports horses in the United Kingdom, 65%[60]; and in endurance horses, 27 to 33%.[25,26] Abattoir studies have reported prevalences of 57% to 67%[56-58] in a variety of horse types.

Information on risk factors for EGGD are limited and occasionally contradictory. What is obvious from these studies, however, is that risk factors for EGGD are different to ESGD. Warmbloods are at greater risk for developing EGGD than are other horse types.[61,62] In Thoroughbred racehorses, trainer was identified as a risk factor independent of other management factors.[32] Exercising for more than 4 or 5 days per week has been shown to be a risk factor in both Thoroughbreds using for racing[32] and in showjumpers,[63] whereas intensity of exercise was not. Horse experience was inversely correlated with prevalence of EGGD in both polo ponies[64] and showjumpers,[63] which may suggest adaptation to type of work or differences in management of elite horses.[1] A study in endurance horses demonstrated a doubling in EGGD prevalence during the competition season in comparison with off-season activity,[26] which, as in human athletes, may be related to reduction in gastric and splanchnic blood flow during exercise.

Stress is an important risk factor in the development of glandular lesions in people.[65-67] Horses with severe EGGD have greater increases in cortisol in response to novel stimuli,[68] and in response to exogenous adrenocorticotropic hormone,[69] which suggests that these horses may be more sensitive to stress. There is controversy regarding the association with stereotypies; no association was found in one study,[32] whereas

VetBooks.ir

was an association with crib-biting was found in another.[70] These differences may be explained by the high prevalence of both conditions in a given population, particularly as stereotypies are often regarded as a coping strategy in horses. What would be more interesting to evaluate is disease prevalence in animals that are prevented from exhibiting stereotypical behavior. The lower prevalence in more experienced polo ponies and showjumpers[63,64] may relate to adaptation to physiological stress. Cortisol concentrations have been shown to be lower in more experienced show and showjumping horses than in less experienced horses.[71,72] It is challenging to know what is stressful to an individual horse; changes to minimize stress should be tailored to an individual and ideally kept consistent.

It is often perceived that there is an association between orthopedic and EGGD, but thus far no such association has been demonstrated,[32] and care is warranted because animals that present with poor performance often have multiple abnormalities that contribute to presenting signs.

There is currently no evidence to indicate an association between diet and EGGD, and thus making recommendations are challenging. However, grazing should be maximized (if this does not result in stress), and animals should not exercise on an empty stomach.[1]

In humans, bacterial agents and NSAIDs are the predominant causes of gastric disease; *Helicobacter pylori*–negative, NSAID-negative gastric disease is rare.[73] In horses, however, there is no evidence that bacteria are involved in the pathogenesis of EGGD. Several investigations in horses have failed to consistently identify *Helicobacter*-like organisms in EGGD lesions.[56,57,74,75] Other bacterial species such as *Escherichia fergusonii*, *Streptococcus bovis*, and *Enterococcus faecium* are potentially pathogenic and have been associated with EGGD lesions, but their pathogenicity remains unproven; they may simply be colonizers. Studies on the gastric microbiota have failed to identify a difference between horses with EGGD and those without.[76] Thus no current data suggest that bacteria are an important cause of EGGD, although the potential for bacteria to cause this disease is plausible.

The theoretical potential for NSAIDs to cause EGGD is plausible as cyclooxygenase (COX) inhibition could reduce gastric and splanchnic blood flow. Glandular lesions can be induced if flunixin, phenylbutazone, and ketoprofen are administered at doses 50% higher than typically recommended,[62] whereas at clinical doses, phenylbutazone and suxibuzone did not induce gastric disease when administered for 15 days.[63] Moreover, the administration of NSAIDs has not been identified as a risk factor.[28,32,62-64,77,78] Thus at doses commonly used in clinical cases of horses that are otherwise healthy, the risk of EGGD associated with short-duration NSAID therapy is negligible.

TREATMENT. It is widely accepted that ESGD and EGGD cannot be managed in the same way. In three studies, only 25% of glandular lesions healed with 28 to 35 days of omeprazole monotherapy at 4.0 mg/kg PO q24h, in direct contrast to an ESGD healing rate of 78%,[28,37,38] which suggests that this treatment is not appropriate for EGGD and that other treatment is required.

One plausible treatment option for EGGD is a combination of oral omeprazole (4 mg/kg PO q24h) and sucralfate (12 mg/kg PO q12h). Sucralfate is known to provide a physical barrier that prevents acid diffusion, stimulates mucus secretion (which blocks acid diffusion), inhibits pepsin and bile acid secretion, promotes epithelialization by preventing fibroblast degradation, stimulates epidermal and insulin-like growth factors, and increases mucosal blood flow through increased production of prostaglandin E. Data on its efficacy varies between studies. One study[79] demonstrated an 80% improvement and a 63% healing rate with this combination at 28 days, whereby healing was reported to represent grade 0 or 1 EGGD lesions, although improvement rates were lower for lesions around the pyloric antrum (67.5%). Another study,[80] in which the end point for healing was a completely normal appearance of the pyloric antrum, demonstrated a healing rate of only 22% at 28 days, although improvement rates were similar to those in the previously described study. If this combination is to be used, omeprazole should be administered on an empty stomach, and the animal should not be fed for 30 to 60 minutes after administration.[1] Sucralfate is not licensed for veterinary use, and so appropriate consent should be obtained before administration.

A second plausible treatment for this condition is administration of oral misoprostol (5 µg/kg q12h), which is licensed for treatment of refractory gastric disease in humans; however, it is not licensed for veterinary use. Misoprostol is a prostaglandin E analogue and as such probably improves mucosal blood flow. It has also been shown to effectively suppress acid production in horses[81] and inhibits neutrophilic inflammation.[82] One study[80] demonstrated healing, defined as return to normal appearance, in 73% of horses with significant pyloric glandular lesions that were treated with misoprostol; in contrast, the healing rate among those treated with combined omeprazole and sucralfate therapy was only 22%. Side effects are rare, but those reported with misoprostal administration include mild, transient diarrhea, mild abdominal pain, and urticaria. Care must be taken in administration to pregnant mares because this drug can induce abortion, although some safety data suggest that it can be safely administered to mares between 100 and 130 days pregnant.[83] Appropriate consent should be obtained before administration because this drug is not licensed for veterinary use and because of the potential for causing abortion in people, it should not be dispensed to women who are pregnant or planning to be pregnant. There is no rationale for combining this drug with oral omeprazole.

A third plausible option for the treatment of EGGD is long-acting injectable omeprazole. This drug administered at 4 mg/kg IM has been shown to be more effective than oral formulations in increasing pH in the ventral portion of the stomach[51]; acid suppression is maintained for 4 to 7 days, and so this drug should be administered at 5- to 7-day intervals. Thus far, the data available on the efficacy of this drug in clinical cases are limited. However, in a small study of Australian racehorses, 75% healing and 100% improvement was reported at 2 weeks after two injections.[51] Some unpublished data from sports and leisure horses demonstrated 64% healing, defined as mucosal appearance returning to normal and 96% healing at 2 weeks after two injections given 7 days apart.[1] Transient swelling has been reported in fewer than 10% of cases at the injection site, which is most common if administered into the pectoral muscle or neck. It is thus recommended that this drug be administered, after warming, as a deep intramuscular injection into the gluteal muscle. Appropriate consent should be obtained when this drug is used because it currently is not licensed for veterinary use.

If some of these lesions are extensions of inflammatory bowel disease, there may be some rationale in the use of glucocorticoids. Anecdotal reports indicate that they are beneficial in the subgroup of animals that do not respond to more conventional therapies listed previously. In a consensus, morning administration of prednisolone, 1 mg/kg PO q24h, or dexamethasone, 0.05 to 0.1 mg/kg PO q 24h, was suggested. Either dosage can be tapered over a 4- to 5-week period.[1] Other recommendations may include simplification of the diet (in view of underlying causes of IBD in other species, such as cereal proteins or alfalfa).

As stated previously, the role of bacteria in EGGD is unknown, but *Helicobacter*-like organisms are not consistently identified and are not considered an important factor in the

VetBooks.ir

initiation or perpetuation of EGGD.[22] In one study, the combination of omeprazole (4 mg/kg PO q24h) and trimethoprim-sulfadimidine (30 mg/kg PO q24h) failed to improve the treatment response in comparison with omeprazole therapy alone (4 mg/kg PO q24h).[54] In one consensus, investigators believed that antimicrobials were not an appropriate first-line treatment for EGGD; their use was deemed appropriate only if based on histologic and bacteriologic findings[1] and was necessary in fewer than 1% of cases.

There is no evidence that ranitidine, aloe vera, pectin-lecithin complexes, polysaccharides, kaolin, bismuth subsalicylate, sea buckthorn, acupuncture, or homeopathy is efficacious in the treatment of EGGD.[1]

If ESGD and EGGD lesions are found concurrently, treatment should be aimed at EGGD. No additional treatments are required because ESGD would be expected to heal with any of the first-line treatments discussed for EGGD (combined omeprazole-sucralfate, misoprostal, and injectable omeprazole).

Expectations for Healing and Monitoring. Rates of healing are difficult to predict and probably vary by lesion. Raised, nodular, and fibrinosuppurative lesions probably take longer to heal than do flat, hemorrhagic lesions. Mucosal restitution can occur within 3 to 5 weeks, but complete resolution may take several months, especially where raised areas or nodules are visible.

Affected horses should be evaluated monthly with gastroscopy until resolution is complete. Once lesions have resolved, treatment should be discontinued. There is no rationale for reducing the dose of the drugs discussed previously, with the exception of glucocorticoids. Affected horses should also be monitored for return of clinical signs. The need for follow-up gastroscopy depends on the case being managed.

MANAGEMENT OF REFRACTORY CASES. Because many EGGD lesions are not healed in 28 to 35 days, it is prudent to have a rational plan of what to do when lesions are still present. The aims of treatment should be complete resolution with a mucosa that has a normal appearance. If treatment is prematurely discontinued, lesions may worsen again and clinical signs will recur.[1]

If first-line treatment yields no improvement at 28 to 35 days, or if an affected horse's condition deteriorates, an alternative first-line treatment should be used. If the alternative treatment produces improvement, it should be continued up to a maximum of 3 months. If the lesions have not resolved by 3 months, biopsy samples of the lesions should be obtained and investigations performed to establish evidence of concurrent intestinal disease.[1] If the biopsy reveals neutrophilia and if cultures of multiple sections yield a predominant bacterial species, treatment with an antimicrobial is warranted; many clinicians opt for oral doxycycline. If there is evidence of lymphocytic-plasmacytic inflammation or of IBD, then glucocorticoid treatment may be warranted. The finding of an eosinophilic infiltrate may be suggestive of parasitic organisms (*Habronema* spp. or *Draschia* spp.), and management with anthelmintics is warranted; these organisms, however, are extremely rare.

PREVENTION OF RECURRENCE. Prevention of EGGD, either as primary disease or as recurrence, is problematic. In a series of studies, worsening of EGGD grade was observed in 23% of horses despite omeprazole monotherapy at doses ranging from 1 to 4 mg/kg PO q24h.[38,47,48] Furthermore, it has been suggested that gastric hyperplasia may be present in a percentage of EGGD cases, and that in such cases omeprazole therapy is contraindicated.[84] As stated previously, no data are available as to whether long-term omeprazole therapy results in acute kidney injury, as it does in humans.[53]

On the basis of the known risk factors for EGGD listed previously, which differ from those for ESGD, the following management changes are recommended. Ideally, horses should have a minimum of 2 rest days per week if possible. Stress should be minimized; for example, environments should be calm, and affected horses should have a minimal number of carers and the same equine field companions. Horses should be turned out, unless this is obviously stressful to a horse. Horses should be fed 2 L of chaff or equivalent of forage 30 to 60 minutes before exercise.[1] If IBD is suspected, diets should be simplified to include one straight and forage. Any irritant supplements (such as those containing magnesium sulfate) should be stopped.

In one study, the addition of corn oil, 0.3 to 0.45 mL/kg/day (150 to 225 mL/day for a 500-kg horse), decreased gastric acid output and increased prostaglandin E_2,[85] both of which are, in theory, beneficial in the treatment and prevention of EGGD. Thus addition of corn oil at a rate of up to 0.5 mL/kg/day may be beneficial. Lastly, in view of the fundamental role of failed mucosal defenses in the pathogenesis of EGGD, the use of mucosal barrier protectants is logical, and the use of pectin-lethicin at 150 g q12h or feeding sugar beet pulp (a cheaper alternative) may be beneficial.[84]

DIAGNOSIS. Gastroscopy remains the only reliable method for diagnosing ESGD and EGGD. Adequate patient preparation, plus some operator skill and patience, is required for a complete diagnostic evaluation of the entire stomach. A fasting period of at least 12 to 16 hours is required in most horses, and even small amounts of residual food hamper access to the pyloric antrum. In horses on low-roughage diets (e.g., racehorses), the duration of fasting may be shorter. Removal of water 1 hour before examination is advantageous but not mandatory. Examination of the stomach should be complete and methodical. Observation of the squamous mucosa is straightforward, whereas passage through to the pyloric antrum is more technically demanding. However, observation of the pyloric antrum is critical because the majority of glandular lesions in adult horses occur in this region.[32,38,47,48,86] Observation of the most ventral portion of the fundus is typically not possible because of the presence of fluid, but it can be possible with adequate patient preparation; however, disease in this region is rare.[84] The squamous and glandular mucosa should be assessed and scored separately and, although a variety of scoring systems have been described, the author prefers the system first described by the Equine Gastric Ulcer Syndrome (EGUS) council,[87] shown in Table 32.2, for squamous disease. It is now widely accepted that the grading system for EGGD does not reflect severity of disease and until a better system is developed, lesions should be described according to the consensus statement by the European College of Equine Internal Medicine and the American College of Veterinary Internal Medicine.[22] These descriptors include *focal*, *multifocal*, and *diffuse; mild*, *moderate*, and *severe; nodular*, *raised*, *flat*, and *depressed;* and *erythematous*, *hemorrhagic*, and *fibrinosuppurative*. A more recent consensus statement focused on EGGD suggested that flat, erythematous lesions were likely to heal more rapidly than were those with a nodular, raised, and fibrinosuppurative or hemorrhagic appearance.[1] Examples of the normal appearance of the gastric and duodenal mucosa and lesions encountered in horses and foals undergoing gastroscopy are shown in Color Plates 32.4 through 32.12.

Fecal occult blood tests[88] and sucrose permeability tests[89] for diagnosing gastric disease in adult horses have been shown to be unreliable and cannot be recommended.

Gastric Disease in Foals and Weanlings

Gastric disease is commonly identified in foals; the prevalence ranges from 21 to 98%.[90-94] Before weaning, the prevalences of squamous and glandular disease is similar,[94] whereas after weaning, the prevalence increases to levels similar to those

VetBooks.ir

TABLE 32.2

Scoring System for Equine Gastric Ulcer Syndrome

Grade	Squamous Mucosa	Glandular Mucosa
0	Intact epithelium, no appearance of hyperkeratosis (yellow appearance to the mucosa)	Intact epithelium, no hyperemia (reddening) of the mucosa
I	Intact mucosa, but areas of hyperkeratosis	Intact mucosa, but areas of hyperemia
II	Small single, or multifocal lesions	Small single, or multifocal lesions
III	Large single or multifocal lesions, or extensive superficial lesions	Large single or multifocal lesions, or extensive superficial lesions
IV	Extensive lesions with areas of apparent deep ulceration	Extensive lesions with areas of apparent deep ulceration

among adults, and lesions are twice as likely to be found in the squamous mucosa as in the glandular mucosa.[94] As in adults, diagnosis is confirmed with gastroscopy. Results of one study suggested that a sucrose permeability test is a useful screening tool for detecting gastric disease in weanlings; with a sucrose cut-off level of of 24 µmol/L, this test had excellent sensitivity (84 to 95%) and average to good specificity (47 to 71%).[94]

The pathophysiologic origins of this condition in foals are probably complex and, as in adults, probably differ between the squamous and glandular mucosa. Acid production is extremely variable in foals; in fact, gastric fluid is often alkaline,[95] which suggests that acid damage is unlikely to be a prevalent cause. Underlying diseases such as perinatal asphyxia syndrome, hypovolemia secondary to other disease and use of NSAIDs probably results in reduced gastric and splanchnic blood flow, and improvement of this should be the focus for prevention and treatment. Gastric disease in foals often co-occurs with lesions that extend into the esophagus and duodenum.

Clinical signs observed in this age group are nonspecific but are often more severe than in adults; they include diarrhea, abdominal pain (restlessness, rolling, lying on the back), excessive salivation, bruxism, and anorexia.[96] However, with such high prevalence, determining which lesions are clinically significant in the absence of clinical signs is challenging,[93] but because of the risk of intestinal perforation, which is fatal, many authors believe that these lesions should be treated.[96,97]

Because of the pathophysiologic process of this condition, the rationale for the use of sucralfate[98] or misoprostal[81,99] for prevention and treatment is significant. Omeprazole may play a role in the treatment of gastric lesions but should not be used for prophylaxis. Use of omeprazole prophylaxis in human patients was associated with an increased risk of pneumonia and *C. difficile* diarrhea,[100,101] and in foals in a multicenter study, it was associated with an increased risk of diarrhea.[102]

Gastric Impaction Gastric impaction is relatively common. Clinical signs are diverse, with inappetence the most common manifestation and representing 50% of cases in one study.[103] Affected horses typically eat small amounts and have a significantly decreased total daily intake. Acute and recurrent colic are also common manifestations.[103,104] The causes of gastric impaction are unclear, and although poor dental care has been proposed as a predisposing factor,[105] cases commonly occur in horses with no dental abnormalities. Three types of gastric impaction are recognized: Type I is impaction of feed material without increase in the stomach size; type II is impaction of feed material with increase in the stomach size and, although difficult to prove, an underlying motility disorder is suspected in these cases on the basis of the poor response to treatment and prognosis; and type III impactions occur after the formation of a phytobezoar secondary to persimmon seed ingestion.[104,106] Classification of the type of gastric impaction is important because treatment and prognosis vary depending on the type. Distinguishing between types I and II can be difficult.

Diagnosis of gastric impaction in the field is difficult, but it should be part of the differential diagnosis in any horse with signs of mild abdominal pain that dramatically worsen after the administration of fluids via a nasogastric tube; in horses with unexplained inappetence; and horses with abdominal pain that appears to resolve with fasting, only to relapse with the reintroduction of feed. The clinical signs observed with type I impactions are typically mild, with a normal heart rate.[70] Signs may be more pronounced in type II impactions, and displacement of the spleen may be palpable on rectal examination. Type III impactions more commonly manifest with mild to severe colic, weight loss, or both.[104,106] Definitive diagnosis is made when, after an appropriate period of starvation, entry to the stomach with a gastroscope is obstructed by feed material. Alternatively, in type I, the stomach can often be entered and distended with air, but a clearly defined ball of feed material extending above the level of the margo plicatus is visible. In type III impactions a phytobezoar is typically visible once the stomach has been otherwise emptied of feed material. Ultrasonography can help distinguish between type I impactions, in which visualization of the stomach is difficult or limited, and type II impactions, in which the stomach distention often extends for several rib spaces.

In all cases, any concurrent systemic abnormalities such as hypovolemia, dehydration, and electrolyte derangements should be corrected, and resolution of the impaction should be confirmed by gastroscopic examination before food is reintroduced. The different types are treated as follows:

- For type I, the use of enteral fluids is highly effective; isotonic electrolyte solution (1 L/100 kg q2h) is administered via an indwelling large-bore nasogastric tube. Depending on the response, the rate and volume can be increased or decreased Administration of analgesia (e.g., flunixin meglumine, 1.1 mg/kg IV q12h) is recommended until resolution of the impaction, because signs of abdominal discomfort are common. The use of indwelling, small-bore nasogastric tubes for the administration of enteral fluids has been described[107]; in theory, the bolus administration of fluids should result in a more pronounced stimulation of the gastrocolic reflex, but the use of these tubes will probably cause less abdominal discomfort. With enteral fluid therapy alone, the prognosis is excellent (90% survival to discharge),[103] and so alternative therapies probably offer little advantage, although gastric lavage with water or the addition of carbonated cola drinks may be helpful.
- For type II impactions, treatment is similar to that of type I impactions, but caution should be exercised in the volume of fluids administered because the stomach wall is often friable and gastric rupture can occur. Concurrent intravenous fluid therapy should be considered if hypovolemia cannot be corrected and maintenance fluid requirements cannot be met with enteral therapy alone. The response of type II cases to treatment is often poor, and the addition of prokinetics may be beneficial in some cases; however, the response to prokinetic therapy is often disappointing. Bethanechol (0.025 mg/kg SC q4-6h) is the prokinetic of choice,[17] but

VetBooks.ir

it is often difficult to obtain; erythromycin (1 mg/kg IV q6-8h) is a reasonable alternative. Surgery should be considered for types I and II impaction if the animal is showing signs of systemic deterioration or if the impaction does not resolve with medical therapy within 5 to 7 days; successful treatment by gastrotomy has been reported.[108] The prognosis for type II impactions has not been reported, but in anecdotal reports, it is guarded because gastric rupture can occur (even without enteral fluid therapy) and recurrence is common. The use of low-bulk diets during the refeeding stage is logical.

- Type III impactions by persimmon seed phytobezoars are generally refractory to standard enteral and intravenous fluid therapy. The use of carbonated cola drinks has been reported with a variety of techniques ranging from constant infusion of 1 L/h for 1 to 3 days to bolus administration of 700 mL q12h via nasogastric tube. The mechanism is believed to be a combination of the mucolytic effects of sodium bicarbonate, the acidifying effects of the cola, and mechanical disruption of the fibers of the phytobezoar by the stable carbon dioxide bubbles.[104] Constant infusion via a small-bore nasogastric tube appears to be the treatment of choice, and the use of caffeine-free diet cola is recommended to reduce the risk of caffeine toxicosis or laminitis secondary to carbohydrate overload. The prognosis for type III impactions appears to be good; five of eight horses responded to medical therapy in one report.[104] In the same report, two additional horses were successfully treated surgically via laparotomy, with manual manipulation of the phytobezoar but without gastrotomy; the horse in which a gastrotomy was attempted was euthanized at surgery because of extensive contamination of the abdominal cavity.[104]

Miscellaneous Diseases of the Stomach

A variety of miscellaneous disease conditions, including gastric rupture, abscesses, tumors, and pyloric stenosis, also affect the stomach of horses.

GASTRIC RUPTURE. Gastric rupture is most commonly secondary to obstruction of the small intestine or chronic gastric impaction. Idiopathic rupture accounted for 17% of cases in one report,[109] which suggests that a variety of other causes can result in rupture.

GASTRIC ABSCESSATION. These lesions are rare and are most common in foals. They can be secondary to gastric disease, *R. equi* bacteremia, foreign body penetration, and septic peritonitis. Signs are nonspecific and include fever, neutrophilia, increased serum concentrations of fibrinogen and serum amyloid A, anemia, weight loss, and, on occasional. abdominal pain. Diagnosis usually is made through gastroscopy and ultrasonography. Often a diagnosis is not made until a late stage of the disease, and although long-term antimicrobial therapy can be attempted, the prognosis is usually poor.

GASTRIC TUMORS AND OTHER MASSES. Squamous cell carcinoma (Fig. 32.53) is the most commonly reported of the tumors that affect the equine stomach, representing nearly 80% of cases in one report.[110] Other neoplastic conditions that affect the equine stomach include primary gastric adenocarcinoma, metastatic lymphoma, mesothelioma, and bile duct carcinoma. Gastric squamous cell carcinoma affects the squamous mucosa and can metastasize to other abdominal viscera or extend into the esophagus. As with other forms of neoplasia, presenting signs include chronic weight loss, abdominal pain, and spontaneous nasogastric reflux. No breed or sex predilection exists, and a wide range of ages are affected, although gastric squamous cell carcinoma usually affects older horses. Diagnosis is typically based on gastroscopic and ultrasonographic examination findings, and the prognosis is poor because there is no described treatment.

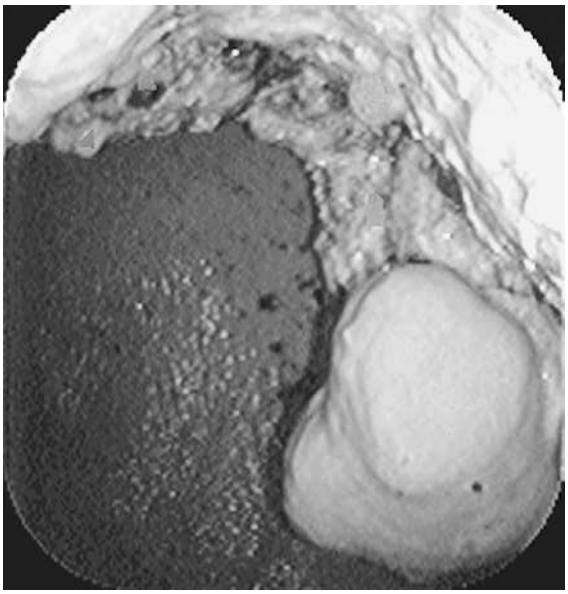

FIG. 32.53 Endoscopic view of a gastric squamous cell carcinoma.

Nonneoplastic masses that can be identified in the stomach include lesions associated with *Draschia megastoma*, *Habronema* spp. (Fig. 32.54), proliferative granulation tissue, and adenomatous masses in the antrum and pylorus. Lesions around the pylorus can be challenging to differentiate from EGGD.

PYLORIC STENOSIS. Pyloric stenosis is an uncommon condition that typically affects foals and young horses,[111] although horses of any age can be affected. It is thought to result most commonly from chronic gastric disease, although other space-occupying lesions may be the cause. Affected animals typically have a history of weight loss, poor appetite, postprandial abdominal pain, or recumbency.[111] Excessive ptyalism or spontaneous reflux of gastric contents from the nasal passages is common. Diagnosis is typically made via gastroscopy, although ultrasonography and contrast radiography can be useful adjunctive tests. Conservative management involves acid suppression therapy; omeprazole (4 mg/kg PO q24h) is effective in less severe cases. Intravenous fluid therapy and parenteral nutrition is indicated in patients with spontaneous reflux of gastric contents or in cases in which gastric emptying is significantly delayed. Long-acting injectable omeprazole at (4 mg/kg IM every 5 to 7 days) has not been reported for management of these cases, but it is likely to be more efficacious than oral medication.[51] Administration of bethanechol or erythromycin may be advantageous. Response to medical therapy is often disappointing and early surgical intervention is indicated in such cases. Long-term survival rates of 50 to 69% have been reported for gastrojejunostomy,[112,113] which further supports early surgical intervention in nonresponsive cases.

Endotoxemia and Sepsis

Kelsey A. Hart • Erin McConachie Beasley • Robert J. MacKay

Definitions

The term *endotoxin* was originally coined to describe toxic bacterial components that were contained within or on the bacterial cell, in comparison with exotoxins that were secreted from outside bacterial cells. The heat-stable endotoxic activity of *Vibrio cholera*, identified by Richard F. J. Pfeiffer in the late nineteenth century, resides in lipopolysaccharide

VetBooks.ir

FIG. 32.54 Images from the pylorus and pyloric antrum of a horse with recurrent colic. Biopsies of these lesions confirmed gastric habronemiasis. The horse was treated on several occasions with ivermectin, and within 3 months the lesions had resolved and clinical signs disappeared.

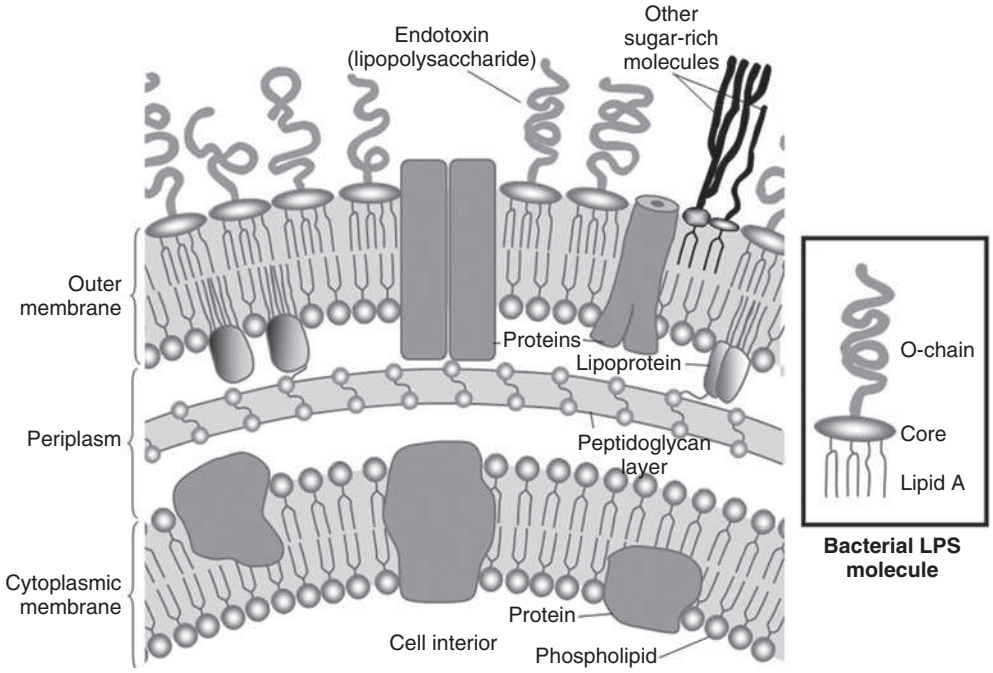

FIG. 32.55 Illustration of a cross-section of the double lipid bilayer that forms the cell membrane of Gram-negative bacteria. Lipopolysaccharide (LPS) is the principal component of the outer leaflet of the outer membrane. The *insert* shows a single LPS molecule with an O-polysaccharide chain, a two-part core oligosaccharide, and a hydrophobic lipid A phospholipid. R-mutant bacteria lack the O-chain and the phospholipid; varying amounts of the core oligosaccharide are present.

(LPS), the principal component of the outer leaflet of the outer membrane of all Gram-negative bacteria[1] (Fig. 32.55). Today, the terms *endotoxin* (the activity) and *LPS* (the molecule) are used synonymously to refer to this specific Gram-negative bacterial membrane component, except when purified LPS is being referenced.[2] Each LPS molecule has three structural domains: a polar polysaccharide O region, which projects into the aqueous extracellular environment; a hydrophobic lipid A region, which is largely buried in the bacterial outer membrane; and a core acidic oligosaccharide region connecting the other two. The O-region is highly variable, consisting of repeating units each of one to eight glycosyl residues, and contains antigens specific for each bacterial strain; the core glycolipid region is relatively constant among bacteria and mediates most of the toxic effects of endotoxin. On bacterial death or during bacterial proliferation, large (molecular mass > 10^6 D) aggregates of LPS and membrane protein are released. It is these protein-lipid micelles that constitute native endotoxin.

Endotoxemia literally is the presence of endotoxin in the blood. However, when the term is used clinically, it implies the presence of clinical signs typically caused by the inflammatory response to circulating endotoxin. Endotoxemia—actual circulating endotoxin or related clinical signs—can occur with Gram-negative bacterial infection in any tissue or through

exposure to Gram-negative enteric bacteria any time the intestinal mucosal barrier is compromised.

The ability to respond to minute local concentrations of endotoxin by mounting vigorous inflammatory responses is well conserved across species.[3] Endotoxemia as a clinical syndrome in equine patients was first recognized in the mid-1960s.[4] The potential clinical importance of equine endotoxemia is clear from reports that intravenous infusion of LPS into horses reproduced many of the adverse clinical signs of diseases such as colitis, metritis, and strangulating intestinal obstruction.[5-10] Further evidence of the importance of endotoxemia was the detection of circulating endotoxin in some horses with experimentally induced laminitis[11] or intestinal strangulating obstruction[12] and in horses with naturally occurring gastrointestinal diseases or septicemia,[13-17] hemostatic disorders,[16] and exhaustion associated with endurance[18] or racing[19] events. Since these original descriptions, a large body of review literature has documented the efforts that have been made to understand and, more importantly, treat equine endotoxemia.[20-23]

Endotoxemia should not be confused with either *bacteremia*, which refers only to the presence of viable circulating bacteria and can occur without clinical signs, or *septicemia*, which refers to systemic disease caused by any circulating microorganisms or their products, or both. *Sepsis* is a related term that is best defined as clinical evidence of an infection (documented or suspected) coupled with the presence of a *systemic inflammatory response syndrome* (SIRS).[24,25] SIRS is characterized in humans and animals by alterations in any two or more of the following: body temperature, heart rate, respiratory rate, and leukogram parameters (Table 32.3).[24-28] The presence of SIRS does not confirm infection, inasmuch as a variety of noninfectious conditions—such as trauma, hemorrhage, thermal injury, or toxin exposure—that result in the release of tissue damage-derived host molecules can also induce a systemic inflammatory of response. However, clinical findings consistent with SIRS should raise the clinician's level of suspicion that an infectious process is present and support a diagnostic search for a potential infectious process.

A scheme showing increasingly severe stages of SIRS and sepsis, from local infection to death, is shown in Fig. 32.56, and adapted definitions for SIRS in horses and foals are listed in Table 32.3. In general, *severe sepsis* includes sepsis (infection plus SIRS) and evidence of organ dysfunction, and *septic shock* includes severe sepsis plus acute circulatory failure (usually manifested by persistent hypotension after appropriate volume resuscitation).[25] Dysfunction of two or more organs in severe sepsis/septic shock is termed *multiple-organ dysfunction syndrome* (MODS) and has a high rate of mortality in human beings[29] and in horses with gastrointestinal disease.[30,31] The lethality of each grade increases from the base to the apex of Fig. 32.56; reported mortality rates for sepsis are 10 to 20%, those for severe sepsis are 20 to 50%[31] and those for septic shock are 40 to 80% in humans.[32] Comparable mortality data in horses are not currently available for increasing severity of sepsis. However, in horses with gastrointestinal disease, the presence of SIRS, increased severity of organ dysfunction and increased number of dysfunctional organs are all associated with an increased risk of death.[28,30]

TABLE 32.3

Criteria for Diagnosis of Systemic Inflammatory Response Syndrome in Horses and Foals[28,30,41,44]

Criteria[a]	Adult	Foal
Alteration in body temperature	<98°F (36.7°C) or >101.5°F (38.6°C)	<99 °F (37.2°C) or >102.5°F (39.2°C)
Alteration in the leukogram	<4,500/μL or >14,500/μL or >10% band neutrophils	<4,000/ μL or >12,500/ μL or >10% band neutrophils
Tachycardia	>52 beats/min	>120 beats/min
Tachypnea	>25 breaths/min or $PaCO_2$ < 32 mm Hg	>30 beats/min
		Evidence of sepsis, cerebral ischemia or hypoxia, and or trauma

[a]For diagnosis, two or more criteria must be present. $PaCO_2$, Partial pressure of arterial carbon dioxide.

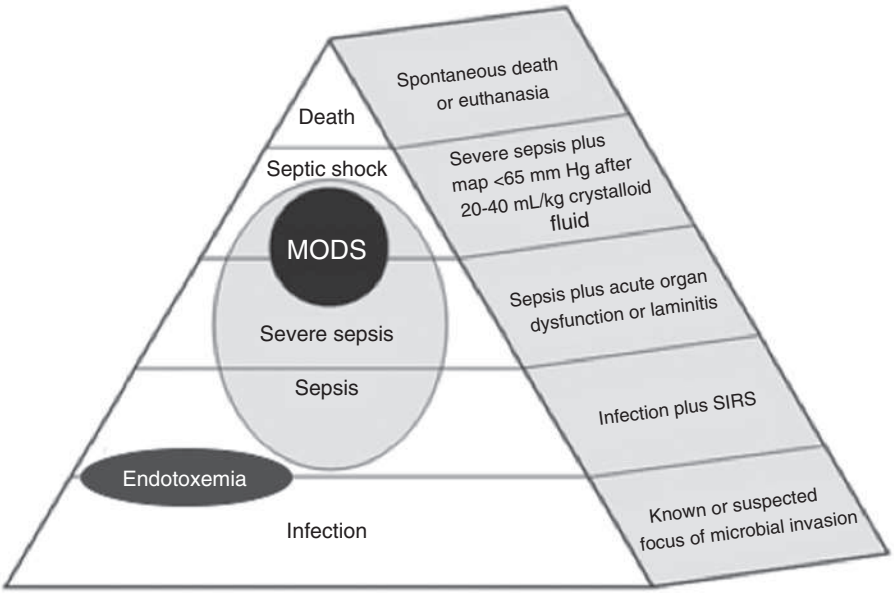

FIG. 32.56 Scheme for classification of the degree of sepsis. Systemic inflammatory response syndrome (SIRS) and organ dysfunction are defined in Tables 32.1 and 32.2 and in several studies.[28,30,41,44] *MODS*, multiple organ dysfunction syndrome.

VetBooks.ir

TABLE 32.4

Criteria for Multiple-Organ Dysfunction Syndrome in Neonatal Foals[41,44,a]

Neurologic	Clinical diagnosis of perinatal encephalopathy
Renal	Anuria, oliguria, or persistent azotemia (levels ≥ 2.2 mg/dL for ≥72 hours) after initial fluid resuscitation
Hemostatic	Clinical diagnosis of disseminated intravascular coagulopathy
Respiratory	Hypoxemia, hypercapnia necessitating intranasal oxygen insufflation or ventilation
Gastrointestinal	Persistent ileus necessitating withholding of enteral feeding for >24 hours
Cardiovascular	Vasopressor therapy for >24 hours

[a]For diagnosis, two or more criteria must be present.

The fundamental difference between serious sepsis in humans and the syndromes seen in equids is the propensity for the latter to be associated with laminitis. In the context of sepsis, laminitis is often life-threatening. Moreover, it appears that the same types of global inflammatory and coagulation disorders that lead to MODS in patients with sepsis also are involved in the pathogenesis of both carbohydrate- and black walnut–induced experimental laminitis.[33-37] In view of their likely common pathogenesis, laminitis is considered—along with evidence of cardiac, renal, hepatic, neurologic, coagulation, or gastrointestinal compromise—part of the spectrum of MODS in equine sepsis.[30] Several researchers have utilized these or similar criteria for SIRS, MODS, or septic shock in horses or foals (Table 32.4; see Table 32.3 and Fig. 32.56).[28,30,38-44]

The extraordinary ferocity of SIRS as triggered by endotoxin was nicely captured by Thomas[45]:

"The Gram-negative bacteria…display lipopolysaccharide…in their walls and these macromolecules are read by our tissues as the very worst of bad news. When we sense lipopolysaccharides we are likely to turn on every defense at our disposal; we will bomb, defoliate, blockade, seal off, and destroy all tissues in the area…. Cells believe that it signifies the presence of Gram-negative bacteria, and they will stop at nothing to avoid this threat."

Although this modern conception of the early immune response to endotoxin is still accurate, it has become clear that a variety of other pathogen-derived molecules set off similar or identical host responses. For example, toxic shock syndrome resulting from *Staphylococcus aureus* infection[46] and streptococcal toxic shock[47] are examples of hyperinflammatory septic syndromes in horses that resemble diseases characterized by true endotoxemia (circulating LPS). Thus in sepsis—including putative endotoxemia in horses—it is likely that the clinical presentation is an aggregate of responses to multiple or varied microbial signals, as well as to certain "danger" signals generated by the host itself. In the case of horses, circulating endotoxin is not always detectable in horses described as "endotoxic"—in fact, it is typically found in fewer than 30%[48,49]—which suggests that other microbial components and host inflammatory molecules probably trigger similar clinical signs. Thus *sepsis* or *SIRS* is a more appropriate term than *endotoxemia* for the accurate description of the clinical findings usually attributed to endotoxin in horses (e.g., hyperemic or toxemic mucous membranes, fever, tachycardia, tachypnea, leukopenia). In this section, *sepsis* implies SIRS in response to any microbial infection, and *endotoxemia* refers specifically to the presence of endotoxin in the blood or to the specific clinical signs related to documented circulating endotoxin. However, the molecular basis of sepsis in horses via mechanisms other than endotoxemia is poorly understood at best, and so the majority of the following discussion centers on endotoxemia as an important component of equine sepsis.

Pathophysiology

ENTRANCE OF ENDOTOXIN OR OTHER MICROBIAL PRODUCTS INTO THE CIRCULATION. Although endotoxin and other microbial components are ubiquitous in the environment, both free and as a component of intact bacteria, these components normally are excluded from the body by the skin and mucous membranes. If the protective integument or mucosae are subjected to bacterial infection or otherwise damaged, bacteria or bacterial components such as endotoxin may reach the blood in sufficient amounts (<1 μg of purified LPS in experimental situations) to cause clinical signs. Gram-negative bacterial enterocolitis (e.g., salmonellosis), metritis, pleuropneumonia, and neonatal septicemia are common pathways to endotoxemia in horses. Because 1-g amounts of free endotoxin normally are safely sequestered within the intestine of adult horses, damage to the gut wall is particularly likely to result in endotoxemia. Such damage can occur as a result of tissue hypoxia, either local (e.g., intestinal volvulus, infarction, incarceration) or systemic (e.g., hypovolemic shock); inflammation (e.g., duodenitis–proximal jejunitis [DPJ] or clostridial enteritis); mechanical trauma (e.g., rectal perforation, prolonged exercise); or intraluminal acidification (e.g., grain overload). In highly contaminated environments, potentially harmful amounts of endotoxin can be introduced into the lungs via inhalation.[50] Endotoxin may even be delivered directly into the blood via contaminated parenteral solutions (e.g., plasma/blood products or homemade intravenous fluids). Other microbes and microbial components (e.g., flagellin) or secreted toxins (e.g., staphylococcal exotoxins) can enter the circulation in similar ways, but these pathways in horses are not well understood.

INTERACTION WITH PATTERN RECOGNITION RECEPTORS. The mammalian immune system has the ability to recognize many distinctive patterns on molecules that signal potential danger. As a group, these molecules include microbial signals such as endotoxin, collectively termed *pathogen-associated molecular patterns* (PAMPs) and *damage-associated molecular patterns* (DAMPs, also called *alarmins*), which are host-produced molecules that originate from damaged or inflamed tissues (Table 32.5). A limited number of germ-encoded receptor types, both soluble and cell-associated, are dispersed throughout the body to detect potential threats (both septic and nonseptic). These are pattern recognition receptors (PRRs) and are exemplified by Toll-like receptors (TLRs) on (and in) cells and by complement receptor proteins and Hageman factor in plasma.[51-53] These and other PRRs are listed in Table 32.6. The interaction between PAMPs/DAMPs and PRRs is the initial event in the innate immune responses that result in the clinical presentation of endotoxemia or other forms of sepsis.

Initially, endotoxin was widely believed to enter cells not via engagement of cell-surface receptors, as it truly does initiate innate immune responses, but by hydrophobic insertion into the membrane (Fig. 32.57). Since then, sequential discoveries of a plasma LPS-binding protein (1989 in humans,[54] 2005 in horses[55]), cluster of differentiation 14 (CD14; 1990 in humans,[56] 2003 in horses[57]), and TLRs (1998 in humans,[58] 2005 in horses[59]) have elucidated the molecular processes of endotoxin binding and signaling (see Fig. 32.57). LPS first interacts with LPS-binding protein, a normal plasma acute-phase protein; this interaction facilitates binding to the soluble or cell-associated co-receptor CD14. The LPS/LPS-binding protein/CD14

TABLE 32.5

Partial List of PAMPs and DAMPs[44,45,224,225]

PAMPs	DAMPs
LPS (endotoxin)	HMGB1
Lipoprotein	S-100 proteins[a]
Peptidoglycan	HSPs
Flagellin	Defensins
Lipoteichoic acid	Cathelicidins
Zymosan	Serum amyloid A
Viral double-stranded RNA	Genomic DNA
N-acetyl glucosamine	Mitochondrial DNA

[a]Proinflammatory proteins released by phagocytic cells during innate immune responses.

DAMPs, Damage-associated molecular patterns; *HMGB1*, high-mobility group box 1 protein; *HSPs*, heat shock proteins; *LPS*, lipopolysaccharide; *PAMPs*, pathogen-associated molecular patterns.

TABLE 32.6

Partial Listing of Pattern Recognition Receptors[44-46,224,226]

Cell-Associated	Soluble
Toll-like receptors (TLRs; e.g., TLR1 to TLR13 in mice)	Hageman factor
C-type lectin receptors (CLRs; e.g., Dectin-1)	MBL
Nucleotide-binding oligomerization domain receptors (NLRs; e.g., Nod1/Nod2)	C3b, Bb
AIM2-like receptors (ALRs, e.g., AIM2)	Ficolins
CD14 (membrane-anchored form)	CD14 (soluble form)

AIM, Absent in melanoma; *CD14*, cluster of differentiation 14; *MBL*, mannan-binding lectin.

complex recruits and activates Toll-like receptor 4 (TLR4) dimer and an accessory component, lymphocyte antigen 96 (MD-2), in preparation for LPS signaling. On ligation of the receptor, the conserved intracellular domain of TLR4 (Toll–interleukin-1 receptor) initiates multiple downstream pathways that culminate in translocation to the nucleus of inducible transcription factors, including nuclear factor κB (NF-κB) and activator protein 1.[60] NF-κB binds to consensus sequences on the promoter or enhancer regions of an array of genes whose products are involved in the inflammatory response.[60] It has been argued that the global activation of TLR4 typical of sepsis also requires the actions of endogenous agonists (e.g., proteases).[61] Endotoxin also may activate NF-κB via TLR4-independent interactions with β_2-integrins, heat-shock proteins, and the intracellular Nod1 receptor.[62]

Endotoxin engages TLR4 on cells of the innate and adaptive immune systems, especially mononuclear phagocytes (monocytes and macrophages), neutrophils, endothelial cells, and dendritic cells. Although endotoxin binds predominantly to TLR4, a number of TLRs (13 identified in mammals to date) are available to bind to other PAMPs/DAMPs (Table 32.7).[63] During sepsis, this diversity of TLRs allows redundant signaling of inflammatory cells. For example, non-LPS components of Gram-negative bacteria may bind other TLRs (e.g., flagellin binds to TLR5, lipoprotein and peptidoglycan bind to TLR2), whereas PAMPs from Gram-positive bacteria, viruses, or fungi bind different TLRs in the course of polymicrobial sepsis.[63] Equine TLR signaling has been characterized in many cells and tissues.[64-66] Of interest is that whereas LPS is a potent stimulator of equine monocytes via TLR4, flagellin (via TLR5) preferentially stimulates neutrophils and induces little response from monocytes,[67] which suggests differential expression of these TLRs between cell types in horses that could play a role in clinical sepsis. Thus although TLR ligand-specificity appears to be well conserved across species, specific TLR expression varies among cells, tissues, and species and can result in varied responses to the same PAMP. Tissues subject to attack by mediators produced after the initial round of TLR binding can also amplify the inflammatory response by releasing DAMPs

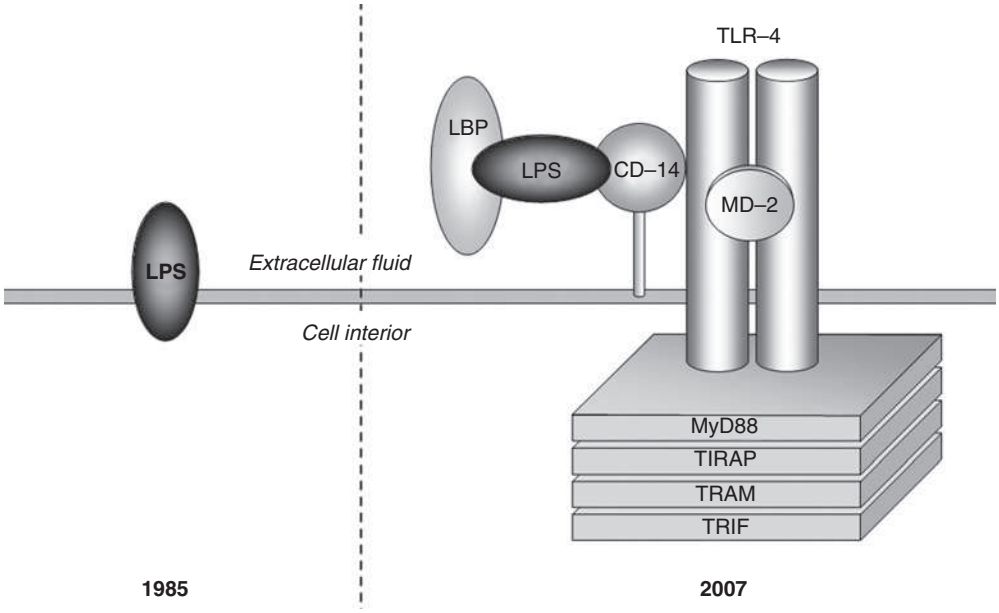

FIG. 32.57 Binding of lipopolysaccharide (LPS) to mammalian cell membranes. Initially (in 1985) it was widely believed that LPS initiated cellular signaling by hydrophobic interactions with the plasma membrane, but by 2007 the components of the signaling complex were more fully understood. In addition to the extracellular receptor components (discussed in the text), the intracellular Toll–interleukin-1 receptor (TIR) domain is shown interacting with four adaptor molecules (MyD88, TIRAP, TRAM, TRIF) to initiate a molecular signaling cascade that ultimately leads to gene activation. CD-14, cluster of differentiation 14; MD-2, lymphocyte antigen 96; TLR, Toll-like receptor.

TABLE 32.7

Seven Ligands for Human Toll-Like Receptors[56,226]

TLR1	Triacyl lipopeptides
TLR2	Lipoprotein
	Peptidoglycan (Gram-positive bacteria)
	Lipoteichoic acid (Gram-positive bacteria)
	Zymosan (yeast)
	Lipoarabinomannan (mycobacteria)
TLR3	Viral double-stranded RNA
TLR4	LPS
	Respiratory syncytial virus fusion protein
	HSP70
TLR5	Flagellin
TLR6	Diacyl lipopeptides
	Zymosan
TLR7	Viral single-stranded RNA
TLR8	Viral single-stranded RNA
TLR9	CpG oligodeoxynucleotide
	Herpes virus DNA
TLR10	Not determined
TLR11	Profilin-like protein (*Toxoplasma gondii*)
TLR12	Profilin-like protein (*Toxoplasma gondii*)
TLR13	23s Ribosomal RNA (bacteria)

CpG, Cytosine triphosphate deoxynucleotide followed by guanine triphosphate deoxynucleotide, linked by phosphodiester; *HSP*, Heat shock protein; *LPS*, lipopolysaccharide; *TLR*, Toll-like receptor.

(e.g., high-mobility group box 1)[68], which in turn can bind to TLR or other PRRs.

During cellular activation, endotoxin and other microbial products can also interact with soluble PRRs normally present in plasma. Of particular importance is that endotoxin binds to complement proteins to initiate the lectin-dependent and alternative pathways of complement activation and activates coagulation factor XII (Hageman factor) to set off the "contact" system of coagulation.

RELEASE OF MEDIATORS. Endotoxin-induced NF-κB activation in peripheral blood and tissue leukocytes (and many other cell types) acts via multiple signaling pathways to induce the expression of more than 200 genes, many of which are involved in the pathogenesis of sepsis.[52,60,69] These include genes for proinflammatory cytokines (e.g., tumor necrosis factor [TNF], interleukins 1β, 6, 8, 12, and 18 [IL-1β, IL-6, IL-8, IL-12, IL-18]), chemokines (e.g., IL-8, macrophage inflammatory protein [MIP]), type 1 interferons (IFNs), procoagulants, adhesion molecules, immunoreceptors (e.g., TNF receptors), enzymes (e.g., elastase), and acute-phase proteins (e.g., fibrinogen). NF-κB activity is further amplified by the paracrine actions of these proinflammatory cytokines and by other DAMPs, cellular hypoxia, cellular necrosis, and chemical stress (including oxidant stress). Two of the cytokines secreted by macrophages, IL-12 and IL-18, stimulate IFN-γ synthesis and secretion from natural killer and other cells.[70] Because IFN-γ is a potent stimulator of both innate and acquired immune responses, it is considered a principal link between the two systems.

Endotoxin activates coagulation factor XII (Hageman factor), which leads both to liberation of bradykinin and to initiation of intravascular coagulation. Of even more importance is that complement is activated by alternative, lectin-mediated, and classical pathways to yield numerous active peptide products that play a role in opsonization, inflammatory cell trafficking, and microbial cell lysis. Other microbial structural components and products similarly stimulate inflammation, complement activation, and coagulation, although specific pathways and molecular mechanisms are less well characterized in humans than in horses.

Systemic Inflammatory Response Syndrome in Early Sepsis

The initial (early) phase of sepsis is often referred to as the "hot" phase and is characterized by inflammation, coagulation, and necrosis. The principal NF-κB–mediated events during early sepsis are summarized in Fig. 32.58. This phase has been described as a "cytokine storm," during which there is flooding of inflammatory, procoagulant, and vasoactive mediators throughout the body. The net effects of these mediators promote microvascular injury and hypotension. The singular contributions of many mediators to sepsis is demonstrated by experiments with sepsis models in which blocking or deleting a single mediator has had a positive effect on outcome.

In early stages of sepsis, large numbers of neutrophils accumulate on the endothelial surfaces of organs undergoing failure, and insult to one organ can trigger the widespread recruitment and sequestration of neutrophils in others. Such a scenario may contribute to the association of laminitis with severe intestinal disease,[71-74] although altered insulin and glucose dynamics,[75,76] vascular derangements,[72] or contributions of multiple inflammatory mediators[77] may also play a role in the development of laminitis in septic horses.

PAMPs (including LPS), inflammatory cytokines, and complement peptides induce expression of selectins on endothelial cells, and neutrophils.[52] Selectins E and P on endothelial cells and selectin L on neutrophils reciprocally engage glycoprotein ligands to "tether" the neutrophil to the endothelial surface. A series of these transient interactions between ligands and receptors allows neutrophils to roll along the endothelial surface (Fig. 32.59). Neutrophil capture is most efficient in areas of low shear force such as the walls of postcapillary venules and in pulmonary capillaries. During rolling, neutrophils are activated by selectins, chemokines, and platelet-activating factor expressed on endothelial cells. The firm attachment or arrest step of the cascade is mediated by the avid interaction of neutrophil integrins with adhesion molecules of the immunoglobulin superfamily expressed on endothelial cells. During firm attachment the activated neutrophil spreads out and, in the healthy animal, squeezes between the intercellular junctions of adjacent endothelial cells and migrates into tissues up a gradient of chemotactic factors such as microbial chemotaxins, leukotriene B_4, IL-8, or complement component 5a (C5a). In contrast, in comparison with normal neutrophils, those found in septic animals have defective chemotactic responses but bind with greater avidity to the endothelium and to other neutrophils. When cultured, macrophages and neutrophils from patients with Gram-negative sepsis are hyporesponsive to LPS, which suggests a functional switch to LPS tolerance during the early stages of endotoxemia[78] (see Fig. 32.59). Sequestration of neutrophils on activated endothelium and in neutrophil aggregates accounts for the neutropenia found in most horses with endotoxemia. Of interest is that the life span of these sequestered neutrophils is prolonged during sepsis because normal apoptosis is prevented,[79] which might potentiate the inflammatory response during early sepsis.

Tightly adherent neutrophil-endothelial conjugates formed during sepsis seal off microscopic pockets between the juxtaposed cells into which cellular products can be concentrated. Of particular significance are the reactive oxygen species (ROS) produced as a result of the activation of the reduced forms of nicotinamide adenine dinucleotide (NADH) oxidase and of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in neutrophils (respiratory burst) and xanthine oxidase in endothelial cells.[51,69] Digital laminae of horses may be particularly vulnerable to the effects of ROSs because of low content of the endogenous oxidant scavenger superoxide dismutase.[80]

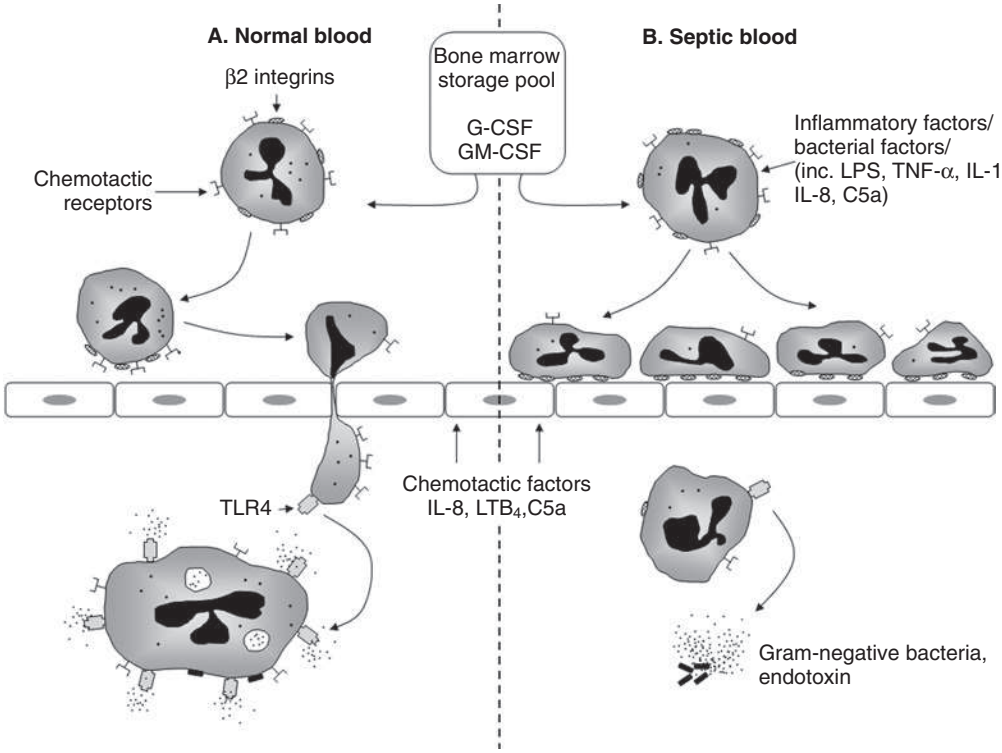

FIG. 32.59 Recruitment and activation of neutrophils in response to bacterial infection in healthy horses and septic or endotoxemic horses. In response to bacterial infection, cytokines are generated that induce the release of neutrophils from the bone marrow. In the normal state, large numbers of blood neutrophils enter sites of bacterial infection by first adhering to the activated endothelium of local postcapillary venules before migrating up a concentration gradient of chemotactic factors. Endotoxin is bound to Toll-like receptor 4 (TLR4), and bacteria are eliminated by phagocytosis. In patients with endotoxemia or sepsis, high levels of circulating inflammatory factors promote upregulation of surface integrins to promote firm endothelial adhesion to postcapillary venules. However, some of these factors also downregulate the expression of chemotactic receptors. Consequently, neutrophils are strongly bound but less responsive to underlying chemotactic factors. *C5a*, complement component 5a; *G-CSF*, granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *IL*, interleukin; *LPS*, lipopolysaccharide; *LTB4*, leukotriene B_4; *TNF-α*, tumor necrosis factor α. *(Modified from Brown K, Brain S, Pearson J, et al. VetBooks.ir

In the presence of neutrophil granule myeloperoxidase and H_2O_2, highly toxic hypochlorous acid is formed on the endothelial surface. Superoxide anion generated as part of the neutrophil respiratory burst also reacts with nitric oxide (a reactive nitrogen species [RNS]) from endothelial cells to yield reactive peroxynitrite radicals (another RNS). Other potentially corrosive substances are contributed by neutrophil granules and include elastase, serine proteases, matrix metalloproteinases, and defensins. In addition to direct damage caused by membrane lipid peroxidation, ROSs and RNSs indirectly stimulate the expression of multiple inflammatory, procoagulant, and vasoactive mediators through activation of NF-κB in both neutrophils and endothelial cells.[51] Mediators such as bradykinin, platelet-activating factor, C3a, C5a, and leukotriene B_4 directly increase vascular permeability by promoting active retraction of endothelial cells via phosphorylation of the light chain of nonmuscle myosin.[51] Vascular leak then facilitates the movement of these potentially harmful substances into tissues.

In health, the antithrombotic phenotype of endothelial cells is maintained by the presence of low amounts of prostacyclin (prostaglandin I_2) and nitric oxide, and surface expression of thrombomodulin, protein S and protein C complex, and tissue plasminogen activator.[81] During endotoxemia, endothelium supports extrinsic pathway activation because of leukocyte-induced physical damage, expression of the procoagulant tissue factor, downregulation of antithrombin-III and protein C, and inhibition of fibrinolysis through expression of plasminogen activator inhibitor 1.[82-84] Additional procoagulant effect may be provided by deposition on the endothelial surface of all of the components of the intravascular coagulation system. Microvascular perfusion is further compromised by sepsis-associated increase in "stiffness" of both RBCs and WBCs,[85] which renders such cells less able to deform and squeeze through narrow capillaries.

The effect of endotoxemia and sepsis on vascular tone depends on the stage and severity of disease and the particular organ (vascular bed) considered. Neuroendocrine responses to sepsis lead to the upregulation of predominantly pressor mediators including arginine vasopressin, angiotensin II, serotonin, epinephrine, and norepinephrine. Inflammatory mediators are a mix of vasoconstrictors (thromboxane A_2, endothelin, C3a, C4a, C5a) and vasodilators (prostaglandins E_2 and I_2, adenosine, bradykinin, nitric oxide). In animals with serious sepsis, balances of constricting and dilating influences unique to each vascular bed, loss of vasoregulatory tone, and refractoriness of damaged endothelium to vasoactive substances causes maldistribution of blood flow among organs and systemic hypotension.

Because of poor perfusion pressure, direct microvascular injury, thrombosis, and loss of endothelial integrity (capillary leak), ischemia and hypoxia of organs and tissues occur.[33] In fact, the fundamental event in serious sepsis is the development of global tissue hypoxia, perhaps also complicated by *dysoxia*.[52]

Global tissue hypoxia results when systemic oxygen delivery fails to meet the oxygen requirements of tissues, and dysoxia results when tissues are unable to effectively utilize delivered oxygen. During serious sepsis, widespread microvascular and mitochondrial injury decrease oxygen delivery and consumption at the cell, tissue, and organ levels.[51,86,87] Oxygen delivery to tissues is a product of cardiac output and oxygen content (which itself is a product of hemoglobin oxygen saturation and hemoglobin concentration). Systemic oxygen delivery multiplied by the percentage of oxygen extracted (normally ≤25%) by the tissues is the systemic oxygen consumption. The balance between systemic oxygen delivery and consumption is reflected by the mixed venous hemoglobin oxygen saturation (SVO_2). SVO_2 has been shown in other species to be a useful surrogate for cardiac index as a target for goal-directed therapy.[88] Central venous oxygen saturation, measured through a central venous line, is a reasonable and easily measurable substitute for SVO_2 (which must be measured via a Swan-Ganz catheter).

Various hemodynamic combinations may create a systemic imbalance between tissue oxygen supply and demand[52,89]:

- *Hypovolemia*. Because of decreased preload caused by hypovolemia, concomitant left ventricular dysfunction, and reflex systemic arterial vasoconstriction, early endotoxemia is often characterized by low cardiac output (i.e., hypodynamic circulatory insufficiency).
- *Compensated but maldistributed perfusion*. After fluid-electrolyte resuscitation, compensatory mechanisms and low afterload drive transition to a hyperdynamic state. Even with normal or increased cardiac output, perfusion abnormalities may persist because of regional hypoperfusion associated with derangements in blood flow distribution, loss of vasoregulatory control to vascular beds, and endothelial dysfunction.[90] This state is often described as *distributive shock*.
- *Myocardial depression* secondary to effects of inflammatory mediators and apoptosis of cardiomyocytes is the predominant cause of death in severe sepsis and septic shock.[91] Myocardial injury—as indicated by increased cardiac troponin concentrations—was reported in horses undergoing emergency abdominal surgery,[92] which suggests that similar pathologic processes probably develop in horses with sepsis and SIRS.
- *Increased metabolic demands*. SIRS increases metabolic demands, as evidenced by increased splanchnic and total body oxygen consumption.
- *Impaired oxygen utilization*. The bioenergetics of cellular extraction and use, as well as respiration, may be abnormal at least partially because of mitochondrial dysfunction.[51,86,87]

The effects of these hemodynamic derangements on clinical measures cardiovascular function and perfusion are detailed in Table 32.8.

In summary, the pathophysiologic mechanisms of early sepsis are currently thought to support development of a

VetBooks.ir

self-perpetuating imbalance in the systemic redox state, which results in oxidative stress that is believed to be at the root of SIRS and resultant organ dysfunction in sepsis.[51,86,87] Activation of local and systemic inflammatory responses results in production of ROS and RNS, which can directly and irreversibly damage cells and inhibit normal cellular activity, as described previously. In health, ROS and RNS production is tightly regulated by inducible antioxidant enzymes, production of which is regulated by the nuclear transcription factor Nrf2.[51] However, Nrf2 activity is impaired by excessive ROS and RNS production, which results in less activation of these antioxidant pathways and the generation of an overall oxidant environment.[51] Mitochondria are a key source of ROS and RNS but are also very sensitive to oxidative injury. Mitochondrial dysfunction and oxidative stress can result in tissue dysoxia and organ failure, as well as further stimulate inflammatory responses and NF-κB activation, creating the vicious cycle characteristic of SIRS and MODS.

Immunosuppression in Late Sepsis

It has become apparent that many horses with sepsis are profoundly immunosuppressed, as evidenced by lymphopenia, anergy, and susceptibility to opportunistic infections[51,52,93] (e.g., pulmonary aspergillosis in horses with enteric salmonellosis[94,95]). This immunosuppression, termed the *compensatory anti-inflammatory response syndrome* (CARS), has been explained by the reactive production of antiinflammatory mediators in response to the cytokine storm.[96] Although many such mediators are produced and actually can have favorable antiinflammatory effects when used as therapy in models of sepsis, it is now clear that three additional and primary mechanisms involving both innate and adaptive immune responses contribute to sepsis-associated immunosuppression: (1) widespread apoptotic death of lymphocytes (particularly B cells and $CD4^+$ T-helper cells) secondary to activation of intracellular caspases; (2) dendritic cell loss and dysfunction, which leads to inefficient or impaired antigen presentation; and (3) impaired phagocyte chemotaxis and killing responses.[51,93,97,98] Of interest is that macrophages and neutrophils are spared premature apoptotic death; neutrophils actually are prevented from physiologic apoptosis during sepsis and remain viable in sequestered sites.[79] In humans with sepsis, aspects of this immunosuppression are characterized by loss of cutaneous delayed-type hypersensitivity responses,[51] but this has not been investigated in horses to date. The relationship and interplay between SIRS and immunosuppression in sepsis is still unclear, and these phases may not always occur sequentially in the same patient.

Signs of Endotoxemia and Sepsis

CLINICAL SIGNS. In horses given intravenous endotoxin experimentally, the clinical signs may range from fever without obvious malaise to multiple organ failure and death. Obviously, signs of the primary disease resulting in endotoxemia (e.g., severe pain caused by intestinal strangulation or diarrhea in horses with *Salmonella* colitis) may greatly influence the overall clinical presentation of horses with naturally acquired endotoxemia. The clinical signs of polymicrobial or Gram-positive sepsis are generally indistinguishable from the signs associated with endotoxemia/Gram-negative sepsis described later.[46,47,99,100]

Typically, in an adult horse given a moderate sublethal dose of endotoxin intravenously (e.g., 0.1 to 1 μg of LPS per kilogram of body weight), an early period of mild tachypnea peaks within 30 minutes and resolves within 2 hours. During this period, mucous membranes are pale. Beginning within 90 minutes after LPS injection, depression, restlessness, and inappetance are present and rectal temperature begins to rise. Auscultable intestinal sounds usually cease during this period and remain depressed for several hours. Intermittent signs of colic usually are seen, including recumbency (usually without rolling). Small amounts of loose feces usually are passed. The heart rate peaks during the stage of maximal abdominal discomfort (approximately 2 hours after administration of endotoxin) and then temporarily declines. During this time, mucous membranes become congested, the capillary refill time is prolonged, and a dark "toxic" line may become apparent around the gingival margins of the teeth. Beginning 4 to 6 hours after endotoxin administration, there is a secondary phase of tachycardia and tachypnea that is probably related to development of systemic hypotension and fever. This secondary phase persists for several hours. Horses that present clinically with mild to moderate endotoxemia or sepsis usually resemble experimental animals during the period 2 to 6 hours after intravenous endotoxin administration.

At higher LPS doses (e.g., 100 μg/kg) in experimental animals, or in patients with severe endotoxemia/sepsis, signs of circulatory failure and disordered hemostasis dominate the clinical picture. Usually affected horses are stuporous and totally anorexic. Signs of dehydration such as reduced skin turgor, dry mucous membranes, and sunken eyes are obvious. As systemic blood flow becomes more compromised, rectal temperature may drop into or below the normal range. Urine output is reduced or nonexistent. There are dark, congested mucous membranes, rapid and weak peripheral pulses, cold extremities, and sweating, and affected horses may have muscle tremors or become recumbent.

Vascular damage may be seen as petechial and ecchymotic hemorrhages on mucous membranes. A poor prognostic sign is the development of a hypercoagulation syndrome, during which routine venipuncture or catheter placement initiates thrombosis along the entire visible length of the jugular veins (or other superficial veins). If both jugular veins are thus occluded, there usually is massive swelling of the soft tissues of the head, and associated laryngeal edema may cause signs of upper respiratory tract obstruction. In some horses, thrombosed superficial vessels can easily be palpated through the skin of the legs and abdomen. Infarction of bowel segments or lungs may cause severe clinical signs that are unresponsive to treatment. A rare syndrome of thrombosis of major limb arteries found in young foals is probably a result of sepsis syndrome.[101,102] At the time that hypercoagulation syndrome is recognized clinically, there is often also evidence of a secondary bleeding tendency (a consequence of platelet and clotting factor depletion and uncontrolled activation of fibrinolysis in disseminated intravascular coagulation), manifesting as prolonged hemorrhage from venipuncture sites and widespread mucosal petechiation. In cases with a severe pulmonary component, there may be hemorrhage into the respiratory tract with progressive tachypnea and dyspnea. Alterations in coagulation (both hypercoagulable and hypocoagulable states) were shown to be associated with incidence of SIRS and mortality in horses with acute gastrointestinal disease[30,40,103,104] and with mortality in septic foals.[105]

If moderately to severely affected animals survive for more than 24 hours, they usually exhibit visible edema of the ventral abdomen and limbs. Signs of MODS may first become apparent at this stage (see Table 32.2).[30] In adult horses, laminitis may develop or progress in severity as a result of mechanical failure of the lamina, even after improvement or resolution of other systemic signs of SIRS and sepsis. Of importance is that experimental endotoxin infusion does not reliably reproduce laminitis in horses, so other DAMPs or cellular responses in the sepsis syndrome probably play a role in laminar failure in equine sepsis.

CLINICOPATHOLOGIC SIGNS. Profound leukopenia occurs early and is caused principally by neutropenia (usually accompanied by left shift and a toxic appearance of stained cells). Lymphopenia (<1000/μL) is found in the most severe cases

VetBooks.ir

and probably reflects sepsis-induced apoptosis and immunosuppression. Adult horses often are hyperglycemic at presentation, whereas neonates with sepsis are typically hypoglycemic. Other abnormalities are nonspecific and reflect altered tissue perfusion and variable organ dysfunction (see Table 32.2).[30]

In moderate and severe cases of endotoxemia, there also may be clinicopathologic evidence of disordered hemostasis, including any or all of the following: reduction in the circulating platelet count (<100,000/μL); reduction in plasma fibrinogen concentration; prolongation of the activated partial thromboplastin, prothrombin, or thrombin time; increased activity of plasminogen activator inhibitor 1; and increased concentration of fibrin degradation products. Studies in which viscoelastic coagulation testing was used to provide a more global assessment of coagulation function in horses with SIRS and foals with sepsis have provided further documentation of hypercoagulable and hypocoagulable states and of the association between coagulation derangements and increased disease severity and mortality in equine sepsis.[40,105] In horses with acute gastrointestinal diseases, there also is increased activity in peritoneal fluid of many of the elements of the fibrinolytic system, including tissue plasminogen activator. Depletion of key clotting factors can be detected most simply as prolongation of plasma recalcification time.[106]

Although the measured concentration of endotoxin in blood is not strongly correlated with incidence or severity of clinical signs, demonstration of circulating endotoxin obviously is definitive proof of endotoxemia. Of horses with acute gastrointestinal disease, 12 to 29% have detectable plasma endotoxin.[48,49] In experimental conditions, plasma endotoxin usually is assessed by some variant of the *Limulus* amebocyte lysate bioassay, which requires anticoagulation of samples with LPS-free heparin. A simple horse-side test for endotoxin that was marketed for use in clinical practice is no longer commercially available, but measurement of endotoxin activity in equine blood via neutrophil chemiluminescence has been described.[107] Tests for other microbial PAMPs that could play a role in equine sepsis (e.g., staphylococcal toxins, flagellin) are currently unavailable or limited to research settings.

Assessment of the Stage of Sepsis

Staging criteria for horses and foals with signs of SIRS/sepsis/endotoxemia are detailed in Fig. 32.56 and Tables 32.1 and 32.2.[26-28,30] Validated criteria for diagnosing and staging MODS in horses with GI disease are now available and may be applicable to horses and foals with other clinical conditions.[30] It is especially important to recognize that horses with serious sepsis need aggressive intervention in order to survive.

Treatment of Sepsis

There is no surefire treatment of sepsis or endotoxemia. Almost without exception, potentially novel treatments for Gram-negative sepsis that have been promising at the experimental level have failed when applied in clinical settings in human beings. A short list of treatments used in such trials includes anti–tumor necrosis factor α (TNF-α), IL-1 receptor antagonist, ibuprofen, platelet-activating factor antagonist, elastase inhibitor, nitric oxide synthase inhibitor, antithrombin III (AT-III), tissue factor pathway inhibitor, and drotrecogin alfa (activated protein C).[108] It is clear that most experimental sepsis models do not replicate naturally occurring sepsis, at least as it occurs in humans and probably in horses. Even among sepsis models, results for the same candidate treatment are often inconsistent. For example, neutralization and inhibition of inflammatory cytokines such as TNF-α usually have salutary effects in LPS-infusion experiments; however, equivalent studies involving the cecal ligation-puncture model in mice (widely considered to be one of the best experimental sepsis models) usually have shown either neutral or negative effects on mortality.[109]

Several of many plausible explanations for the disparity among and between the results of experimental, single-center, and large clinical studies are (1) heterogeneity of presentations among enrollees in clinical studies; (2) diversity in genetic susceptibility to sepsis among outbred populations; (3) differences between experimental and clinical study species; (4) differences in timing of potential treatments in relation to the onset of sepsis between the two study populations; and (5) a preponderance of immunosuppressive states in naturally occurring sepsis, in comparison with the "cytokine storm" of early sepsis usually re-created in experimental models.

Fortunately, there is powerful evidence to support the use of early aggressive cardiovascular resuscitation in sepsis management in clinical settings. Previous work in humans documented a reduction in in-hospital mortality from serious sepsis, from 46.5% in the group that received standard therapy to 30.5% in the group that received early goal-directed therapy (EGDT; Fig. 32.60): oxygen, fluids, pressors, inotropes, and packed RBCs during the first 6 hours after admission to achieve a sequence of physiologic goals.[110] However, more recent studies have demonstrated conflicting results, with some failing to demonstrate any benefit of EGDT over standard therapy.[111-113] In view of the constant improvements in standard of care in human medicine, it seems possible that reaching the specific physiologic goals laid out in EGDT protocols is less important than general aggressive cardiovascular support and close monitoring during initial stabilization. Comparable aggressive cardiovascular resuscitation protocols for equine patients with SIRS, sepsis, and septic shock are detailed in the next section.

Improvements in cardiovascular support of horses with sepsis will continue to be of much more value than any single therapeutic agent available now or in the future. In fact, because clinical sepsis probably is almost always caused by multiple pathogen and host-derived DAMPs stimulating multiple, complementary, and redundant inflammatory pathways, management of sepsis is much more likely to be successful when therapy focuses on combatting the clinical sequelae of severe SIRS and subsequent immunosuppression rather than targeting a specific inflammatory mediator or PAMP. A prioritized strategy for management of horses with sepsis or endotoxemia should include (1) cardiovascular resuscitation; (2) laminitis prevention; (3) removal of the causes of sepsis; (4) neutralization of circulating endotoxin or other PAMPs; and (5) inhibition of PAMP-induced inflammation.

CARDIOVASCULAR RESUSCITATION. Expansion of blood volume remains the cornerstone of treatment for horses with SIRS/sepsis/endotoxemia. Most cases can be treated successfully with intravenous balanced polyionic solution according to guidelines for estimating water deficits provided in the Fluid Therapy for Horses with Gastrointestinal Diseases section of this chapter. Urination should begin during the rapid replacement of estimated losses. Ideally, the fine control of fluid replacement is based on clinical evidence of blood volume and perfusion (e.g., mucous membrane color, heart rate, capillary refill time, pulse quality, jugular refill time, extremity temperature), as well as serial measurements of packed cell volume (PCV) or plasma protein concentration and blood lactate concentration. Some clinicians prefer the early use of compatible plasma (20 to 40 mL/kg) to replace the extravasated colloid lost as a result of vascular leak. Plasma has the advantage of providing immunoglobulin, acute-phase proteins, and anticoagulants and can provide antiendotoxin antibodies (described later). Synthetic colloids such as 6% hetastarch (hydroxyethyl starch solution) were advocated as excellent colloid replacement in sepsis and septic shock because of their superior oncotic activity. However, studies have demonstrated impairment of hemostasis and development of acute kidney injury in septic patients receiving some synthetic colloids, and the use of 6% hetastarch is now considered contraindicated in human sepsis.[114]

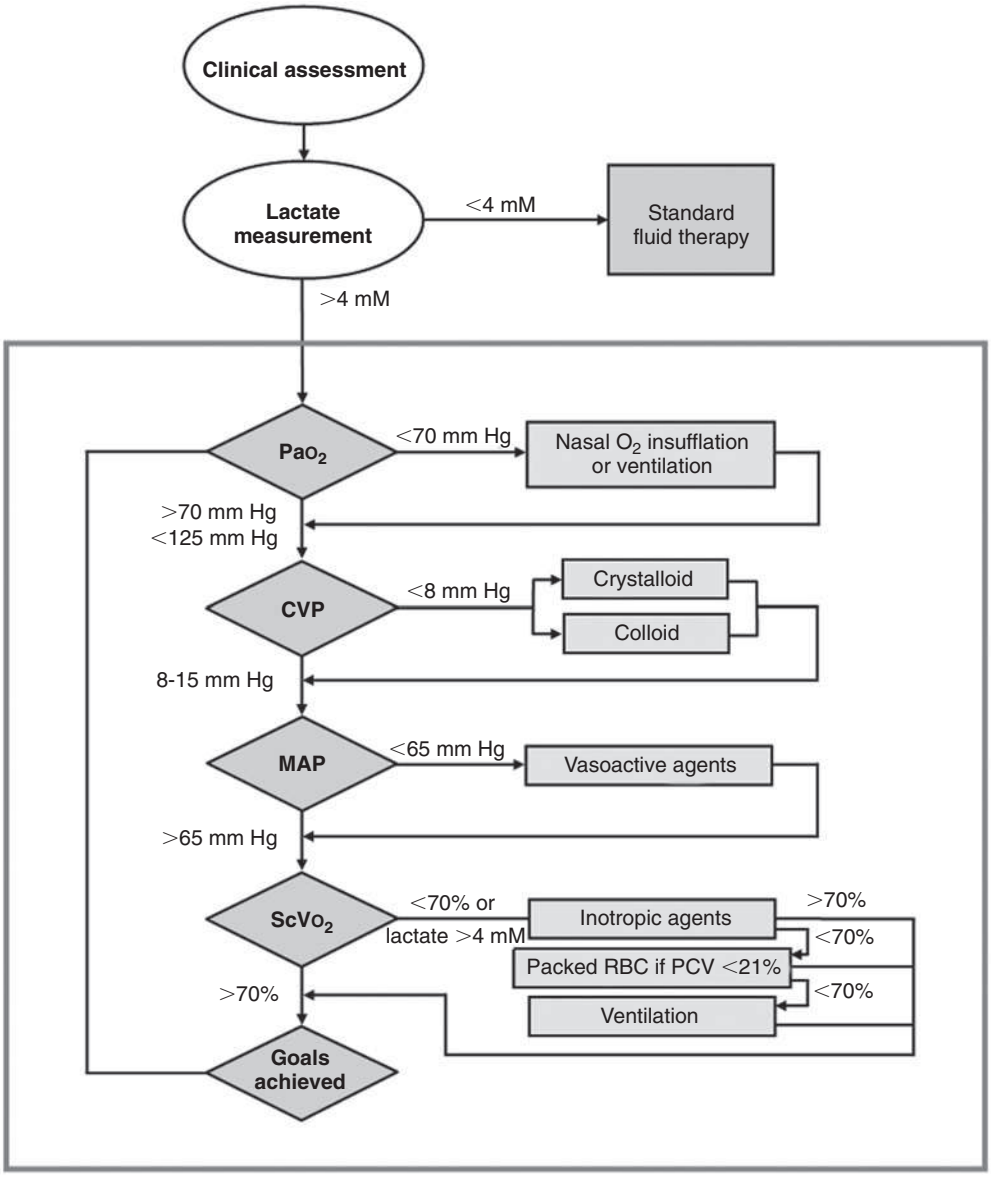

FIG. 32.60 Protocol for early goal-directed therapy. An initial 20-mL/kg bolus of isotonic crystalloid (or equivalent colloid) is given, followed by boluses of 10 mL/kg every 30 minutes until central venous pressure (CVP) reaches 8 to 15 mm Hg. If adjusted mean arterial pressure (MAP) at the heart base is still less than 65 mm Hg, vasopressors are given to effect. Norepinephrine, dopamine, or vasopressin can be used according to the clinician's preference. If the central venous oxygen saturation ($ScVO_2$) is still less than 70%, the continuous-rate infusion of dobutamine can be increased in increments up to 15 µg/kg/min. If the packed cell volume (PCV) is less than 21% after the preceding steps and $ScVO_2$ is less than 70%, packed cells should be given to increase oxygen-carrying capacity. *Pa_{O_2}*, Partial pressure of arterial oxygen; *RBC*, red blood cells.

In horses with severe sepsis, septic shock, or MODS, aggressive hemodynamic stabilization and monitoring is indicated. Owners should be informed that such treatment still carries at best a guarded prognosis for survival, substantial financial commitment, transfer to a referral center, and great risk of potentially life-threatening complications such as laminitis. However, early and aggressive intervention is essential in sepsis therapy; in critical care parlance, terms such as the "golden 6 hours" and the "silver 24 hours" exemplify this concept.[89]

Specific and critically evaluated guidelines for initial resuscitation and stabilization in equine sepsis are not available, but much has been extrapolated from human critical care. Initial fluid resuscitation should include a balanced polyionic crystalloid at 20 mL/kg as an intravenous bolus followed by reassessment of hemodynamic parameters; fluids with high chloride levels such as 0.9% sodium chloride should be avoided. Boluses of 10 to 20 mL/kg should be repeated until hemodynamic improvement is reached or three or four boluses have been given (total, 60 to 80 mL/kg).[115,116] Both clinical and clinicopathologic parameters should be monitored and at minimum should include heart rate, body temperature, mentation, capillary refill time, peripheral pulse quality, warmth of extremities, peripheral lactate, partial pressure of arterial oxygen, and mean arterial pressure (MAP). Central venous pressure (CVP) and central venous oxygen saturation can also be measured to guide resuscitation if suitable equipment is available.[117] Hypoxemic patients should receive nasal oxygen insufflation, and ventilation may be needed for severely hypercapneic or hypoxemic patients. Steady improvement in these parameters with return to reference values within the first 6 to 8 hours of therapy is ideal but not always possible. If the patient is still not improved after three or four fluid boluses, as mentioned, and oxygen/ventilatory

support, additional therapy with colloids (plasma, or whole blood if anemia is also present), inotropes, vasopressors, or a combination of these should be considered.

Once the patient is stabilized, fluid management should continue according to standard protocols (see the Fluid Therapy for Horses with Gastrointestinal Diseases section) with adjustments made according to the results of continued monitoring of clinical signs of blood volume status and perfusion, blood acid-base status, partial pressure of arterial oxygen, central venous oxygen saturation, lactate, CVP, and MAP. If the blood bicarbonate concentration is less than approximately 16 mmol/L after volume restoration, sodium bicarbonate should be given IV to replace calculated deficits. During correction of acidemia, intravenous fluids should be supplemented with potassium (10 to 20 mmol/L) to prevent correction-induced hypokalemia. A maintenance-rate infusion of glucose should be given to neonates with sepsis (4 mL of 5% dextrose–containing fluids per kilogram per hour) and hypoglycemic adults (2 mL of 5% dextrose or 0.2 mL of 50% dextrose per kilogram per hour). Glucose concentration should be regularly monitored, and the use of concurrent insulin therapy should be considered in persistently hyperglycemic animals.

LAMINITIS PREVENTION. Adult horses with sepsis are at high risk for the development of laminitis. Among the clinical risk factors that are probably operative in the setting of sepsis are underlying endocrine disease, previous episodes of laminitis, a period of 24 hours or longer since onset of signs of endotoxemia or sepsis, fever, prolonged central reaction time, and cold extremities. The digital laminae are probably injured early in sepsis, potentially irreversibly, by processes associated with the cytokine storm and resultant global tissue hypoxia. Insulin resistance, hyperglycemia, microvascular injury and thrombosis, and protease activation all may also be involved in the pathogenesis of sepsis-associated laminitis. There is no ideal laminitis prevention strategy that is universally effective, but according to the current understanding of laminitis pathophysiology, a combination of prompt fluid resuscitation to restore appropriate digital perfusion, NSAIDs to decrease inflammatory mediators, and digital cryotherapy is generally accepted as the minimal standard of care, and some evidence supports their use in equine sepsis.[118,119] Laminitis prophylaxis must be implemented very early (preferably before an increase in digital pulses is detected) and is not universally protective.

The use of insulin infusions in septic horses may also be indicated to combat persistent hyperglycemia associated with sepsis-mediated insulin dysregulation, inasmuch as insulin dysregulation is associated with endocrinopathic laminitis. However, because insulin infusions at very high rates have been associated with laminitis development in healthy horses and ponies[120,121] and hyperinsulinemia is associated with endocrinopathic laminitis,[122] glucose or insulin infusions could possibly potentiate the development of laminitis in susceptible animals with sepsis. The use of insulin-sensitizing drugs such as metformin or pioglitazone could have potential in treating sepsis-mediated insulin dysregulation in horses, but to date these drugs have not been examined in clinical equine sepsis; current evidence suggests that their effects on insulin sensitivity in horses may be variable at best.[123-125] If laminitis is already present, or if it develops during the course of treatment, it should be treated as described in Chapter 38.

REMOVAL OF THE CAUSE OR CAUSES OF ENDOTOXEMIA AND SEPSIS. Removal of the cause of sepsis usually involves both removal of the source of endotoxin or other microbial PAMPs, as well as correction of the abnormality that allows endotoxin or other PAMPs to enter the blood. In some cases, the source can be mechanically removed; for example, bacteria and associated inflammatory effusion can be drained from pleural or peritoneal cavities or lavaged from the postpartum uterus. Early and appropriate antimicrobial therapy also is essential. In general, broad-spectrum bactericidal drugs should be selected because septic horses may be immunosuppressed. In horses in which endotoxemia or sepsis is associated with diarrhea or other signs of colitis or typhlitis, the use of antimicrobial drugs is controversial because of their causal association with severe colitis. Antimicrobials should probably should be given to equids with colitis only in the following situations: (1) The affected horse is younger than 6 months of age; (2) clostridial or antimicrobial-associated enteritis is suspected (use of metronidazole should be considered); (3) the horse has a severe degenerative left shift or severe leukopenia with total neutrophil count of less than 1000 µg/mL; (4) the horse has concurrent peritonitis; or (5) the horse shows clinical evidence of dyshemostasis (e.g., jugular thrombosis or abnormal coagulogram). However, these recommendations and outcomes after treatment of equine colitis with and without antimicrobials have not been critically evaluated to date. Furthermore, effective antimicrobial therapy could temporarily worsen clinical signs by causing the release of endotoxin from killed bacteria. This possibility should be anticipated and minimized by the timely use of NSAID or other antiendotoxic therapy (see later discussion).

When intestinal strangulation is the cause of sepsis, surgical correction obviously is of paramount importance. For the purposes of perioperative management, however, it should be noted that resumption of intestinal blood flow could worsen endotoxemia and sepsis: Sequestered endotoxin and other microbial components may be flushed into the circulation through compromised intestinal walls. At least in the case of small intestinal ischemia, the mucosal barrier to endotoxin may be further compromised by ischemia-reperfusion injury when full blood flow is restored by luminal decompression or other manipulation. Prophylactic or intraoperative administration of NSAIDs, ROS scavengers, polymixin B, hyperimmune plasma or serum (as described later), or a combination of these before or immediately after correction of a strangulating intestinal lesion may be warranted.

NEUTRALIZATION OF CIRCULATING ENDOTOXIN

Hyperimmune Plasma and Serum. An antiserum (Endoserum; Immvac Inc., Columbia, Mo.) and several hyperimmune plasmas (e.g., Equiplas-J, Plasvacc, Templeton, Calif.) produced by immunization of horses against R-mutant endotoxins are used in horses with suspected endotoxemia (in some cases, this is an off-label use). As is the case with studies in humans and small experimental animals, use of cross-reactive endotoxin antibodies in horses with either experimentally or naturally acquired endotoxemia has yielded conflicting results. Several studies demonstrated impressive reduction of mortality rate or improvement in clinical signs when antiendotoxin serum or plasma was given to horses[126-128]; in other studies, however, no improvement was demonstrated.[129,130] Pretreatment of foals with antiserum was associated in one report with significant worsening of clinical response to IV administered endotoxin in comparison with foals that received no pretreatment.[131] These disparate results probably reflect, at least in part, variation in the quality of antisera and experimental conditions; therefore no blanket recommendation can be made as to the clinical use of such products.

As evidence of the potential general value of hyperimmune plasmas, a reduction in mortality was achieved when antiendotoxin plasma raised against the *E. coli* mutant J5 was given to bacteremic humans (39% for controls versus 22% for those given antiendotoxin plasma) in a masked, well-controlled study at a single hospital.[132] In contrast, subsequent large multicenter studies of two different antiendotoxin monoclonals failed to show beneficial effects.[133,134] An equine study demonstrated no

effect of hyperimmune plasma on clinical parameters or peak plasma TNF-α concentrations in horses undergoing an experimental low-dose endotoxin challenge, although peak plasma TNF-α bioactivity was reduced in horses receiving plasma in comparison with controls.[135] This suggests that hyperimmune plasma may contain factors such as soluble TNF-α receptor that could limit the activity of endotoxin-induced inflammatory cytokines. Hyperimmune plasmas (raised against any antigen) also contain colloid, anticoagulant, and increased amounts of substances such as acute-phase proteins, which might have nonspecific beneficial effect in the setting of endotoxemia and sepsis. Therefore the use of 5 to 40 mL of hyperimmune plasma (of any specificity) per kilogram can be justified in treatment of serious endotoxemia or sepsis in horses.

Polymyxin B. Polymyxin B is a broad-spectrum cyclic peptide antibiotic with potent endotoxin-binding activity. Potentially lethal side effects (respiratory paralysis and nephrotoxicity) have precluded use of this agent as a systemic antimicrobial drug; however, polymyxin B retains endotoxin-neutralizing capacity at nontoxic dosages. Pretreatment of foals with polymyxin B at a dosage rate of 6000 U/kg significantly suppressed clinical and cytokine responses to intravenous endotoxin without causing toxic side effects.[131] Repeated administration to ponies of 15,000 U/kg also produced no sign of toxicity.[136] At a dose of 5000 U/kg, polymyxin B provided protection even when given 30 minutes after the start of LPS infusion.[137] The results of a pharmacokinetic and pharmacodynamic study of polymyxin B in horses suggested that the drug could safely be given at 6000 U/kg every 8 hours to maintain continuous endotoxin neutralization.[138] Lower doses (1000-2000 U/kg) also appear to have anti–TNF-α effects, but for shorter time periods.[137,139] Thus in horses with moderate or severe endotoxemia, IV polymyxin B (Polymyxin B sulfate; Bedford Laboratories, Bedford OH) can be given cautiously two or three times daily at a dosage rate of 1000 to 6000 U/kg. Each treatment should be diluted in saline and infused over at least 15 minutes. However, of importance is that although polymyxin B and the nontoxic polymyxin B–dextran 70 conjugate PMX-622 safely prevented signs of endotoxemia when given before LPS to otherwise healthy horses,[137,139,140] the drug has not advanced beyond phase 1 trials in human patients because experimental studies showed that it did not protect mice if given after intraperitoneal administration of endotoxin.[141]

INHIBITION OF ENDOTOXIN-INDUCED INFLAMMATION AND RELATED SEQUELAE

Nonsteroidal Antiinflammatory Drugs. Through inhibition of COX, NSAIDs reduce the formation of prostanoid metabolites (e.g., thromboxanes and prostaglandins) from arachidonic acid and thereby attenuate much of the adverse effect of endotoxin. Flunixin meglumine, phenylbutazone, ketoprofen, carprofen, meloxicam, firocoxib, and aspirin are examples of this class of drugs used in horses. When flunixin is administered at 0.25 mg/kg every 6 to 8 hours in horses, endotoxin-induced prostanoid production is prevented, and antiendotoxic effects are maximal in experimental situations without obscuring the signs of colic or increasing the risk of toxic side effects of the drug.[142] Flunixin, however, does not reduce endotoxin-induced leukopenia. Because there is evidence that aspirin does not prevent endotoxin-induced aggregation of equine platelets,[143] there appears to be no rationale for the practice of adding aspirin to the NSAID regimen. Most NSAIDs inhibit constitutive COX-1 activity (in addition to endotoxin-induced COX-2 activity), and so some morbidity is associated with their use. Gastric ulceration, right dorsal colitis, renal papillary necrosis, and possibly impairment of intestinal motility may develop.[144,145] Moreover, flunixin meglumine has been shown to slow mucosal healing and increase mucosal permeability by LPS in ischemic-injured equine jejunum,[146,147] although similar inhibition of mucosal barrier function does not appear to occur in the equine colon.[148] However, concurrent administration of misoprostol (a prostaglandin E_1 analogue)[149] or a constant-rate infusion of lidocaine[150] ameliorated these effects in an equine model, which suggests these drug combinations might be more appropriate than flunixin alone for horses with endotoxemia caused by intestinal ischemia.

In view of this toxic potential of equine NSAID use, it has also been suggested that administration of COX-2–selective drugs may minimize side effects while maintaining efficacy. Three NSAIDs with documented analgesic effect in horses—firocoxib, carprofen, and meloxicam—have been shown to be COX-2–selective.[151,152] Etodolac, a COX-2–specific drug in dogs and humans, is not COX-2–selective in horses when used at analgesic doses (23 mg/kg PO once or twice daily).[153] Firocoxib and meloxicam do not appear to retard small intestinal mucosal healing or increase LPS permeability in ischemic-injured equine jejunum as flunixin can.[146,154] Of importance, however, is that COX-2 activity may also have potentially beneficial effects in horses with sepsis; for instance, COX-2 products (e.g., prostaglandins E_2, and I_2) mediate epithelial restitution in damaged equine colon[144] and are thought to be important in maintaining the antithrombotic phenotype of normal endothelium. NSAIDs in the coxib class, which are potently COX-2 specific, have also been shown to increase the risk of atherosclerotic cardiovascular disease in humans.[155] Similar risks for coxibs in horses have not been described, but at present firocoxib and meloxicam are the only drugs in this class labeled for equine use, and neither is yet available globally.

Finally, although various NSAIDs have been shown to effectively prevent the clinical and molecular sequelae of equine endotoxemia in experimental models,[83,142,156-163] no study has shown convincingly that NSAIDs actually save lives in human or equine patients with naturally occurring sepsis. A large multicenter, controlled, masked, prospective study of ibuprofen in humans with sepsis syndrome showed no effect of this drug on the development of shock or the acute respiratory distress syndrome, and no improvement in survival.[164] Similar studies have not been conducted in horses to date.

Methylxanthine Derivatives. Inflammatory cytokine production by macrophages is suppressed in dose-dependent manner by methylxanthine derivatives. This effect appears to be caused by phosphodiesterase inhibition and consequent elevation of intracellular cyclic adenosine monophosphate. Pentoxifylline, a drug that used widely by humans as a hemorheologic agent, has also been shown to increase RBC deformability in horses.[165] Pentoxifylline also inhibits TNF-alpha production in horse blood and in cultured equine macrophages while increasing secretion of prostacyclin.[166,167] Studies in other species suggest that pentoxifylline stimulates production of the antiinflammatory cytokine IL-10, suppresses neutrophil activation, and inhibits activation of NF-κB.[168] A pharmacokinetic study in horses has indicated that administration at 10 mg/kg PO two times daily provides serum concentrations equivalent to those used therapeutically in humans.[169]

Finally, intravenous pentoxifylline significantly, albeit only partially, reduced adverse signs in horses given LPS.[170] The usefulness of this finding is called into question, however, by the observation that the lethality-sparing effect of pentoxifylline in endotoxemic mice was removed if the drug was given in combination with indomethacin, a potent NSAID.[171,172] In this study, the investigators concluded that upregulation of prostacyclin production by pentoxifylline, which was prevented by concurrent indomethacin, reduced mortality in subject mice by preventing endotoxin-induced leukopenia. Of interest is that pentoxifylline alone increased WBC counts in horses, but this effect is prevented by flunixin.[167,170] Thus there might be a conceptual and potential beneficial effect of pentoxifylline

VetBooks.ir

therapy (10 mg/kg PO bid) in endotoxic horses, although any effect could be partially or wholly neutralized by concurrent NSAID administration (as is commonly done in equine practice).

Corticosteroids. The corticosteroid class of drugs theoretically has many useful actions in combating inflammation in endotoxemia and sepsis. These include reduced production of cytokines, inhibition of TNF-alpha production by macrophages, stabilization of cell membranes, and prevention of neutrophil activation. It is surprising, however, that neutral or negative effects of moderate or high-dose steroid use were found in large, multicenter studies of humans with Gram-negative sepsis,[173] probably in relation to immunosuppressive effects at these doses. Corticosteroids also are widely believed to increase susceptibility to laminitis in endotoxemic horses, perhaps by increasing the sensitivity of digital vessels to the constrictive actions of circulating catecholamines or by inducing insulin resistance and hyperglycemia.[174] Use of high-dose corticosteroids is currently contraindicated in the treatment of endotoxemia or sepsis in humans and horses.

Some human patients with sepsis appear to respond to low "physiologic" doses of hydrocortisone.[174-178] Most such patients have high baseline cortisol concentrations but are thought to be in a state of adrenal insufficiency termed *critical illness-related corticosteroid insufficiency* (CIRCI), a syndrome that also appears to occur in some septic neonatal foals and some horses with systemic illness and SIRS.[41,179-181] Low-dose hydrocortisone is associated with reduced need for vasopressor use and lower mortality rates in humans with septic shock, according to a number of reports,[175,176,182-184] but other studies have not demonstrated a beneficial effect.[185] At present, low-dose hydrocortisone therapy is recommended for humans with sepsis who meet criteria for CIRCI but not universally for all septic patients.[183] The use of low-dose hydrocortisone therapy has not yet been reported in septic equine patients, but a 3.5-day tapering regimen of low-dose hydrocortisone (1.3 mg/kg/day divided q4h IV) administered to healthy neonatal foals was shown to ameliorate LPS-induced inflammatory cytokine production from peripheral blood leukocytes without impairment of neutrophil function in an ex vivo model.[186]

Anticoagulant Therapy. The use of anticoagulants such as heparin in horses with endotoxemia is somewhat controversial. Heparin prevents microvascular thrombosis principally by promoting the anticoagulant activity of AT-III. Unfortunately, heparin cannot reverse existing thrombosis, and because AT-III is consumed during severe coagulopathy, it may not prevent additional intravascular coagulation in such cases. Fresh and fresh-frozen plasma are good sources of AT-III but also provide clotting factors that could potentiate intravascular coagulation. When given at the recommended intravenous or subcutaneous dose of 40 U/kg tid (fresh plasma) or 150 U/kg bid (fresh-frozen plasma), unfractionated heparin causes intravascular agglutination of equine RBCs.[187] Therefore it could be argued that the use of heparin might actually exacerbate intravascular cellular plugging, which is theorized to play a role in some cases of laminitis in equine sepsis. This side effect can be avoided with the use of *low-molecular-weight heparin* (LMWH), which is nonagglutinating but retains anticoagulant activity, principally via inhibition of factor Xa.[188] Two clinical studies have suggested that LMWH may have benefits over unfractionated heparin in the prevention of jugular thrombosis or laminitis in some equine patients with colic,[189,190] but this suggestion is not universally accepted. The use of heparin could be considered in horses with sepsis that have evidence of hypercoagulation syndrome (early evidence of dyshemostasis such as abnormal coagulogram or spontaneous venous thrombosis), or possibly in those that are at high risk for laminitis (e.g., DPJ, colitis, or grain overload). In general, heparin should be given with plasma (10 to 40 mL/kg) at a dose of either 200 to 300 IU/kg/day for unfractionated heparin (either divided bid-tid IV or SC or as a continuous intravenous infusion) or 50 IU/kg for LMWH (SC sid). Foals at risk for thrombosis may require a higher dose of LMWH, in the range of 100 IU/kg.[191]

Other anticoagulants that inhibit platelet function, including clopidogrel and aspirin, have also been evaluated in horses and are sometimes recommended in equine sepsis. Both clopidogrel (4 mg/kg PO once for loading dose and then 2 mg/kg PO q24h) and aspirin (5-10 mg/kg PO q24-48h) appear to be effective anticoagulants in horses by inhibiting platelet activation [192-194]; however, aspirin's effects are irreversible, which could be problematic if surgery or invasive diagnostic testing is required during sepsis treatment. Clopidogrel has been evaluated in horses with experimental endotoxemia, and attenuation of LPS-induced tachycardia was noted, but specific LPS-induced platelet hyperreactivity was not seen.[194]

Scavengers of Reactive Oxygen Species. ROSs are thought to cause corrosive tissue damage during endotoxemia and potentiate the production of inflammatory cytokines through activation of NF-κB. Surgical deflation of distended small intestine is thought to lead to ischemia-reperfusion injury, a process that generates ROSs from epithelial xanthine oxidase. The life-saving and necessary process of fluid resuscitation in horses with septic shock may even lead to whole-body ischemia-reperfusion and systemic release of ROSs. Despite these key associations between oxidant stress and sepsis, little effort has been made to intervene therapeutically at this level.

There is some evidence that allopurinol, a hydroxyl radical scavenger and inhibitor of xanthine oxidase activity, has positive clinical effect during sublethal endotoxin infusion in horses.[195] A recommended dose for allopurinol is 5 mg/kg IV. Because dimethyl sulfoxide (DMSO) has been shown to be a potent scavenger of hydroxyl radicals with efficacy in rodent sepsis models,[196] it has been considered for use in the treatment of equine endotoxemia, although effects in experimental models have been variable. DMSO is typically administered by rapid intravenous infusion (or by nasogastric tube) as a 10% to 20% solution in saline at dose of 0.02 to 1 g/kg every 6 to 12 hours. However, intravenous infusion of DMSO at the low and high ends of this dose range was recently shown to have little to no effect on clinical signs (with the exception of fever at the high dose), on clinicopathologic abnormalities, and on TNF-α production after endotoxin infusion in horses.[197] At high concentrations intravascularly, DMSO can cause hemolysis.

Ethyl pyruvate, a stable analog of pyruvate, has been shown to have remarkable protective efficacy in a variety of models of septic and nonseptic shock in rodents and other species; its beneficial actions are ascribed to its antioxidant effects.[198] Because this agent is inexpensive and can be given in intravenous crystalloid fluids, it could have potential for the treatment of endotoxemia and sepsis in horses. Reports about equine experimental endotoxemia support this theory, demonstrating beneficial effects on clinical manifestations of endotoxemia (except fever) and suppression of proinflammatory gene expression.[199-201] Use of ethyl pyruvate in clinical cases of equine sepsis or endotoxemia is not described to date, and other antioxidants that have shown benefit in rodent sepsis models and are considered for use in some human patients with sepsis (e.g., vitamin C, vitamin E, and *N*-acetylcysteine) have not been evaluated in equine sepsis.

MISCELLANEOUS TREATMENTS. A number of other treatments for endotoxemia and sepsis have been described in horses and other species, though on the whole, currently available data are less supportive of their use in clinical cases. Naloxone, a narcotic antagonist, at a dose of 0.2 mg/kg, blunted some of the cardiovascular effects of high-dose endotoxin in one study,[202] but a dose of 1 mg/kg had no effect in another.[203] Of importance, 0.75 mg/kg naloxone caused signs of colic in conscious horses,[204] probably by blocking the actions of

VetBooks.ir

endogenous β-endorphins at the high affinity μ-receptor. The detergent tyloxapol was remarkably effective in preventing the effects of endotoxin in anesthetized horses.[205] The mechanism of antiendotoxic action of tyloxapol is unknown, but the detergent has been shown to have wide-ranging effects on cells and proteins, some of which may preclude its use in clinical cases. For example, the detergent has been shown to inhibit cellular phagocytosis, clearly an important event in innate immunity and sepsis. Also, this agent induces marked hyperlipidemia (lipid levels up to 100-fold higher than in controls) in horses because of interference with lipoprotein metabolism. Similarly, a phospholipid emulsion effectively prevented adverse effects of subsequent endotoxemia; however, the treatment induced hemolysis sufficient to preclude its use in clinical cases.[206] A published report[207] on the use of the sulfonyl analog of the spin trap molecule alpha-phenyl-*N*-tert-butylnitrone suggests that this agent was effective in reducing clinical signs in horses given endotoxin. However, a cautionary note was the observation that in some rodents given the same agent at high doses, the endotoxin-induced mortality rate was actually higher.

Platelet-activating factor inhibitors have been effective anti-endotoxic agents in some species but have not yet shown much positive clinical effect in horses or humans.[208] In dogs and other experimental animals, inhibitors of nitric oxide production such as N^G-monomethyl arginine reverse endotoxin-induced (or more probably TNF-alpha-induced) hypotension;[209] however, nitric oxide synthase inhibitors generally have no protective effect in sepsis models. Furthermore, nitric oxide production may not be increased in horses with endotoxemia.[210] The antifibrotic pyridine compound pirfenidone (5-methyl-1-phenyl-2-[1H]-pyridone) had no effect on endotoxin-induced clinical signs, leukopenia, or TNF-α production in horses.[211] Hyperbaric oxygen therapy also did not appear to have any protective effect on clinical or cytokine changes in experimental endotoxemia in horses.[212]

Constant-rate infusion of ketamine has been theorized to have beneficial effects in equine endotoxemia after it was shown in vitro to suppress the production of inflammatory mediators by LPS-stimulated equine peritoneal macrophages.[213] Constant-rate infusion of ketamine at 1.5 mg/kg/h for 320 minutes achieves blood concentrations compatible with this inflammatory effect and has been shown to be safe and nonsedating in horses. However, pretreatment with ketamine had no effect on clinical signs, leukopenia, or inflammatory cytokine in horses after endotoxin infusion.[214] The putative antiinflammatory actions of ketamine appear to be mediated by the actions of adenosine on the adenosine A_{2A} receptor[215]; because the equine adenosine A_{2A} receptor was cloned and characterized pharmacologically, it itself may prove a potential direct target for antiinflammatory drugs in the future.

FUTURE TREATMENT CONSIDERATIONS. In summary, current research in horses, humans, and experimental animals suggests that a single therapeutic agent with universal benefit in endotoxemia and sepsis will be very hard (or impossible) to find. Most antiinflammatory approaches that show promise in experimental endotoxemia, even if they are aimed at the initiating steps of the inflammatory cascade (e.g., NF-κB activation), do not work consistently in severe sepsis models (e.g., cecal-ligation puncture) or in phase III clinical trials with human patients. A substantial proportion of the morbidity and mortality associated with sepsis may result as much from immunosuppression in the later stages of sepsis as from the cytokine storm in early sepsis. Immunosuppressed patients could be injured further by antiinflammatory therapy, which potentially explains some of the discrepancy between specific therapeutic efficacy in experimental sepsis and that in clinical sepsis. This emphasizes the need for accurate recognition of—and possibly tiered treatment protocols for—the various stages of sepsis. Plasma biomarkers such as adrenomedullin, procalcitonin, C-reactive protein, or high-mobility group box 1 levels have been used to diagnose sepsis, define sepsis categories, and provide prognostic information in humans,[216,217] but a universally reliable biomarker or combination of markers has yet to be identified. Similar markers need to be integrated more fully into equine sepsis diagnosis, staging and management, although several of the aforementioned human biomarkers (e.g., C-reactive protein) do not appear to be useful in equine sepsis diagnosis.[115]

Some different treatment approaches have the potential to be both effective and affordable. There is some indication that IFN-γ, a cytokine that is pivotal in both innate and acquired immunity, may be beneficial for combatting immunosuppression in bacterial sepsis.[218] Il-7, IL-15, and IL-17 may also prevent or modulate immunosuppression in sepsis by preventing leukocyte apoptosis and supporting both innate and adaptive immune function.[51,219] There also remains enthusiasm in human critical care for antioxidant strategies aimed at effective means to suppress or scavenge ROSs.[51,86,87] In this regard, the remarkable effects of ethyl pyruvate in multiple models of inflammation, which probably mediates through its antioxidant actions, offer considerable promise. So-called "metabolic resuscitation" with a combination of low-dose hydrocortisone, vitamin C, and thiamine appeared to have a beneficial effect on survival in one human study[220] and, if truly effective, might be both beneficial and cost-effective in the treatment of equine sepsis. Inhibition of complement activation with anti-C5a antibody show promise in some sepsis models and is currently in clinical trials in humans.[51,221] Finally, two of the most exciting possibilities in the distant future are the use of genotyping to target sepsis diagnosis and treatment and the potential use of even gene therapy to transiently transfect host cells in a targeted way with genes supporting immune and bactericidal function.[222,223]

Medical Disorders of the Small Intestine

Ulcerative Duodenitis

PATHOPHYSIOLOGY. Ulcerative duodenitis is a rare condition that most often affects foals and, to a lesser degree, yearling horses. In one retrospective study, of 691 nonsurviving foals, 32 (4.6%) had ulceration of the duodenum, and only 1 of those foals (0.14% of 691) had duodenal involvement alone.[1] Lesions occur primarily in the proximal duodenum and may include erosions, focal ulceration, and diffuse inflammation with or without ulceration. The terms *duodenal ulceration* and *ulcerative duodenitis* may refer to differing clinical manifestations of the same problem, but they are considered the same entity in this section.

The pathophysiology of duodenal ulcer disease in foals is not understood as well as gastric ulcer disease. The disorder is classically considered to be a peptic disease, similar to that seen in humans, in which damage to the duodenal mucosa results from excessive exposure to hydrochloric acid and pepsin. However, in humans, most cases of duodenal ulcer disease are associated with *H. pylori* infection,[2] whereas *H. pylori* bacteria have not been reported as a major cause of equine gastrointestinal diseases. In addition, in humans the incidence of duodenal ulcer disease increases with age,[3] in contrast to horses, in which duodenal ulcer disease occurs primarily in animals younger than 1 year of age.[4]

Ulcerative duodenitis and inflammation have occurred in geographic clusters (same farm) and in temporal clusters. All affected foals had moderate to severe gastric ulceration and extensive inflammation with varying degrees of erosion or ulceration in the proximal duodenum (see Color Plates 32.10

VetBooks.ir

and 32.11). A similar temporal and geographic association was reported in two cases of ulcerative duodenitis in yearlings.[5] These findings seem inconsistent with a purely peptic insult as the cause for the ulcerative duodenitis. In one report of seven foals with ulcerative duodenitis,[6] lesions typically extended into a large area of the proximal duodenum and were characterized by mucosal necrosis, and areas of affected and more normal-appearing mucosa were often sharply demarcated. In the foals of that report, no common microbial organism other than *E. coli* was identified, and a cause for the ulcerative duodenitis was not determined. In most foals with duodenal disease, the lesions were not focal ulcers but rather appeared as more generalized inflammation. The origin of duodenal disease in foals is probably multifactorial and may involve a combination of breakdown of duodenal mucosal defenses, interaction of gastrointestinal peptides, and possible pathogenic agents.[7]

CLINICAL SIGNS. The signs of ulcerative duodenitis have been classically described like those of gastric ulcer signs but more severe,[8] and in many cases, duodenal and gastric ulcers occur simultaneously. The gastric ulceration is probably secondary to physiologic or anatomic obstruction to gastric emptying, tends to be severe (see Color Plate 32.12), and potentially leads to gastroesophageal reflux, esophagitis and ptyalism. Until the gastric ulceration becomes severe, the primary signs of duodenitis can be nonspecific; they include fever, mild to moderate abdominal discomfort, mild obtundation, and diarrhea.

In general, the sequelae of ulcerative duodenitis are more severe than those of primary gastric ulceration. Complications of ulcerative duodenitis include duodenal perforation with peritonitis or adhesions, duodenal stricture with complete or partial obstruction (Figs. 32.61 and 32.62), ascending cholangitis and hepatitis, and ascending pancreatitis.

DIAGNOSIS. Duodenoscopy is the most specific means of diagnosis. An endoscope with at least a 200-cm working length is used in foals up to 6 months of age, and in older foals, a longer endoscope is needed to examine the duodenal mucosa. Because of the size of the stomach and the anatomic configuration of the duodenum in foals, it is usually not possible to advance the endoscope past the duodenal ampulla. Therefore a diagnosis is most readily made when lesions are diffuse or located within the ampulla. Excessive enterogastric reflux of bile through the pylorus is consistent with duodenal dysfunction. Ulceration at the pylorus or pyloric antrum may accompany ulcerative duodenitis and thus provide an indication of potential duodenal involvement.

The peritoneal fluid may show signs of inflammation, infection, hemorrhage, or a combination of these, depending on severity of disease. CBC often reveals peripheral blood leukocytosis and hyperfibrinogenemia. Serum chemistry studies may reveal elevations in liver enzymes, particularly biliary system–associated enzymes (γ-glutamyltransferase [GGT], ALP) and serum bile acids. With severe ulcerative duodenitis, survey radiographs of the cranial abdomen may reveal accumulation of fluid within the stomach and gas ascending the biliary ducts.[9] If barium contrast medium is placed into the stomach, complete emptying is usually delayed (>2 hours), and an irregular mucosal border may be noted in the descending duodenum. In most cases, however, radiography would not contribute to a diagnosis of duodenal ulcer per se, although duodenal stricture may be noted. If the descending duodenum is to be imaged, the volume of contrast medium placed in the stomach should not exceed 0.5 to 1 L in a foal and 1 to 2 L in a weanling or yearling; otherwise, the proximal descending duodenum will be obscured by contrast medium within the stomach.

TREATMENT. The effectiveness of treatment of ulcerative duodenitis depends on the extent and severity of ulceration and the presence or absence of complications. Treatment objectives are to decrease duodenal inflammation, treat secondary gastric and esophageal ulceration, promote gastric emptying, and treat related problems such as peritonitis. If ulcerative duodenitis is confirmed or even suspected on the basis of clinical signs, treatment should be aggressive.

Inflammation may be an important part in the perpetuation of disease. In acute cases of ulcerative duodenitis, there usually is a pronounced lymphocytic infiltration of the mucosa. In more chronic cases, there is a mixture of neutrophils, macrophages, fibroblasts, and fibrinonecrotic exudate. Definitive antiinflammatory therapy has not been described for these cases, and the use of corticosteroids or NSAIDs is controversial because they may worsen gastric ulcer disease through inhibition of protective prostaglandin synthesis.

Suppression of gastric acid secretion is still an important objective in the treatment of ulcerative duodenitis in foals because most affected foals have gastric ulcers. Initially, acid suppression should be accomplished via parenteral administration of H_2

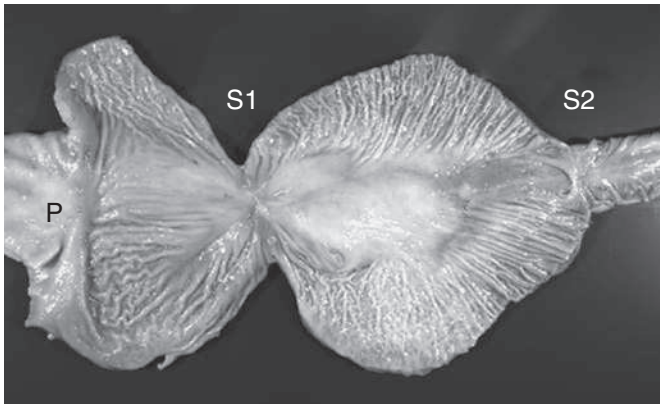

FIG. 32.61 Proximal duodenum of a 10-month-old horse with a history of chronic poor appetite and condition. The pylorus *(P)* is at the left. There are two strictures in the duodenum: *S1* is orad from the major duodenal papilla, and *S2* is aborad from the duodenal papilla. FIG. 32.62 Duodenal stricture *(S1)* in the horse described for Fig. 32.68. The diameter of the duodenal lumen at the stricture is only 3 mm. *(Courtesy Dr. M.J. Murray.)*

VetBooks.ir

antagonists (cimetidine, 7 mg/kg IV q6h, or ranitidine, 1.5 mg/kg IV q8h) or proton pump inhibitors (pantoprazole, 1.5 mg/kg IV q24h). Oral medications are unlikely to be adequately delivered to, or absorbed from, the small intestine in the first days of treatment. Gastric emptying can be enhanced with bethanechol (0.02 mg/kg SC q6-8h or, when the foal can consume orally, 0.35 mg/kg PO q8h). In foals that have severe duodenal disease or that have required surgery, bethanechol has been given for up to 3 months. Once the foal can accept oral medication, it should be treated with the proton pump inhibitor omeprazole at a dose of 4 mg/kg orally once daily in the paste formulation. In the 24 hours after the first dose, acid suppression is incomplete, and maximal suppression of acid secretion is achieved between days 1 and 5.[10] Therefore a common practice is to combine an H_2 antagonist IV for the initial 2 days of treatment with omeprazole in foals with duodenitis.

Misoprostol is a synthetic prostaglandin E_1 analog that has been used successfully in treating ulcerative duodenitis in humans. Doses of 2 to 5 µg/kg q8-12h can be used in horses, although side effects may include abdominal pain and diarrhea. Sucralfate promotes duodenal mucosal healing in humans.[11] The dose of sucralfate that is effective in humans with ulcerative duodenitis ranges from 1 to 2 g two to four times daily. Foals treated for ulcerative duodenitis that do not have impaired gastric emptying should be administered 2 to 4 g of sucralfate three times daily. Sucralfate, however, should not be used as the sole therapeutic agent for ulcerative duodenitis.

Foals with duodenitis must usually be prevented from nursing or eating for 1 to 3 days. During this time, parenteral feeding should be considered. Depending on the age of the foal, administration of parenteral nutrition should provide 40 to 60 kcal/kg/day.

If medical therapy is ineffective or if sequelae of ulcerative duodenitis cause complications, surgical intervention may be required. Gastroenterostomy has been reported to be effective in some cases through bypassing the affected portion of duodenum and allowing for an alternative route for gastric emptying.[9] However, short-term survival and long-term quality of life and use are often unsatisfactory. Patients that have a successful surgical outcome require long-term aftercare and usually require long-term maintenance acid suppression and treatment with a prokinetic drug until gastric emptying is normalized. Therefore an owner should be prepared to make a significant time and financial commitment before surgery is considered.

Duodenitis-Proximal Jejunitis

DPJ, also known as *anterior enteritis* or *proximal enteritis*, is a clinical syndrome characterized by inflammation and edema of the duodenum and proximal jejunum, excessive fluid and electrolyte secretion into the small intestine, and, consequently, large volumes of enterogastric reflux. The syndrome of DPJ was first described in 1982[12] and was more fully characterized in 1987.[13] A subsequent report[14] described clinical and clinicopathologic parameters in horses with DPJ that differed somewhat from cases in the 1982 report, which suggests that either the cases were of similar etiopathogenesis but of different severity or that the cases were of different etiopathogeneses whose only similarity was the segment of bowel affected. A diagnosis of DPJ is often applied when affected animals exhibit abdominal discomfort, small intestine distention, and excessive enterogastric reflux without obstruction; however, it is unclear whether all of these cases lie along a spectrum of severity of DPJ or whether they are several disease entities that affect the proximal small intestine and that share clinical features. The latter seems more likely.

PATHOPHYSIOLOGY. In horses with DPJ, lesions are consistently found in the duodenum, but the severity and frequency of lesions in the jejunum are variable. Serositis is a consistent finding, characterized by bright red to dark red petechial and ecchymotic hemorrhages on the serosal surface.[13] Histologic lesions include hyperemia and edema of the mucosa and submucosa, villous epithelial degeneration, epithelial cell sloughing, neutrophilic pleocytosis, hemorrhages in the muscular layers, and fibrinopurulent exudation on the serosa.

DPJ causes an increase in the volume of duodenogastric reflux, typically 50 to 100 mL/min. This reflux has been considered to result from increased intestinal fluid secretion and decreased motility. Mechanisms of intestinal fluid secretion include passive transmucosal exudation, secondary to mucosal and submucosal inflammation and characterized by a protein-rich fluid secretion, and active fluid secretion, caused by increased cyclic nucleotides and characterized by fluid with a high electrolyte content and low protein content. The components of fluid in the intestines of horses with DPJ have not been characterized, but they probably result from a combination of passive and active secretion. In some horses the hemorrhagic nature of the gastric reflux implies increased capillary permeability of the duodenal mucosa, whereas in other horses the watery nature of the reflux, the presence of serum electrolyte disturbances,[15] and the absence of peripheral hypoproteinemia are most consistent with an active secretory process.

Another potential source of the large volume of fluid secreted into the proximal small intestine and flowing back into the stomach is the pancreas. Normally there is periodic orad movement of duodenal contents into the stomach, which has been observed endoscopically and has been documented by collecting gastric contents with and without pyloric obstruction.[7] The duodenal contents have a large component of water, sodium, and bicarbonate, as well as bile salts from the liver. These secretions are presumed to originate from the pancreas, as well as the liver, and pathologic features of either of those organs may contribute to the pathophysiologic manifestations in cases of DPJ.

Suppurative cholangiohepatitis has been reported in cases of small intestinal inflammation secondary to DPJ.[16,17] The pathophysiologic origins of this observation may be related to an increased luminal pressure in horses with DPJ, which increases the likelihood of intestinal content regurgitation into the bile ducts. It is also possible that horses with DPJ absorb inflammatory mediators or bacterial products from the small intestine via the portal blood flow or systemic circulation.

Although the exact cause of DPJ is not known, several bacteria and toxins have been implicated. *C. difficile* has been frequently implicated in causing the disease. One prospective study cultured toxigenic species of *C. difficile* from the reflux of all 10 horses with a diagnosis of DPJ and only 1 of 16 horses with diagnoses of other causes of nasogastric reflux. Of the strains cultured, those in 8 of the 10 horses with DPJ produced both A and B toxins, whereas the those in the remaining 2 produced only toxin B.[18] This is significant in that toxin B may cause inhibitory electromechanical disturbances to smooth muscle in the small intestine, which may be a possible cause of ileus in these horses.[19] Toxin A has also been shown to promote inflammatory cell infiltration into the smooth muscle layers.[20] Influx of neutrophils and release of inflammatory mediators in the intestinal wall activate nitric oxide pathways, which results in inhibition of the enteric nervous system, increases in sympathetic tone, and a subsequent reduction of contractile activity in the gut.[21] Experimental intraduodenal inoculation of crude *C. difficile* toxins in fasting horses resulted in clinical signs of DPJ in 33% of cases; however, all cases had histopathologic changes consistent with DPJ.[22] *C. difficile* can also be cultured from the proximal intestinal tract in horses without evidence of gastrointestinal disease, however, and these strains can produce both toxin A and B.[23] *C. perfringens* and *Salmonella* spp. have also infrequently been associated with DPJ, but the significance of these pathogens remains unknown.

VetBooks.ir

Feeding practices may be associated with the development of DPJ. In one study, horses with DPJ were fed significantly more concentrate and were significantly more likely to have grazed on pasture than were horses with other types of colic or horses with lameness.[24] This may indicate that these horses are exposed to some type of toxin or infectious agent through different types of feed. *Fusarium moniliforme* has been cultured from the feed of horses with naturally occurring DPJ. Under experimental conditions, *F. moniliforme* producing fumonisin B1 mycotoxins also caused lesions consistent with DPJ in two horses.[25] Neurologic lesions were present in those horses, however, and both died with lesions consistent with equine leukoencephalomalacia. Cantharidin toxins can also cause reddening of the mucosa in the small intestine, as well as excessive gastric reflux,[26] and may be a cause of DPJ in some cases. It is possible that this one syndrome has multiple initiating causes and that no one causative agent will ever be definitively identified.

CLINICAL SIGNS AND DIFFERENTIAL DIAGNOSIS. The differential diagnosis for DPJ includes simple or strangulating small intestinal obstructions. Differentiation can be extremely difficult in some cases and may delay surgical intervention in cases of small intestinal obstruction, to the detriment of the patient. The criteria used to discriminate between DPJ and obstructive lesions include degree of pain after reflux, presence of fever, and changes in hematologic parameters and abdominal fluid.

Horses with DPJ have a history of acute-onset moderate to severe abdominal pain, often followed by varying degrees of depression. Nasogastric intubation yields a large volume of enterogastric reflux, which is frequently orange-brown in color, with a fetid odor. Rectal palpation reveals multiple loops of mild to moderately distended small intestine. The initial volume of reflux may range from as little as 4 to 5 L to as much as 32 L. The duration of the reflux may be as short as 24 to 48 hours, but it usually lasts 3 to 7 days. Many affected horses are febrile (rectal temperature higher than 38° C [101° F]) and dehydrated and have injected mucous membranes, prolonged capillary refill time, diminished intestinal sounds, tachycardia (>60 beats/min), and tachypnea.[12-15,27,28] Horses with DPJ also tend to have a higher incidence of gastric ulceration than do horses with abdominal pain secondary to other causes.[29] Although abdominal pain usually abates after gastric decompression, most affected horses remain depressed, which perhaps is the most consistent and characteristic clinical sign of the disease. If the fluid that accumulates in the proximal intestinal tract is not removed periodically, signs of abdominal pain recur.

Assessments of the degree of small intestine distention and the thickness of the intestinal wall can be useful indicators. Many horses with DPJ have generalized distention of small intestine, but when palpated rectally, the intestine does not feel taut. In many cases of small intestinal obstruction, the bowel is tightly distended on palpation, but this is not universally true. Ultrasonography can be used, both transrectal and transabdominal, to determine the diameter of the small intestine, evaluate contractions, and measure the thickness of the wall of the intestine. With acute obstruction, several segments of small intestine that are 6 to 10 cm in diameter, have no contraction, and have a wall diameter of 3 to 5 mm are visible. With DPJ, small intestinal diameter may be less, and the thickness of the intestinal wall may exceed 6 mm.

Culture of the reflux for *Clostridium* and *Salmonella* spp. can be attempted. This can be difficult, however, given the special conditions required for anaerobic cultures, as well as the intermittent shedding of *Salmonella* spp. into the gastrointestinal tract of normal horses. Also, the large volume of reflux in these cases may dilute the bacterial population to the point at which isolating low numbers of bacteria is difficult.

CLINICOPATHOLOGIC FINDINGS. Clinical laboratory findings include increased PCV and total plasma proteins (hemoconcentration). Abdominocentesis often reveals an elevated total protein concentration in peritoneal fluid and a mild to moderate increase in the peritoneal WBC count (>5000 cells/μL).[27] The peritoneal fluid is usually yellow and turbid, but in severe cases, diapedesis of RBCs occurs, which results in a serosanguineous color. In abdominal fluid, a total protein concentration above 3.5 g/dL is associated with a poorer prognosis.[27] The WBC count in the peripheral blood may be normal, increased, or decreased.[13,14] In addition, hypocalcemia, hyponatremia, hypochloremia, hypokalemia, and acid-base alterations have been reported in horses with DPJ.[15] An elevated anion gap may be present, secondary to either decreased calcium and magnesium concentrations or increased lactate or albumin concentrations.[27] Increases in the anion gap to 15 mEq/L or higher have also been associated with a poor prognosis. Horses with enteritis have been found to have higher plasma D-dimer concentrations and more severe coagulopathies on admission than do horses with other types of colic.[30]

Activity of liver enzymes, particularly GGT, may be elevated in horses with DPJ, and such elevation may be a useful way to help differentiate between DPJ and strangulating lesions of the small intestine.[16,17] According to a retrospective study of a large series of DPJ cases to determine the prevalence of hepatic damage in horses with small intestinal inflammation, horses with DPJ had significantly higher hepatic enzyme activities than did the control group of horses with small intestinal strangulating obstruction (SISO).[17] More than 50% of horses with DPJ had biochemical evidence of hepatic disease (high GGT, aspartate aminotransferase, or ALP activity). In addition, horses with DPJ had a 12.1-fold higher risk of having high GGT activity and a 1.8-fold higher risk of having high aspartate aminotransferase activity than did horses with SISO. Aspartate aminotransferase activity in horses with proximal enteritis ranged from 133 to 2994 IU/L (reference range, 215.8 to 365 IU/L), GGT levels ranged from 7 to 117 IU/L (reference range, 6.2 to 19.1 IU/L), and ALP levels ranged from 86 to 1103 IU/L (reference range, 69.4 to 293.7 IU/L). Bile acid concentrations were rarely abnormal, which indicates that hepatic failure was uncommon. Histopathologic evidence of liver disease was a common biopsy and necropsy feature in the horses with proximal enteritis. Centrilobular necrosis and inflammation were noted in some cases.

TREATMENT. Because the causative agent or agents of DPJ are unknown, treatment remains empirical and consists of aggressive supportive therapy. The continuous production of enterogastric reflux necessitates gastric decompression every 1 to 2 hours to relieve pain and to prevent gastric rupture. The stomach should be decompressed frequently, regardless of whether the horse is showing signs of abdominal pain, as these signs may be masked by severe depression or the administration of analgesic or antiinflammatory medications. Horses should receive nothing by mouth until small intestinal function has returned, recognized clinically by cessation or reduction of the nasogastric reflux to 1 to 2 L over a 4-hour period and increased frequency of borborygmi. The time necessary for gastric decompression varies with each patient. Repeated rectal examinations after the first day of therapy inconsistently reveal distended loops of small intestine, depending on the frequency of removal of the reflux and the severity of the initial lesion. Ultrasonography may reveal fluid-filled small intestine when the bowel is not discernible by rectal palpation. Loops of small intestine are most frequently visualized in the ventral flank area, near the udder or prepuce; therefore this area should be examined in all cases of suspected small intestine distention.

Intravenous administration of a balanced electrolyte solution is necessary to maintain intravascular fluid volume and

VetBooks.ir

cardiovascular performance. In some horses even rapid administration of fluid fails to adequately restore and maintain intravascular volume because of enteric fluid losses that can be as great as 8 L per hour. In addition, the very large volume of isotonic crystalloid fluid that must be given intravenously to keep pace with enteric fluid losses in horses with DPJ may accelerate the flux of fluid from the vasculature into the intestinal lumen because of reduced intravascular oncotic pressure, increased capillary perfusion pressure, and increased capillary permeability in the inflamed intestine. Consequently, the balance between adequate hydration and the volume of enterogastric reflux obtained requires careful and frequent monitoring.

Administration of colloid solutions may be of benefit in preserving intravascular volume without promoting enterogastric reflux. The colloids most frequently used in horses include hyperimmune plasma and hetastarches. Plasma products require a large volume of administration to exert a colloidal effect, which is cost prohibitive in many cases. Smaller doses, however, may have a beneficial effect in horses with DPJ, particularly in animals showing signs of sepsis or endotoxemia. Hetastarches have been shown to significantly increase plasma oncotic pressure in ponies administered 10 mL/kg[31] and represent a reasonably priced alternative to plasma. These solutions have been associated with changes in the hemostatic profile in normal ponies at higher doses[32] and should be used with caution only in horses already at risk for coagulopathies, particularly with the higher-molecular-weight formulations.

During the initial hours of therapy, even aggressive intravenous fluid administration may result in only moderate clinical improvement. A positive clinical response—as evidenced by improved hydration status, decreased heart rate, decreased enterogastric reflux, improved attitude, and improvement in parameters reflecting kidney function (decreased blood urea nitrogen [BUN] and serum creatinine levels)—is correlated with resolving intestinal inflammation.

NSAIDs should be used judiciously to prevent the masking of the clinical signs of a potential surgical lesion. Flunixin meglumine can be used at a dose of 0.25 to 0.5 mg/kg PO every 6 hours to reduce the untoward effects of arachidonic acid metabolites.

Antimicrobial agents are typically administered to horses with DPJ, although the necessity for antimicrobial treatment in horses with DPJ is uncertain. Because of the association of DPJ with *C. difficile*, administration of intravenous penicillin G sodium or potassium (22,000 to 44,000 IU/kg IV q6h) is warranted. Metronidazole also has excellent activity against *C. difficile;* however, administration is difficult because nothing can be administered orally. Rectal administration of metronidazole has been studied[33] and can be used in these cases. The dose and frequency of administration should be increased because bioavailability after rectal administration is much less than after oral administration (30% vs. 74%, respectively). Broad-spectrum antimicrobial treatment may be indicated in horses with low WBC counts, but care must be taken in selecting an antimicrobial to avoid potential adverse effects, particularly nephrotoxicosis with aminoglycosides in a dehydrated patient with compromised renal function.

Horses with DPJ may have to be kept from eating for several days and are often in a hypermetabolic state; therefore they rapidly develop a negative energy and nitrogen balance. In these horses, parenteral nutritional support should be considered. Parenterally administered solutions containing glucose, balanced amino acid solutions, lipid emulsions, balanced electrolyte and trace minerals, and vitamins have been administered to adult horses with a variety of intestinal disorders, including DPJ. Part of a horse's nutritional requirements (8000 to 12,000 kcal/day) can be provided with glucose–amino acid solutions that are of moderate cost. The rationale for this treatment is that through provision of nutritional support to an anorexic, severely ill horse, the healing process is facilitated, complications are minimized, and the duration of hospitalization may be shortened. Thus the overall cost of providing nutritional supplementation, enteral or parenteral, to horses with DPJ may well be offset by quicker recoveries and diminished requirements for other costly treatments.

Prokinetic agents may also be useful in cases of DPJ. Of the available prokinetics, lidocaine is used most frequently.[34] A slow intravenous loading dose of 1.3 mg/kg in a bolus, followed by a continuous infusion of 0.05 mg/kg/min, has been shown to shorten the time of reflux and shorten the hospital stay of horses with DPJ.[35] It may do this by decreasing sympathetic tone, acting as an analgesic agent, affecting ion channels, or decreasing granulocyte infiltration in the intestinal wall. Its use should be reserved for horses in which a surgical lesion has been ruled out because it can effectively mask intestinal or foot pain. Horses should be refluxed frequently during the infusion and checked for other signs of complications, such as laminitis, routinely. Metoclopramide, erythromycin lactobionate, and cisapride are also used in cases of DPJ.[34] The efficacy of prokinetics in this disease is debated, mainly because the intestine must be healthy in order for the drugs to exert an effect. A more in-depth discussion of prokinetic agents can be found in the Gastrointestinal Ileus section.

Medical therapy is sufficient in most cases of DPJ; however, surgical exploration is sometimes necessary for definitive diagnosis; if horses show uncontrolled pain, have prolonged nasogastric reflux (>7 days), or have excessive fluid losses that cannot be corrected with conventional fluid therapy; or if clinical and laboratory findings are strongly suggestive of an intestinal obstruction. Retrospective comparisons of medical and surgical therapy of DPJ showed that in surgical cases, survival rates were significantly decreased and the nasogastric reflux lasted longer and continued in larger total volume. The horses in surgical cases were also more likely to develop complications such as diarrhea and showed a higher rate of incisional infection than did horses that underwent surgery for other types of colic.[36]

COMPLICATIONS. Complications of DPJ include septic peritonitis, cholangiohepatitis, myocardial and renal infarction, aspiration pneumonia, adhesions of the proximal small intestine, and laminitis. In severe cases of DPJ, a segment of the small intestine may become infarcted, which necessitates surgical removal. The prognosis for surviving the initial intestinal insult is good in cases of DPJ. Death and function losses from this disease are more commonly related to the secondary complications such as laminitis and intraabdominal adhesions. In one report, laminitis occurred in 28% of horses with DPJ, and associated factors were high body weight and hemorrhagic gastric reflux.[37] Laminitis prophylaxis is routinely incorporated into the medical therapy and can include cryotherapy, NSAIDs, topical glyceryl trinitrate, and DMSO (200 mg/kg given as a 10% solution in normal saline). In one study, horses that received heparin as a prophylactic treatment for laminitis were less likely to develop clinical laminitis than were horses that did not receive heparin.[37]

Equine Proliferative Enteropathy

Nicola Pusterla

Equine proliferative enteropathy (EPE) is a disease of foals caused by the obligate intracellular organism *L. intracellularis.* It affects mainly weanling foals and occasionally young adult horses and is characterized by fever, lethargy, peripheral edema, diarrhea, colic, and weight loss. The diagnosis of EPE may be challenging and relies on the presence of hypoproteinemia resulting from hypoalbuminemia, thickening of segments of the small intestinal wall observed on abdominal ultrasonography,

positive serologic findings, and molecular detection of *L. intracellularis* in feces. The disease occurs almost worldwide and has been reported in the United States, Canada, Europe, South Africa, Australia, Brazil, and Japan.[38-42]

EPIDEMIOLOGY. In pig populations, the chronic form of the disease is maintained by subclinically affected pigs or is established environmentally in some sites, allowing transmission of *L. intracellularis* to serial flows of pigs.[43] Mice and rats have been shown to be important reservoirs of *L. intracellularis* on pig farms; prevalences of animals with positive PCR assay results vary substantially between farms (4% to 83%).[44,45] Rodents appear to be suitable reservoir hosts because of their susceptibility to *L. intracellularis*, their close contact with domestic animals, and their high reproductive rate, and they maintain *L. intracellularis* across generations. The source of infection has not been determined for horses. Exposure to pig feces has been speculated as a potential source of infection for horses since cases of EPE were first reported. However, in most cases of EPE, no history or evidence of direct or indirect exposure to pigs or pig feces has been reported. Moreover, multilocus variable-number tandem repeat profiles of pig and equine isolates differ greatly. One experimental study demonstrated host specificity for *L. intracellularis* isolates cultured from pig or horse intestines.[46] The study showed that clinical signs, longer periods of shedding, and stronger serologic immune responses were observed in animals infected with species-specific isolates. Previous studies showed that a variety of wild and domestic animals (including dogs, cats, rabbits, opossums, skunks, mice, and coyotes) can shed *L. intracellularis* on farms with diagnosed EPE cases.[47,48]

Fecal-oral transmission of *L. intracellularis* has been documented in naive foals housed with foals clinically infected with an equine isolate of *L. intracellularis*.[49] One study showed that feces from rabbits experimentally infected with an equine isolate of *L. intracellularis* served as infectious material for weanling foals.[50] Although infected rabbits and foals remained asymptomatic, infection was supported by fecal shedding of *L. intracellularis* and detection of specific antibodies to *L. intracellularis*. Although the natural infectious dose for foals has not been determined, pigs receiving as low as 10^5 *L. intracellularis* organisms have been shown to develop infection.[51]

In piglets, large group size, weaning, transportation, diet change, and mixing have been associated with clinical disease. Predisposing situations such as the stress of weaning, overcrowding, decline in *L. intracellularis*–specific colostral antibodies, endoparasitism, and introduction of new animals have been suggested as factors in the development of EPE in foals.[38] In pigs, infection and fecal shedding of *L. intracellularis* may persist for as long as 12 weeks.[51] This is in sharp contrast to experimentally infected foals, which show onset and duration of fecal shedding ranging from 10 to 14 days and 17 to 27 days, respectively.[49] Previous work has shown that *L. intracellularis* is likely to survive in environmental conditions for 1 to 2 weeks at 5°C to 15°C.[52]

PATHOPHYSIOLOGY. The mechanism of enteritis after infection with *L. intracellularis* involves invasion of the proliferating crypt cells in the ileum, causing excessive mitotic division and severe hyperplasia.[53,54] The hyperplastic mucosa becomes grossly thickened and develops a corrugated appearance. As would be expected, this thickening of the mucosa, along with the proliferation of immature crypt cells rather than mature villous cells, leads to a limited brush border development and a decreased absorptive capacity, which results in the weight loss and hypoproteinemia characteristic of these cases. The organism can divide within the infected cells and migrate up to the mucosal layers as the cells proliferate and advance. The differential diagnosis in these cases mainly includes *R. equi* enteritis, which can also cause ulceration in the areas of Peyer patches throughout the small intestine, cecum, and colon.

CLINICAL AND LABORATORY FINDINGS. EPE manifests in characteristic signalment, seasonality, clinical signs, and blood work abnormalities. The disease is generally manifested in foals younger than 1 year of age and, in North America, often between August and February.[39] Although the disease is common in weanling foals 4 to 7 months of age, cases of EPE have been seen in young adult horses.[42] Lethargy, anorexia, fever (>38.5°C), peripheral edema (ventrum, sheath, throatlatch, and distal limbs), weight loss, colic, and diarrhea are among the most common clinical findings in affected foals. Early clinical signs are generally unspecific and include mild depression, partial anorexia, and fever. Although diarrhea is common in affected foals and the character can vary from cow pie to watery, some affected foals produce normal feces. Fatal necrotizing enteritis associated with *L. intracellularis* has been reported in foals that developed acute onset of clinical signs, followed by rapid clinical deterioration and death caused by endotoxemia, bacteremia, or disseminated intravascular coagulation.[55]

Foals with EPE may also have concurrent disorders such as respiratory tract infections, gastric ulcerations, and intestinal parasitism. Signs of EPE may resemble those of more common gastrointestinal disorders such as parasitism, bacterial infections (*Clostridium* spp., *Salmonella* spp., *R. equi*, *N. risticii*), rotavirus, coronavirus, ulcerations, sand accumulation, intestinal obstruction, and intoxication with plants, chemicals, and pharmacologic agents such as NSAIDs or antimicrobials. As in pigs, the disease can be subclinical in foals and be manifested by a self-limiting and transient decrease in total serum protein concentration, coupled with decreased daily weight gain, in comparison with unaffected foals.[49] It remains to be determined whether growth retardation or unthriftiness are associated with subclinical infection.

The most consistent laboratory finding of clinical EPE is hypoproteinemia resulting from hypoalbuminemia. Total protein concentration is generally less than 5.0 g/dL, and albumin concentration is usually less than 2.0 g/dL. In one case report, hypoalbuminemia was the only consistent clinicopathologic abnormality of 57 affected foals; albumin concentrations ranged from 0.9 to 3.3 g/dL (normal reference range, 2.7 to 4.2 g/dL).[39] The exact mechanisms by which hypoalbuminemia develops in affected foals have not been investigated. It appears that decreased feed intake, coupled with malabsorption and protein-losing enteropathy resulting from the proliferative nature of the disease, may explain why albumin levels are low.[56] Affected foals may also demonstrate nonspecific blood abnormalities such as anemia or hemoconcentration, leukocytosis or neutropenia, hyperfibrinogenemia, increased activity of muscle enzymes, and electrolyte abnormalities (hypocalcemia, hypochloremia, and hyponatremia). Urine analysis to rule out protein-losing nephropathy and cytologic evaluation of abdominal fluid to rule out protein lost to a third space yields generally unremarkable results.

DIAGNOSTIC WORKUP. A presumptive diagnosis of EPE is generally based on age of the affected animal, clinical signs, hypoproteinemia/hypoalbuminemia, presence of thickened loops of small intestine on ultrasonographic evaluation, and absence of other causes of enteropathy and protein losses. Abdominal ultrasonography, although not very sensitive, may show segments of thickened small intestine and excessive abdominal fluid. In these cases, abdominocentesis yields a noninflammatory transudate. An antemortem diagnosis is generally confirmed through PCR detection of *L. intracellularis* in feces or rectal swab or serologic findings.

It is essential to perform both molecular and serologic diagnostic testing because these modalities have high analytical

VetBooks.ir

VetBooks.ir

specificity but variable sensitivity, depending on the situation. Negative PCR results can be expected if the fecal samples are collected from foals that have received prior antimicrobial treatment or those in an advanced disease stage, when *L. intracellularis* organisms are no longer expected in the feces. Negative serologic results can be expected in the early stage of the disease, when humoral immune responses are not yet strong enough to be detectable by serology. Moreover, differences in sensitivity among different PCR and serologic assays can lead to divergent results. Among PCR assays, the use of a real-time platform has been shown to yield the best sensitivity and to reduce the likelihood of crossover or carryover contamination (i.e., false-positive results).[57-59] Several serologic assays, including indirect fluorescent antibody test, ELISA, and immunoperoxidase monolayer assay, have been validated and established for pigs.[60-62] A comparative study with equine serum samples has shown that various serologic assays yield accurate results; however, the immunoperoxidase monolayer assay is the most specific in determining the presence of anti–*L. intracellularis* antibodies in adult horses with EPE.[63]

PATHOLOGIC FINDINGS. Lesions are most frequently found in the distal jejunum and ileum, although diffuse thickening of the small intestine may occur.[53] A classical finding is pronounced mucosal thickening with varying severity of ulceration and transmural edema. The affected bowel appears to be stiff, and the mucosal surface has a corrugated appearance. Mucosal pleocytosis is a common feature, but in different cases the predominating inflammatory cell type differs. A lymphocytic or plasmacytic cellular infiltration may be present. Crypt proliferation is accompanied by crypt elongation and epithelial hyperplasia. The villi are blunted and may become fused. Silver staining with Warthin-Starry stain reveals elongated, curved bacilli in the apical zone of the crypt epithelial cells.

TREATMENT. It is important to treat affected animals early, before lesions become advanced and result in marked weight loss and critically low serum protein values. Treatment of EPE in horses involves the use of antimicrobials such as macrolides, alone or in combination with rifampin, chloramphenicol, oxytetracycline, doxycycline, or minocycline, administered for 2 to 3 weeks. The choice of antimicrobial in the treatment of EPE should account for the risk of inducing disturbance of the gastrointestinal flora and renal toxicity. This is especially a concern in treating older foals with severe hypoalbuminemia. Supportive therapy with crystalloid fluids is necessary to correct dehydration, electrolyte imbalances, and azotemia secondary to fluid losses from profuse diarrhea. Colloidal support with plasma or hetastarch can help correct the edema and decreased colloid oncotic pressure. NSAIDs should be used with caution in foals showing signs of dehydration.

The prognosis in these cases is generally good with early and correct diagnosis of the problem. Therapy can be prolonged and should be continued until the diarrhea and hypoproteinemia have resolved and there is no longer evidence of thickened small intestine on ultrasonography.

Concurrent medical conditions should also be addressed. Clinical improvement after treatment is rapid; however, it may take weeks for the hypoproteinemia to resolve. Spontaneous recovery of clinically infected foals has not been documented, and up to 93% of treated foals survive the disease.[39] In general, nonsurvivors develop complications associated with gastrointestinal translocation, gastrointestinal perforation, or kidney failure.[55] Frazer reported that clinically affected and successfully treated foals sold for an average of 68% of the average price of unaffected foals by the same stallion.[39] However, their monetary earnings from racing were not significantly different from those of other horses.[64]

MONITORING AND PREVENTION. Early recognition of clinical cases and separating affected animals from the rest of the susceptible foals until full recovery or cessation of fecal shedding appears to be a logical biosecurity measure to prevent spread and environmental contamination. The monitoring of a herd with endemic EPE status includes the regular physical evaluation of resident foals and the monthly or bimonthly assessment of total protein concentration and monthly serologic status. Monitoring for exposure to *L. intracellularis* and hypoproteinemia/hypoalbuminemia should begin at least 4 weeks before the historical first detection of clinical cases.
