Parasite Control Programs

SHERRILL A. FLEMING, *Consulting Editor*
MARTIN K. NIELSEN and LORA RICKARD BALLWEBER

The traditional approach to parasite control programs has focused on using the appropriate anthelmintic at appropriate intervals. Parasitic disease in domestic animals was assumed to be the result of not dosing the animals often enough with anthelmintics. Scant consideration has been paid to the interaction of the parasite with the host and the environment because of the reliance on anthelmintics. These drugs have been placed directly into the hands of the livestock owner because the expertise of a veterinarian did not seem necessary in the control of parasites. However, reports of resistance to anthelmintics and emergence of new manifestations of parasitism are surfacing throughout the world. It has become increasingly apparent over the past 25 years that this approach to parasite control is no longer sustainable.

Secondary to the notion that parasitism is under control is the decrease in research to develop new anthelmintics. There has been little pharmacologic development other than in variations on the current anthelmintics. Recently two new anthelmintic classes have been developed but are not commercially available internationally. Research programs in parasitology of domestic animals are facing funding reductions as research priorities shift to other diseases. As producers and owners struggle to deal with the realities of anthelmintic resistance, veterinary medicine must reassess traditional approaches to parasite control programs. Veterinarians need to reeducate themselves away from the traditional tools of deworming, anthelmintic rotation, and pasture rotation. Integrated and holistic management strategies incorporating selective use of anthelmintic agents, enhancement of host immunity to parasitic infection, and grazing and environmental management have become increasingly important in the design of sustainable parasite control programs.

The impact of parasitic infection varies widely with geographic area and management system. General guidelines may be suggested for parasitic control, but it is inadvisable to adhere to any rigid anthelmintic schedules or even management recommendations. The best parasite control programs are those designed with the goals of the producer in mind, as well as the costs and returns of treatment. Other factors that must be considered include the animal's environment, climatic variations, and geographic location. Although many producers and owners would like a "cookbook" approach to parasite control, these are rarely effective across the various management conditions. It is unfortunate that an epidemiologically and economically sound parasite control program designed for animals in one geographic area may be neither efficient nor effective in another location.

The most important concept in the design of sound parasite control programs is the interaction of the parasite with the host and the environment. An understanding of the life cycle and epidemiology will suggest the most effective methods for parasite control. In this chapter, parasite factors, host factors, and environmental factors affecting transmission and disease expression are discussed for each major class of parasites in each host species (horses, cattle, small ruminants). The methods of monitoring parasite infections and anthelmintic resistance are presented in detail. Coccidiosis in cattle and small ruminants is summarized and, finally, the classes of anthelmintics and their modes of action are discussed at the end of the chapter.

Equine Parasitic Disease

Martin K. Nielsen

The changed approaches being promoted for control of equine gastrointestinal helminths are based on the scientific concepts outlined in the following section. The recommendations given today are based on our best knowledge of parasite and host biology as well as mechanisms of anthelmintic resistance. Some of these recommendations are likely to change as new information is generated. In essence, the traditional strategies used for equine parasite control were based on the best scientific evidence available at the time, and the recommendations now given are merely a response to the experiences gathered over the past decades. The concepts underlying the modern approaches for equine parasite control are presented here.

Anthelmintic Resistance

Anthelmintic resistance can be defined as "the loss of treatment efficacy of a given anthelmintic formulation that used to have efficacy against the same parasite species and stage in the same host animal, at the same dosage, and by the same route of administration." From this sentence, we can learn several things: (1) If a drug formulation never had efficacy against the parasite and stage in question, we are not facing resistance. (2) In cases of nonlabeled use of anthelmintics, we cannot make any conclusions regarding resistance because we have no information about the expected level of efficacy. (3) Horses are always infected with several different species of parasites at the same time, and resistance often occurs in some but not all of these species. (4) The expected level of efficacy needs to be defined for each parasite species for each drug in order to evaluate the possible presence of resistant parasites.

VetBooks.ir

TABLE 49.1

Current Levels of Resistance by Major Nematode Parasites to the Three Anthelmintic Classes in Managed Horse Herds

Drug Class	Cyathostomins	Large Strongyles	*Parascaris* spp.
Benzimidazoles	Widespread	None	Early indications
Pyrimidines	Common	None	Early indications
Macrocyclic lactones	Early indications	None	Widespread

The current levels of anthelmintic resistance in equine parasites are presented in Table 49.1. Resistance has been widely documented in cyathostomins (small strongyles) and *Parascaris* spp. It is worth noticing that as a general pattern, the resistance profiles are almost completely complementary between the two parasite categories. The drugs that seem to still work well against *Parascaris* spp. often have no or little efficacy against cyathostomins, and vice versa. However, levels of anthelmintic resistance are constantly developing, and this pattern therefore may very well be shifting. As described in the following section on egg reappearance periods, signs of emerging ivermectin and moxidectin resistance have been reported in cyathostomins,[1-4] and total drug failure is a realistic possibility in this parasite group. No new anthelmintic formulations with new modes of action are expected to be introduced to the equine market in the foreseeable future.

The only available method for evaluating anthelmintic efficacy in horses is the fecal egg count reduction test (FECRT). This method is outlined in Box 49.1 along with some suggested cutoff values for determining anthelmintic resistance.

BOX 49.1

Fecal Egg Count Reduction Test (FECRT)

The FECRT evaluates the efficacy of an anthelmintic drug based on its ability to reduce the fecal egg output after treatment. Fecal egg counts (FECs) are performed just before (or at the time of) and 14 days after treatment. The fecal egg count reduction (FECR) is calculated for each individual horse according to the following formula:

$$\%\text{FECR} = \left(\frac{FEC_{pre} - FEC_{post}}{FEC_{post}}\right) \times 100\%$$

It is recommended to use an egg counting technique with a detection limit of less than 25 eggs per gram (EPG). Always use the same technique consistently. Include horses with the highest possible pretreatment egg counts, and never use horses with counts below 200 EPG.

The FECRT should be established on the farm level by calculating the FECR for a number of individual horses and then calculating the average FECR for the treated group. It is recommended to include at least 5 to 10 horses on each farm if possible.

Suggested cutoff values for resistance depend on the drug tested and the number of horses investigated, but the following cutoff values are recommended as general guidelines for strongyle and ascarid nematodes:

Benzimidazoles:	95%
Pyrantel:	90%
Ivermectin:	95%
Moxidectin:	95%

If the farm average FECR falls below these values, anthelmintic resistance should be suspected. However, it is important to rule out other causes of decreased efficacy, such as misdosing, inadequate storage, etc. One must also consider how many horses were tested and how high the starting FECs were. Due to inherent variability in the measurement of FEC when performing FECRT, interpretation of the data can sometimes be difficult when results fall into the borderline zones. In such cases, it is recommended to repeat the FECRT.

There are currently no available methods for diagnosis of anthelmintic resistance in equine tapeworms.

Egg Reappearance Period

Egg reappearance periods (ERPs) are defined as the period of time from anthelmintic treatment until parasite eggs are found in the feces again. Although ERPs could potentially be established for a number of different parasite categories, they are most often referred to for strongyle (i.e., cyathostomin) parasites. The ERPs were initially defined for each anthelmintic class to help identify the optimum interval between anthelmintic treatments, and this was the basis for launching the so-called interval dose program in the 1960s.[5]

Nowadays, ERPs are used for an entirely different purpose. It has been observed that the first sign of developing anthelmintic resistance to a given drug is often a gradual shortening of the ERP until reduced efficacies can finally be found with the FECRT. This concept is highly relevant for monitoring the efficacy of ivermectin and moxidectin against cyathostomin parasites. Initially ERPs were reported to be at least 9 and 16 weeks for ivermectin and moxidectin, respectively,[6-8] but recent publications reported egg reappearance at around week 4 to 5 for both drugs.[1,4] Necropsy-based studies have suggested that these observations were due to survival of luminal yet premature stages of cyathostomin larvae.[2,3]

Prepatent Period

Prepatent periods (PPPs) should not be confused with the egg reappearance periods defined above. Although the latter defines a response to anthelmintic treatment, PPPs are defined in the absence of anthelmintic intervention. The PPP for any given parasite is defined as the time elapsed from the uptake of the infective stage of the parasite until it reaches patency and starts shedding eggs to be detected in the feces. Thus the PPP represents the duration of the parasitic part of the life cycle. Table 49.2 presents PPPs for some of the most important equine helminth parasites. It should be noted that although the PPPs for cyathostomin parasites generally are relatively short, they can undergo arrested development for up to several years, which thereby dramatically lengthens the PPP.[9]

Information about PPPs can be considered when identifying optimal times for routine collection of fecal samples and anthelmintic intervention.

Parasite Distributions

Regardless of parasite and host species, distributions of parasites among their hosts always seem to follow the same pattern. Hosts of similar age and breed and kept under identical management grazing in the same pasture can have widely different parasite

VetBooks.ir

TABLE 49.2

Prepatent Periods of Some Important Equine Parasites

Species	Prepatent Period	Reference
Cyathostomins	2–3 months[a]	113
Parascaris equorum	2½–3 months	114
Anoplocephala perfoliata	1½–4 months	115
Strongylus edentatus	11–12 months	116
Strongylus equinus	8 months	117
Strongylus vulgaris	6–7 months	116

[a]Encysted larval stages can remain dormant for years.

burdens. Parasites never follow a symmetric normal distribution but are rather said to be overdispersed.[10] Technically speaking, this means that the variance is larger than the mean, but in practical terms this has been translated to the so-called 20/80 rule.[11] This refers to the observation that about 20% of the host animals harbor approximately 80% of the parasites. Similarly, about 20% of horses are shedding 80% of the total strongyle egg output. This phenomenon is most pronounced in adult horses, where a large majority is shedding low numbers of strongyle eggs and very few individuals can be observed with very high counts. This pattern has been found to be consistent in individual horses over time, and the tendency is particularly strong among horses with zero or low strongyle egg counts.[12-14] Taken together, these observations have become the foundation for the selective therapy principle discussed later in this chapter.

Parasite Refugia

The term *parasite refugia* has become generally accepted as an important factor affecting the rate of development of anthelmintic resistance in large animal parasites.[15] Parasites in refugia are the parts of any given parasite population (including all stages, both internal and external) that are not exposed to the anthelmintic drug at the time of treatment. It can be said that these parasite stages in a way "escaped" the drug and can be viewed as refugees, hence the terminology. Logically, all stages on pasture, such as eggs and preinfective larvae, are always in refugia. In addition, animals left untreated are contributing significantly to the refugia, and some parasitologists therefore distinguish between "pasture refugia" and "animal refugia." Finally, some anthelmintic formulations have no efficacy against some parasite stages within the horse, and these can be regarded as part of the refugia as well. Examples of this include pyrantel formulations that have no efficacy against parasite stages present outside the gastrointestinal lumen and ivermectin, which has no documented efficacy against encysted cyathostomin larvae.

The parasites in refugia are hypothesized to play a role in diluting out resistant parasites whenever the animals are dewormed. A simplistic explanation of this concept is the larger the refugia, the more the dilution of resistant parasites, and the slower the development of resistance. In a theoretical example, let us consider a horse herd that is dewormed with a drug that has efficacy against all parasitic stages of the parasites, and the treatments are carried out at time of the year when no eggs or larvae are present on pasture. This would represent a scenario with no parasite refugia. Because no anthelmintic treatment is 100% efficacious, there will always be a few parasites surviving and passing their genes to the next generation. In a situation with low or even no refugia, all eggs being passed in the feces after deworming will be progeny of resistant parasites mating in the intestinal tract. However, if some of the horses in the herd were left untreated or treatments were carried out under circumstances with eggs and larvae present on pasture, then the few resistant worms surviving treatment would be diluted out by the many nonresistant worms, eggs, and larvae, and the progression of resistance in the parasite population would be much slower.

The role of parasite refugia in the development of anthelmintic resistance was initially shown in a sheep study,[16] and recent work with a combination of computer simulations and field studies with ruminants has provided solid evidence behind the concept.[17-19] Most recently, computer simulation models have been established for *Parascaris* spp. and cyathostomin parasites,[20-21] and studies confirm the value of parasite refugia in these parasites.

Important Parasites Infecting Horses

Over the past five decades the emphasis has shifted several times in terms of which parasites are considered the major targets of the control programs. When the first modern paste dewormers were introduced in the 1960s, the large strongyle *Strongylus vulgaris* was considered the most important threat to equine health and was therefore identified as the main target for the interval dose program.[5] As time went on and new anthelmintic drug classes were introduced, this parasite went from being present in virtually all horses to becoming very rare.[22-23] At the same time, cyathostomins were recognized as major pathogens and identified as the new primary target of parasite control programs.[24] More recently, the tapeworm *Anoplocephala perfoliata* has been associated with an increased risk of specific colic types.[25] In addition, *Parascaris* spp. are identified as the major parasitic pathogens in foals.[26-27] These are the four major parasite pathogens, but others can play a role as well. Less important but widely occurring parasites include *Strongyloides westeri*, *Oxyuris equi*, and the bot larvae of *Gasterophilus* spp. Finally, the insect-borne nematodes *Thelazia* spp., *Habronema* spp., and *Setaria* spp. can occur at significant levels in certain habitats and are included in this chapter.

Parascaris Species

Recent work has recognized the presence of two *Parascaris* spp. infecting horses: *Parascaris equorum* and *Parascaris univalens.* These two species are morphologically identical but can be differentiated by karyotyping and counting the number of chromosomes. Available data suggest that *P. univalens* is the predominant species, while *P. equorum* may be extremely rare.[28]

The equine roundworm has gained status as perhaps the most significant parasitic threat to equine health in managed horse populations. The major reason for this shift of emphasis is the high level of ivermectin and moxidectin resistance observed worldwide (see Table 49.1). *Parascaris* spp. are the primary parasites in foals until about the time of weaning. Between 6 and 12 months of age, most horses clear infection with this parasite, and the strongyles become the predominating parasite group instead. However, a smaller second wave of ascarid infections can be observed around 8 to 10 months of age.[29] Equine ascarids are ubiquitous in foaling operations, although prevalence differences can be observed between individual farms.[30-31] Patent infection is not uncommon in adult horses, particularly brood mares that are highly exposed to infection.

The life cycle is classic ascarid. Eggs are often claimed to be highly resilient to environmental influences, but very little evidence exists to substantiate these claims. Work with eggs of the pig roundworm, *Ascaris suum*, has substantiated this, but very little work has been done with *P. equorum* eggs. The infective stage is the embryonated egg, which hatches in the stomach and small intestine of the horse. Larvae then penetrate the mucosal lining and migrate the classical hepatotracheal route. Passing through the lungs has been associated with airway symptoms in young foals,[32] but the major pathogenic role is played in the small intestine. Here, the parasites compete with their hosts for nutrients, which can result in ill-thrift, weight loss, rough hair coat, and pot-bellied appearance.[26,32]

VetBooks.ir

The major clinical impact is associated with verminous small intestinal impactions.[26] Surgery is often required to relieve the condition, and prognosis for long-term survival is guarded with only 11 of 37 published cases surviving beyond 1 year after the colic incident.[26] Rather ironically, anthelmintic treatment has been shown to be a significant risk factor for this condition.[26] The instant paralysis elicited by most dewormers can cause the worms to aggregate in the lower parts of the jejunum and ileum. Benzimidazole-type drugs are not acting through paralysis of the worms and appear to be less associated with this condition.[26] Given that benzimidazoles have maintained efficacy against roundworms, they appear to be a good first choice for this parasite in most instances.

Cyathostomins

Historically, this group is also referred to as small strongyles. It consists of 50 different species belonging to 14 different genera.[33] However, some of these species and genera have been described as infecting equids other than horses, such as donkeys and zebras. Horses are always infected by multiple species, and there currently is limited knowledge about the pathogenic role of individual cyathostomin species. Cyathostomins are truly ubiquitous, and all grazing horses are exposed to infection.

The cyathostomins all follow the same basic strongyle life cycle. Strongyle eggs are passed in the feces, where they will hatch, and larvae develop through the first (L_1) and second (L_2) stages until they finally reach the third, infective stage (L_3). Hatching and subsequent larval development is highly temperature-dependent. At temperatures below 6° C, eggs do not hatch but remain viable. Hatching and larval development occurs at increasing rates up to about 40° C. At temperatures above this level, eggs and larvae quickly die out. Optimal conditions for development of eggs and larvae are in the temperature range of 25° to 33° C, where L_3 is reached within 3 to 4 days. In comparison, this takes several weeks at around 10° C. When molting from L_2 to L_3, the larvae retain their L_2 cuticle on the outside of the new sheath. This makes L_3 particularly resistant to environmental influences such as desiccation and freezing. Thus, for this stage, the widespread notion of the "killing frost" is a myth. In addition, intact fecal balls provide excellent protection of larvae, enabling them to further withstand desiccation and freezing temperatures well.[34] Due to the double-layered cuticle, L_3 cannot uptake feed and thus live on carbohydrates and lipids stored in their cells. The more active these larvae are, the shorter they live. As larval activity is highly temperature dependent, it can be deduced that the higher the temperature, the shorter the survival. Dry conditions, as achieved with freezing or desiccation, limit larval movement and therefore facilitate their survival. However, repeated cycles of frost and thaw have a deleterious effect on most free-living stages of strongyle, although this can be mitigated by snow cover, which tends to stabilize temperatures right at the freezing point, which is optimal for survival of eggs and L_3.[34]

Inside the horse, the L_3 exsheath in the stomach and subsequently reach the colon and cecum. Here, they enter the glands of Lieberkühn and penetrate cells at the base. From here, some species appear to penetrate deeper into the submucosa, while others remain in the mucosa. A fibrous capsule is formed around each larva, and then a fluid-filled cyst is formed. Larvae can remain encysted for several years,[9] but encystment appears to be a strategy for the parasites to make it through the winter, where conditions on pasture are unfavorable for parasite transmission. Interestingly, in warmer climates, encystment appears to occur over the hot summers. Horses can harbor several hundred thousand encysted cyathostomin larvae without showing any sign of discomfort. The major clinical consequences are associated with the process of excystment, where the L_4 penetrate their cysts and migrate the short distance back to the intestinal lumen. This causes a small local inflammatory reaction around the vacated cyst. In rare cases, synchronous emergence of large numbers of larvae from their cysts can cause a severe generalized acute typhlocolitis, called larval cyathostominosis.[24] This condition is characterized by profuse watery diarrhea and pronounced dehydration as well as protein loss and ventral edema. The case fatality rate is reported to be 50%.[24] Identified risk factors for larval cyathostominosis include horses aged 1 to 4 years, anthelmintic treatment within 14 days prior, and late fall, winter, or early spring in temperate climates.[35] The luminal worm burden appears to elicit some sort of a repressive signal, which prevents the encysted stages from resuming development. If the luminal burden is removed by anthelmintic treatment, this repressive signal disappears abruptly, and a synchronous emergence is triggered. Treatment of acute larval cyathostominosis involves intensive fluid therapy, which can be combined anti-inflammatory drugs and antibiotics. The anthelmintic drug of choice is a single dose of moxidectin (400 µg/kg PO) because of its efficacy against encysted larvae. The 5-day elevated dose of fenbendazole (10 mg/kg PO once daily) is also labeled for treatment of encysted cyathostomins, but larvicidal resistance has recently been reported to this regimen, making it unlikely to have maintained full efficacy once adulticide resistance has been documented to the single dose.[36]

Chronic cases of larval cyathostominosis also occur. These are typically characterized by weight loss and loose feces or intermittent diarrhea, often over an extended period. Plasma protein and albumin levels can be lowered, and ventral abdominal edema can be observed. Horses usually recover, although it may take time for them to regain full body condition.

Tapeworms

Three species of tapeworm infect horses: *A. perfoliata*, *Anoplocephala magna*, and *Anoplocephaloides (Paranoplocephala) mamillana*. Of these, *A. perfoliata* is by far the most common, and it is the only species that has been associated with clinical disease. Being a cestode, the life cycle involves intermediate hosts, which are oribatid mites that feed on the organic material present in the feces. During this process, the mites can ingest tapeworm eggs present in the feces. Inside the mite, eggs develop to infective cysticercoids over a period of approximately 2 to 4 months. Horses inadvertently ingest these mites during grazing. In the gastrointestinal tract, the cysticercoids are liberated from the mites, and the scolexes attach to the mucosal lining around the ileocecal valve in the cecum.

Prevalence of *A. perfoliata* has been reported to vary widely between farms and regions, often ranging between 20% and 80% of horses.[25] Prevalence appears to be habitat-dependent, and it is likely associated with conditions favoring survival of the oribatid mites. However, the most significant factor appears to be access to pasture. The longer the time spent on pasture, the higher the tapeworm exposure seems to become.[37] Horses younger than 2 years and older than 15 years of age have been reported to have significantly larger *Anoplocephala* burdens than horses between these ages.[38-39] While this could be explained by the assumed incomplete levels of immunity in these age groups, it is equally likely that these age groups simply spend more time on pasture. Tapeworm burdens appear to be accumulating through the grazing season to reach their highest point in the fall and winter.[38-43]

An increasing number of case-control studies has associated *A. perfoliata* infection with colics originating from the ileal region.[25] These include ileal impactions and ileocecal intussusceptions, which are sometimes complicated by intestinal rupture.[44-45] Taken together, these studies indicate that tapeworms can play a role in the development of colic, but this is often largely confounded by the multifactorial nature of colics and regional differences in climate and management.

Two anthelmintics are labeled for treatment of equine tapeworms: praziquantel and pyrantel pamoate. Praziquantel is a sole tapeworm drug that has no efficacy against nematodes. For this reason, it is most often formulated in combination with ivermectin or moxidectin, although it exists in a standalone formulation for horses in Europe. Pyrantel, on the other hand, is widely acting against luminal stages of nematodes as well as cestodes. At the dosage labeled for nematode treatment (6.6 mg/kg), the efficacy of pyrantel pamoate is greater than 80% against *A. perfoliata*.[46] A double dosage of pyrantel pamoate (13.2 mg/kg) is a substitute for tapeworm treatment, and the efficacy of this has been found to be greater than 95%.[47]

Strongylins (Large Strongyles)

The strongylin group comprises the three *Strongylus* species—*S. vulgaris*, *Strongylus edentatus*, and *Strongylus equinus*—as well as *Triodontophorus* spp., *Craterostomum acuticaudatum*, and *Oesophagodontus robustus*. As mentioned, large strongyles have generally become quite rare in managed equine establishments. The most common of these nowadays is probably *Triodontophorus* spp., but the *Strongylus* species, particularly *S. vulgaris*, are considered the most pathogenic of helminths infecting the horse.

The development of the external stages of the strongylins is virtually identical to what is already described for the cyathostomins. Inside the horse, larval migrations are widely different. The three *Strongylus* species all have PPPs of 6 months or more, and they spend several months migrating in various tissues and organs of the horse. Major pathologic lesions have been ascribed to these migrations, whereas the adult worms are found to do little harm to their hosts. The lesions caused by migrating stages of *S. vulgaris* are classic in equine parasitology and very well described.[48] L_3 invade the mucosa of the small intestine, cecum, and colon. They then molt to L_4 before they enter local arterioles. Inside these, they migrate beneath the endothelium toward the root of the cranial mesenteric artery, leaving characteristic fibrous tracts on the intimal surface. Upon reaching their destination about 14 days post infection, they enter the lumen of the vessel and remain there, embedded in thrombus masses. Here, they grow in size and molt to L_5, while causing a pronounced verminous endarteritis with roughened intima, fibrosis of arterial walls, and increased diameter of the vessels. After about 4 months, the L_5 are transported by the bloodstream to the walls of the ventral colon and cecum, where pus-filled nodules are formed around them in the submucosa. These nodules eventually open into the intestinal lumen, and the young adult worms emerge. After another 6 weeks, the worms become sexually mature and start shedding eggs. Although the lesions are pronounced, they are relatively rarely accompanied by disease. A classical syndrome of thromboembolic colic has been described,[49] where thrombi detach from the arteritis lesions and are carried distally until they reach a terminal branch sufficiently small to become occluded. This causes ischemia and infarction of intestinal segments, which is very painful to the horse. However, the primary manifestation in many cases appears to be peritonitis due to bacterial overgrowth of the devitalized intestinal segment, and the prognosis for survival is reserved.[50]

Larvae of *S. edentatus* migrate via the portal system to the liver, where they molt to the fourth stage within the parenchyma. They migrate within the liver, and then migrate sub- and retroperitoneally via the hepatorenal ligament to the adipose tissue in the abdominal walls. Larvae can also be found in the perirenal fat tissue. Here, larvae eventually molt to L_5 and migrate retroperitoneally back to the intestinal walls. Described lesions include a filamentous peritonitis, especially around the liver and diaphragm, as well as hemorrhagic and inflammatory lesions in the abdominal wall.[51] The third *Strongylus* species, *S. equinus*, is probably the rarest, at least in managed horses on the northern hemisphere, where it is hardly encountered at all. As opposed to *S. edentatus*, it migrates within the peritoneal cavity and passes through the pancreas, where it can cause significant damage.[52] Despite their obvious pathologic impact, neither *S. edentatus* nor *S. equinus* have been associated with defined clinical syndromes.

None of the strongylins have been reported as resistant to any of the anthelmintic drug formulations available. Treatment efficacies against *S. edentatus* appear to be more variable than in the other species,[53] but this seems to always have been the case and thus cannot be concluded to be resistance.

Other Parasites

Other parasites frequently infect equines but are generally considered of lower importance. For completion, they are briefly covered here.

S. westeri, or the equine threadworm, parasitizes the small intestine of suckling foals. This parasite is remarkable because it is able to maintain a full life cycle outside its host, and only female worms seem to infect the foals. Infection occurs via three possible routes: skin penetration by L_3, ingestion of these larvae from the environment, or lactogenic transmission from the mare.[54] Infection usually occurs within the first weeks of life, and infected foals are usually asymptomatic. However, one study reported an association between diarrhea and high *Strongyloides* egg counts (>2000 eggs per gram [EPG]),[55] and another study described a "frenzy" syndrome in foals exposed to apparent percutaneous penetration of L_3 from the environment.[56] Because of *S. westeri*, it has become a widely used practice to deworm mares at or just before foaling. However, it remains unclear how effective this measure is, as *S. westeri* prevalence has been observed to increase in managed equine populations in recent years.[57]

O. equi, the equine pinworm, is widely prevalent, but eggs are rarely encountered in fecal samples, as they are laid outside the digestive tract. Adult worms live in the dorsal colon. The female worm migrates through the descending colon and rectum to protrude from the anus and deposit her eggs in patches on the perianal skin. When these egg patches dry up, they become very itchy to the horse, and horses begin rubbing their tails against various objects. This serves as an excellent means to spread eggs in the environment. The infective stage is the embryonated egg, which is inadvertently ingested from the contaminated environment. Besides the tail-rubbing, *O. equi* does not cause disease or discomfort to the horse, and there is no justification for routinely targeting this parasite in the parasite control program. Recent studies have reported apparent resistance to ivermectin in isolates of *O. equi*.[58,59]

Gasterophilus spp. are the widely occurring botflies, whose larval stages overwinter in the intestinal tract and then pass in the feces during the spring. They then pupate in the loose soil for a couple of months until the adult flies emerge. The two most common species are *Gasterophilus intestinalis* and *Gasterophilus nasalis*. Eggs are glued onto the hair coat, and larvae make their way into the oral cavity either by crawling on the skin *(G. nasalis)* or when the horse grooms itself or another herd member *(G. intestinalis)*. In the mouth, the larvae spend several weeks burrowing into the tongue and subsequently spend time in the interdental spaces before reaching the stomach.[60] In the stomach, *G. intestinalis* attaches to the mucosal lining by the margo plicatus, whereas *G. nasalis* can be found in the pyloric region. Characteristic lesions have been described at the attachment site,[61] but these have not been consistently associated with disease. With the emergence of equine dentistry over the past decades, the lesions in the oral cavity are gaining more attention, as *Gasterophilus* spp. can cause oral discomfort.[62]

The equine eye worm, *Thelazia lacrymalis*, is transmitted by muscid flies and can be found within the conjunctival sac of horses, where they generally appear to do very little or no harm to the eye. However, abscess formation and inflammation

VetBooks.ir

of the lacrimal glands have been described.[63] Prevalence rates in the range of 20% to 42% have been reported in managed horses.[64,65]

The group of stomach worms comprises *Habronema* spp., *Draschia* spp., and *Trichostrongylus axei*. *Habronema* and *Draschia* spp. have very similar life cycles. Like *Thelazia* spp., they are both transmitted by muscid flies. The flies acquire the infective larvae while feeding on the feces. Horses get infected by accidentally ingesting infected flies. Here, the larvae eventually reach the stomach, where *Habronema* larvae apparently cause no gross lesions, but adult specimens of *Draschia* spp. can be found embedded in large tumor-like fibrous masses around the margo plicatus.[66] Common to both of these species is that the larvae can be deposited by the flies in or near wounds or mucocutaneous junctions. For the parasite, this represents a dead-end pathway, from which the life cycle cannot be completed.[67,68] When larvae are deposited in this manner, they cause a condition usually referred to as cutaneous habronemiasis or draschiasis, or "summer sores." This is characterized by persistent, eosinophilic granulomatous lesions with eosinophilia and fibrosis. A rare, pulmonary form of habronemiasis has been described as well.[69] Anthelmintic resistance has not yet been reported in *Habronema* or *Draschia* spp., but several veterinary practitioners from subtropical and tropical regions report that skin lesions consistent with cutaneous habronemiasis do not resolve upon treatment with a macrocyclic lactone (ivermectin or moxidectin). The prevalence of *Draschia* spp. seems to have decreased dramatically after the introduction of ivermectin.[70]

T. axei possesses the rare capacity of infecting both ruminants and monogastrics such as pigs and horses. The external part of the life cycle is similar to that of the strongyle parasites described in this chapter. Inside the horse, it develops within the gastric glands, where it can cause hypertrophy of the mucosa.[71] In horses, *T. axei* has not been found to affect pH or levels of plasma pepsinogen.[72] The parasite is a rare finding in horses, but prevalence has been found to increase when horses are co-grazed with sheep.[73,74]

Setaria and *Onchocerca* spp. are filarial nematodes infecting horses. Infective L_3 are transmitted by blood-sucking arthropods feeding on the horses. The larvae then migrate to their predilection site, which is the connective tissues (*Onchocerca* spp.) or the abdominal cavity *(Setaria equina)*. Here, they develop into adult worms, which then release microfilariae intro the bloodstream. These microfilariae in turn will enter the blood-feeding arthropods, and the cycle is complete. The intermediate hosts for *Onchocerca* spp. are biting midges (*Culicoides* spp.) and black flies (*Simulium* spp.), whereas the hosts for *S. equina* are mosquitoes. The latter parasite is regarded as nonpathogenic, whereas *Onchocerca* spp. have been associated with pronounced skin reactions. Microfilariae of *Onchocerca cervicalis* tend to congregate in certain regions of the body, including the ventral midline and face, where they are ingested when *Culicoides* feed in these regions.[75] This results in a verminous dermatitis characterized by intense pruritus.[76] Lesions can be effectively treated with macrocyclic lactones.[77] However, there is no known therapy to eliminate adult *O. cervicalis* from the connective tissue around the ligamentum nuchae of horses. Therefore infected horses will need periodic retreatment with ivermectin or moxidectin to prevent or control recurrence of clinical signs.[78,79] Treatment of the skin-dwelling microfilariae has been associated with an inflammatory reaction to the dying parasites,[80] which can be confused with the widely occurring *Culicoides* hypersensitivity (summer eczema, sweet itch).

Adult *Parafilaria multipapillosa* is another filarial nematode that occurs in subcutaneous and intermuscular connective tissue of horses outside North America. Nodules form in the overlying skin and may rupture and bleed or leak tissue fluids. This condition is often referred to as "summer bleeding,"[81] not to be confused with the "summer sores" described with cutaneous habronemiasis or draschiasis. L_1 are present in the exudate from bleeding lesions and ingested by feeding horn flies *(Haematobia irritans)*. Larvae develop to the infective third stage within the fly and are transferred to horses when flies feed on lachrymal secretions or skin wounds. The larvae then migrate in the subcutaneous tissues and develop to the adult stage within a year. Eggs and microfilariae can readily be identified in smears taken from lesion exudates.[82] Little is known about anthelmintic efficacy, but lesions have been observed to recur after treatment with macrocyclic lactones.

The equine lungworm, *Dictyocaulus arnfieldi*, is covered in the Lungworm Infection in Large Animals section later in this chapter.

Halicephalobus gingivalis (formerly *Micronema deletrix*) is a free-living nematode belonging to the order Rhabditida. It is widely present in the soil and humus but possesses a capacity to also invade living tissues. Infection appears to occur through soil-contaminated wounds or nasal mucosal membranes with apparent predilection in the head region,[83-86] but penile infection has also been described.[87] Inside the host, the nematode reproduces tremendously, and the larvae invade deeper into the tissues. Larvae appear to have a special affinity for the central nervous system (CNS) and the kidneys.[85] Lesions are multifocal, eosinophilic, and pyogranulomatous. Once the CNS is affected, symptoms often slowly progress into a very grave state. Symptoms include blindness, ataxia, loss of proprioception, head pressing, coma, recumbency, and death.[85,88,89] Treatment options are very limited. Surgical debulking can be combined with repeated high doses of fenbendazole (50 mg/kg) or ivermectin (0.55 mg/kg),[90] but the overwhelming majority of published cases had a fatal outcome. Similarly, *Halicephalobus* spp. infection has been reported to be extremely rare but fatal in humans.[91-93]

Diagnostics

The cornerstone of diagnostics in equine parasitology remains the fecal egg counting methods. Before these are discussed, it should be emphasized that egg counts can be performed for at least three purposes: (1) evaluation of anthelmintic efficacy with the FECRT (see Box 49.1); (2) identification of low, medium, and high strongyle egg shedders for a targeted treatment approach; and (3) diagnosis of parasite infection in clinical cases. When discussing the usefulness of fecal egg counts, it is important to note that this largely depends on the purpose. In other words, fecal egg counts are not equally useful for all three purposes.

Numerous techniques exist with various names such as Stoll,[94] Wisconsin,[95] or McMaster,[96] but they are all based on the same simple principle. A flotation medium is usually constructed with some sugar or chemical salt solution to have a specific density higher than most parasite eggs but lower than the fecal matter. Examples of components used in flotation media include glucose, sucrose, sodium nitrate ($NaNO_3$), sodium chloride (NaCl), magnesium sulfate ($MgSO_4$), and mercury chloride (HgCl). Very frequently used media are saturated glucose-NaCl and Sheather's sugar solution, which are relatively cheap and easy to compose. The numerous different egg counting techniques and the even more modifications of these can appear confusing, but in reality there are only three factors to consider when the choice of method has to be made: (1) the level of accuracy and precision associated with the technique, (2) the detection limit of the technique, and (3) the equipment requirements and time consumption in the laboratory.

The accuracy of a given technique is a measure of how close the determined egg counts are to the true egg count in a given sample. All of the different available techniques are associated with a certain degree of egg loss in the process of

VetBooks.ir

mixing, filtering, and flotation, so the eggs counted are only a subset of the true number of eggs per gram of feces. Similarly, precision is a measure of repeatability between repeated counts from the same sample. As a general rule of thumb, the simpler and perhaps more user-friendly methods come with lower accuracy and precision, whereas the more refined techniques that use centrifugation-enhanced flotation and larger counting chambers usually have higher precision and accuracy. The McMaster technique, for example, comes with low to moderate accuracy and precision,[97] whereas the FLOTAC system is very accurate and precise.[98] However, the FLOTAC is much more time consuming and includes a centrifugation step. A recently developed modification of the FLOTAC principle, the Mini-FLOTAC, is relatively user friendly as it does not involve centrifugation and has been found to have better precision and accuracy than the McMaster method.[97] These features are important when interpreting the FECRT. Low precision allows for high levels of variability in the FECRT. This is the reason why the FECRT always must be performed by averaging values across several horses on each farm.

The choice of detection limit will depend on the purpose of the egg count. If FECRTs are performed, it is crucial to be able to detect low egg counts in the posttreatment samples to possibly discover early signs of reduced anthelmintic efficacy. A crude McMaster, which is performed by many practice laboratories, usually comes with a detection limit of 25 or 50 EPG, which makes it very unsuitable for the FECRT, unless the pretreatment levels are very high. The FLOTAC technique mentioned above comes with a detection limit of 1 EPG. While this can also be achieved by a more traditional technique such as the Wisconsin, FLOTAC has been shown to have much higher precision.[98] For identification of high strongyle shedders for a targeted treatment approach, the detection limit is not important, and McMaster methods can be used.

Until recently, there were no published studies evaluating egg counts as a diagnostic test for horses. From the database generated over 50 years of equine parasitology research at the University of Kentucky, fecal egg counts were related to total intestinal worm counts from close to 700 horses.[99] Results indicated a high positive predictive value, indicating that an egg count–positive horse is very likely to also harbor worms in the intestine. However, the negative predictive value was low, emphasizing that 0 EPG does not necessarily indicate zero worms. Further, there were no direct linear correlations between strongyle and ascarid egg counts and the corresponding intestinal worm burdens. Thus higher egg counts do not necessarily equate to larger worm burdens. However, strongyle egg counts in the range of 100 to 500 EPG did correspond to significantly smaller strongyle burdens than egg counts above this level.[99] Taken together, this information illustrates that fecal egg counts can be used to qualitatively detect presence of strongyle or ascarid burdens, but that there are considerable limitations to these techniques as quantitative diagnostic tools. Furthermore, it should be borne in mind that much of the parasitic disease observed in horses is caused by migrating or encysted larvae that are not shedding any eggs. Detecting eggs in the feces cannot be used to estimate the probable presence of larval burdens. Also, strongyle eggs are practically ubiquitous in equine fecal samples, and their mere presence cannot be used to suggest parasitic disease. In foals and weanlings, egg counts can be very useful for determining whether parasite burdens are dominated by strongyles or ascarids, which is crucial information for selecting the right anthelmintic (see Table 49.1).

Another weakness of strongyle fecal egg counts is that up to 50 strongyle species have been described infecting horses,[33] and it is not possible to morphologically distinguish between their eggs. Larval cultures can be performed to differentiate large and small strongyles and for species-specific detection of the three *Strongylus* species.[100,101] In a retrospective validation, larval cultures were found to have high positive and moderate negative predictive values with no direct linear correlation between larval counts and worm counts.[99] Thus larval cultures should be interpreted with the same caution as egg counts. A pragmatic approach has been to pool feces from several horses into one pool, but this cannot be recommended, as diagnostic sensitivity is greatly lost with this approach and the negative predictive values are likely to be much lower.

Diagnosing tapeworm infection is a particular challenge despite the availability of several different techniques. Anoplocephalid eggs may show up on routine egg counts from time to time, but validation studies have shown that the diagnostic sensitivity of the simple McMaster is less than 10%.[25] The reason for this is believed to be the uneven distribution of tapeworm eggs in the feces. Eggs are released in clumps often retained within a tapeworm segment, which then disintegrates on its way through the cecum and colon. The eggs remain in their clumps, and egg counting methods examining just a few grams of feces can easily miss detecting these eggs. A modified egg counting technique that analyzes 40 g of feces has been found to have a diagnostic sensitivity and specificity of 0.61 and 0.98, respectively.[102] However, this was based on detection of cestode burdens comprising only a single worm. If the threshold were adjusted to detect 20 or more tapeworms, the sensitivity was improved to about 90%.[25] Thus the tapeworm infections most likely to not be detected with this method are small burdens unlikely to cause clinical disease. Several enzyme-linked immunosorbent assays (ELISAs) have been made commercially available for detecting anti-*Anoplocephala* antibodies.[25] These assays have been found useful for evaluating the level of tapeworm exposure on the herd level. Optical density (OD) values correlate positively with worm burdens, and the assays can be helpful for generating information to help balance the level of tapeworm-directed treatments on each farm. It should be emphasized that serology is generally less useful for diagnosis on the individual level. Antibody levels are too variable, horses remain titer-positive for months after tapeworm treatment,[103] and one recent study suggests cross-reactivity with the less common *A. magna*.[104] In the United States, the diagnostic laboratory at the University of Tennessee, College of Veterinary Medicine, offers a modified version of the *Anoplocephala* ELISA, but no information is available on the performance of this test. There are currently no available methods for diagnosis of anthelmintic resistance in equine tapeworms.

Integrated Parasite Control

It is often said that a "one size fits all" parasite control program does not exist. There is no simple chart to hang on the wall in the horse barn, and follow the same guidelines for all of the horses. To the frustration of many horse owners, farm managers, and veterinary practitioners, it is much less straightforward to identify what to do. This section outlines the elements to incorporate in a modern evidence-based equine parasite control program.

The most important evidence to incorporate on each farm is the efficacy of the anthelmintic drugs used. Although Table 49.1 can be used to predict the drugs more likely to still have efficacy on a particular farm, the only way to really know is to evaluate the efficacy with the FECRT, as described in Box 49.1. Ideally, all drugs used should be tested on every farm each year. Regardless of the deworming program incorporated, it is very important to know the efficacy of the drugs used. Veterinary practitioners who provide recommendations on the choice of anthelmintic should realize that these recommendations cannot be given without knowing the efficacy on the given farm. For ivermectin and moxidectin, the efficacies measured on day 14 post treatment should still be 100% in the large majority of instances, but the ERP may be shortened considerably on

VetBooks.ir

some farms. Thus it may be a pragmatic solution to perform the posttreatment egg counts in week 4 or 5 after treatment to evaluate whether there is evidence of a shortened ERP. A shorter ERP should not necessarily discourage people from using the drug, as there may not be valid alternatives, but it provides useful information about the level of parasite control achieved by using these drugs.

Egg counts can also be used for two other purposes. In foals, they can readily tell whether parasite burdens are predominantly *Parascaris* spp. or strongyles. This is crucial information, as the drugs that are likely to work against *Parascaris* spp. would not have efficacy against strongyles on many farms, and vice versa. In adult horses, a few egg counts repeated over time can be used to identify horses that are consistently shedding low, moderate, and high egg numbers.[11,105,106] This can then be used in a targeted selective approach, where the consistent high shedders can receive more anthelmintic treatment and horses consistently shedding low numbers can receive less treatment. Simulations have shown that treating all horses shedding 200 strongyle EPG or more with a drug with a 99.9% efficacy yields an overall reduction of the strongyle egg shedding of 94%.[11] However, when using 200 EPG as a treatment threshold, only about 50% of adult horses will need treatment, so with just half as many treatments, close to the same overall egg count reduction can be reached. This selective approach increases parasite refugia, slows down the development of anthelmintic resistance, and is widely implemented in some countries.

Recent studies have illustrated that in a system basing all anthelmintic treatments on fecal egg counts, some horses will not be dewormed for years.[107] This gives room for the large strongyle species, particularly *S. vulgaris*, to reemerge, which has been documented in Denmark.[107,108] Here, about 80% of farms using selective therapy had at least one horse infected with *S. vulgaris*, which was twice as much as in farms not using selective therapy. Although none of the horses showed clinical signs of disease, the pathogenic potential of *S. vulgaris* does suggest that horse populations would benefit from a basic foundation of anthelmintic treatments applied to all horses. Given the long life cycles and no apparent development of resistance in large strongyle species, just one or two yearly treatments with ivermectin or moxidectin would effectively reduce the occurrence. Further treatments beyond this basic foundation should be directed at high strongyle shedders in a selective approach as described above.[109]

Tapeworms need to be considered in every parasite control program. They should be assumed to be present under most circumstances, although large regional differences in prevalence can occur.[25] As indicated in the previous section, the serum ELISA could be useful for generating information about the level of tapeworm exposure in a herd. If OD values are consistently high (i.e., many horses above the level of 1.0 to 2.0) or if confirmed clinical cases have occurred, a more aggressive treatment approach can be taken. In most cases, however, annual treatments in the fall appear to be of greatest benefit to minimize burdens and prevent the development of gravid forms that will otherwise contaminate pastures in the coming season. With an ivermectin-praziquantel combination formulation, this could easily be incorporated into the basic treatment foundation described above.

It has been a widely used strategy to regularly rotate between anthelmintic drugs when deworming horses. The theoretical basis for this strategy all makes good intuitive sense; parasites carrying genes that enable them to survive treatment with one drug can be killed by applying another drug with a different mode of action. Unfortunately, there is no evidence to support this hypothesis. In fact, one equine study clearly suggested that rotating drugs with each treatment did not appear to slow development of resistance.[110] Computer modeling studies with both ruminant and equine parasitology data have convincingly shown that rotating drugs does not prevent accumulation of resistant genetic alleles and therefore does not slow down the development of resistance.[111,112] Besides, rotation would only make sense if several anthelmintic drugs to which no resistance had already developed were available. As shown in Table 49.1, there are only three drug classes to choose from. Thus it will be difficult to find many horse farms without resistance already developed to one or maybe even two of them. Further, when rotation is carried out blindly without testing the efficacy of all drugs used, alternating between drugs may very well mask resistance so that it takes longer for it to be discovered. In summary, drug rotation does not appear to prevent or reduce the development of resistance, and it may create a false sense of security for the horse owner, who will believe that a solid strategy is in place.

Foals and young horses require specific consideration with regard to parasite control, as they are the most susceptible to infection, often shed the highest egg numbers, and are more at risk for parasitic disease than their older counterparts. As a rough guideline, most foals should require approximately five anthelmintic treatments during their first 15 months of life. Higher treatment intensity can be justified in cases of on high infection pressure or documented clinical problems in the herd. Less than four treatments would be considered inadequate unless low parasite transmission levels or absence of *Parascaris* spp. can be consistently documented.

The major helminth pathogen in foals younger than 6 months of age is *Parascaris* spp. Treatments targeting this parasite should be timed around the age of 2.5 to 3 months of age, when the first worms will have reached the intestine and started shedding eggs. Considering the increased risk of impactions from paralytic anthelmintics, benzimidazoles may be the best choice at this time. If this treatment is delayed just a couple of months, the worms will have grown much larger and increased in numbers, posing an increased threat of verminous impaction. A second deworming treatment should be targeted around or preferably just before the time of weaning. This is a stressful period for the foal, and large parasite burdens are undesired. At weaning, the main parasitic threat is still likely to be *Parascaris* spp., but strongyle parasites may start to play a role as well. Therefore fecal egg counts yield useful information about the presence of ascarids and strongyles and help guide the veterinarian to select the right anthelmintic.

Benzimidazoles are unlikely to be effective against cyathostomins on many farms, so other drug classes should be considered. Similarly, ivermectin has lost efficacy against *Parascaris* spp. across the world. Again, it is crucial to routinely evaluate the efficacy of the anthelmintics chosen with the FECRT. A third treatment should be considered for the weanlings or yearlings at about 8 to 10 months of age, which would be in the late autumn or early winter in most cases. This should target strongyles and tapeworms, while ascarids should be considered only in the case of positive egg counts. The next treatment could coincide with the fecal testing and treatments that are carried out in the spring for adult horses on many farms. In areas with defined grazing seasons, a fifth treatment should be considered about midway through the grazing season. Yearlings are considerably more susceptible to parasitic infection than older horses, and leaving them untreated for an entire grazing season of 5 to 9 months' duration puts them at risk of acquiring large parasite burdens.

Gastrointestinal Nematode Infections in Cattle

Lora Rickard Ballweber

Cattle are hosts to numerous species of gastrointestinal nematodes (GINs) that, together, cause parasitic gastroenteritis (PGE).[1-3] Within the strongyle-type nematodes, *Ostertagia*

ostertagi and species of *Cooperia* have been the most prevalent parasites across the United States, followed by species of *Haemonchus*, *Trichostrongylus*, and *Oesophagostomum*. Other species within the genera *Nematodirus* and *Trichuris* complete the GIN population in the United States. The various GINs do differ somewhat with respect to their site of infection and pathologic effects, but their general life cycle patterns are quite similar. The hookworm *Bunostomum phlebotomum*, the threadworm *Strongyloides papillosus*, and the roundworm *Toxocara vitulorum* are not widely distributed within the United States and not considered a part of the "normal" GIN population.

Life Cycle Adult female nematodes produce eggs that pass out of the host with the feces. Under optimal conditions in the external environment, first-stage larvae (L_1) can develop and hatch from eggs within 24 hours. L_1 grow and develop to second-stage larvae (L_2), which in turn grow and develop into third-stage larvae (L_3). In general, the third stage is the infective larval stage. After ingestion, L_3 develop into fourth-stage larvae (L_4), which then develop into immature adults. Sexually mature adult nematodes develop within 2 to 4 weeks after ingestion of the L_3 unless arrested development occurs. The life cycle of *Nematodirus* is the same except that development to infective L_3 occurs within the egg before hatching. For *Trichuris*, development to the infective L_1 occurs within the egg, which does not hatch until ingested by the animal. Approximately 8 weeks are required before sexually mature *Trichuris* are present.[1,3]

Climate and management of pastures and animals are among the numerous factors that influence the level and extent of parasitism. Although temperature is considered the driving force behind larval development, larval development can proceed only in the presence of adequate moisture. Larvae of all stages can be killed by extremely low or high temperatures, desiccation, and/or direct sunlight. Larval development and transmission tend to occur in predictable seasonal patterns based in part on regional climatic differences.[1-4] In the southern United States, infective L_3 persist longest when conditions are cool and wet (October to May), but die off quickly during the summer after rain-induced liberation from the fecal pat.[5,6] Nematodes acquired by grazing cattle during the summer months come from eggs recently deposited on pasture. In the northern United States, infective L_3 may be on pasture year-round. Significant numbers of *Cooperia* and *Nematodirus* may be acquired for up to 12 months after deposition of eggs on pasture, with acquisition of fewer numbers for up to 24 months. Acquisition of low levels of *Ostertagia* can occur for at least 14 months after deposition of eggs. In subtropical climates, seasonality may be much less marked and pasture infectivity may follow the rainfall pattern. In arid climates, large numbers of larvae may be present on the pasture whenever local conditions permit lush grass growth.[2,7-9] Sufficient moisture, usually in the form of rainfall, is also of critical importance to transmission, to release larvae from the fecal pat and provide a film of moisture for migration onto vegetation.[1,4]

Not only can larvae survive on pasture, but some species can arrest development within the host. This usually occurs when adverse environmental conditions would decrease larval survival in the external environment. Best known for this phenomenon is *O. ostertagi*. In northern temperate climates, pasture larval populations peak in the summer and early fall, and L_4 tend to overwinter in the host, resuming development in the spring. In warmer climates with hot, dry summers, the highest numbers of infective larvae may be found in the late spring to early summer, and L_4 tend to oversummer in the host, resuming development in the fall.[2,10,11]

Pathophysiology Of all the cattle nematodes, *O. ostertagi* has long been considered the most pathogenic nematode in temperate regions. The pathophysiology of ostertagiasis centers on the development of larvae within the gastric glands of the abomasum. As the larvae develop within the lumen of the glands, hyperplasia and intense eosinophilic infiltration occur. Mucosal glandular cells lose their differentiation, and cell junctions are weakened. Albumin is lost into the lumen. Parietal cells cease to function, causing a decrease in hydrogen chloride (HCl) production. The change in pH stimulates overproduction of gastrin, which initiates cell proliferation and hyperplasia. Alkalinity also decreases the bacteriostatic activity of the abomasum. When the pH exceeds 5, the conversion of pepsinogen to pepsin is inhibited. As a result, pepsinogen is released into the blood through permeable cell junctions. Initially, cellular changes occur within the parasitized glands, but as the glands distend due to nematode growth, the changes encompass the surrounding, nonparasitized glands as well. Widespread hyperplasia creates the typical "Moroccan leather" appearance of the abomasum. In experimental models, *Ostertagia* infection in calves is also associated with elevated peripheral eosinophil counts and decreased lymphocyte counts.[1,3,12]

Populations at Risk Although infections with some GINs readily induce immune responses that limit future populations of nematodes within the gut, cattle remain susceptible to *O. ostertagi* for many months. Protective immunity is usually not evident without prolonged exposure and may not occur until the animals are 2 years of age or older.[1] Consequently, clinical type I ostertagiasis occurs primarily in young cattle (up to ≈18 months of age) during their first grazing season (primary exposure), and type II disease is present in older animals (2 to 4 years of age). Adult cattle, after the second grazing season, rarely show signs of nematode infection or require anthelmintic treatment. Although mature cattle ingest infective larvae, fewer larvae establish infections, so parasite numbers and the magnitude of fecal egg shedding are generally decreased. Most preventive and treatment strategies therefore are directed at young grazing stock, primarily beef calves and dairy replacement heifers.

Clinical Manifestations In young animals, GINs may simply cause poor growth and ill thrift, or they may cause serious clinical illness and even death. Inappetence, a common feature of PGE, contributes to reductions in weight gain, growth, and possibly onset of puberty.

The synchronous development and maturation of inhibited larval *O. ostertagi* can result in severe clinical disease, called *type II ostertagiasis*. Usually seen in cattle months after their first grazing season on contaminated pastures, it is characterized by intermittent profuse watery diarrhea accompanied by thirst, anorexia, ill thrift, and hypoproteinemia. Fever, anemia, and submandibular edema may also be present. Conversely, *type I ostertagiasis* results from the rapid acquisition of large numbers of larvae that complete development to the adult stage within the usual 3-week time frame. The primary physiologic change is appetite suppression. Although the underlying mechanism for the two types is the same, the seasonal occurrence of each type varies in accordance with the epidemiologic patterns of the area.[1,3]

For both types I and II ostertagiasis, reduced feed intake and diarrhea have a negative effect on animal weight; however, leakage of endogenous protein into the gastrointestinal tract has greater impact on the loss of production. The need to replace these proteins (e.g., albumin, immunoglobulins) occurs at the expense of muscle proteins and fat deposition.[1,3]

Compounding the effects of *O. ostertagi* are the other GINs. Larval and adult *Haemonchus* parasites inhabit the abomasum and are avid bloodsuckers, capable of producing severe anemia. *T. axei* inhabits the abomasum, producing local and systemic changes like those produced by *O. ostertagi* with similar clinical

VetBooks.ir

signs. *Cooperia* species live in the small intestine, inducing tissue changes resulting in fluid, electrolyte, and protein losses and reduced feed intake. Infection with *Oesophagostomum radiatum* produces structural and functional changes, including anemia, hypoproteinemia, diarrhea, anorexia, and weight loss.[1,3,13,14]

Control of Gastrointestinal Nematodes

GINs affect ruminants in one of two ways—economically or clinically. Clinical disease is the manifestation of abnormal signs resulting in severe morbidity or mortality. In contrast, economic disease is the level of parasitism preventing an animal from reaching its genetic potential, which translates into loss of milk or meat production. Most parasite losses are economic rather than clinical.[1] The goal of any control program should be to decrease the chances of acquiring large numbers of GINs. Control programs must consider the expected species present, the environment, host nutrition, husbandry, and time of year. Given the higher stocking rates today versus 30 years ago, the concomitant reduction in alternative control practices, and the widespread availability of inexpensive, safe, and effective dewormers, maintaining acceptable levels of animal production in the face of GINs has relied heavily on the use of anthelmintics. Management, however, provides a much cheaper and more effective means for controlling GINs than anthelmintics alone.[1,15,16]

ANTHELMINTICS. Anthelmintics and their doses used in cattle are given in Table 49.3. Animals benefit from the removal of the parasites, as well as from preventing immediate reestablishment of infections by those compounds with persistent activity. Macrocyclic lactones and benzimidazoles are currently the most popular compounds in use. Levamisole and morantel tartrate are less commonly used, and availability in some areas is limited. Drug withdrawal times must always be considered, and the manufacturers' recommendations must be followed.

Historically, anthelmintic-resistant GINs have been far less of a problem in cattle than in sheep or goats. Unfortunately, this situation has changed. Anthelmintic-resistant nematodes of cattle have been confirmed in the United States and elsewhere, with resistance reported in all classes of compounds currently available.[1,16-20] Species of *Cooperia*, which are the dose-limiting parasites for the macrocyclic lactones, are most commonly associated with these reports; however, resistant species of *Ostertagia*, *Haemonchus*, and *Trichostrongylus* have also been documented.[15-18] Regrettably, producer concerns regarding anthelmintic resistance remains secondary to the production benefits gained by their use.[21] Even where anthelmintic resistance is identified as a problem for the beef cattle industry, the preventive steps taken actually contribute to the selection for anthelmintic resistance alleles.[22] Such strict reliance on anthelmintics without regard for good pasture parasite management will lead to more rapid selection of nematodes with resistance alleles.

Producer concerns may also be influenced by the fact that *Cooperia* species are most commonly associated with anthelmintic resistance, and these species are considered of minor pathogenic importance.[1] Thus resistance in *Cooperia* would be a less severe problem than resistance in the highly pathogenic *O. ostertagi*. Recently, though, negative production effects associated with *Cooperia punctata* have been demonstrated,[23] as has an increased pathogenicity of an isolate of macrocyclic lactone-resistant *Cooperia oncophora*.[19] In addition, single-species infections are uncommon in cattle entering feedlots, and production losses where anthelmintic-resistant *Cooperia* was a component of the GIN population have been documented.[24]

Simultaneous administration of anthelmintics with a similar spectrum of activity but different mechanisms of action has been suggested as a means of providing GIN control in the face of single- or multiple-drug resistance while prolonging the effective life of available compounds. The expectation is that GINs surviving one anthlemintic will likely be killed by the second.[25,26] Computer simulation models also indicate that reversion toward susceptibility is more likely to occur when drugs were used in combination rather than in rotation.[27] Although combination anthelmintic products are available elsewhere in the world, licensure in the United States has not yet occurred.

TABLE 49.3

Efficacy of Various Anthelmintics Against Gastrointestinal Nematodes in Ruminants Without Resistance Issues

Drug	Dose (mg/kg)[a] Sheep	Goats	Cattle	Adults	Hypobiotic Larvae
Benzimidazoles					
Albendazole	5–7.5	20	10	+	+
Febantel	5		7.5–10	+	±
Fenbendazole	5	10	5–10	+	±
Mebendazole	15–20			+	±
Netobimin	7.5		7.5	+	+
Oxfendazole	5		7.5	+	+
Oxibendazole	15		15	+	±
Levamisole, Morantel and Pyrantel					
Levamisole	5–7.5	12	5–7.5[b]	+	–
Morantel	5–12.5	10	10	+	–
Pyrantel	25			+	–
Macrocyclic Lactones					
Ivermectin	0.2	0.4	0.2[c]	+	+
Doramectin	0.2[d]	0.2[d]	0.2[c]	+	+
Eprinomectin			0.5–1.0[e]	+	+
Moxidectin	0.2	0.4	0.2[c]	+	+
Other Drugs					
Closantel	5–10			+[f]	–
Nitroxynil	10			+[f]	–

[a]All doses are for oral administration unless otherwise indicated.

[b]10 mg/kg for topical administration.

[c]0.2 mg/kg for oral, subcutaneous, or intramuscular administration; 0.5 mg/kg topically as a pour-on.

[d]Injectable not recommended for use in sheep and goats by injection or pour-on.

[e]0.5 mg/kg for topical administration; 1.0 mg/kg in extended-release formula for injectable administration; not recommended for sheep.

[f]Effective against *Haemonchus contortus* only.

+, Highly effective; ±, moderately effective or effective according to some authors; –, ineffective.

Note: Administration of some of these products may constitute extralabel use in sheep and goats; follow manufacturers' guidelines for meat and milk withdrawal in cattle; not all compounds are available in all countries.

Treatment Intervals. The choice of drug and treatment interval should be formulated for an individual herd or farm, as part of an overall GIN control program. Factors to consider include the geographic location, time of year, and grazing management.[1] There are several options for preventing clinical disease and maximizing gains in first-season grazing calves using strategic anthelmintic treatments. It should be noted, however, that these recommendations reflect the practices currently in use and assume anthelmintic resistance is not an issue on the farm in question. Recommendations are based on the calendar in the northern hemisphere, and not all products are available in every country.

- *Prophylactic anthelmintic use.* (1) Two or three treatments between turnout and midsummer to minimize the number

VetBooks.ir

of eggs deposited on pasture. For calves turned out in early May, two treatments 3 and 6 weeks later are used. For calves turned out in April, three treatments at 3-week intervals are recommended. If using parenteral or pour-on macrocyclic lactones, the interval is extended to 5 (ivermectin) or 8 (doramectin, eprinomectin, moxidectin) weeks due to the residual activity against ingested larvae.[3,20] (2) Use of an intraruminal bolus at turnout or weaning. This provides either the sustained release of anthelmintic drugs or pulse release of therapeutic doses of anthelmintic at 3-week intervals. This strategy may be most cost-effective on farms where pasture infectivity is high. However, evidence suggests that young cattle protected with these products are more susceptible to infection in their second year at grass.[3] Likewise, the use of extended-release injectibles at turnout provides the ability to treat existing infections while preventing new infections with anthelmintic-susceptible GINs for approximately 120 days.[28]

- *"Dose-and-move" strategy.* This strategy consists of treating calves with a single dose of anthelmintic, then moving them to a "safe" pasture (risk of infection is low) just before the anticipated peak in pasture infectivity (e.g., early to midsummer in temperate climates). This strategy minimizes the number of anthelmintic treatments during the grazing season. However, it is effective only on farms where such pastures are available. Furthermore, any residual nematodes left behind will likely possess resistant genes; therefore contamination of the "safe" pasture will be with resistant nematodes. This must be considered when planning for the future use of the pasture (discussed later). Also, sufficient numbers of overwintering L_3 *O. ostertagi* may be present in the spring in some years, resulting in heavy infections and clinical disease.
- *Targeted strategic treatment.* This strategy relies on the selective use of anthelmintics by targeting individual animals within a herd rather than using whole-herd treatments. Promoted for sheep and horses, this strategy has not been embraced by the beef cattle industry. However, a recent investigation of dairy cows indicates that selective treatment strategies can compete economically with whole-herd treatment strategies.[29]

Integrating effective pasture management can reduce the number of anthelmintic treatments necessary[1,30]; however, there currently is no realistic alternative to the continued use of available compounds in intensive production systems. Therefore it is imperative that the efficacy of these compounds be maintained for as long as possible. Recommendations designed to promote this in beef cattle include the following: (1) do not treat second-year (unless not previously pastured) or adult cattle to maintain a population of unexposed nematodes (refugia) on the farm; (2) do not graze first-year calves on the same pasture each year (avoids exposure to larvae produced from resistant nematodes); and (3) do not use the same family of anthelmintic year after year in calves.[31]

Adult Cattle. In general, the cattle most at risk for clinical disease and production losses are beef calves and dairy replacement heifers in their first season at pasture.[2] Development of immunity should protect the animals during their subsequent grazing seasons. Treatment of adult beef cattle is generally unnecessary, unless immunity is inadequate or pasture infectivity is exceptionally high. Anthelmintic treatment may be warranted in first-calf heifers and newly acquired cows that may not have been pastured as heifers. In some situations it may be beneficial to treat beef cows after spring calving. Despite these recommendations, a recent survey showed that approximately 86% of U.S. beef cow and calf producers routinely treat their cows one or more times per year.[22] Benefits of treating adult dairy cattle depend on a variety of factors, including grazing management options and levels of GINs.[1,27]

OTHER STRATEGIES. Alternate grazing of cattle and sheep is promoted as an effective control measure. Ideally, a 3-year rotation of cattle, sheep, and crops is used. Few GINs cross-infect cattle and sheep. Adding this to the infective L_3 life span on pasture of less than 1 year, this scheme could provide good control of bovine ostertagiasis. Annual rotation of beef cattle and sheep in marginal areas has been reported to provide adequate parasite control.[3] However, in areas where *Haemonchus* is prevalent or where *Haemonchus contortus* cycles in cattle,[15,17,24] co-grazing these two species may be dangerous. Rotational grazing of calves with adult cattle has been shown to be an effective control practice.[2,3]

Vaccination for the control of *O. ostertagi* has been an ongoing area of research for many years with mixed results.[32,33] Given that it has taken more than 20 years for development of a commercially available vaccine against *H. contortus*, it is unlikely that a viable *O. ostertagi* vaccine will come to market in the near future.

EVALUATION OF CONTROL PROGRAMS. Success of control programs is based on the producer's expectations. Because most control programs are based on anthelmintic use, the response to treatment is the criterion by which control programs are currently evaluated.[15,22] As long as animal production meets producer expectations, the control program is considered to be a success. Fecal egg counts are most useful as a tool to evaluate pasture contamination and assess treatment efficacy; however, most U.S. producers do not have this done. In fact, most cow and calf producers do not even involve a veterinarian in the diagnosis or treatment of PGE.[22]

Lack of expected response to anthelmintic treatment may be the first indication of program failure in the form of a resistance problem.[15,17] However, inappropriate administration or underdosing of the anthelmintic may also be responsible, and determining the root cause of the treatment failure is vital for future control efforts. Detection of anthelmintic resistance currently depends on the FECRT. This test only detects clinical resistance or when less than an expected response to treatment occurs. This usually occurs only when the frequency of resistant alleles in the population reaches 25%.[34] The FECRT estimates anthelmintic efficacy by comparing pretreatment and post-treatment fecal egg counts. Fecal samples are collected immediately before or at the time of treatment and then 10 to 14 days later. Although guidelines for using FECRT in cattle were proposed in 1992, they lack detail, particularly in interpretation of data.[19,35] Comparing FECRT with controlled efficacy studies showed FECRT results to be reliable for detecting ivermectin-resistant *C. oncophora* and *O. ostertagi* and moxidectin-resistant *O. ostertagi*. However, due to reduced fecundity of moxidectin-resistant female *C. oncophora*, FECRT results were equivocal, with day 7 results showing efficacy but day 14 results indicating resistance.[36] Thus, for cattle, waiting the full 14 days before collection of the second sample is vital. A method for using composite fecal samples in the FECRT has been described with the aim of reducing costs to the producer; however, it still requires the collection of individual fecal samples.[37] Because cattle tend to have lower fecal egg counts than sheep, use of appropriate flotation techniques capable of handling low fecal egg counts is important.[1]

Clinical Management

DIAGNOSIS. Antemortem diagnosis of ostertagiasis in young animals is primarily based on clinical signs of inappetance, weight loss, and diarrhea at a time of the year that is consistent with the parasite's epidemiology.[3] In temperate areas, type I disease usually occurs in fall, and type II occurs in the late spring. Grazing history is important because clinical disease can develop in older animals that have not previously grazed pastures. Affected farms usually also have a history of previous

outbreaks. Plasma pepsinogen levels are useful in animals up to 2 years old; however, the test is less reliable in older cattle.[1]

The most reliable method for diagnosis of ostertagiasis or PGE is necropsy. The "Moroccan leather" abomasal lesion is pathognomonic for *Ostertagia*. For PGE, casual examination of the lumen of the gastrointestinal tract is unlikely to find any of the strongyle-type nematodes because the worms are small and easily overlooked. Adult *Nematodirus* are larger and may be more readily seen, but alone they are unlikely to be the cause of PGE. Nodules associated with larval *Oesophagostomum* can be found in the wall of the lower small intestine, as well as the upper large intestine, and adults can be found in the contents of the large intestine. *Trichuris* will be partially embedded within the cecum; removing the contents is necessary in order to see them. Abomasal wall digestion techniques can be used to identify the presence of larval *Ostertagia*.[2,3]

TREATMENT. Animals with type I ostertagiasis can be expected to respond well to treatment with the standard dose of any of the current anthelmintics, as long as resistance is not an issue. These animals should also be moved to a less contaminated pasture. Because any parasites not removed by proper administration of the drug will have resistance alleles, targeted strategic treatment, rather than whole-herd treatment, may be beneficial in keeping the population of resistant nematodes low.

Successful treatment of animals with type II ostertagiasis requires compounds that are effective against arrested larvae, as well as the developing larvae and adults. Only the modern benzimidazoles and macrocyclic lactones are effective at standard doses. Even though the larvae may be killed, the damage to the abomasal mucosa may limit complete recovery. Animals with profound hypoproteinemia and dehydration respond poorly compared with those showing only mild diarrhea and slight hypoalbuminemia. Severely affected animals may need supportive treatment to survive. Recovered animals often fail to thrive.

Gastrointestinal Nematode Infections in Sheep and Goats

Sherrill A. Fleming

Gastrointestinal nematode (GIN) infections in sheep and goats are responsible for severe clinical syndromes and profound production and death losses. Young animals, periparturient ewes and does, and animals on substandard planes of nutrition are most susceptible to outbreaks of parasitic disease. The GINs of small ruminants include *H. contortus*, *Teladorsagia circumcincta* (formerly *Ostertagia*), *T. axei*, *Nematodirus* spp., and *Cooperia* spp.[1] The proportions of each of these nematodes in small ruminant populations vary according to geographic location. *H. contortus* is usually the most significant pathogen in wet, temperate climates such as the southeastern United States. *T. circumcincta* may be the predominant infection in northern or arid climates such as England. *H. contortus* and *T. circumcincta* represent the majority of parasite burdens seen in small ruminants.[2] Anthelmintic resistance is present in all these parasites, but the prevalence is highest for *H. contortus*, making it the most economically important GIN of sheep and goats.[3]

The problem of anthelmintic resistance in GINs of small ruminants has been reported in South Africa, Australia, New Zealand, Malaysia, Spain, France, Denmark, the United Kingdom, Brazil, and the United States.[4-7] In the United States, resistance to all classes of anthelmintics has been documented.[5,7] Resistance to two and three classes of anthelmintics was found on 14 of 15 farms and 6 of 18 farms, respectively, in a survey of 18 goat flocks in Georgia and South Carolina.[5] The first report of total anthelmintic failure was made on a meat goat farm in Arkansas in 2005.[7] It is no longer acceptable to plan parasite control programs solely on the basis of the use of anthelmintics. Veterinarians and producers must customize programs to control exposure to infection and reduce the use of anthelmintics. A thorough knowledge of the biology of GINs is necessary to plan effective control programs.

Life Cycle and Epizootiology[8,9]

The life cycle of a GIN is direct and consists of a host phase and a free-living phase. Worms mate in the host, and females lay eggs that pass in the feces. Eggs hatch and develop to infective larvae while remaining in the fecal mass. Infective larvae then move from the fecal mass onto the surrounding forage, where they can be consumed during grazing, thus completing the cycle. The time from ingestion of infective larvae to egg-laying adults, the prepatent period, is about 3 weeks. The time for development from egg to infective larvae can be as short as 4 to 10 days (especially during the summer months); therefore transmission (reinfection) and continual pasture contamination can be rapid. During the colder months, development is delayed and may take 1 to 2 months to reach the infective larvae stage, so pasture contamination and reinfection are minimized. The infective larvae have a protective sheath, making them relatively resistant to adverse environmental conditions, and they can survive for months, thus extending transmission potential. As long as the temperature and moisture conditions remain favorable, development and survival continue; conditions that are too hot, too cold, and/or too dry threaten parasite survival.

The life cycle of a GIN has four phases.

PHASE 1—SYMBIOTIC/PARASITIC PHASE. Phase 1 is the interaction between host and parasite. During this phase, the parasite must develop and survive in the host. After ingestion, infective larvae lose their protective sheath and invade the mucosa of the abomasum, small intestine, or large intestine depending on the GIN species involved. While in the mucosa, larvae develop to the next larval stage and then return to the surface of the gut mucosa, where they become adult worms. The host defense mechanism is immunity. When the infectious agent enters the body, the immune system reacts to mobilize various components (antibodies, killer cells, etc.) to inhibit or kill the invaders. These components act on larval stages in the mucosa and the adults in the lumen. The strength of the immune response depends on the age of the host, nutritional status, and concurrent stressors. The immune system matures with age with young naive animals susceptible to infection and older animals more resistant. As a result, young animals usually harbor the highest GIN populations and suffer the most severe consequences, whereas adult animals have lower infection levels. Under poor nutrition and/or stressful conditions, the immune system is compromised and cannot respond adequately, regardless of the age of the animal.

The prepatent period of most worms is about 3 weeks, but this period can be extended for worms that can enter a period of delayed development called *hypobiosis*. This occurs during the season of the year when the environmental conditions are unfavorable for development and survival of the free-living larval stages. Depending on the worm and the environment, this happens during either summer or winter.

PHASE 2—CONTAMINATION PHASE. Phase 2 involves eggs being passed in the feces. The magnitude of this phase is affected by stocking rate, age of the animals, season of the year, and hypobiosis. The higher the stocking rate, the more feces are deposited on the grazing area, thus the more eggs are passed, and vice versa. More eggs are also passed from young versus older animals. Most worms have a definite seasonality, resulting in higher egg production and deposition during different times of the year. Of particular note is the periparturient rise

VetBooks.ir

(PPR) in fecal egg count (FEC). This occurs at or around parturition and extends through most of the lactation period because these are stressful conditions when the dam's immune system is compromised. The existing female worms increase the number of eggs deposited in the feces. If a worm species undergoes hypobiosis, the development time to the adult stage is extended. This will result in fewer adult worms over time and fewer eggs deposited in feces. However, when these hypobiotic larvae resume development, massive numbers become mature adults over a short period of time, and the resultant egg production and deposition in the feces can be high.

PHASE 3—FREE-LIVING PHASE. Phase 3 involves larval development and survival, which depend on prevailing environmental and nutritional conditions. The development and survival from egg to L_1, then to L_2, and finally to L_3 or infective larvae occur within the fecal mass. L_1 and L_2 are unprotected and require oxygen and energy (feeding on nutrients and microorganisms) to grow. L_3 are enclosed in a protective sheath and do not feed. Temperatures conducive for normal development and survival are between 65° and 85° F. With lower or higher temperatures, development and survival are reduced. Moisture is also crucial for development and survival. Because the initial development and survival occur within the fecal mass, moisture is usually adequate to allow development to the infective larvae; however, if the fecal mass dries out quickly due to high temperatures and/or physical disruption of the fecal mass, the L_1 and L_2 are susceptible to desiccation and will die. Generally, L_3 can survive very low temperatures, but sustained temperatures above 95° F are usually lethal. When infective larvae migrate out of the fecal mass, they are relatively resistant to environmental conditions encountered due to their protective sheath. Temperature is usually the only factor that may adversely affect L_3. The moisture conditions at ground level under forage cover are usually adequate for L_3 to move around and survive. Because they do not feed, length of survival depends on how fast they use energy reserves. The hotter it is, the faster they move and use up energy stores, which decreases survival. Infective larvae move up and down the forage when there are moist condiitons (i.e., advancing and receding dew). Rain also provides a moisture medium for larval movement on forage. For the most part, infective larvae do not move much past 30 to 50 cm from the fecal mass or 5 to 6 cm up the forage. Therefore the lower the animals graze and the closer they are to the fecal mass, the greater the consumption of L_3.

PHASE 4—INFECTION PHASE. Phase 4 occurs when available L_3 are consumed during grazing. This phase is affected by stocking rate in two ways. The stocking rate determines how many eggs initially contaminated the pasture and, consequently, how many L_3 will be available to consume. If the initial contaminating animals are removed and replaced by new animals, the new stocking rate will determine the level of exposure each animal has to infective larvae during grazing (i.e., the higher the stocking rate, the more chance of exposure, and vice versa). Grazing animals usually do not graze close to fecal masses, so the greater the distance between masses, the less the exposure. Eventually fecal masses disintegrate, forage grows well with the fertilization, and animals will graze over the area where exposure can be high. Natural sources of water, such as streams, ponds, or lakes, provide moisture along the banks, where forage can grow readily. When animals congregate to drink and consume the attractive forage, defecation in these areas usually leads to increased contamination and eventually to more L_3. Essentially, a high stocking rate has been artificially created in a relatively small area. The same can be said for areas where supplements, especially hay, are fed if conditions are favorable. Once L_3 are consumed, phase 1 is repeated.

Pathophysiology of Gastrointestinal Nematode Parasites

The damage done by *H. contortus* is the result of the blood sucking by L_4 and adult parasites. The pathogenesis of *Teladorsagia* in sheep is similar to that described for *Ostertagia* in cattle and is a result of destruction of abomasal mucosa. *T. axei* causes abomasitis, whereas *Trichostrongylus colubriformis* and other *Trichostrongylus* spp. penetrate beneath the duodenal mucosa and result in generalized enteritis, including hemorrhage and plasma protein loss into the intestinal lumen.

Clinical Signs of Gastrointestinal Nematode Parasites

Most animals acquire mixed infections of nematodes. Clinical signs may therefore reflect the effects of more than one species of parasite. There appears to be some synergism between *T. circumcincta* and *T. colubriformis*, which makes the effect of the combined infection more severe than that of either alone. Although mixed infections with GINs are assumed, the actual population of parasites in small ruminants varies depending on the geographic location. In general, most clinical illnesses results from *H. contortus* infections. Most parasitic infections in small ruminants are associated with altered gut function, anorexia, ill-thrift, weight loss, and hypoproteinemia. Diarrhea is a variable sign (black scours). Animals may die suddenly without overt clinical signs or may exhibit chronic wasting. Clinical signs of *H. contortus* infection can vary from peracute to chronic and result from decreased nutrient use and anemia/hypoproteinemia. The most common signs are failure to thrive, weight loss, and decreased appetite. Weakness, bottle jaw, pale mucous membranes, poor capillary refill time, and possibly diarrhea develop with more severe or long-term infections. Following sudden exposure to large numbers of L_3, animals can die acutely, even before the infection is patent. Other diseases such as pneumonia and heat stress may result secondarily.

Anemic Crisis and Patient Management

The anemia created by *H. contortus* is due to blood consumed by the parasite and is usually chronic. Parasitized patients present with lethargy and weight loss and often have hematocrits of less than 10%, yet many are still capable of rising and walking. Addressing the anemia by blood transfusion must be weighed carefully against stress to the patient caused by restraint, jugular catheterization, and blood administration, as well as by the hemolysis of these same cells several days later. Obviously, in life-threatening circumstances (a patient unable to stand), administration of whole blood can be critical. In a chronic situation (patient rising and/or eating), treatment with an effective anthelmintic should eliminate the parasite and halt blood loss. Because *H. contortus* consumes blood, the affected animal actually loses substrates essential to erythrocyte production (iron, cobalt, copper). Providing supplemental iron and B-complex vitamins should speed reversal of the anemia. Assuming blood loss has been halted, a 1- to 1.5-point rise in the hematocrit per day is expected when the bone marrow is maximally stimulated. In most parasitized patients, a rise of one half of this value is a more realistic expectation.[10]

If blood is to be given, it is essential to be certain that the donor has a normal packed cell volume (PCV). Blood collected from animals in the same environment may be as anemic as the patient, but the individual is more capable of dealing with the anemia. In lambs weighing less than 45 kg, 1 unit of whole blood (≈450 mL) is often sufficient to survive a crisis, provided *H. contortus* has been controlled.

Populations at Risk

Young animals are most susceptible to infection and clinical manifestations of disease. Lambs and kids may become heavily infected with parasites and shed large numbers of nematode eggs. In sheep, some degree of immunity develops as the animal approaches 1 year of age. Adult animals

typically have complete immunity against *Nematodirus* and variable resistance to *Trichostrongylus* spp. Some immunity to *Haemonchus* and *Teladorsagia* spp. develops with age; compared with lambs or kids, adults are more resistant to infection with these species. However, even mature animals may succumb to parasitic infection when malnourished or challenged with heavily contaminated pasture. A periparturient rise in fecal egg production is seen in ewes and does.

Goats are more susceptible to GIN infections than are sheep. The difference lies in part in the host's immunologic responses to nematode antigens. Goats prefer to browse on brush and trees and only graze grass when forced to by management. Under natural conditions, goats would have a low level of exposure to infective larvae, and this may explain their lower level of natural immunity compared with sheep.[11,12]

Refugia

Most parasitologists now consider levels of refugia (see Parasite Refugia section earlier) as the single most important factor in selection for anthelmintic-resistant parasites.[13,14] Worms in refugia provide a pool of genes susceptible to anthelmintics, thus diluting the frequency of resistant genes. For many years parasitologists and veterinarians have recommended that all animals on a premise be treated with an anthelmintic at the same time. However, this strategy has proven problematic, and a selective approach is now recommended. Only those animals in danger of severe parasitism should receive medication. This selective approach is highly compatible with host-parasite dynamics because 20% to 30% of animals harbor about 80% of the parasites.[15] Animals with low worm burdens are an important source of refugia, are not in danger of the negative effects of parasitism, and should not be treated.

Management of Gastrointestinal Nematodes in Small Ruminants

The traditional approaches of deworming often, rotating class of anthelmintics, and moving to clean pastures has ensured development of anthelmintic resistance to all classes of drugs and disseminating these resistant parasites over a wide area. It is obvious that drastic changes in the management of GIN in sheep and goats are long overdue. Several countries have developed websites and/or companies that make recommendations for specific geographic areas.[16] WormBoss in Australia and SCOPS in Great Britain are two good examples that attempt to give specific management advice.[16,17] A New Zealand company sells a system of record keeping and testing complete with a computer system for keeping farm records.[18]

FAMACHA OR SMART DRENCHING METHOD.[19] To maintain adequate levels of refugia, it is necessary to leave a portion of the herd or flock untreated. FAMACHA is a selective approach for *H. contortus* that targets the portion of the herd or flock with high worm burdens, including those animals that are poorly resilient to worm infections.[20] This approach will successfully control parasites in the entire group and delay the development of anthelmintic resistance. Failure to observe animals closely for clinical signs may result in the death of some individuals. It is necessary to know which anthelmintics are effective before beginning this system. The differences among farms in overall quality of management, stocking rates, breeds of animals, preexisting levels and spectrum of anthelmintic resistance, presence of nematode species other than *H. contortus*, and production targets need to be considered before implementing FAMACHA on individual farms. This system was developed in South Africa for identifying sheep that are anemic, and it has been extended to use in goats.[21] In this method the ocular mucous membranes of sheep and goats are categorized by comparison with a laminated color chart bearing pictures of sheep conjunctivae classified into five categories ranging from red (A/1; normal) to practically white (E/5; severe anemia). Because anemia is the primary pathologic effect from infection with *H. contortus*, this system can be an effective tool for identifying animals that require treatment (but only for *H. contortus*). FAMACHA has been tested extensively and validated in both sheep and goats in South Africa and in the southern United States.[22,23] In all studies, the numbers of false negatives were low, suggesting that when using FAMACHA according to recommended guidelines, death from anemia would be rare.

Based on the results of recent studies in the United States and numerous studies performed in South Africa, guidelines for using FAMACHA have been developed, and it is suggested that these guidelines be read in their entirety before FAMACHA is practiced.[20] Individual animals are scored 1 to 5 by comparing their mucous membrane color with a laminated chart. It is recommended that treatment be withheld until animals score a 4 or 5 as long as animals are in good body condition and good overall general health, animals are examined frequently (e.g., every 2 weeks), and good husbandry is used to identify animals in need of treatment (e.g., unthrifty, anorexic, lagging behind, bottle jaw) between FAMACHA examinations. Using this approach, the number of anthelmintic treatments administered will be reduced greatly, resulting in significantly diminished selection pressure for resistance and therefore a reduction in drug costs. Due to the increased handling of animals, labor costs will be increased. *Only adult animals should be managed with this system.* Lambs and kids have comparatively small blood volumes, poor immunity, and poor resilience and can progress rapidly from moderate to severe anemia. This precaution should also be extended to ewes and does during the periparturient and early lactation period because these animals have decreased immunity to GINs.[19,24-26] These and other animals that may be stressed by disease or in poor body condition should always be treated if scored as 3. Alternatively, in the northern parts of the country where *H. contortus* is an important problem but resistance prevalence is much lower, it may be reasonable to be more liberal when making treatment decisions (i.e., treat all 3, 4, and 5). Many more treatments are given when all animals with scores of 3 and higher are dewormed, but a significant number of animals will remain untreated to supply refugia. These refugia combined with a relatively short transmission and treatment period are likely to produce a slow evolution of resistance, but the more intensive treatment protocols will improve animal productivity.

On farms where low to moderate levels of resistance have been diagnosed to one or more drugs (60% to 90% reduction in FEC), a useful strategy to help gain the full benefits of both treatment and resistance prevention could be to use these "less effective" drugs either singly or in combination on all animals scored as 3. There is evidence that using dewormers with different modes of action in combination has greater efficacy and does not cause a more rapid development of resistance.[27] Using drugs that are less effective in this group is unlikely to lead to clinical problems because the few 3 scores that are moderately anemic and in need of treatment should receive a sufficient reprieve from infection until the next FAMACHA examination, and the majority of the 3 scores that are not anemic do not need to be treated. This strategy helps to preserve the efficacy of the drugs that are still fully effective by saving them only for the 4 and 5 categories and also helps to decrease egg contamination of pastures.

Training of producers is critical when using this method. It is the responsibility of veterinarians and other animal health professionals to ensure that standards of training are maintained by using the "Train the Trainer" seminars through the American Consortium for Small Ruminant Parasite Control (ACSRPC, formerly Southern Consortium or SCSRPC) at www.acsrpc.org or www.wormx.info. When using FAMACHA, it is extremely important that efficacy of anthelmintics is known because animals are not treated until they become anemic.

VetBooks.ir

VetBooks.ir

Treating anemic animals with a drug that has moderate to poor efficacy due to worm resistance may result in animal deaths. Other important precautions when using FAMACHA include but are not limited to (1) the card is an aid in the control of *Haemonchus* spp. only; (2) the system should be used by producers only where technical assistance is available from a veterinarian or other animal health professional; (3) other management-based worm control practices must be maintained; (4) smart drenching principles should be used; (5) paleness or reddening of the conjunctivae may have other causes; (6) animals should always be scored with the help of the chart, not from memory; (7) animals are examined at least every 2 to 3 weeks at the beginning of the expected period of *Haemonchus* spp. challenge in climates where a seasonal incidence of infection occurs, and during critical periods weekly examinations may be necessary; (8) the card is protected from light when not in use and replaced after 1 year of use.[4,28]

Maintaining records of treatments that are included with the FAMACHA kits gives the owner the ability to rate the genetic merits of individuals on the premises. Host resistance to infection with *H. contortus* measured on the basis of FEC and PCV is a moderately heritable trait, and it has been demonstrated that the same animals tend to exhibit the highest FEC and lowest PCV on each occasion they are measured.[29-31] Importantly, data from recent investigations examining the heritability of resistance and resilience of Merino sheep to infection with *H. contortus* indicate a high heritability for the clinical estimates of FAMACHA scores.[22] Removing the most susceptible animals from the breeding pool each year will have the long-term effect of improving the overall innate genetic resistance and/or resilience of the herd or flock to *H. contortus*.

FIVE-POINT CHECK.[32] Because FAMACHA is based on anemia and focuses on parasitism by *H. contortus*, a combined system that could identify problems with a variety of other potentially pathologic parasites (*Oestrus ovis*, *Teladorsagia* spp., *Trichostrongylus* spp., *Nematodirus* spp., and *Oesophagostomum columbianum*) has been proposed. This is the Five-Point Check, which includes checking for nasal discharge, submandibular edema, back body condition scoring, and fecal staining of perineum in addition to ocular membrane color. Anthelmintic recommendations were made based on the points that identified poor scores. Pilot studies showed good acceptance and usefulness of this system, but further studies need to be completed to determine the efficacy and economy of this approach.

GRAZING STRATEGIES. The goal of pasture management is to provide safe pastures for grazing by reducing the exposure of susceptible hosts to infective larvae.[33,34] A safe pasture is one that has had no sheep or goats grazed on it for 6 months during cool or cold weather or for 3 months during hot, dry weather. Weaning sheep and goats at 2 months of age and rotating them through pastures ahead of the adults while forage is longer will minimize the exposure of susceptible animals to infective larvae. Pastures should be subdivided into smaller lots to allow longer rest periods between grazings. Pastures that are overgrown provide a good environment for larval survival because ultraviolet light and dry conditions are effective in killing larvae. Keeping pastures clipped will also assist in weed and parasite control and improve forage quality. Short-duration grazing carries pasture rotation to a level that maximizes forage production and harvesting by controlled animal grazing. It is management intensive but can be effective in controlling parasite burdens. Tilling and reseeding heavily contaminated pastures will convert them to safe pastures and provides an opportunity to improve the forage quality. Taking a cutting of hay from a pasture assists in reduction of infective larvae, but one report indicates GINs and tapeworms developing in "worm-free" lambs after feeding hay from heavily infected pastures. During the most dangerous part of the grazing season, it may be necessary to dry lot the flock and feed hay and grain from elevated feeders.

Stocking rate is an important consideration in parasite control because it affects the exposure to infective larvae and the contamination of the pasture. It is impossible to make a general recommendation on stocking rate because this will vary according to the type of pasture, time of year, current weather conditions, and type of animal being grazed. Thumb rules include five to seven goats or five sheep being the equivalent of one cow and suggest five to seven goats per acre. Goats prefer to browse brush and trees, whereas sheep prefer to graze near the ground. Pasture management must include monitoring the condition of herbage to ensure that overgrazing does not occur and to maintain a productive pasture.

In the early spring or at the onset of the rainy season, reduced pasture contamination is the most important aspect of control. The ewe or doe in the periparturient relaxation of resistance, even if she has the genetic capacity for resistance, will be a source of eggs for the environment. Strategic deworming to remove arrested or recently emerged larvae before they contaminate the pasture will have a great impact on pasture contamination. Treatment 2 weeks after a rain that removes recently acquired worms before they can begin passing eggs will also decrease pasture contamination. Providing sufficient dietary protein is vital during the periparturient period and during rapid growth so that animals will tolerate the worm burden better, as well as increase resistance to infection.[35-37] A strong link between nutrition and parasitism has been illustrated between protein intake and resistance to GIN infection. The most dramatic has been the abolishment of the periparturient egg rise in lambing ewes by providing protein at 130% of requirements. Immunity is closely related to protein repletion. GINs increase the demand for amino acids by the sheep. Lambs will voluntarily select a higher protein diet when infected with GINs compared with uninfected lambs. There is conflicting documentation that sheep will decrease feed intake when initially infected with GIN. Some authors hypothesize that the decrease in intake may be due to stimulation of the immune system or that the host is becoming selective in its diet.

Pastures may be used for hay cropping and grazed during the last half of the grazing season to effectively reduce GIN challenge. When plants high in condensed tannins are grazed, incoming larvae are adversely affected, and these plants provide bypass protein for the host.[38-40] There is growing evidence in work from New Zealand and Europe that grazing or feeding of plants containing condensed tannins (CTs) can reduce FEC, larval development in feces, and adult worm numbers in the abomasum and small intestine. Preliminary tests with *Sericea lespedeza* (also known as *Lespedeza cuneata*), a perennial warm-season legume, have shown positive effects of reduced FEC in grazing goats, and in sheep and goats in confinement when the forage was fed as hay. In addition, an effect on reducing worm burden has also been reported. *S. lespedeza* is unfortunately considered to be an invasive exotic species in the United States. Similar results have been observed using quebracho extract for small intestinal worms, but not abomasal worms. In addition to its potential use in controlling worms, *S. lespedeza* is a useful crop for limited resource producers in the southern United States. It is adapted to hot, dry climatic conditions and acid, infertile soils unsuitable for crop production or growth of high-input forages, such as alfalfa. It can be overseeded on existing pasture or grown in pure stands for grazing or hay. In addition to hay, *S. lespedeza* is being evaluated in the form of meal, pellets, and cubes to be fed as a supplement to grazing animals, or as a deworming method under temporary short-term confinement. The physical structure of some plants may challenge larvae to ascend vegetation or may provide protection from adverse pasture conditions. If animals are allowed to

VetBooks.ir

browse, their chances of acquiring larvae diminish as the distance from the ground increases. Most infective larvae are found within 2 inches (50 mm) of the soil surface.

Alternate grazing or co-grazing with other species of livestock may harvest *Haemonchus* larvae from the pasture. Small ruminants can graze after cattle, and this is considered a safe pasture, assuming adequate parasite control in the cattle. For the most part, each livestock species harbors its own parasite fauna except for overlap between sheep and goats. Only *T. axei*, a minor abomasal worm, is found in all livestock species. In general, the *Haemonchus* in sheep and goats do not do well in cattle, and vice versa. However, some populations of *H. contortus* may thrive in calves. If practical, cattle and small ruminants can be grazed together where each consumes the parasites of the other, which reduces available infective larvae for the preferred host species.

Anthelmintic administration should be coordinated with the weather. During hot, dry weather, there will be little or no exposure to L_3. As soon as there is significant rainfall (0.5 to 1 inch), larvae exposure goes up exponentially as previously inactive larvae become active and new larvae are hatched. Producers should be trained to plan deworming within 3 weeks of significant rain after a dry spell. Similar strategies can be used during cool weather. Once ambient temperatures drop below 50° F, the flock can be dewormed and no further treatments are necessary until temperatures become favorable to larval development and activity.

ALTERNATIVE THERAPIES

1. *Copper oxide wire particles (COWPs)* have been marketed for years as a supplement for livestock being managed in copper-deficient areas.[41] COWPs come in adult cattle, calf, and ewe boluses (25, 12.5, and 4 g, respectively). Only the cattle boluses are available in the United States. Due to potential toxicity in sheep, only one dose per year is recommended. It is also well known that copper has some anthelmintic activity against abomasal worms but not other gastrointestinal worms. That makes COWP a narrow-spectrum product. However, in view of anthelmintic resistance by *H. contortus*, recent work has revisited the possibility of using COWP to specifically target *H. contortus*. Such work has shown that as little as a gram or less and 2 g may remove substantial numbers of *H. contortus* in lambs and ewes, respectively. Similar work in goats has not been tested adequately to establish what is needed, but similar doses may be appropriate. As mentioned, copper must be used cautiously in sheep because toxicity can develop due to liver accumulation. Toxicity may not be an issue in goats because they have been reported as not being as sensitive to excess copper intake. Thus higher doses and/or more treatments during haemonchosis season may be useful in goats.
2. *Other nutritional considerations* include phosphorus, cobalt, and molybdenum.[42] Supplementation with phosphorus has been shown to prevent worm establishment. Cobalt deficiency has also been associated with reduced immunity to GINs. The addition of molybdenum at 6 to 10 mg/day decreased worm burdens in lambs. This effect was not attributable to the expected copper deficiency. Molybdenum may have a role in increasing jejunal mast cells and blood eosinophil numbers.
3. *Nematode-trapping fungi* included in feed or supplements have demonstrated potential for biological control of the free-living stages of GIN parasites under experimental and natural conditions.[43-45] These fungi naturally inhabit soil throughout the world where they feed on a variety of free-living soil nematodes. These fungi capture nematodes by producing sticky traps on their growing hyphae. Of the various fungi tested, *Duddingtonia flagrans* possesses the greatest potential for survival in the gastrointestinal tract of ruminants. After passing through the gastrointestinal tract, spores germinate and looped hyphae trap the developing larval stages in the fecal environment. This technology has been applied successfully under field conditions and is an environmentally safe biological approach for control of worms under sustainable, forage-based feeding systems. The major drawback is that the fungal spores must be fed daily. Daily feeding, which ensures that all animals consume an equivalent amount of feed, is necessary. For adequate control of larvae during the transmission season, spores must be fed for a minimum of 60 days. This can be expensive and time consuming. A bolus prototype that would allow a single administration where spores would then be slowly released over a 60-day period is being developed. This product is not available in the United States at this time.
4. *Vaccines* have been explored for management of the negative consequences of parasitism.[46-48] Successful vaccines have been developed for lungworms in cattle and tapeworms in sheep. The most promising vaccine for small ruminant worms has been what is called a "hidden gut" antigen and specifically targets *H. contortus*. This antigen is derived from the gut of the worm, and when administered to the animal, antibodies are produced. When the worm ingests blood during feeding, it also ingests these antibodies. The antibodies then attack the target gut cells of the worm and disrupt the worm's ability to process the nutrients necessary to maintain proper growth and egg production. This vaccine is currently available in Australia and has been shown to alleviate losses from *H. contortus* in sheep when used according to directions (Barbervax®). Multiple vaccinations are required prior to and during the active parasite season.[49] There are also reports of successful use in goats.[50,51] Vaccines for other worms that do not feed on blood have focused on using antigens found in worm secretory and excretory products. Protection has been variable, and marketing of such products has not been pursued.
5. *Genetic improvement in resistance* to nematode infection is most likely based on inheritance of genes that play a primary role in expression of host immunity.[52-54] Based on survival of the fittest management conditions, several breeds around the globe are known to be relatively resistant to infection. Such breeds include Scottish Blackface, Red Maasai, Romanov, St. Croix, Barbados Blackbelly, and the Gulf Coast Native. Katahdin sheep have been considered more parasite resistant, but studies to document this are few and not conclusive. Using such breeds exclusively or in crossbreeding programs would certainly lead to improved resistance to worm infection, but some level of production might be sacrificed. Selection of more resistant stock can be accelerated by identifying sires that produce relatively resistant offspring. Computer programs have been used in New Zealand and Australia to rank sire genetics based on resistance to GIN infections, but change takes up to 8 to 10 years. Heritabilities for FEC, a common measurement for assessing parasite burden, range from 0.22 to 0.40, which is relatively high. Thus selection for resistance using a measurement such as FEC has been moderately successful.
6. *Replacement of resistant nematodes with susceptible parasites.* Genomic studies and identification of resistance genes are working on inserting susceptible genes to create susceptible populations that can be introduced to contaminated pastures to compete with resistant parasites.[55-58]

ANTHELMINTIC USE. Anthelmintics have deliberately been left to the end of this section because drugs cannot be considered the most important aspect of a parasite control program. Guidelines for drug dosages are contained in Table 49.3. At this time, only oral administration of anthelmintics

VetBooks.ir

is recommended in small ruminants. In general, goats require 1.5 to 2 times the dosages of sheep, with the exception of levamisole, due to more rapid gastrointestinal transit times. It is critical that producers accurately assess weights of individual animals and dose appropriately. If an approximate dose is going to be used in all animals, that dose should be for the heaviest animal in the group.

The challenge of anthelmintic resistance is life threatening in small ruminants. There is no point in repeatedly deworming with expensive drugs if that drug is no longer effective. See the following section, Evaluation of Parasite Control Programs, for information on detecting anthelmintic resistance. On farms where low to moderate levels of resistance have been diagnosed to one or more drugs (60% to 95% reduction in FEC), a useful strategy to help gain the full benefits of both treatment and resistance prevention could be to use these "less effective" drugs either singly or in combination. Drugs in the benzimidazole family may be effective if multiple-day dosing regimens are used.

Evaluation of Parasite Control Programs

Sherrill A. Fleming

The efficacy of a given parasite control program should not be assumed; it should be assessed on a regular basis. The routine performance of quantitative tests for parasite burdens allows veterinarians to identify the development of anthelmintic resistance. Although fecal flotation is useful in identifying the presence of parasites, the use of the McMaster technique allows an estimation of the numbers of parasites. Both procedures are relatively simple and can easily be performed in the practice setting. Alternatives to the McMaster technique include FLOTAC, Mini-FLOTAC, and smartphone automated parasite egg counting systems to determine fecal egg counts (FECs).[1] Once resistance has been documented, it is important to identify the species involved through larval identification.

FEC and FEC Reduction Tests[2-6] (Box 49.2)

Determining numbers of nematode eggs in feces is the simplest and least invasive way to evaluate a parasite control program. Fecal examination may be of limited value in an individual animal because animals dying of parasitic infection may have no eggs in the feces, whereas animals with high FECs may be clinically normal. Nevertheless, FECs can provide information on the level of infection present in an individual animal, particularly when egg counts are repeated over the course of 2 to 3 weeks. Herd average FECs are more useful and provide an accurate reflection of the degree of environmental contamination and rate of infection. Pretreatment and posttreatment FECs can also be used to establish the efficacy of an anthelmintic in a particular group of animals. A quantitative McMaster or Stolley technique, rather than simple flotation, is crucial for accurate monitoring.

It is suggested that guidelines published by the World Association for the Advancement of Veterinary Parasitology (WAAVP) be used to perform and evaluate data from an FECRT, applying practical modifications to fit the situation on the farm.[3] Briefly, groups of 15 animals that have not been treated within the past 8 weeks are randomly allocated to treatment groups, and FECs are performed using a modified McMaster technique 10 to 14 days after treatment. An untreated control group must be included. If fewer than 12 to 15 animals per group are available, treatment groups should be balanced by performing a pretreatment FEC. Animals are then stratified by FEC from highest to lowest, blocked by number of treatment groups, and then within each block randomly assigned to treatment. Alternatively, where *Haemonchus* is the primary parasite, animals may be scored using the FAMACHA method as they come through the chute, blocked by FAMACHA score, and then randomly assigned to treatment within blocks. This approach is a bit more complicated but will result in groups that are balanced, which will result in a more accurate test. Calculations are performed using the following formula:

$$\text{FECR\%} = 100 \times \left(1 - \frac{X_{t_2}}{X_{t_1}} \frac{X_{c_1}}{X_{c_2}}\right)$$

where X_c and X_t are the geometric mean or arithmetic mean EPG for control (c) and treated (t) groups before (1) and after (2) treatments, respectively.[6] Free software that performs all calculations and gives data interpretation is available.[7] If the RESO calculator is used, the assignment of resistance status is based on both percent reduction and the 95% confidence intervals. If the RESO calculator is not used, the following guidelines can be applied: reductions of greater than 98% indicate high efficacy, reductions of 90% to 98% indicate efficacy, reductions of 80% to 89% indicate moderate efficacy, and reductions of less than 80% indicate insufficient efficacy. FECRTs yield reliable data only if FECs are sufficiently high to properly measure a reduction from treatment. If the control group's mean FECs are below 150 EPG, objective assessment of resistance will not be reliable. Group mean FECs of less than 150 EPG can be common in adult sheep; therefore when FECRT is performed on a sheep farm, it is preferable to use weaned lambs if available. With goats, low FECs are usually not a problem.

Larval Identification

Ideally, if there is less than a 90% egg count reduction, the eggs should be hatched and the larvae species identified. In the majority of cases these will be *H. contortus*, but other species, especially *Trichostrongylus* species, readily develop resistance as well. One can sometimes be fooled into an improper interpretation of egg count reduction results if mixed species are present and only one is resistant.

Egg Hatch Assays and Larval Development Tests[3]

Eggs from feces are incubated with concentrations of the anthelmintic to be tested and the eggs hatched. A dose-response curve is generated (DrenchRite test from Horizon Technology, Sydney, Australia).[4] The advantage of this test is that a single fecal sample can be tested for all available classes of anthelmintics simultaneously. The cost of this test has recently increased and may discourage owners from pursuing this diagnostic. However, when compared with the cost of using anthelmintics that are ineffective, it is easy to justify the use of this test. It is important to read instructions for submitting this test and scheduling a testing date before the samples are collected.

Larval Culture

Larval cultures can be used to distinguish between large and small strongyles in horses and to identify the various nematode species in ruminants. Most parasitology laboratories can perform this examination. It requires submission of 200 to 400 g of fresh feces. Pooled samples from several herd members are often used.

Pasture Larval Counts[8]

Counts of parasitic larvae on herbage are useful to indicate the level of exposure experienced by the grazing animal. This examination is somewhat tedious but can be performed by many university laboratories. A 2-kg sample of forage is gathered for submission to the laboratory. The grass is sampled by walking a V pattern across the acreage and stopping every three paces to sample grass. The samples are subsequently washed and passed through screening to isolate and identify larvae.

VetBooks.ir

BOX 49.2

Modified McMaster Technique (Fecal Egg Count)

This is one method for performing a McMaster fecal egg count. Similar protocols are used routinely in many laboratories, so you may see a slightly different procedure recommended elsewhere. The important point is to use the same procedure each time.

The first step is to collect freshly passed feces uncontaminated by soil or bedding. The best way to accomplish this is to wear a rubber glove and extract feces directly from the rectum. Alternatively, feces can be picked up off the ground if done soon after deposition. The collection container should be labeled with the identification of the animal and the date of collection. Fresh samples work best, but accurate results can be obtained if the sample is refrigerated during the interim. If samples are not refrigerated, the eggs will hatch within 12 to 24 hours. Once hatched, eggs cannot be counted.

Materials

Compound microscope
Scale
Saturated sodium chloride (table salt)
50-mL centrifuge tube, with screw cap and marked with milliliter increments
Pipette (1-mL syringe or eye dropper works well)
McMaster egg counting slide (Chalex Corporation, Issaquah, Wash.)
Paper towels
A fresh fecal sample, refrigerated until tested

Procedure

1. Weigh out 2 g of feces into a 50-mL centrifuge tube and fill to 30-mL line with salt solution. It is recommended to weigh feces on a small scale, but if you do not have a scale you can still get a close estimation by putting 28 mL of salt solution into a 50-mL centrifuge tube first and then adding feces until a volume of 30 mL is achieved.
2. Pour off approximately 25 mL of the salt solution into another small container, keeping feces in the tube (use tongue depressor).
3. Soak feces for a few minutes and mix (soft feces) or break up (fecal pellets) with tongue depressor.
4. Add back approximately one half of the salt solution and mix well, breaking up any remaining feces as well as possible.
5. Add back the remaining salt solution and screw the cap back onto the tube.
6. Shake tube vigorously for approximately 1 minute to disrupt any remaining feces as much as possible.
7. Set tube aside for a few minutes to let bubbles dissipate.
8. Wet McMaster chamber with water and dry top and bottom on paper towels.
9. Rock (do not shake) tube several times to thoroughly mix solution without causing large air bubbles to form.
10. Immediately pipette (using 1-mL syringe or eye dropper) a sample of the suspension and fill both sides of counting chamber. Work quickly. If it takes more than a few seconds to load the first chamber, mix the fecal solution again and refill pipette before loading the second chamber.
11. Let the sample stand for 1 to 2 minutes to allow eggs to float.
12. Count all eggs inside of grid areas (more than one half of eggs should be inside grid) using low-power (10×) objective. Focus on the top layer, which contains small air bubbles (small black circles; if numerous large air bubbles are visible, remove the fluid and refill).
13. Count only trichostrongyle and strongyle eggs (oval shaped, approximately 80 to 90 microns long). Do not count *Strongyloides* species (oval, ≈50 microns long), tapeworm eggs (triangular or D shaped), or coccidia (various sizes). Note the presence of other species but count only the trichostrongyle and strongyle eggs.
14. Once filled, the chambers can sit for no longer than 60 minutes before counting without causing problems. After 60 minutes, drying and crystal formation may begin.
15. Total egg count (both chambers) × 50 = EPG (eggs per gram).

Notes

This is a dilution technique, and theoretically this ratio of feces to flotation solution will not detect infections with fewer than 50 EPG of feces (one egg seen on slide), so it is not accurate for samples with low numbers of eggs. On a practical level this is not important because from a clinical standpoint, slight differences in results when egg counts are low do not matter.

Fairly soon after counting is complete, thoroughly rinse out the McMaster chamber with warm running water. Doing so will keep the chamber clean and ready to be used again. If fecal solution dries in the chamber, do not soak in soapy water for long periods because this will cause the chamber to become cloudy. If the chamber gets dirty, soak for only a few minutes in water containing dish soap and then rinse completely with tap water.

Necropsy Evaluation

The nature and magnitude of parasitic infections can be established by necropsy examination. Gross examination and an estimate of adult worm population in the gut lumen are often sufficient. Many worms detach from the mucosa as the carcass cools; however, the damage done by the parasites can be seen on gross or histologic examination. Occasionally it is necessary to use digestion techniques or histologic examination to document the presence of hypobiotic larvae.

Future Evaluation Techniques

Research is developing to make identification procedures more rapid. Validation and refinement of automated smatrphone apps for performing egg counts and identifying egg species has been reported and is expected to improve with continued use.[1] The use of deep amplicon sequencing (rDNA ITS-2) has great potential for improving the identification of populations of nematodes, the "nemabiome" that will identify the species present and their population percentages.[9] These approaches have been validated for cattle and small ruminants. These techniques have great potential for being able to identify the populations present, the anthelmintic resistance level, and response to treatments more quickly.[9,10]

Lungworm Infection in Large Animals

Lora Rickard Ballweber

Traditionally, lungworms are those nematode parasites that reside in the lung as adults. In domestic ruminant and equine species, most clinical cases of lungworm involve the genus *Dictyocaulus*. Species of *Dictyocaulus* tend to be host specific, with *Dictyocaulus viviparus*, *Dictyocaulus filaria*, and *Dictyocaulus arnfieldi* found in the bronchi of cattle, small ruminants, and equids (horses, ponies, donkeys), respectively. Sheep and goats may also be infected with *Protostrongylus rufescens* and *Muellerius capillaris*.[1,2] This section focuses on *Dictyocaulus* infection, with a brief discussion of other lungworm parasites found in small ruminants.

Because verminous pneumonia requires specific treatment, it is important to distinguish it from diseases caused by other infectious agents. Often the role of lungworm in the cause of

respiratory disease is obscured by a parasite-induced hypersensitivity response or by superimposed secondary bacterial infections.

Life Cycle The life cycle of *D. viviparus* is direct, with no intermediate host involved. Adults produce embryonated eggs that hatch shortly after oviposition. L_1 migrate up the trachea, are swallowed and passed in the feces, where they develop to L_2 and infective L_3 within a week under optimal environmental conditions. After the L_3 are ingested, they exsheath within the abomasum and migrate through the wall of the intestine to the mesenteric lymph nodes, where they molt to the L_4. The L_4 then migrate through the lymphatics and bloodstream to the lungs, arriving as early as 7 days after infection. L_4 may then develop to sexually mature adult worms, or they may arrest development as late L_4 or molt to immature adults and then arrest. Arrested development can prolong the normal prepatent period from 3 to 4 weeks to approximately 5 months.[1,2]

Most problems with cattle lungworms in North America occur in areas of moist climates or areas of intense irrigation where larvae on pasture are protected from desiccation and larval dispersal away from the fecal pat onto herbage is facilitated. Under favorable conditions, infective L_3 can survive on pasture for as long as 11 months.[1] These larvae, plus the larvae produced from carrier animals harboring small numbers of adults or adults that developed from arrested larvae, can result in high levels of contamination on spring pastures. In subtropical climates, larvae are virtually absent during the hot summers; larval contamination of pastures peaks in the autumn because of carrier animals.[2]

The life cycle of *D. filaria* is similar to that of *D. viviparus*, including the ability of the larvae to arrest development. The prepatent period is approximately 26 days, with peak larval output occurring 39 to 57 days post infection. As with *D. viviparus*, *D. filaria* is more prevalent in moist climates, and larvae can survive on pasture throughout the winter. Spring pastures contaminated with overwintering larvae and larvae produced from adults developing from arrested larvae in carrier animals are sources of infection for susceptible lambs or kids.[1,2]

The life cycle of *D. arnfieldi* is similar to that of other species of *Dictyocaulus*, except that larvated eggs are passed in the feces with the L_1 hatching almost immediately thereafter. The prepatent period is 2 to 3 months.[2,4]

Unlike species of *Dictyocaulus*, *M. capillaris* and *P. rufescens* have indirect life cycles that involve molluscan intermediate hosts. Adults, occurring in the parenchyma *(M. capillaris)* or small bronchioles *(P. rufescens)*, produce eggs that develop and hatch. L_1 are passed with the feces; once on pasture, larvae invade the foot of a susceptible species of snail or slug and develop to infective L_3. Sheep and goats become infected when ingesting the mollusk while grazing. The larvae penetrate the intestine and migrate to the lung in much the same manner as *Dictyocaulus*. Early L_4, developing L_4, and adult *M. capillaris* become embedded in fibrous nodules within the parenchyma. *Protostrongylus* larvae mature in the alveoli and enter the bronchioles as adults. The prepatent period for both species is 5 to 6 weeks, although arrested development may prolong the prepatent period of *M. capillaris*. Patency for both species is very long (>2 years).[2-4]

Pathophysiology Clinical bovine dictyocaulosis is characterized by bronchitis and pneumonia. The disease process is divided into four phases: penetration, prepatent, patent, and postpatent. In the penetration phase (days 1 to ≈7), no clinical sign or significant respiratory pathology occurs as the larvae migrate to the lungs. The prepatent phase (days 7–8 to 25) starts with the arrival of larvae in the alveoli and ends with immature adults in the bronchi. An eosinophilic infiltrate blocks bronchioles; excess mucus production and alveolar collapse occur. Respiratory failure resulting from severe interstitial emphysema and pulmonary edema can lead to the death of heavily infected animals beginning about day 15 onward. The patent phase (days 25–26 to 55–60) is associated with egg-laying adults in the bronchi and trachea. Bronchial and tracheal epithelial damage occurs, air passages are blocked by exudate, and consolidation of lobules results from aspiration of eggs and L_1 into bronchioles and alveoli. Bronchitis, tracheitis, and pneumonia follow. The postpatent phase (days 61 to 90) is normally the recovery phase and is associated with the expulsion of adult nematodes. Clinical signs begin to diminish; however, peribronchial fibrosis and epithelialization of alveoli may remain. A frequently fatal syndrome, called *postpatent parasitic bronchitis*, can occur in about 25% of heavily infected animals during the postpatent phase. This syndrome is characterized by proliferation of type 2 pneumocytes in the alveoli, impaired gas exchange at the alveolar surface, interstitial emphysema, and pulmonary edema and is thought to result from the aspiration of dead and dying worm material into the alveoli. Fatal secondary bacterial infections, resulting from weakened pulmonary defenses, may also occur.[1,2]

Goats tend to be more susceptible to infection with *D. filaria* and more severely affected than sheep, although individual susceptibility to infections does occur. Heavy infections in both species produce bronchitis, pulmonary edema, atelectasis, and emphysema, although death is uncommon. As with *D. viviparus*, secondary bacterial infections can occur.[1]

The characteristic lesions of dictyocaulosis in horses and donkeys are similar. Pathologic changes include discrete circular areas of overinflation (not emphysema) surrounding affected bronchi primarily in the caudal lung lobes. Histologically these areas contain a small bronchus packed with nematodes. The small airways are often occluded with exudate. Adult worms may also be found in the main bronchi surrounded by small amounts of mucus with little cellular reaction; however, if L_1 are present, they are surrounded by an intense mucopurulent reaction. In horses, in addition to these types of lesions, many immature nematodes are present in smaller bronchi, accompanied by bronchial epithelial hyperplasia with large amounts of mucus and pus. Many areas of alveolar hemorrhage and edema are also present.[2,4]

Pathologic changes caused by *P. rufescens* result from occlusion of small bronchioles by mature worms, resulting in clogging of lesser branches with eggs, larvae, and cellular debris. Other changes include desquamation of alveolar and bronchial epithelium and cellular infiltration and proliferation of connective tissue. The results are small areas of lobular pneumonia that appear as gray to yellowish conical lesions whose base is on the surface of the lung. In sheep and goats infected with *M. capillaris*, distinct subpleural nodules containing adults and L_1 are common. However, infections in both hosts may be more diffuse with interstitial pneumonia, bronchopneumonia, or fibrinous pleuritis. Secondary bacterial infections can also occur.[1,2,5]

Populations at Risk Clinical dictyocaulosis occurs most frequently in pastured calves, lambs, and kids in the first grazing season. Clinical disease is also reported in adult cattle as a result of primary exposure as adults, exposure of a previously immune animal whose immunity has waned due to lack of reinfection, or exposure of an immune animal to a massive challenge of infective larvae *(reinfection syndrome)*.[1,2,6-8] Although dairy or dairy-cross calves are most frequently affected, beef calves are also susceptible to *D. viviparus*.[2,9,10] Many infections with either *M. capillaris* or *P. rufescens* are subclinical; however, goats do appear to be affected clinically more often than sheep with *M. capillaris*.[1,2]

Immunity to *D. viviparus* occurs after first exposure and can develop before the end of the first grazing season. However,

it is variable in both degree and duration. Cattle may be immune for 7 to 12 months after infection. In subsequent infections most larvae are either killed before reaching the lung or are inhibited from maturing into adults. Usually the immunity developed during the first grazing season is boosted by reinfection in subsequent years and prevents manifestations of disease. However, without reexposure to infective larvae or vaccination, immunity wanes and disease can occur in adult cattle.[1,2,8]

Occasionally, outbreaks of acute lungworm disease are seen in adult cattle on pasture whose immunity is overwhelmed by ingestion of large numbers of larvae. This condition is called the *reinfection syndrome*. Although most ingested larvae are killed or fail to mature, some reach the lung and incite an acute, immune-mediated reaction.[2]

Both sheep and goats develop a strong immunity to *D. filaria*. Thus disease is more common in young animals. As with cattle, the strength and duration of immunity depend on the level of and number of reinfections, as well as the length of time between events.[1] Although not common, cattle can be infected with *D. filaria*. Patent infections do not establish, but clinical disease may occur.[1,11]

Individual horse or pony susceptibility to infection with *D. arnfieldi* is evident, with infections occurring during any time in the life of the animal. Patent infections can establish in foals (<5 months old) without accompanying clinical signs. Patent infections are rarely established in older horses, where clinical disease is more common. Donkeys apparently do not develop an immunity to infection, with larval excretion increasing with age.[2-4]

Although immunity to *M. capillaris* appears to be incomplete (adult nematodes can live for up to 4.5 years), responses to subsequent infections do limit the numbers of adults that will develop and the numbers of larvae shed in the feces. However, reinfections may be cumulative, resulting in older animals harboring larger numbers of worms.[1]

Clinical Manifestations

Clinical disease ("husk") caused by *D. viviparus* in cattle can occur within 1 or 2 weeks of the introduction of susceptible animals onto contaminated pasture. However, disease most often occurs 2 to 4 months into the grazing season. Severity of disease depends on the number of larvae ingested, the animal's level of immunity, and the number of larvae reaching the lungs. Within an affected group, differing degrees of clinical severity will occur. Coughing, dyspnea, and loss of condition are typical. Slight increases in respiratory rate may progress to severe tachypnea and dyspnea characterized by the classic "air-hunger" position of head and neck extended with open-mouth breathing. Auscultation of the lungs reveals vesicular murmurs and bronchial tones that progress to moist rales as fluid accumulates. Emphysema may occur with crackling noises heard on auscultation. Mild pyrexia may be present. Milk production is usually depressed in adult dairy cattle. Morbidity rates are high, with most animals gradually recovering. Secondary bacterial infections can lead to recurrence of clinical signs during the postpatent phase, leading to acute interstitial pneumonia.[1,2,7] Acute dictyocaulosis in calves, resulting from a massive primary infection, can occur during the prepatent period with sudden onset of severe dyspnea followed by death within 24 to 48 hours.[2] Reinfection syndrome in adult cattle shows frequent coughing and slight tachypnea and, for dairy cattle, a sudden drop in milk production starting approximately 2 weeks after being placed on heavily contaminated pastures. Deaths rarely occur.[2]

Coughing and unthriftiness are the usual signs of infections with *D. filaria*. In severe cases, dyspnea, tachypnea, and nasal discharge can occur. Death is uncommon.[1,2]

In horses, lungworm infection may or may not cause clinical signs. When present, the typical syndrome is similar to chronic obstructive pulmonary disease and includes persistent coughing, nasal discharge, and increased respiratory rate; death is uncommon. Donkeys tend to remain asymptomatic, although hyperpnea and harsh lung sounds may be present on close examination.[2-4]

Infections with *M. capillaris* are generally asymptomatic; however, impaired pulmonary gas exchange, reduced weights and breeding performance, and increased mortality have been reported.[1,12,13]

Control of Lungworm Infection

Control of dictyocaulosis in cattle has depended on vaccination and/or prophylactic use of anthelmintics, whereas management strategies designed to decrease numbers of infective larvae ingested are more common recommendations for sheep and goats. These strategies include providing dry pastures to decrease larval development and survival; grazing older, clinically immune animals that shed larvae away from susceptible lambs and kids; and grazing lambs on pastures that have not been grazed by adults during the previous year. Treating or culling infected adults can also help reduce pasture contamination. Limiting contact with intermediate hosts and providing mollusk-free housing will decrease infections with parasites that require these intermediate hosts. Treatment of animals before the start of the grazing season has also been suggested to reduce subsequent infection levels in the intermediate hosts.[1,2]

For cattle, leaving contaminated pastures ungrazed for at least 6 weeks during the summer in temperate regions can reduce pasture infectivity because larvae will not survive dessication. Young, susceptible stock may be given a prophylactic treatment in midspring or early summer to prevent or limit clinical disease. Housed animals, in particular 1- to 2-year-olds with subclinical but potentially patent infections, should be treated before being turned out to pasture in the spring. All early clinical cases should be treated in an effort to limit disease severity and decrease pasture contamination.[1,2,14,15]

Control of lungworms in horses and ponies depends on control in donkeys. Co-grazing with donkeys should not occur. If it does, donkeys should be monitored for L_1 and treated to reduce larval output and pasture contamination.[2]

ANTHELMINTICS. Several anthelmintics are effective against lungworms (Table 49.4).[1,3,4,16-20] The macrocyclic lactones are particularly effective against both adult and developing L_4 stages and have prolonged residual activity that prevents appearance of larvae in the feces for at least 60 days.[21,22] Concerns that such highly efficacious anthelmintics would prevent induction of immunity in first-season grazing animals by killing ingested larvae, before they can penetrate the intestine and thus stimulate an immune response, appear to be largely unfounded. The immune response may be attenuated, but exposed animals still develop some degree of immunity to lungworm infection despite prophylactic treatment with these drugs.[22-26] The exception to this may be sustained-release intraruminal devices containing ivermectin, levamisole, or a benzimidazole or long-acting injectables. Although their use can prevent clinical disease for several weeks or months during the grazing season,[26-31] some studies have shown that use of these delivery systems impaired the development of immunity in treated calves.[26,30] Other studies, however, showed that treated calves can develop immunity during the grazing season.[32] Regardless, vaccination of treated animals before their second grazing season may be advisable.[2,8]

VACCINES. An effective vaccine has been developed against *D. viviparus* in cattle and is available in the United Kingdom and parts of western Europe. Two doses of live, irradiated larvae are administered by mouth 4 weeks apart. The larvae migrate to mesenteric lymph nodes and provoke an immune response but die before they reach the lung. Management considerations associated with use of the vaccine include the

VetBooks.ir

TABLE 49.4

Drugs Used to Control Lungworm

Drug	Dose[a]
Macrocyclic Lactones	
Cattle: ivermectin, abamectin, doramectin, eprinomectin, moxidectin	0.2 mg/kg PO, 0.5 mg/kg topical
Sheep: moxidectin, ivermectin	0.2 mg/kg PO, SC
Goats: ivermectin	0.2-0.3 mg/kg PO, SC
Equids: ivermectin, moxidectin; eprinomectin	0.2 mg/kg, 0.4 mg/kg PO; 0.5 mg/kg topical
Others	
Albendazole	7.5-10 mg/kg PO (O, C, B)
Fenbendazole	7.5 mg/kg PO (O); 15-30 mg/kg PO (C); 5 mg/kg PO (B)
Mebendazole	15-20 mg/kg PO (O, C)
Oxfendazole	4.5 mg/kg PO (B), 7.5-10 mg/kg PO (O, C)

[a]Dose depends on the product and species; follow manufacturers' recommendations; multiple treatments may be warranted depending on host species; sheep and goats should be dewormed by mouth; be aware that some recommendations constitute off-label use.

B, Bovine; *C*, caprine; *O*, ovine; *PO*, by mouth; *SC*, subcutaneously.

following: (1) calves must be at least 2 months old; (2) vaccinated calves should not be placed on pasture for at least 2 weeks after the second dose; (3) vaccinated calves must not be placed onto heavily infected pastures, nor should they be mixed with animals showing signs of lungworm disease or with unvaccinated calves; (4) animals should not be treated with an anthelmintic during vaccination or the larvae in the vaccine will be killed; (5) immunity is not long-lasting, so animals must continue to ingest low levels of infective larvae to maintain immunity; and (6) the vaccine has a short shelf life and is relatively expensive. Farms with contaminated grazing areas and a history of lungworm disease benefit most from vaccination.[8,14,33]

Evaluation of Preventive Programs

The efficacy of preventive programs is best assessed by evaluating the number of susceptible animals that demonstrate signs of infection. Because total eradication of the lungworms is difficult and low numbers of parasites produce minimal problems and maintain immunity, a useful goal is the control of clinical signs and achievement of production goals.

Clinical Management

DIAGNOSIS. Presumptive diagnosis of clinical lungworm infection is based on clinical presentation, farm history, seasonal prevalence, and response to treatment.[1-4] Verminous pneumonia may mimic respiratory diseases caused by other agents that require specific treatment. Although definitive diagnosis is difficult, it is important.

To document the presence of lungworm infection, it is necessary to demonstrate larvae or adult worms. In cattle and small ruminants, the presence of specific L_1 in fresh feces indicates lungworm infection.[1,14,34] The Baermann technique is the technique of choice for detection of L_1 in feces and is considered to be very sensitive for the diagnosis of patent primary bovine lungworm infections beginning about 3.5 weeks after infection, provided a sufficient number of animals are sampled.[34] Antibody detection tests have also been developed and are commercially available for use in cattle. Evaluation of their application for testing bulk milk tank samples indicates these tests appear to be most useful in diagnosing suspected dictyocaulosis in moderate to severe outbreaks. In mild outbreaks where just a few animals are coughing or on farms where prevalence is low (<20%), examination of serum and/or feces from individual animals is preferred.[35,36]

Although examining donkeys co-grazing with horses has been the standard recommendation for the antemortem diagnosis of *D. arnfieldi*,[4] diagnosis of lungworm infection in horses is often presumptive and usually based on resolution of clinical signs after treatment.[2,3]

Transtracheal wash may demonstrate a large number of eosinophils, which is supportive of verminous pneumonia, and eggs or larvae are occasionally seen with patent infections. This procedure can also help rule out bacterial pneumonia. Finding nematodes at necropsy is definitive. Adult *Dictyocaulus* are usually found in the bronchi or bronchioles, whereas adult *P. rufescens* tend to be in the bronchioles and adult *M. capillaris* are found in subpleural nodules on the dorsal aspect of the diaphragmatic lobes. Nematodes and the eggs may also be found in histologic section of the lung.

TREATMENT. Animals that are only coughing and/or tachypneic usually have small numbers of *D. viviparus*, and their treatment should result in a rapid recovery. For animals that are dyspneic and anorexic with or without a fever, lung damage is likely severe and anthelmintic treatment is unlikely to result in complete recovery. In some animals, anthelmintic treatment worsens clinical signs, and some heavily infected animals may die. In severely affected individuals, hydration status should be monitored, particularly if the animal is not drinking. Antihistamines and antibiotics may also be included in the therapeutic regimen. Goats infected with *M. capillaris* may need multiple treatments; even so, pathologic changes can still be evident 3 months after parasite elimination.[2,8,14,37]

Coccidiosis in Food Animals

Lora Rickard Ballweber

Coccidiosis causes serious economic losses in a variety of food animal species. Regular infections with a mixture of species generally occur throughout the life of the animal. Infections tend to be asymptomatic and self-limiting unless management or other factors allow the abnormal concentration of oocysts in the environment or when host defenses are compromised. Kids are especially susceptible to coccidiosis and may develop chronic diarrhea as a consequence. In many production operations, coccidiosis is an annual event.

Life Cycle

Coccidiosis in ruminants is caused by intracellular parasites of the genus *Eimeria*. They are strictly host specific, developing within cells at species-specific sites along the intestinal tract. The life cycle is complex, involving both sexual and asexual phases within the same host. Unsporulated oocysts (noninfective) are passed in the feces and subsequently sporulate (in as little as 1 to 4 days under ideal conditions) under suitable conditions of oxygen, moderate temperatures, and high moisture. The now infective sporulated oocysts are ingested by the host with contaminated food or water. Digestive enzymes activate the sporozoites within the oocysts, which excyst in the intestine and enter intestinal cells. The asexual phase of development, in which two or more cycles of merogony occurs, is then initiated. Asexual fission results in the production of merozoites. Mature meronts rupture (along with the host cell), releasing merozoites, which enter other cells and repeat the cycle or progress to the sexual phase of development (gamogony). In this phase, merozoites enter new cells and produce macrogametes and microgametes. Microgametes are

VetBooks.ir

released by cellular rupture and fertilize a macrogamete to form a zygote. A cyst wall then forms around the zygote, resulting in the next generation of oocysts. Once again the host cell ruptures, releasing oocysts into the lumen of the intestine, where they are then passed with the feces. The prepatent period is generally 1 to 4 weeks, depending on the particular species of *Eimeria*.[1-4]

Pathophysiology Most intestinal *Eimeria* develop exclusively in the intestinal epithelial cells, although a few exceptions (e.g., *Eimeria bovis*) do exist. As a result of the developmental cycle, infected host cells are destroyed. However, the degree of damage depends on the species of *Eimeria* involved; the site of infection (discussed later); the number of oocysts ingested; and various host factors, including age, physical condition, and premunition.[1-4] If the number of oocysts ingested is low, nonimmune healthy animals may tolerate infection and show no signs of disease. However, if nonimmune animals ingest many oocysts, widespread rupture and exfoliation of intestinal cells alter gut function, allowing loss of blood, fluid, albumin, and electrolytes into the gut. Secondary bacterial invasion can also occur. Sections of sloughed intestinal mucosa and fibrin casts may be seen in the feces, which may be blood tinged.

The most pathogenic species of ruminant coccidia are those that destroy the cells of the large intestinal mucosa (*Eimeria alabamensis*, *E. bovis*, and *Eimeria zuernii* in cattle; *Eimeria crandallis* and *Eimeria ovinoidalis* in sheep; *Eimeria ninakohlyakimovae* and *Eimeria caprina* in goats) or involve deeper layers of the lower small intestine (*Eimeria christenseni* in goats).[3] Because the ruminant small intestine is very long, providing many host epithelial cells, enormous parasite replication can occur with minimal damage. If nutrient absorption is compromised, the large intestine can compensate to a certain extent. Conversely, the rate of cell turnover in the large intestine is much lower than that in the small, it is much shorter in length, and other regions of the gut cannot compensate for its impaired function.[3]

A condition called nervous coccidiosis has been described, primarily in weaned beef cattle.[4-8] The pathophysiology of this manifestation has never been definitively established, and conflicting theories have been proposed, including copper imbalance, plasma electrolyte imbalances, a neurotoxin, and a combination of stressors in which coccidia are only one factor.[4,8]

Populations at Risk Infections with mixtures of pathogenic and nonpathogenic species of *Eimeria* occur throughout the life of most ruminants and usually do not cause clinical signs because species-specific immunity is acquired quickly and maintained by continuous reinfection. The net effect of the immune response is a reduction in clinical signs and a decrease in oocyst production.[3] Therefore adults help maintain the parasite but are not usually the source of heavy environmental contamination; rather, nonimmune animals, whose initial infections result in excretion of massive numbers of oocysts, are primarily responsible.[3,4] Clinical coccidiosis is therefore a disease of young, nonimmune animals that ingest large numbers of sporulated oocysts from heavily contaminated environments.[1-4] Calves 6 to 12 months of age are most susceptible to infection, as are lambs and kids 1 to 6 months of age; however, most clinical disease in lambs and kids occurs at 4 to 8 weeks of age. Conditions favoring coccidiosis include overcrowding, housing multiple age groups together, and pens that are not cleaned regularly.[1-4,9] Thus coccidiosis is a disease of management. Although stress, such as from shipping, weaning, dietary changes, and/or adverse weather, appears to facilitate outbreaks, the mechanisms are not fully understood.[1-4,10]

Even though reported in range animals, coccidiosis is chiefly a disease of confinement leading to heavily contaminated environments. Clinical disease can occur in cattle at any age but is evident most often in calves from 3 weeks to 6 months of age.[3,4,11] In dairy cattle, coccidiosis is most common in calves when they are taken from hutches into group calf pens or mini–free-stall barns. In beef cattle the disease is most prevalent in feedlot calves. In sheep, disease is usually limited to lambs younger than 6 months old. Coccidiosis is most common in intensively reared lambs, although suckling lambs on pasture in constant use at high stocking rates are also at risk. Young kids appear particularly susceptible to coccidiosis, with clinical disease especially prevalent 2 to 3 weeks after weaning. Occasionally, adult animals develop coccidiosis either from impaired cellular immunity or when stressed (moved into a new herd, prolonged travel, extreme weather conditions).[3,4]

Clinical Manifestations The destruction of epithelial cells and subsequent loss of blood, albumin, fluid, and electrolytes typically cause a profuse, sometimes bloody, diarrhea. Despite the blood loss, anemia is not usually apparent. Death is usually from dehydration. Light to moderate infections in cattle may cause watery feces, poor condition, and reduced weight gain. Severe infections cause projectile, bloody diarrhea with mucus, rectal tenesmus, inappetence, dehydration, and weight loss. Clinical signs last approximately 1 week. In lambs, clinical signs are similar to those of cattle except blood and tenesmus are less common than cattle. In kids, clinical signs include pasty, watery diarrhea and dehydration.[1] Sudden death can occur in both lambs and kids, but the case fatality rate is usually low in most outbreaks. After recovery from the disease the gut does not return to normal function for several weeks, and concurrent appetite suppression leads to poor growth and/or stunting.

Cattle considered to have nervous coccidiosis exhibit muscle tremors, hyperesthesia, nystagmus, and seizures. Interictal periods are normal or near normal. The mortality rate is high.[2,4-6]

Control of Coccidiosis

The presence of coccidiosis depends on the amount of environmental contamination; thus the level of infection is directly related to the level of fecal contamination. Houses and pens used for sequential groups of young animals often become highly contaminated and serve as the source of infection for subsequent groups. Therefore minimizing exposure of susceptible animals to infective oocysts depends on management techniques that focus on either sanitation to avoid the buildup of environmental contamination or elimination of environmental conditions conducive to oocyst survival (or both).[3,4,9] Decreased stocking rates, proper manure disposal, elevated feed bunks, and routine cleaning of water troughs will help reduce contamination and exposure to oocysts. Sunlight and low humidity will kill oocysts, as does disinfection with formaldehyde, ammonia, or methylbromide; however, proper cleaning is a prerequisite for efficient disinfection.[4,9] Prophylactic use of coccidiostats is inevitable if conditions of animal husbandry cannot or do not improve.

DRUGS. The various drugs that have been used to prevent or treat coccidiosis in ruminants are listed in Table 49.5.[2-4,12-19] Be sure to pay strict attention to local regulations surrounding the use of any drug in food or farm animals.[2] Therapeutic anticoccidials are used in acute outbreaks; particularly useful here in calves are the benzeneacetonitrile compounds (diclazuril, toltrazuril), which currently are not labelled for use in food animals in the United States.[4] Scouring calves should be removed from the group, and supportive therapy, including electrolytes, glucose, and antidiarrheals, may help to improve survival.[3]

Often outbreaks of coccidiosis can be predicted based on farm history. Addressing husbandry issues that promote

VetBooks.ir

TABLE 49.5

Drugs Used for Treatment and Prevention of Coccidiosis in Ruminants

Drug	Treatment[a]	Prevention[a]
Amprolium	10 mg/kg for 5 days (B) 25–40 mg/kg for 5 days (O, C) 65 mg/kg once (O, C)	5 mg/kg for 21 days (B) 50 mg/kg for 21 days (O)
Decoquinate		0.5 mg/kg for 28–30 days
Diclazuril		1 mg/kg once; a second dose can be given 14 days later
Lasalocid		1 mg/kg continuously (B) 25–400 mg/ton feed, continuously (B, C) 80 mg/kg milk replacer (neonatal calves) Free choice in salt at 0.75% total salt mixture
Monensin	2 mg/kg for 20 days (O)	1 mg/kg for 28 days 10–20 ppm in feed, continuously 16–33 g/ton of feed, continuously
Nitrofurazone[b]	15 mg/kg for 5–7 days In feed at 0.04% or in water at 0.0133% for 7 days	33 mg/kg for 14 days In feed at 0.04% for 21 days
Salinomycin		10 ppm in feed (O)
Sulfadimethoxine		50 mg/kg for 5 days (O)
Sulfamethazine	247 mg/kg day 1, 123 mg/kg days 2–5 140 mg/kg for 3 days 140 mg/kg once, then 70 mg/kg for 5–7 days	35 mg/kg for 15 days (B) 25 mg/kg for 7 days (O) 55 g/ton of feed (C)
Sulfaquinoxaline	10–20 mg/kg for 5–7 days	
Toltrazuril	20 mg/kg	20 mg/kg once, timing depends on production system

[a]Oral administration; dose or regimen may vary among references.

[b]No published data, and extralabel use prohibited in cattle in the United States.

B, Bovine; *C*, caprine; *O*, ovine.

Note: Coccidiostats used in poultry feeds may be toxic to ruminants.

contamination with and survival of oocysts should be addressed first; however, where these issues cannot be improved, it is best to use drugs prophylactically or metaphylactically rather than therapeutically to prevent losses. Administration of anticoccidials during this time does not completely prevent infection but prevents clinical disease without interfering with the production of protective immunity.[4] Timing is also crucial, as improper metaphylactic use could result in wasted money or increased susceptibility to massive infections later in life.[18] Preventive measures are best used during periods of highest risk, such as in calves after weaning or in crowded conditions. If coccidiosis occurs in nursing calves, addition of anticoccidials to creep feed may be necessary. In contrast, lambs and kids are most at risk while still nursing. Thus administration of anticoccidials for 30 days prior to lambing or kidding has been recommended to reduce environmental contamination of the lambing or kidding areas.[2] Resistance to anticoccidials can occur and is a problem in the poultry industry; however, evidence for resistance in livestock is mostly circumstantial and unproven.[2]

OTHER STRATEGIES FOR MINIMIZING CLINICAL INFECTIONS. No vaccine for ruminant coccidiosis exists. Immunization of calves with a "trickle dose" of oocysts before turnout onto infected pasture attenuates the effects of natural challenge[20] but is not commonly used. Use of growth implants containing estradiol and progesterone can attenuate the effects of high oocyst challenge in dairy calves but is not used for this purpose.[21] It has been reported that oocysts of *E. alabamensis* may survive the hay-making process,[22] and hay from infected pastures should not be used to feed susceptible calves. However, whether all species of *Eimeria* can survive the hay-making process or how common survival is with various types of hay production is unknown.

Concerns regarding the potential impact of anticoccidial drug use within the food chain and on the environment has sparked increasing interest and efforts to find novel agents characterized by low risks for consumer health and better environmental compatibility as well as sustainability.[23] Evaluations of secondary plant metabolites, including polyphenols, flavonoids, tannins, and saponins, show promise in animal models (mice) or poultry,[23] but few efforts have addressed livestock. Because much effort has focused on the anthelmintic properties of tannin-containing legumes and their use in controlling GINs of ruminants,[24] particularly where anthelmintic-resistant populations of these parasites occur, some efforts evaluating their use as anticoccidials have occurred.[25-31] The primary focus has been on small ruminants. Although all studies varied in their design (e.g., plus/minus concurrent GIN infections) and some lack certain information (e.g., species of *Eimeria* present), these data do indicate an overall reduction in oocyst excretion, which would aid in reducing environmental contamination.

Evaluation of Preventive Programs

Evaluation of any coccidiosis prevention plan is based on the presence and extent of clinical disease. Herds or flocks that require preventive strategies do so because they usually have a history of prior disease. Program efficacy therefore is evaluated on the basis of a decrease in prevalence of clinically ill animals.

Clinical Management

DIAGNOSIS. Diagnosis is presumptive and based on history (which may include a stressful event), thorough knowledge of the herd or flock management, and clinical signs of severe diarrhea (usually young animals). Postmortem findings of inflammation, hyperemia, and thickening of the cecum with masses of gamonts and oocysts in mucosal scrapings will be confirmatory. Because pathogenicity varies by species, the value of fecal oocyst counts is debated. In general, fecal oocyst counts alone are not helpful *if the species of coccidia present are not identified.* The mere presence of oocysts does not itself indicate disease, as high numbers of nonpathogenic species can be present in animals with other causes of diarrhea. Clinical signs can also develop in the early stages of the life cycle before

VetBooks.ir

oocyst shedding. If fecal examinations are done during a suspected outbreak, multiple animals should be sampled. Due to the short life cycle, oocyst counts are highest in early patency and drop quickly after about 1 week. Thus fecal samples should be collected when diarrhea starts. Any standard fecal flotation method can be used to find oocysts.[2-4]

TREATMENT. Drugs used in the treatment of coccidiosis are listed in Table 49.5. Supportive therapy, when indicated, is primarily directed at replacing fluid losses and supporting the animal until the gut epithelium regenerates.

Anthelmintic Use[1]

Sherrill A. Fleming

An anthelmintic is defined as an agent that acts to destroy or expel parasitic intestinal helminths. Anthelmintic drugs are used to treat animals that are suffering the adverse effects of a parasitic burden. They may also be used to prevent and minimize the economic losses associated with parasitic infection. Anthelmintics may be used on individual animals or a group of animals.

Drug Action

To use an anthelmintic properly, it is necessary to consider its mode of action, spectrum of activity, and duration of effect. The pharmacodynamics of an anthelmintic is specific for each species that is treated. Efficacy for a given drug may be defined as its ability to kill adult or larval parasites, suppress parasitic egg production, or promote the expulsion of worms from the gastrointestinal tract.

The emergence of drug-resistant strains of nematodes has necessitated the use of each class of anthelmintic to be customized to the premise where it will be used. Package inserts should be regarded as guidelines rather than gospel. Refer to the Anthelmintic Drugs and the Evaluation of Parasite Control Programs sections for particulars on anthelmintic performance. Readers should refer to the sections on horses, cattle, and small ruminants for more specific recommendations.

Anthelmintic Drugs (see Table 49.4)[1,2]

Avermectins and Milbemycins

The avermectins and milbemycins are macrocyclic lactones. They act by increasing the permeability of parasite cell membranes to chloride ions, which results in nonspastic paralysis and death of the parasite. These drugs may also act by potentiating presynaptic release of γ-aminobutyric acid (GABA), an inhibitory neurotransmitter, although this theory has been challenged.

These products have a high level and broad spectrum of activity against adult and larval nematodes. They are also effective against various ectoparasites such as mites, lice, ticks, bots, and cattle grubs; however, they are ineffective against flukes and tapeworms. These drugs suppress nematode egg production for longer than other anthelmintics. Because of its long duration of effect, moxidectin suppresses fecal egg counts and protects against reinfection for longer than ivermectin. Concern has been expressed about the environmental impact of these long-acting anthelmintics in grazing animals.

Several products have been developed for use in animals. The avermectins include ivermectin, abamectin, doramectin, and eprinomectin. The milbemycins include nemadectin and moxidectin. Oral (drench, sustained-release intraruminal device), topical (pour-on), and injectable formulations are available, depending on the drug. Ivermectin is safe to use during pregnancy, but currently it is not approved for use in lactating dairy animals or females of breeding age. Similarly, doramectin and moxidectin are not approved for use in female dairy cattle of breeding age. Eprinomectin is unique in that it has no withholding period for milk or meat, so there are no restrictions on its use in cattle. At labeled doses, moxidectin is a safe drug; however, accidental overdosage has caused neurologic signs in foals and miniature horses. Some of these products have extended efficacy periods but run the risk of having subtherapeutic periods, which increase the selection for resistant nematodes.

Benzimidazoles

The benzimidazoles (BZDs) comprise a large class of anthelmintics that interfere with parasitic carbohydrate metabolism by inhibiting the enzyme fumarate reductase. Many BZDs have been developed and marketed. They include albendazole, fenbendazole, mebendazole, oxfendazole, oxibendazole, parbendazole, ricobendazole, thiabendazole, triclabendazole, and the probenzimidazole drugs febantel and netobimin.

BZDs are widely used in horses and ruminants. In general, they exhibit a high degree of safety and a broad spectrum of activity against GINs and lungworms. Some members of this class (e.g., albendazole) are also active against liver flukes and certain cestodes in ruminants. Albendazole and netobimin can cause teratogenicity and embryo toxicity in sheep when given during early pregnancy. Fenbendazole, oxfendazole, and oxibendazole are considered safe for use in pregnant animals.

Resistance to BZDs has been documented in certain equine, ovine, and caprine parasites (see species-specific sections). In general, a strain of parasite resistant to one BZD drug quickly develops resistance to other BZDs or pro-BZDs, a phenomenon known as *side resistance*.

Levamisole (Imidazothiazoles)

Levamisole acts by causing neuromuscular depolarization and paralysis of the parasite. It has been widely used in ruminants to treat GINs and lungworm infections. However, levamisole resistance has become a problem in many areas. Levamisole is the only anthelmintic that has shown resistant parasites reverting to sensitivity if not used for several years. Recurrence of resistance will develop fairly rapidly with reuse of levamisole.

The dose of levamisole should be calculated carefully because toxic doses are only one to two times therapeutic doses. Signs of toxicity may mimic those of organophosphate (OP) toxicity, including muscle fasciculations around the lips and eyelids, hypersalivation, spastic movements, depression, and diarrhea. In ruminants, muzzle foam may develop after oral administration of the drug but usually disappears within a few hours after administration. In horses, transitory excitement has been seen after treatment. Levamisole is not recommended for use as an anthelmintic in horses. Concurrent administration of morantel, pyrantel, diethylcarbamazine, or OPs could enhance the toxic effects of levamisole.

Morantel and Pyrantel (Tetrahydropyrimidines)

The tetrahydropyrimidines morantel and pyrantel are cholinergic agonists that exert their anthelmintic effect by depolarizing neuromuscular junctions and causing irreversible paralysis of susceptible parasites, similar to the action of imidazothiazoles. Morantel is slower in its onset of action but much more potent than pyrantel. These products are effective against many species of adult nematodes but do not appear to be active against larval stages. Pyrantel is also effective against tapeworms in horses when given at twice the recommended dose. The margin of safety is relatively wide, and there is no contraindication to using morantel or pyrantel with other cholinergic drugs. However, it is recommended that morantel and pyrantel not be used concurrently and that neither be given with levamisole. Piperazine antagonizes the effects of morantel and pyrantel, so

VetBooks.ir

it should not be used with either of these drugs. Resistance to morantel and pyrantel has been documented in strains of *H. contortus* and in some cyathostomes (equine small strongyles).

Organophosphates

OPs block neurotransmission by inhibiting acetylcholinesterase. Various formulations of OP drugs are available for treating gastrointestinal nematodiasis. Commonly used OPs include haloxon, coumaphos, trichlorfon, and dichlorvos. Toxicity occurs with these products in a dose-related manner, so dosages should be calculated with care. In addition, the potential danger to humans administering these products should not be overlooked. Atropine is recommended in cases of overdose in livestock.

Phenothiazine

The mode of action of phenothiazine (PTH) has not been clarified; it is thought to interfere with anaerobic metabolism of nematodes. The various formulations of PTH differ in purity and particle size. The purified product (99% PTH) with small particle size (2 μm) is the most effective.

Although PTH is effective against a wide spectrum of GINs, resistant strains of parasites have emerged in several species. The drug is synergistic with piperazine; combinations of these drugs have effective activity against PTH-resistant nematodes. PTH used in combination with piperazine can be administered at a much lower dose.

PTH toxicity has been reported. Toxic reactions include corneal inflammation, abortion, ataxia, hemolytic anemia, photosensitization, and nephrotoxicity. The drug should not be administered to debilitated or anemic animals or to animals in the last month of pregnancy.

Piperazine

Piperazine salts block neuromuscular transmission, resulting in paralysis of susceptible GINs. The worms are then passively removed from the gastrointestinal tract by intestinal peristalsis. Piperazines have low toxicity and are safe in young or pregnant animals. However, their spectrum of activity is limited, in practical terms, to ascarids. Piperazine must be used with caution in horses heavily infested with ascarids because the paralyzed ascarids can cause an impaction that may culminate in bowel rupture. Diethylcarbamazine is a piperazine derivative that has been used to control lungworm infection in sheep and cattle.

Monepantel

Monepantel is a new amino-acetonitrile derivative (ADD) compound that has a unique mode of paralyzing nematodes and is intended to be used as an oral drench. This product has been released for use in New Zealand but is not available in the United States at this time. The countries that do have this drug available are beginning to report resistance in nematode populations.[3,4]

Combination Dewormers

Combination dewormers have been shown to extend the effectiveness of anthelmintics. Many of the newer products reaching the market contain two or more classes of anthelmintics, but to date none of these products is available in the United States. One study showed that not only did combination anthelmintics not increase resistance development but there was some evidence of reversion to susceptibility in *T. circumcincta* populations.[5]

Other Anthelmintics

Praziquantel is a cesticidal drug that causes spastic paralysis, decreased glucose uptake, and disruption of the tapeworm's tegument. Although not approved for this use, praziquantel is effective for treating tapeworm infestation in horses. It has also been used to control various cestodes in small ruminants. Nitroxinil is a halogenated phenol that has flukicide activity *(Fasciola hepatica)* and some nematodes and is available in some countries as an injection. Salicylanilides are a chemical class of antiparasitic active ingredients with efficacy against certain roundworms, tapeworms, and/or flukes. The class includes closantel (flukes and some nematodes), niclosamide (tapeworms and rumen flukes [*Paramphistomum* spp.]), oxyclozanide (some flukes), and rafoxanide (some flukes and nematodes).

Nutrition of the Sick Animal

ELIZABETH A. CARR and MARIE-EVE FECTEAU, *Consulting Editors*
MICHELLE LINTON

Introduction

Horses, cattle, and other large animal species evolved as grazing herbivorous animals, meeting energy and nutritional needs with forage, salt, and water. In most cases, feeding based on teleologic principals is best, unless the individual is unwilling or unable to eat. There are little data on feeding critically ill or hospitalized large animal species and its association with or effect on morbidity and mortality or hospital stay.

Protein/Calorie Malnutrition

It is generally agreed on that feed can be withheld from healthy, "nonstressed" adult individuals for 2 to 3 days. The average, healthy adult horse or ruminant can apparently tolerate food deprivation (protein/calorie malnutrition [PCM] or simple starvation) for 72 hours with few systemic effects. In humans a decline in blood glucose concentration results in a fall in insulin concentration. During the first hours to days of starvation, glycogen stores are mobilized from various tissues (liver, kidney, muscle) for glucose production. As glucose becomes limited, many body tissues begin to rely on fatty acid oxidation and the production of ketone bodies as energy sources. Glycerol produced from lipid degradation, lactate from the Krebs cycle, and amino acids provided from muscle tissue breakdown continue to be used for gluconeogenesis to provide energy to glucose-dependent tissues (central nervous system and red blood cells). This response to starvation correlates with an increase in circulating levels of growth hormone, glucagon, epinephrine, leptin, and cortisol and a decrease in insulin and thyroid hormones. During PCM there is an increased drive to eat and a decrease in energy expenditure. Metabolism slows in an effort to conserve body fuels, and the body survives primarily on fat stores, sparing lean tissue until refeeding occurs.

Although similar adaptive responses to PCM can occur in the healthy older foal, the neonate has limited body reserves. The healthy newborn foal should have enough liver glycogen to support energy needs for several hours of life. However, glycogen stores at birth can vary significantly with illness or prematurity. Lack of early nutritional support can result in hypoglycemia or hypothermia and quickly affect the ability to maintain functions and behavior.

Catabolic Response to Injury

During illness or after trauma, food intake frequently falls. However, despite this decline in intake, the adaptive responses to starvation do not occur. In contrast to PCM, in humans and laboratory animals, the metabolic response to injury (critical illness, sepsis, trauma, surgical manipulation, etc.) is characterized by an increased metabolism and the onset of a catabolic process leading to excessive breakdown of tissue proteins. There is a preference to use amino acids from the breakdown of skeletal muscle proteins as a metabolic fuel, in contrast to PCM in which fat is the principal source of energy. The adaptive switch to fat utilization is limited due, in part, to increased concentrations of circulating insulin. Insulin resistance develops, and hyperglycemia may occur despite the absence of food intake. This metabolic state is the result of a complex interaction of inflammatory cytokines, circulating hormones, and neurotransmitters and is designed to provide endogenous substrates for gluconeogenesis, wound healing, immune cell replication, and synthesis of acute-phase proteins.[1] Although this response is beneficial, long-term muscle breakdown results in loss of muscle strength, visceral organ dysfunction secondary to loss of structural and enzymatic proteins, impaired wound healing (due to loss of precursors for wound healing), immunosuppression, and compromise to the patient's overall health.

As sodium retention and water retention are components of this response, weight loss and muscle wasting frequently go unnoticed. Food deprivation during this hypermetabolic/catabolic state results in a much greater loss of lean muscle mass and visceral protein than would be expected during simple starvation. The metabolic adaptations to starvation in a healthy human can result in a 75% decrease in protein loss, whereas the metabolic responses to critical illness result in an increase in energy expenditure and protein metabolism.

Although nutritional supplementation can reverse the catabolic processes occurring during simple starvation, it will not completely reverse those occurring during metabolic stress because as long as tissue injury persists, catabolic processes are maintained.

Summary

In malnourished or debilitated individuals, nutritional supplementation (calories and/or protein) has been shown to be beneficial in improving survival, immune function, wound healing, and gastrointestinal function in humans and animal models.[2-5] Catabolism of lean muscle during critical illness and the resultant weakness have been the rationale for recommendations to increase amino acid supplementation in critically ill humans.[6-10] However, indiscriminate nutritional supplementation in patients without a history of malnutrition has not been clearly linked to improved outcomes and in some studies is associated with increased complications. Anorexia is part of the acute stress response and may be beneficial during illness

VetBooks.ir

as it activates autophagy, a cellular process that results in removal of damaged organelles, protein aggregates, and microorganisms. The autophagic response has been linked to improved outcomes in critical illness.[11] Nutrients (particularly amino acids), growth factors, and insulin suppress autophagy and may ultimately have a negative impact on morbidity and mortality. Recent randomized controlled trials have failed to show a clear benefit to early nutritional support (whether caloric or amino acid supplementation) in critical illness, and some have even found potential harm.[12-19] In human medicine recommendations are to determine nutritional risk factors in both baseline nutritional status and disease severity, as well as complication risks.[18-20] This information is then used to determine route (enteral vs. parenteral), type (standard formulations vs. supplementation of additional components), and rate of nutritional support.[21]

Thankfully, it is rare for large animal veterinarians to have to manage patients with the same severity and types of illnesses and comorbidities found in human intensive care units (ICUs). Exactly when and how much nutritional supplementation is ideal is not known, but extrapolation from human studies would suggest that meeting complete nutritional needs should not be the goal. However, the combination of an increased catabolism and the altered metabolic processes seen with injury and illness do cause significant loss of lean body mass and can impact the return to performance of a competitive athlete. Recently, research in nutritional therapy in humans and laboratory species has been focused on attenuating the metabolic response to stress, preventing oxidative cellular injury and favorably modulating the immune response with the ultimate goal being to reduce disease severity, complications, and length of stay, as well as to improve outcome.[21]

The goals for this chapter are to provide guidelines to help maintain muscle mass, provide essential nutrition, and decrease morbidity associated with illness. While nutritional support recommendations continue to be debated in the human intensive care unit, some tenets are likely to continue to hold true:

1. Hyperglycemia has been shown to negatively impact immune function and may increase the risk of infection. Control of blood glucose with a goal of avoiding severe hyperglycemia without risking hypoglycemia is recommended. At times, an insulin infusion may be necessary to prevent severe hyperglycemia, though careful blood glucose monitoring is recommended to avoid hypoglycemia.
2. Meeting 100% of our patients' nutritional needs is unnecessary and often unrealistic, as volume restrictions for enteral supplementation and costs for parenteral nutrition (PN) frequently limit our ability to provide the calculated requirement in large animal species.
3. Nutritional supplementation can have benefits in minimizing the severity of protein loss, providing both essential and conditionally essential amino acids, vitamins, and minerals, and in decreasing morbidity associated with illness.

Lastly, the approach to nutritional support of the large animal patient should be considered on an individual-case basis. This includes evaluating preadmission nutritional status and activity level, comorbidities that could impact recovery and metabolic response to illness, as well as illness severity and likely recovery time.

Assessment of Nutritional Status

Although the healthy adult horse or ruminant with an adequate body condition score (see Chapter 9) and minor injury or illness rarely requires nutritional supplementation, early nutritional support should be strongly considered in patients with increased metabolic demands, such as young growing animals or lactating dams, individuals presenting with a prior history of malnutrition or hypophagia, patients with underlying metabolic abnormalities that could worsen with feed deprivation, and individuals with an illness such as severe trauma, sepsis, or strangulating bowel obstructions that may result in an increased metabolism and excess losses (e.g., albumin loss through a compromised gastrointestinal tract). Underweight horses with a BCS less than 3.5 out of 9 (though this depends on the breed and individual characteristics) should ideally receive nutritional support early in the disease process rather than waiting to see if the individual will begin to eat on his or her own volition. Obese or overconditioned individuals, particularly pony breeds, miniature horses, donkeys, and camelids, as well as lactating mares, are at risk for developing hyperlipemia and should receive nutritional support, especially if their serum triglycerides are above normal reference values. Lactating dairy cattle or pregnant sheep or goats should also receive early nutritional support to minimize the risk of developing ketosis, fatty liver, or pregnancy toxemia. Patients with pituitary pars intermedia dysfunction (formerly known as equine Cushing's disease) or equine metabolic syndrome are insulin resistant and may also be at greater risk for developing hyperlipemia and fatty infiltration of their liver. Depending on the severity and type of underlying disease process and individual characteristics (breed, body condition), some animals may develop severe hyperlipemia (triglycerides > 500 mg/dL) or ketosis within days of onset of anorexia. The combination of illness and metabolic effects of hyperlipemia or ketosis can worsen the individual's inappetence, creating a vicious cycle. Consequently, if feed deprivation is prolonged (in some cases as little as 1 to 2 days of anorexia can result in moderate to severe hyperlipemia) or there is a concern regarding the individual's desire or ability to eat, early intervention is indicated to prevent more severe metabolic complications.

A list of BCS descriptions for different species is provided in Chapter 9. Changes in weight or BCS are often easily overlooked on day-to-day observations of the patient if a concerted effort is not made at detecting them. Palpation of the animal (ribs, dorsal vertebral processes) is necessary in sheep with a heavy fleece, camelids with long fiber, and horses with a thick winter hair coat.

Nutritional Needs of Sick or Injured Large Animals

Energy Requirements

While the energy requirements of large animal species of various ages, stages of growth, and activity levels have been determined and equations are available to calculate these needs, the energy and protein requirements for the hospitalized, sick patient are not known and likely vary depending on disease state, environment conditions, and level of fitness of the individual. Historically, multipliers have been used to estimate the energy requirements in certain conditions including severe sepsis, trauma, and burn injuries. However, the increased metabolic demand of illness or surgical trauma and recovery is likely to be balanced by the inactivity and decreased metabolic demands of digestion of the patient during hospitalization. Consequently, these multipliers likely overestimate the caloric requirement of certain illnesses. Studies in the human ICU and in sick neonatal foals suggest that the metabolic energy needs may fall more closely within the range of the resting to maintenance energy requirements of the normal, healthy animal.[22-24] The exceptions to this are individuals with extreme trauma, burns or severe sepsis, surgical conditions that require intestinal resection, and patients with large areas of devitalized tissue (such as clostridial myositis patients undergoing multiple fasciotomies). When estimating the energy requirements of the majority of other patients, resting energy requirements (DE_r) are an acceptable target. Resting energy requirements

VetBooks.ir

are defined as the amount of energy needed to maintain an individual (no weight gain or loss) in a *thermoneutral environment without the metabolic demands of digestion*. Maintenance energy requirements (DE_m) include the demands of digestion in this equation and are approximately 30% higher than resting energy requirements. Resting energy requirements will vary slightly depending on the size of the horse but can be estimated using approximately 22 to 23 kcal/kg/day for the average full-size horse. Maintenance energy requirements can be estimated using 30 to 35 kcal/kg/day. If a patient tolerates nutritional supplementation at resting energy requirements, the feeding rate (i.e., calories/kg/day) can be gradually increased if needed.

Protein Requirements

The maintenance protein requirement of the healthy adult horse is estimated at approximately 0.5 to 1.5 g/kg/day. The needs of a growing foal are higher and may approach 7 g/kg/day during maximum growth periods. In addition, the lysine requirements of growing horses are higher than for mature horses.[25] During critical illness or severe injury, protein catabolism and utilization of amino acids as a source of fuel continue despite the presence of other energy stores. Consequently, when calculating protein requirements in human patients, it is recommended to provide the higher end of the estimated need.[22,26] Another consideration is supplementation of nonessential amino acids that may improve outcome in illness. Glutamine is considered a conditionally essential amino acid and is used as a fuel for enterocytes and other rapidly dividing cells.[27] In periods of inappetence the majority of glutamine is produced by mobilization of muscle stores.[28] Glutamine release during critical illness may act as a cell signaling molecule regulating the inflammatory and immune response; however, in periods of illness when glutamine requirements may actually increase, endogenous sources may be inadequate, resulting in relative glutamine deficiency.[29] Glutamine has been shown to be critical in maintaining gut wall integrity, immune function, and antioxidant supplies.[29] In a large-scale review of published meta-analyses and systematic reviews of glutamine supplementation's effect on outcomes, glutamine supplementation was associated with decreased infection complications, length of hospital stay, and mortality, suggesting it may be worth adding to supplementary diets.[30] Other recommendations for amino acid supplementation include branched chain amino acids and arginine supplementation. Arginine, a nitric oxide precursor, is an important vasodilating agent, it upregulates immune function, and may reduce ischemia reperfusion injury.[31-32]

The amount and ideal route of glutamine or arginine supplementation has not been determined in the horse. In one in vitro study, glutamine supplementation improved mucosal restitution in an oxidant-injured equine colon model.[33] Currently the American Society of Parenteral and Enteral Nutrition guidelines do not recommend addition of immune-modulating amino acid supplements due to a lack of evidence for outcome improvement in patients in the medical ICU and concerns about cardiovascular risks associated with modulation of nitric oxide.[9] In actuality, many commercially available parenteral and enteral products contain nonessential amino acids. When feeding by the enteral route, protein needs can be met by feeding a complete feed (which generally contains nonessential or conditionally essential amino acids) or by addition of specific amino acids to a component diet. Alternatively, glutamine can be purchased separately and added to a diet, though recommendations for amounts are currently not available.

Nutritional Support of the Neonate

The healthy, full-term neonate is born with enough body fat and glycogen reserves to provide energy supply for approximately 12 hours. Premature or systemically compromised neonates (such as in-utero sepsis) may lack these minimal reserves, making them at increased risk for hypoglycemia, hypothermia, and organ dysfunction.

TABLE 50.1

Milk Intake Requirements for a 50-kg Foal

Body Weight in Milk/Day	Liters/Day	mL/2-Hour Feedings
5%	2.5	208
10%	5	420
15%	7.5	630

While a healthy, normal foal ingests approximately 15% of its body weight in milk per day during the first few weeks of life (increasing to as much as 30% during the first month), the metabolic demand of a sick, recumbent neonate is likely closer to 5% to 10% (50 to 100 kcal/kg/day).[23] Ten percent body weight in milk/day is typically adequate for growth and activity in neonatal calves. Neonatal small ruminants typically ingest between 10% and 15% of their body weight in milk per day. An example of a feeding schedule and volumes for a 50-kg foal can be found in Table 50.1.

A healthy average-size foal (50 kg) is expected to gain between 0.5 and 1 kg/day. Failure to gain weight can be a sign of an uncontrolled illness (such as a focus of infection) or the result of insufficient nutritional support.

Enteral Routes of Nutritional Supplementation

The choice whether to use the enteral or parenteral route of feeding can be summarized by the simple statement, "if the gut works, use it." While there are conflicting data regarding the pros and cons of parenteral feeding versus enteral feeding, it is clear that enteral feeding has some distinct benefits. Enteral nutrients provide the majority of nutrition to the gut, which is responsible for 15% to 35% of the total body oxygen consumption and protein turnover.[34] Enteral feeding offers the advantage of maintaining the gastrointestinal tract and is generally less expensive. Enteral feeding has been shown to improve gut barrier integrity, gut mass, protein content, motility, and function in piglets.[35] The complete absence of enteral nutrition results in mucosal atrophy, increased gut permeability, and enzymatic dysfunction in critically ill human patients.[36] Even small amounts of enteral feeding may provide benefits. In a neonatal piglet model, provision of 5% to 10% of nutritional needs by enteral feeding resulted in improved intestinal motility and lactose digestion and decreased mucosal permeability. Enteral provision of 20% of energy and nutrient needs for normal growth prevented loss of gut protein mass, whereas 40% to 60% of nutritional needs were needed to maintain normal gastrointestinal growth.[35]

The enteral route of nutritional support is simpler as there is less concern of fluid and electrolyte overload, and this route allows fiber feeding, which cannot be achieved parenterally. That said, clinicians are often hesitant to use the enteral route in patients with gastrointestinal disorders. In the critically ill patient with poor perfusion and decreased oxygen delivery to the tissues, the gastrointestinal tract is one of the most vulnerable organs to ischemia. Decreased oxygen delivery has been shown to increase mucosal permeability, resulting in increased translocation of bacteria and absorption of bacterial toxins.[37,38] Inflammatory mediators, produced in the gut as a result of ischemia, are absorbed across the damaged mucosa and enter the portal and systemic circulations; this absorption has been

implicated in the onset of septic shock or multiorgan failure.[39] Inflammation and enterocyte injury can result in decreased motility and nutrient absorption. In this situation, institution of forced enteral feeding may result in colic, bloat, bacterial overgrowth, diarrhea, and other complications. Because digestion increases the metabolic activity of the enterocytes, enteral feeding during states of poor oxygen delivery may actually worsen the oxygen debt and ischemic injury. In contrast, enteral nutrition has been shown to increase total hepatosplanchnic blood flow in healthy patients, resulting in greater oxygen delivery to the mucosa, suggesting that enteral feeding may be beneficial in the poorly perfused gut.[39] In a rat *Escherichia coli* sepsis model, enteral feeding of glucose resulted in improved intestinal perfusion rates.[40] Given this conflicting information, the decision on the route of administration of supplemental nutrition must be determined on a case-by-case basis, with consideration of the primary disease condition, the status of the gastrointestinal tract, and individual clinician experience. The enteral route is always preferred when the gastrointestinal tract is functional. However, patients with overwhelming bowel ischemia, inflammation, and high risk of ileus or intestinal resection may not always be the best candidates for EN and may be better off started on PN while they are gradually reintroduced to enteral nutrition.

Liquid Diets for Horses

In equids with decreased appetite or complete anorexia, enteral diet choices are limited to those that can be administered through a nasogastric tube. Types of liquid enteral diets include slurry diets composed primarily of normal feedstuffs (Table 50.2), commercial equine enteral diets, liquid component diets that allow the clinician to tailor the feeding regimen adding fiber, vitamins, minerals, and amino acids separately (Table 50.3), and commercially available liquid diets for humans (Table 50.4).

Complete pelleted feeds offer several advantages—they are relatively inexpensive, meet the maintenance nutrient requirements, and contain sources of fiber. Fiber is beneficial in increasing colonic blood flow, enzymatic activity, and ruminal and colonic mucosal cell growth and absorption.[41]

Both human and equine liquid formulations are available and have been used as enteral nutrition support in horses.[42-45] The use of human products (Osmolite and Vital HN) in the mature horse can be expensive and has been associated with diarrhea and laminitis (though cause and effect are not clear); consequently they are rarely used and not currently recommended, having

TABLE 50.4

Nutritional Content of Selected Liquid Diets

	Vital HN[a]	Osmolite[a]	Critical Care Meals/Packet
Cal/L	1000	1008	1066
Protein	41.7 g/dL	40 g/dL	12%
Fat	10.8 g/dL	34 g/dL	1%
Carbohydrate	185 g/L	135.6 g/L	73%

[a]Product formulated for human use.

VetBooks.ir

been largely replaced by equine-specific formulations.[46,47] WellSolve Well Gel (Purina Mills, LLC, St. Louis, Mo.) and Enteral Immunonutrition Formula (Platinum Performance, Inc. Buellton, Calif.) are two diets currently available for use. The major disadvantage of these products over complete pelleted diets is their cost.

Component diets have been described for use in equids.[47] Corn oil may be added to the diet to increase the caloric content but should be added gradually (increasing the intake by ¼ cup or 60 mL daily not to exceed 2 cups or 600 mL total daily intake) to prevent diarrhea.

Liquid diets can be given by continuous flow through an indwelling small-bore (18-French) nasogastric feeding tube (Mila International Erlanger, Ken.) or via periodic passage of a nasogastric tube and administration of larger meals. When using pelleted diets in equids, the authors recommend that 1 kg of a pelleted complete feed be soaked in approximately 4 L of water. Once this water has been absorbed, an additional 2 L of water are added to form a slurry that can be administered via a large-bore (external diameter 305 cm) nasogastric tube. Slurry diets made from complete pelleted feeds may not pass through a nasogastric tube using gravity alone. Instead, the slurry can be administered by use of a marine supply bilge pump. If a bilge pump is not available or a large-bore tube cannot be passed, pulverizing the pellets before adding water may improve gravity flow. The horse should be checked for the presence of gastric reflux before administration, and the slurry should be pumped slowly with attention paid to the animal's attitude and reaction. As the stomach volume of a mature, 450-kg horse is approximately 9 to 11 L, the volume of each feeding should not exceed 6 to 8 L per feeding. The volume fed should be adjusted for smaller horses. Long-term placement of nasogastric tubes in horses is not without the risk of complications.[47] Small-bore, 18-French, softer (polyurethane) tubes (Mila International, Erlanger, Ken.) are recommended if intubation is prolonged, as they are better tolerated by the patient but generally preclude the use of slurry diets. Alternatively, intermittent placement of a nasogastric tube is effective in decreasing complications but can be difficult, and at times traumatic, for the patient. When instituting enteral feeding, particularly in a patient with prolonged anorexia, it is best to start gradually increasing the amount fed over several days (Table 50.5). A maximum of 50% of calculated requirements should be fed in the first 24 hours; if the patient tolerates this level of supplementation, the amount can be increased over the next few days until the target feeding rate is achieved. Rapid changes in feed amount such as feeding 100% of required intake the first day in an animal that has not eaten for 3 to 5 days can be associated with colic, regurgitation, or diarrhea, particularly with liquid diets made for humans or high-fat diets.

Creation of an esophagotomy should be considered when prolonged enteral nutritional support is likely to be required or when medical or surgical conditions prevent passage of a nasogastric tube. Esophagotomy can be performed in a standing, sedated animal and, once in place, allows frequent intubation and feeding while avoiding the trauma and discomfort associated with repetitive nasogastric intubation. Once the animal has recovered and its appetite has returned, tube feeding can be discontinued to allow the esophagotomy incision to heal by second intention.

Liquid Diets for Ruminants

In most cases the most practical and least expensive way to force-feed ruminants is the blender-type or slurry diet. Hypophagic adult cattle and other ruminants may be force-fed a suspension of alfalfa meal and/or slurry made from soaked complete pelleted feeds. Some classic examples where force-feeding may be indicated include cows with hepatic lipidosis, cattle with balling gun injuries/retropharyngeal trauma, mandibular fractures, tetanus, or listeriosis where oral feeding is either impossible or contraindicated. Administration of the enteral feedings can be achieved simply by passing an ororumenal tube (adequate for patients who may only necessitate enteral feeding for a short period of time) or placing a temporary rumen cannula (for patients necessitating enteral feeding for extended periods of time. An additional advantage of rumen cannula feeding is that the clinician is no longer limited to a strictly liquid diet as grain and finely chopped hay can be administered through the rumen cannula. Administration of ruminal liquor obtained from a healthy donor cow provides a good source of microflora, as well as volatile fatty acids and essential amino acids as an energy source in hypophagic cows, and is felt to be beneficial in all ruminant species.[48]

Enteral Supplementation in Neonates

Enteral Support of the Neonate

The enteral route of nutrition is always preferred over parenteral, as enteral feeding has been shown to increase gastrointestinal mass and function compared with the parenteral route. Small volumes (1% to 2% body weight in 24 hours divided into q2h feedings) are recommended when initiating enteral feeding in foals, particularly if there is concern regarding the health of the gastrointestinal tract. Over time, one can gradually increase the volume fed, paying careful attention to changes in intestinal motility, residual volumes of gastric milk, and signs of colic or diarrhea. An example of a gradual feeding schedule for a sick neonatal foal can be found in Table 50.1.

Enteral feeding should be avoided in severely hypotensive or hypothermic neonates. Those with enteropathy, whether secondary to oxygen deprivation or infection, may be unable to absorb nutrients and develop colic and diarrhea when fed. A detailed history and careful repeat assessments of the neonate's gastrointestinal tract (including ultrasound examination if possible) are critical to ensure that the patient can tolerate enteral feedings. Enteral supplementation should be avoided in individuals with a dilated small intestine or ileus or other signs of enteritis. Sequential measurement of abdominal size can be useful to assess gastrointestinal distension and intolerance to feeding. Colic signs in foals are often subtle; foals may appear fussy or agitated and show an increase in heart rate and respiratory rate. If deterioration is noted, enteral feeding should be discontinued or decreased until resolution.

TABLE 50.5

Enteral Feeding Schedule for Adult Horses (450-Kg Horse)

Day 1	Day 1	Day 2	Day 3	Maintenance (1%-1.5% Body Weight)
Number of meals	2-3	3-4	4-6	4-6
Complete feed (kg)/meal	0.5 kg	0.75	0.75-1.0	1.0-1.25
Water (L)/meal	4-6	4-6	6-8	6-8

VetBooks.ir

Foals, beef calves, and neonatal small ruminants normally nurse relatively small amounts of milk frequently throughout the day, whereas dairy calves drink larger volumes less frequently. When foals are fed less frequent meals, hunger may cause them to rapidly ingest larger volumes, overloading the small intestinal ability to digest the nutrients, which can result in bloating, colic, and diarrhea. If this occurs, feeding cold milk may help limit large-volume ingestion. An acidified milk replacer is also available; this product is less likely to become rancid when left out for long periods of time during the warmer season.

Generally, a neonate that is too sick to stand is also unlikely to have an adequate suckle reflex. Bottle or syringe feeding is strongly discouraged when supplementing sick or recumbent neonates. These individuals often have a weak or absent suck, putting them at high risk for aspiration. Small soft nasogastric tubes (MILA International Erlanger, Ken.) that may be sutured in place for longer-term use are available for use in foals and have also been used in neonatal calves. Many of these tubes come with a guide wire, which helps stiffen the tube to make insertion easier. Before feeding, it is important to determine if the tube is in the stomach or abomasum. A radiograph can be helpful to identify the radiopaque strip within the tube. Alternatively, tubes can be detected by ultrasound or careful palpation of the esophagus during passage. Alternatively, calves can be fed using esophageal feeders to ensure milk is deposited in the abomasum and not the immature rumen. In neonatal small ruminants, red rubber catheters are often used for esophageal feeding.

When introducing a foal to nurse, it is often beneficial to milk the mare first and feed the foal via the nasogastric tube. This decreases the risk of aspiration due to large-volume let-down by the mare or extreme hunger by the foal. Auscultating the foal's trachea while nursing can help determine if aspiration is occurring. Bucket feeding allows the foal to nurse with its head down, decreasing the risk of aspiration. Once the foal is trained to the bucket, it can be hung in the stall, allowing them to drink at will. Clinicians should also remember to provide other foodstuffs, as a foal will begin mimicking their dam eating hay and concentrates within the first few days of life.

Enteral Feeds for Neonates

Natural species milk and colostrum are ideal enteral feeds for neonates. When mare's milk is limited, supplementing with goat's or cow's milk is generally recommended at least through the early neonatal period (first 2 weeks of life). Many neonatologists prefer goat's milk as a better replacement to mare's milk. Although comparison of the fat, protein, and calories content among goat, sheep, and cow milk does not seem to reveal any significant benefit of one over the other, the major whey protein in both goat and mare milk is β-lactoglobulin, while the major whey protein in cow's milk is α-lactoglobulin.

If necessary, gradual transition from one type of milk or replacer is recommended, as rapid changes may result in colic, diarrhea, or constipation. If constipation develops, a small amount of mineral oil (5 mL) may be added to tube-fed meals. The fluid characteristics of mineral oil make it unsafe to administer orally, as it will not stimulate a cough reflex if aspirated. Even a small amount of aspirated mineral oil can result in significant pulmonary consolidation and dysfunction.

Unlike calves, long-term supplementation of a foal typically requires switching to milk replacers due to cost and accessibility issues of whole milk products. If using a milk replacer, it is strongly recommended to choose a replacer developed for foals rather than one designed for all large animal species to ensure adequate protein, fat, and carbohydrate concentrations. Replacers that contain whey protein are recommended over other protein sources due to digestibility concerns. In contrast to milk replacers, milk is high in potassium and low in sodium and chloride. When feeding milk replacers, it is important to provide a freshwater source to prevent hypernatremia.

Key Points

- Enteral nutrition provides intraluminal nutrition to the gastrointestinal tract and has been shown to improve gut barrier integrity, gut mass, protein content, motility, and function.
- Enteral feeding needs to be increased gradually with careful assessment of gastric residuals before bolus feeding.
- Enteral nutrition can be tailored using complete feeds or specific components diets.

Parenteral Nutrition

PN' major advantages are its abilities to supply nutrition when the enteral route is unavailable and tailor the types of nutrition provided for each individual animal. PN has been shown to decrease weight loss, particularly lean body mass, and improve wound healing, immune function, and outcome in human and animal studies when the enteral route cannot be used.[49] PN can be used to provide partial nutritional support or total nutritional support. In the adult horse it is most commonly used to supply partial nutrition when oral intake is insufficient or the oral route cannot be used. Horses with proximal enteritis, colitis, postoperative ileus, esophageal lacerations, or obstructions can receive nutritional support until resolution of the underlying problem allows reinstitution of adequate enteral feeding (1.5% body weight or ~23 kcal/kg day). Recumbent or dysphagic animals at risk for aspiration pneumonia and individuals with preexisting protein calorie malnutrition; increased energy demands (late gestation, early lactation, and young, growing animals); metabolic derangements resulting in hyperlipemia; and completely anorexic animals or those with prolonged decreased feed consumption (<25% maintenance for several days) should also be considered as candidates for partial or total PN.

There has been a significant amount of information published in recent years evaluating the pros and cons of PN. Much of the impetus has come from the desire to determine if there is a negative effect of relying on PN as the sole nutritional source. Although the results of studies vary, it appears that the major disadvantage lies in the loss of the beneficial effect of enteral nutrition on maintaining gut function and mass. PN is more expensive than enteral feeding in terms of supplies and time. In humans, the parenteral route may also be associated with an increased risk of infection, although results are contradictory.[49,50] Published reports of PN use in horses primarily consist of case reports with little information evaluating the benefits and risks of PN.[51-55]

In a retrospective study examining 79 equine cases of gastrointestinal disease treated with PN, the most common complication was hyperglycemia.[46] Four horses developed thrombophlebitis. Because no comparison was made between PN-treated individuals and controls, the authors were unable to determine if PN affected outcome.[46]

Dextrose

The simplest and least expensive form of PN is the supplementation of intravenous crystalloid fluids with dextrose. This represents a short-term solution for boosting caloric intake and preventing secondary metabolic derangements when a rapid return to normal feed consumption is anticipated. Dextrose can be added to make a final solution with a concentration that ranges from 2.5% to 5%. If the fluid is infused at a rate to meet maintenance fluid requirements (1 to 2 mL/kg/h), the patient's renal threshold of glucose (10 mmol/L or 180 dL for adult horses; 121 mmol/L or 216 dL for foals) will usually not be exceeded. The energy provided may be calculated on

the basis of 3.4 kcal/g of dextrose. A 450-kg horse treated with fluids supplemented with 2.5% dextrose and infused at a rate of 1 L/h (24 L/day) will receive 2040 kcal from the dextrose (close to 20% of the patient's DE_{rest}). Although protein is not provided with the dextrose therapy, the supplemental energy will blunt the catabolism of endogenous lipid and protein stores. Patients treated with dextrose should have their blood glucose monitored closely.

Complex Parenteral Nutrition

Depending on the desired goals and duration of supplementation, solutions containing various amounts of carbohydrate, amino acids, lipids, vitamins, electrolytes, and minerals can be formulated. Carbohydrates and lipids are used to meet the patient's energy needs, minimizing breakdown of endogenous protein for energy and allowing the administered amino acids to be used for wound healing and immune functions. Carbohydrate is commonly provided using 50% dextrose solutions. These solutions are hyperosmolar (2525 mOsm/L) and should be infused through a central line or large peripheral vein (jugular vein) to reduce the risk of thrombophlebitis. Dextrose provides 3.4 kcal/g or 170 kcal per 100 mL (50 g) of 50% dextrose.

Lipids are recommended to provide the remainder of nonprotein calories. Lipids are isotonic and can be infused separately in a peripheral vein or combined with other components. Lipids come in 10% and 20% emulsion and are composed principally of safflower and soybean oil, egg yolk phospholipids, and glycerin. Lipids should be added to the solution last to avoid destabilization of the emulsion due to an acidic environment. Some clinicians mix PN solutions in isotonic crystalloids to provide both fluid support and nutritional support. When doing so, it is best to separate the lipid component, as the presence of divalent cations can result in destabilization of the emulsion. Some clinicians are reluctant to use lipids in PN solutions due to the costs and risks associated with destabilization, as well as metabolic consequences that may develop (hyperlipemia, fatty liver, lipid thromboembolism). It can be difficult to provide total energy requirements without lipids, especially in insulin-resistant patients or patients with systemic inflammation, as these individuals appear to have a harder time regulating blood glucose. Lipids are calorie dense, containing 9 to 11 kcal/g. Although recommendations vary, lipids can be added to provide 30% to 60% of the nonprotein calories in a PN solution. The addition of lipids to PN is beneficial in patients with persistent hyperglycemia or hypercapnia, reducing the dependency on glucose as the principal energy source. Lipids should be avoided in horses with known hyperlipemia or in horses suspected of being lipid intolerant. Lipid intolerance can be seen in patients with systemic inflammation, sepsis, or underlying metabolic derangements, and triglyceride levels should be monitored regularly.

Amino acid preparations are available in several concentrations; 8.5% and 10% solutions are most commonly used in veterinary medicine. They are approximately twice the osmolarity of plasma and are acidic. Amino acid preparations should be mixed with dextrose before adding the lipid component to prevent destabilization of the lipid emulsion. Solutions containing both essential and conditionally essential amino acids, including glutamic acid, would seem to be preferable, though no data on the benefits of conditionally essential amino acids in horses are available. As already discussed, while resting energy requirements should be used when calculating caloric needs for adult animals, protein requirements should be determined using maintenance requirements of approximately 0.7 g/kg/day or higher. Although there are no clear data on the benefits of a higher protein supplementation, current recommendations in humans are to provide protein in excess of the normal daily requirement because of the higher protein catabolism seen with injury or inflammation. The ratio of nonprotein calories to nitrogen (in the final solution) is recommended to be 120 to 150:1 in healthy humans and 80 to 90:1 in acutely ill humans to limit the use of protein as an energy source. The ideal ratio in equids is unknown; consequently, human targets are typically used. This can be calculated using the conversion of 1 g nitrogen to 6.2 g protein. Protein provides ~4 kcal of energy/g protein, and 100 mL (10 g) of 10% amino acid solution contain 40 kcal.

Additional components may be added to PN or given separately including electrolyte solutions and vitamin and mineral supplements. The vitamin and mineral requirements of the critically ill horse are unknown, but published recommendations for healthy horses (NRC 2007) can be used when determining feeding rates. Multivitamin supplements for humans are available and can be added directly to PN solutions. If possible, however, it is best to limit the amount of additives to PN solutions to avoid contamination or lipid destabilization. On the basis of information in humans, it is strongly recommended to supplement water-soluble B vitamins daily as deficiencies can exacerbate problems associated with refeeding.[56] Though horses and ruminants synthesize some of the B vitamins in their gastrointestinal tract, chronic inappetence or disruption of the normal flora may affect synthesis. Parenteral B vitamins are light sensitive; when added to crystalloids, the fluids need to be protected from sunlight. Some vitamins are best given orally (vitamins C and E) or added to separate crystalloid solutions (B vitamins). Vitamin C is also produced by the horse, and a need for supplementation has not been documented. However, some authors recommend oral supplementation in sick horses with recommendations of 10 to 20 g/horse/day.[57] Fat-soluble vitamins such as E, D, and A are stored in body tissue and generally do not need daily supplementation. However, the antioxidant benefits of vitamin E may make it worth providing oral supplementation early in illness. Doses of oral vitamin E vary significantly from 500 international units (IU)/horse/day to 40 IU/kg/day. Minerals, if required, are best supplemented in separate crystalloid solutions because divalent cations may destabilize lipid emulsions. Although trace mineral requirements for sick animals are not known, trace mineral supplementation is rarely performed except in patients receiving PN as their sole nutritional source for prolonged periods (>7 days). See Table 50.6 for a PN formulation for adult horses.

Parenteral Nutrition in Ruminants

Because of cost, use of PN is usually limited to calves, and little information exists on the use of PN in the adult bovine or ovine and caprine species.

Parenteral Nutrition for Foals and Calves

Because of their poor energy stores, early nutritional supplementation is critical in inappetant neonates. A dextrose infusion

TABLE 50.6

Parenteral Nutrition Formulation for Adult Horses

Ingredient	Dosage Rate	Volume/Day (450-kg Horse)
50% Dextrose	2.8 g/kg/day	2500 mL
10% Amino acids[a]	1.3 g/kg/day	6000 mL
10% Lipid[b]	0.8 g/kg/day	3500 mL

Ratio of dextrose–amino acids–to-lipid is 1:2.4:1.4.

VetBooks.ir

TABLE 50.7

Parenteral Nutrition Formulation for Foals (50 kg)

Ingredient	Dosage Rate	Volume/Day (50-kg Foal)
50% Dextrose	8.7 g/kg/day	870 mL
10% Amino acids	3.0 g/kg/day	1500 mL
10% Lipid	1 g/kg/day	500 mL

can be instituted initially while determining the health and function of the gastrointestinal tract. The placenta is reported to supply approximately 4 to 8 mg/kg min of glucose (~25% to 50% DE_r), and this is a useful target when providing short-term parenteral support with dextrose.[58] This would equate to 4 to 8 mL of a 5% dextrose solution per minute. Glucose infusion alone is inadequate as a long-term nutritional source; therefore more complete PN is needed for prolonged intolerance to enteral feeding.

The initial target energy intake for a critically ill neonatal foal or calf is 40 to 50 mg/kg. Hypertriglyceridemia (>200 mg/dL) has been associated with higher mortality in neonatal foals.[46] To limit complications, lipid calories should comprise less than 50% of the nonprotein calories in a PN formulation.

A PN formulation designed with 8.7, 3.0, and 1 g of dextrose, amino acid, and lipid, respectively, per kilogram body weight (BW) per day provides a total energy of 50 kcal/kg BW/day, a calorie-to-nitrogen ratio of 104:1, and an osmolarity of 1260 mOsm/L (Table 50.7). The PN formulation contains 21% calories from protein, 20% calories from lipid, and 59% calories from dextrose, with lipid comprising 25% of the nonprotein calories. If the foal or calf tolerates the full infusion rate, more calories can be added from all ingredients to achieve a recipe that provides 70 to 100 kcal/kg BW/day. An anabolic state can be achieved solely with PN therapy, but because enteral feeding is the desired goal, EN or oral milk consumption should begin as soon as possible. Changes in the rate of infusion and the PN formulation should be made to prevent hyperglycemia, but insulin can be administered if necessary to maintain blood glucose in a normal range.

The most common indication for the use of PN in calves is diarrhea, particularly in chronic cases accompanied by weight loss.[59] In such cases, if sufficient milk is fed to meet the calf's nutritional needs, the diarrhea is often exacerbated and PN allows the quantity of milk to be reduced without compromising the nutritional status of the patient. The PN regimen provided for foals in Table 50.7 would also be suitable for calves. However, because amino acids and lipids are the most expensive components of PN, a modified formula based on a 10:2:1 glucose-to–amino acid–lipid ratio has been used with success.[26] For a 50-kg calf, this would allow the quantity of milk to be reduced without compromising the nutritional status of the patient. B vitamin or multivitamin products may be added to the formula (≈1 mL of supplement/L PN), but trace minerals are not usually necessary for the short-term administration that is most common in calves.

Preparation and Administration of Parenteral Nutrition (Box 50.1)

Preparation of PN should be performed under a laminar flow hood (or a clean surface away from drafts or excessive dust) using aseptic techniques. Lipids should be added last to prevent destabilization of the emulsion in acidic amino acid solutions. Parenteral solutions are an excellent media for growth of bacteria and ideally should be used within 24 hours of preparation. Before use, they should be kept in a dark, cool area away from direct sunlight to minimize degradation and loss of vitamins (when these have been added to the solution). Over time, lipid emulsions will destabilize and oxidize, so they should not be stored for prolonged periods. The shelf life of a lipid solution will vary depending on the type of lipids and size of the emulsion, so manufacturers' recommendations should be used when determining shelf life. Because PN solutions are hyperosmolar, delivery through a central venous or jugular catheter is recommended. Because of the increased risk of sepsis associated with parenteral feeding, a separate catheter or portal should be designated for PN only. In the authors' clinic, a 14-gauge double-lumen catheter (Arrow Catheter, Reading, Pa.) is used with one port designated for administration of PN. Catheter placement and line maintenance should be performed using strict aseptic technique, and it is currently recommended that all lines be changed daily and that connections should not be broken after changes. Administration of PN solutions should not be stopped suddenly; if the animal needs to be moved, it is best to continue administration during the transfer. Gradual introduction of PN is recommended to decrease the risk of complications. It is recommended to use an intravenous infusion pump to ensure that the rate of infusion is consistent. We generally start with an infusion rate targeting approximately 25% of the daily requirement. The most common complication associated with PN is hyperglycemia, and blood glucose concentrations should be determined before increasing the rate of infusion. If blood glucose levels are within reference ranges, then the rate can be increased by an additional 25% every 4 to 8 hours. In the authors' experience most patients will develop mild hyperglycemia that corrects without treatment. Patients with persistent hyperglycemia may require insulin infusions to control the hyperglycemia and allow continued infusion.

BOX 50.1

Instructions for Compounding a Parenteral Nutrition Solution

1. Compound the solution in a laminar flow hood, if available. Use a clean room in the hospital if a laminar flow hood is not available.
2. Clean the preparation area well, using alcohol as a final preparation on the counter.
3. Wear a gown, mask, and sterile gloves when compounding the parenteral nutrition (PN) solution.
4. Wipe off all injection sites and infusion ports with alcohol before connecting the infusion lines.
5. Use a new transfer set for each PN ingredient.
6. Add the dextrose and amino acid solution to the compounding bag or container. Mix gently.
7. Add the lipid solution *after* the dextrose and amino acid solutions have been mixed together.
8. Gently swirl the solution to mix the ingredients.
9. Add any vitamin or mineral supplements to the solution *after* the macronutrients (dextrose, amino acid, lipid) have been added. Ensure that there are no incompatibilities with the supplemental additives.
10. The PN formulation can be stored in the refrigerator for 24 hours, followed by 24 hours of storage at room temperature. Shield the solution from sunlight.

Complications Associated With Parenteral Nutrition

Hyperglycemia both at admission and during hospitalization has been associated with an increased risk of complications including infections and renal failure, longer hospital stays, and reduced survival in humans and horses with critical illness or injury.[60,61] In a landmark prospective, randomized, controlled

VetBooks.ir

clinical trial of humans admitted to the ICU, tight glycemic control using intensive insulin therapy during hospitalization was associated with a significant improvement in morbidity and mortality compared with the more traditional, less stringent glycemic control.[62] Tight glycemic control (maintained between 80 and 110 mg/dL compared with 180 to 200 mg/dL) decreased the incidence of infections, acute renal failure, and days of mechanical ventilation and improved neurologic outcome in brain injury patients.[63] Additional studies using less stringent glucose control have found similar results.[64,65] As previously mentioned, hepatic gluconeogenesis is upregulated during the acute phase of critical illness. Insulin resistance and loss of exercise-associated uptake of glucose, as well as the increased production of glucose, are thought to result in hyperglycemia. Normal cells downregulate glucose transporters during periods of hyperglycemia to protect against glucose toxicity.[66] During inflammation this protective response is lost, allowing glucose to enter the cell along a steep concentration gradient.[67,68] Elevated intracellular glucose concentrations have been associated with increased oxidative stress, mitochondrial dysfunction, and altered energy metabolism.[69] The use of insulin therapy to maintain blood glucose levels within the normal range has been shown to have the added benefit of correcting dyslipidemias.[70] Additional reported beneficial effects of maintaining euglycemia include improved immune function due to improved phagocytosis, decreased glycosylated nonfunctional immunoglobulin, and blunting of the catabolic process.[71-74]

While extrapolation to a different species with different underlying diseases should always be performed cautiously, it would seem prudent to try to maintain blood glucose concentrations within or close to normal range. It is unclear at this time if strict glycemic control is better than a less stringent control. In cases where hyperglycemia persists, the use of intensive insulin infusions is recommended to attempt to normalize the blood glucose concentration.

Lipid infusions have been associated with allergic reactions, hyperlipemia, alterations in liver function, and fat embolism. The risk of fat embolization is higher in larger droplet emulsions or in emulsions that have been stored too long and have begun to destabilize. Although solutions containing lipids are useful in providing additional calories, their use needs to be determined on a case-by-case basis. Lipids should be avoided in patients with a predisposition to or preexisting hyperlipemia or underlying liver dysfunction. Thrombocytopenia, coagulopathy, fat embolization, and alterations in cellular immunity are reported with lipid infusions. Triglyceride levels and platelet counts should be monitored regularly when lipids are added to PN solutions.

Additional complications reported with PN include hyperammonemia and elevations in serum urea nitrogen due to excess protein catabolism, hypercapnia due to excess carbohydrate metabolism, thrombophlebitis due to hypertonicity, pulmonary embolism (thought due to destabilized lipid emulsions), and sepsis.[46,51,75-77]

Monitoring

It is recommended to monitor blood glucose at least every 4 to 6 hours when starting PN and to adjust the rate to try to maintain blood glucose within or close to the established normal ranges. If significant hyperglycemia (>180 mg/dL) develops and persists for more than 2 to 4 hours, the infusion should be slowed or insulin infusion begun. If costs are a concern, blood values may be monitored less frequently once steady state has been achieved. In addition, daily assessment should include serum electrolytes (especially potassium and phosphorus), TCO_2, blood urea nitrogen, triglycerides (depending on species), and ammonia and liver function during the acclimation period. If possible, the patient should be weighed daily. Once a steady state has been reached, the frequency of blood monitoring can be decreased. The same approach should be used when discontinuing PN.

The most common reason for instituting PN is the unwillingness or inability of a patient to ingest feed. For patients with decreased appetite, palatable feeds should be offered even during PN therapy to try to stimulate appetite. Once a patient has begun to readily ingest and tolerate a reasonable amount of food (25% normal intake or more) and has a steady appetite, PN can be gradually discontinued. Decreasing the supplement by 25% every 4 to 8 hours is generally well tolerated. Frequent monitoring of blood glucose during withdrawal (every 4 hours) is warranted, particularly in foals due to the risk of transient hypoglycemia.

Key Points

- PN allows provision of nutritional support when the enteral route is unavailable.
- PN allows supplementation to be tailored to the individual animal.
- PN must be handled with strict aseptic technique and should be gradually introduced and discontinued to prevent metabolic consequences.

Conclusions

It is clear that nutritional support is an important adjunct to medical therapy in the sick, injured, or debilitated large animal patient. What is not clear is the optimal route, composition, or amounts of support. The enteral route should be chosen whenever possible to maximize the benefits to the gastrointestinal tract, as well as the patient as a whole. Complete or partial PN is most useful as a bridge during recovery and transition to enteral feeding in the horse. Although the exact caloric requirement for sick, debilitated animals is unknown, estimates are available to use as a target for nutritional supplementation. Research in humans and laboratory animals suggests that even a little nutritional support is beneficial, and the reader is encouraged to consider nutritional support, whether enteral or parenteral, in any anorexic, chronically debilitated, or sick large animal patient.

Genetic Disorders

ANGELA M. HUGHES and KARI J. EKENSTEDT, *Consulting Editors*

Inherited diseases and congenital defects are structural or functional abnormalities that may or may not be obvious at birth. There are a wide range of possible defects, from a single structural change (e.g., leg length) to the involvement of multiple organs or systems (e.g., storage diseases, chromosomal abnormalities), depending on the type and extent of toxic exposure during gestation or genetic mutation. It is important to identify animals with genetic or congenital disorders because of the economic and emotional impact on clients, but many disorders can be difficult to recognize and trace, particularly if they lead to embryonic or fetal death, abortion, dysmaturity, premature birth, or full-term stillbirth.

It is important to remember that not all congenital defects are genetic in origin, and making the distinction between conditions caused by an environmental factor or by a genetic cause will help clients make appropriate changes to prevent the disorder in the future. To determine the cause of a disorder, it is vital that each case be examined thoroughly. Each case should be subjected to a full, careful description of the disorder including a complete necropsy. The environment and management conditions should be investigated for potential causative agents, and all available genetic information for the affected animal(s) and unaffected herdmates should be collected including sex, birth date, and breed. Environmental teratogens affecting large animals include toxic plants, drugs, viruses, and physical agents (e.g., hyperthermia, irradiation). Although it may be difficult to identify inciting teratogens, analysis of affected herds will reveal patterns that follow seasonal or management changes or stressful events.

This chapter focuses on the essential genetic information that veterinarians require to inform their clients about genetic diseases, make breeding recommendations, and find information on diseases and traits with a genetic component.

Genetic Information

The basic blueprint for life in most organisms, the genetic material, is deoxyribonucleic acid (DNA). DNA is composed of two strands of *nucleotides:* adenine (A), thymine (T), guanine (G), and cytosine (C). These nucleotides, or bases, align to form complementary pairings such that A always pairs with T and G always pairs with C. These strands can be completely separated and replicated in preparation for cellular division. Alternatively, they can be temporarily partially separated and transcribed into ribonucleic acid (RNA), which is then translated into functional proteins.

The DNA sequence of a mammalian genome is divided into autosomes and a pair of sex chromosomes, X and Y. Each chromosome contains a variety of genes and "filler" DNA that does not code for proteins but may determine where and to what degree each gene is expressed. Genes on each chromosome code for the various structural and enzymatic proteins required for life. One set of chromosomes, and thus one set of genes, is inherited from each parent. As a result, a mammal generally has two copies, or alleles, of any given gene. Simple traits or diseases involving these genes can be inherited in dominant or recessive patterns and involve the autosomes or sex chromosomes. Not all traits or inherited diseases are simple; many involve multiple genes and interactions between genes and the environment, which can unfortunately make it difficult to diagnose and understand a complex disease or trait.

Recessive Inheritance

Traits or diseases with a recessive mode of inheritance require two affected alleles of the gene to express that trait or disease. These conditions can be *autosomal,* involving genes on the autosomes, or *sex-linked,* caused by genes on either the X or Y chromosome. Generally, autosomal recessive traits or diseases are caused by loss-of-function mutations in which the gene product has decreased ability or no ability to perform its original function. When an animal inherits the affected allele from both parents, it is *homozygous* for the affected alleles and is unable to make functionally normal copies of that specific protein. *Heterozygous* individuals inherit only one copy of the affected allele, and they have a "backup" copy of the normal or wild-type allele to provide the functional protein. These heterozygous individuals are carriers of the trait or disease allele and can produce affected offspring if bred to another heterozygous or homozygous affected individual.

The hallmarks of autosomal recessive traits include 1) all offspring of two affected parents are affected, 2) approximately equal numbers of males and females are affected, and 3) unaffected carrier parents can produce affected offspring, and thus the trait or disease can skip generations. In addition, mating an affected individual to a noncarrier (homozygous normal) produces only offspring that appear normal but carry the affected allele. Breeding two carrier individuals results in approximately 25% normal, 50% carrier, and 25% affected offspring.

An example of an autosomal recessive trait is spider lamb syndrome, or hereditary chondrodysplasia. Lambs affected with

VetBooks.ir

this syndrome display several skeletal abnormalities including disproportionately long "spider" legs, curvature of the spine, facial deformities, rib and sternum deformities, lack of body fat, and muscular atrophy. The causative mutation is a single base-pair substitution, from a T to an A, altering a highly conserved and nonpolar valine amino acid to a polar glutamate in the critical tyrosine kinase II region of the fibroblast growth factor receptor 3 *(FGFR-3)* gene. This prevents the receptor from functioning to limit endochondral ossification and thus bone growth.[1] Genetic testing for the causative mutation has helped limit the prevalence of affected lambs; however, they are still occasionally observed, particularly where genetic testing has not been routinely used.[2]

Dominant Inheritance

Traits or diseases with a dominant mode of inheritance only require one affected allele to express the trait or disease, also known as the affected *phenotype*, and there is no distinguishable difference in the affected phenotype of a heterozygote and homozygote (homozygous for the affected allele). Again, the genes that are responsible for these traits or diseases can be on the autosomes or sex chromosomes. Dominant traits or diseases may be caused by gain-of-function mutations that enable the mutant protein to have an altered structure or function. Alternatively, a single, functional copy of a gene may not be enough to achieve normal levels of function ("haploinsufficiency"), resulting in the need for two normal copies of the gene to achieve a normal phenotype.

The main feature of an autosomal dominant trait or disorder is that affected individuals must have at least one affected parent (unless it is a new mutation), and thus the disorder does not skip generations. There is no sex bias with an autosomal dominant trait, and approximately half the offspring of a heterozygous affected individual bred to a normal individual will be affected. Breeding two heterozygous affected individuals will result in 75% affected (one third of which are homozygous and two thirds of which are heterozygous) and 25% normal offspring.

An example of an autosomal dominant disease is myotonia in goats. When startled or when making sudden, forceful movements, these goats can develop severe, acute muscle stiffness causing immobility and sometimes falling over, resulting in descriptions such as "fainting," "nervous," "stiff-legged," or "epileptic" goats. A single nucleotide change, from a G to a C, was identified that substituted a proline amino acid for a conserved alanine in the *CLCN1* gene, a chloride channel in the muscle fibers. This alteration in the chloride channel causes a diminished channel-open probability at voltages near the resting membrane potential of skeletal muscle, resulting in decreased chloride conductance and a significantly decreased electrical threshold for firing action potentials. Ultimately, this altered chloride channel allows conduction of repetitive impulses that result in sustained muscle fiber contraction and stiffness.[3] Far from selecting against this trait, these myotonic or "fainting" goats are purposely bred in some scenarios, where they are generally used for meat production; in fact, they are considered by some to be a breed in their own right.

Codominant Inheritance

The codominant (or semidominant) pattern of inheritance is distinguished by the fact that homozygotes can be differentiated from heterozygotes on the basis of clinical features. A well-known example of a codominant disease is hyperkalemic periodic paralysis (HYPP) in Quarter Horses. In HYPP the voltage-gated sodium channels in the muscle fibers have a mutation, specifically a C to G change that substitutes a leucine residue for a highly conserved phenylalanine, which increases sodium permeability across the skeletal muscle cell membrane. This causes increased muscle mass but also drooling, prolapse of the nictitating membrane ("third eyelid"), respiratory stridor, and weakness. Homozygous HYPP horses experience more frequent and severe clinical signs of disease than heterozygous horses.[4,5] Thus it is important to counsel breeders to avoid producing homozygous affected horses by not mating two heterozygous horses, since approximately 25% of their offspring would be expected to be homozygous affected and 50% would be heterozygous, while only 25% would be homozygous normal. Breeding a heterozygous horse to an unaffected horse will also result in approximately 50% of the offspring being heterozygous with no possibility of producing a homozygous affected foal. It should be pointed out that HYPP heterozygous horses are still considered affected; however, their disease is easier to manage environmentally (via nutrition and management practices) compared with HYPP homozygous–affected horses.

Sex-Linked Traits

Sex-linked traits and diseases involve genes located on either the X or Y chromosome. Males have only one copy each of the X and Y chromosomes, so they are *hemizygous*. As a result, males are particularly susceptible to sex-linked conditions because if they have a mutant allele for one of the genes on either of the sex chromosomes, they lack a "backup" copy of the normal allele and will express the affected phenotype. Females generally are less likely to demonstrate sex-linked recessive traits or diseases because they have two copies of the X chromosome. However, because of random X inactivation in each cell during fetal development, some females may express an affected phenotype. To achieve this, the X inactivation must be skewed such that the unaffected chromosome is inactivated more often than the X chromosome carrying the affected allele. In rare cases in which the inactivation is significantly skewed, females may be mildly to severely affected, depending on the level of expression for the affected chromosome.

Key characteristics of X-linked recessive traits are 1) the trait appears with much greater frequency in males than females, 2) half the sons of carrier females will be affected, 3) half the daughters of carrier females will be carriers, and 4) all of the daughters of affected males will be carriers. Hemophilia A, characterized by a strong tendency to bleed resulting from mutations in the clotting factor VIII gene on the X chromosome, is an example of an X-linked recessive disorder.

X-linked dominant traits are characterized by the following: 1) affected offspring must have at least one affected parent, 2) the disorder does not skip generations, and 3) an affected male mated to normal females will transmit the mutation to all his daughters but not to his sons.

Few Y-linked diseases are recognized in any mammalian species because of the small number of genes on the Y chromosome. In addition, the majority of the genes contained on the Y chromosome are involved in male fertility; thus mutations in these genes generally render the animal sterile, resulting in no transmission of the mutations to future generations.

Polygenic Traits

In addition to the single-gene traits and diseases, numerous conditions are the result of two or more genes and may also involve genetic and environmental interactions. In fact, entire biological pathways can be involved and interconnected, influenced by gene-gene interactions and/or gene-environment interactions; such pathways can turn genes, or groups of genes, on or off. Many of these polygenic traits are economically important. For example, a large number of genes may be contributing a small portion to the overall milk production of a dairy cow,[6] and endocrine fertility traits in dairy cattle are likewise driven by multiple genetic loci.[7] In beef cattle, at least eight genes have been significantly associated with stature and thus the physiology of growth.[8] Other highly polygenic beef cattle traits include carcass and meat quality.[9]

VetBooks.ir

Now that the major large animal species have had their genomes sequenced, cattle and sheep livestock associations and producers are increasingly using whole-genome approaches for genetic evaluation, in an effort to tackle polygenic traits, as well as overall genetic value. For example, dairy cattle geneticists are now using single nucleotide polymorphism (SNP) markers spanning the entire genome, combined with progeny test data, in order to predict genetic merit for polygenic traits for any animal. This can be done before the animal produces any offspring. The swine industry is also using genome-wide data; however, much of these data are proprietary to specific corporations, so they may be difficult to access.

Fueled by decreasing costs, whole-genome sequencing is now becoming broadly available; this allows identification of additional forms of genetic variation such as copy number variations and short insertions and deletions. With data now consisting of entire genomes, more accurate breeding values can be attained, a better biological understanding of the genome can be achieved,[10] and areas of the genome that impact production—even if the physiology is unknown—can be taken into consideration.

Teasing out the details of a complex polygenic system, such as assigning a specific gene and a measure of its contribution to a polygenic trait like milk production or meat quality, is difficult; however, research is ongoing to identify the exact genes involved and the role each gene plays for many economically important traits and diseases. Thus it is anticipated that our understanding of polygenic traits in large animals will continue to increase in the next few years. Companies are already beginning to explore the value of genetic predictions for disease susceptibility and offer products that assist in genetic selection of, for example, dairy heifers, based on various health and disease traits. The full utility of such products is still being evaluated.

Penetrance and Expressivity

For many simple traits, there is an obvious difference between the two phenotypes that can be translated to the alleles involved, or *genotype*, with 100% certainty. A good example of this is albinism, which is considered to be 100% penetrant, with *penetrance* defined as the percentage of individuals within a given genotype that actually show the phenotype associated with that genotype. Influences such as modifying genes or environmental interactions can alter the expression of certain genes such that the exact genotype is not expressed in the outward phenotype. Alternatively, the function of a gene may be subtle, making it difficult to measure distinctions adequately between genotypes. Genotypes that may not be expressed in every individual are considered to be "incompletely penetrant."

Another measure of genetic expression is the concept of *expressivity*. Modifier genes and environmental influences can affect the degree to which a genotype is expressed. For example, "variable expressivity" may be involved in pigment intensity when two individuals have the same genotype at the gene responsible for red pigmentation, but one has clearly darker red hairs than the other.

Incomplete penetrance and variable expressivity can greatly complicate analysis of genetic traits and diseases. These factors can also make breeding decisions more difficult because it may not be possible to classify an animal's genotype solely on the basis of a phenotype. In these more ambiguous cases, genetic testing will play a vital role in the unequivocal determination of genotypes, allowing appropriate and informed breeding decisions.

Chromosomal Abnormalities

Occasionally, problems arise during mitosis, meiosis, or fertilization, resulting in chromosomal, or *karyotype*, abnormalities such as a chromosome missing from a pair *(monosomy)* or an extra chromosome *(trisomy)*. Many karyotypic abnormalities have been identified in all large animal species, but not every chromosomal abnormality has been associated with an overt disease phenotype.[11,12] Some examples of common chromosomal abnormalities include the absence of an X chromosome, called *XO Turner syndrome*, which results in female infertility. An additional X chromosome in *XXY Klinefelter syndrome* causes underdeveloped males with poorly developed male sexual behavior. In addition to abnormal numbers of sex chromosomes, rare trisomies of autosomal chromosomes have been observed in mammals; however, monosomies of autosomes are generally not compatible with life in mammals. An additional chromosomal abnormality can occur when two chromosomes unite into a single large chromosome, called a *Robertsonian translocation*, or centric-fusion translocation, leading to reduced reproductive capacity in some species and early embryonic death in cattle. Because of possible chromosomal abnormalities, several countries have instituted mandatory karyotype examination of some breeding cattle. In addition, clinicians should consider karyotyping any animal that presents for reduced fertility or has multiple abnormalities.

Breeding Schemes

As a result of numerous advances in the field of genetics, the genetic causes of many diseases and traits are known and can be tested before using an animal in a breeding program. As research continues, more DNA-based tests are expected; however, clients may be interested in testing for a disease or trait that does not yet have a known genetic cause. For these situations, sires can be tested using breeding trials, as described in Table 51.1. For example, if a sire is bred to carrier females for a disease of concern, he would have to produce 10 normal offspring to ascertain that he is not a carrier with 95%

TABLE 51.1

Test Mating Schemes to Examine Males for Genetic Traits or Diseases at Various Confidence Levels

	0.05	0.01	0.001
Affected[a]	5	7	10
Normal carriers[a]	10	16	24
Sire's daughters[b]	22	35	52

[a]Tests for only one trait.

[b]Tests for all undesirable recessive traits.

confidence, 16 normal offspring to have 99% confidence, and 24 normal offspring to have 99.9% confidence that he is not a carrier for the disease of concern. The time required to complete test mating can be significantly shortened using superovulated affected females, insemination, and embryo transfer (two per recipient) followed by early cesarean section at 60 days and examination of the offspring for the genetic defect(s) of concern.

It has historically been common practice for artificial insemination (AI) studs to conduct such test matings for recessive genetic diseases. However, now that many of the deleterious mutations are known, genetic testing, rather than test mating, is the current preferred approach. As mentioned previously, the dairy and beef cattle, swine, and sheep industries are aggressively pursuing whole-genome genetic testing, often in combination with offspring data. Test matings are thus largely relegated to the arena of historical interest, although there may be unique situations or other species in which a test mating may still be a legitimate approach.

Positive and Negative Selection

Breeders can improve their breeding stock by selecting for or against specific traits and diseases. These processes are known as *positive* and *negative selection*, respectively. A breeder may choose to breed an animal because it has desirable genes or qualities (positive selection). Alternatively, someone may choose not to breed an animal that has been shown, through either genetic or breeding tests, to carry an undesirable trait or disease (negative selection). Ultimately, both scenarios will achieve the goal of improved breeding stock.

Recommendations for Breeding Programs

When a genetic disease has been identified, it is recommended that parentage be verified by DNA analysis and the extended pedigree be confirmed. In addition, a pathologist should make appropriate examinations of tissues for an accurate diagnosis, and a certified statement detailing the condition should be written by a veterinarian or other third-party witness. The final decision with regard to the status of a particular animal should be withheld until all reasonable doubt has been removed; for bulls, this is usually at least two thoroughly documented cases or a positive genetic test, if available. The AI organization and breed registry should be informed of the status of each animal because disease information is important in future breeding decisions. Many AI organizations list any undesirable recessive alleles in their advertising, and some also remove carrier animals from service (see Box 51.1 for a discussion on genetic counseling recommendations).

Depending on the value of the animal in question, a breeder may choose to remove the animal from the breeding program at the first sign of a potential genetic problem. In these cases, documentation of the abnormal conditions should still be conducted for completeness and for comparison with other cases that may be found in the future.

In some cases, a breed association may choose to formally regulate both testing and registration of individuals with genetic diseases. For example, the American Quarter Horse Association no longer registers Quarter Horse foals born on or after January 1, 2007 that test homozygous positive for HYPP (two affected alleles), and all foals coming from bloodlines known to carry the HYPP affected allele are required to be genetically tested for HYPP and to have genetic parentage verification testing performed.[14]

Caution should be exercised before drastic changes are made in breeding populations. Inbreeding and extreme narrowing of the gene pool, such as by excessive use of a small number of sires, are results that should be avoided. Maintaining diversity in the herd and overall breeding population is important in order to avoid inbreeding depression and the increase of recessive diseases. In some industries, such as swine, where crossbreeding is common, this is less of a concern. In other industries, such as dairy cattle, producers are increasing their utilization of crossbreeding over and above the historical standard. Most commercial AI studs and/or breed association mating programs in the dairy industry are now designed with an option to limit inbreeding, typically accomplished with simple pedigree analysis but increasingly using genomic data; however, the producer must choose to apply that option. Breed associations may eventually need to intervene by actively soliciting and providing incentives for outbred animals. Producers, as well as the commercial stud owners, must carefully balance the short-term gains that may come from inbreeding with the long-term consequences of the overall narrowing of the gene pool.

BOX 51.1

Genetic Counseling for Single-Gene Autosomal Recessive Diseases

From the standpoint of conserving as much genetic diversity as possible within the closed gene pool of registered purebred animals, regardless of species, it is recommended by veterinary geneticists to retain heterozygotes (carriers) of autosomal recessive diseases as breeding animals, assuming they are otherwise good breeding candidates and the disease has a known, genetically testable mutation. If the animal has many other desirable traits, the genes underlying those traits can still be retained in the gene pool by breeding the carrier individual only to homozygous normal (clear) animals for the recessive disease in question. All offspring will be either homozygous normal or, at worst, carriers; no affected offspring will be produced. All offspring should be genetically tested for the gene in question. Exceptional offspring (again, regardless of carrier status) should be retained and used for breeding. Only slowly, and over several generations, using genetic testing, should the carriers be removed from the gene pool. Consider the example of an autosomal recessive hydrocephalus in Friesian horses; this disorder has been associated with a nonsense mutation in *B3GALNT2*, where homozygotes for the affected allele exhibit hydrocephalus, while heterozygotes (carriers) are normal. The frequency of heterozygous individuals in the Friesian breed is ~17%.[13] Immediate removal of 17% of the gene pool, based on carrier status of this one gene, could create catastrophic new genetic bottlenecks. The recommendation in this scenario is to continue breeding heterozygotes, but only to homozygous-clear mates, therefore producing no foals with hydrocephalus but maintaining as much genetic diversity in the breed as possible. Ultimately, veterinary genetic counseling needs to consider which individuals should be bred and to whom they should be mated, keeping both short-term (individual offspring of this mating) and long-term (genetic health of the breed) perspectives. Finally, note that this recommendation is not appropriate in dominant genetic mutation scenarios; heterozygous individuals with dominant mutations are considered affected and typically should not be bred, depending on the severity of the condition.

Obtaining Genetic Information

Because of the ever-increasing wealth of genetic information, the most complete and current information can be found using online resources. There are now hundreds of recognized single-gene traits and diseases across all large animal species; descriptions of each one is beyond the scope of this chapter.

Recommended Websites for Large Animal Genetics

OMIA—Online Mendelian Inheritance in Animals: horse, cattle, sheep, goat, pig, various other species
http://omia.angis.org.au/

U.S. Department of Agriculture, Agriculture Research Service, Animal Genomics and Improvement Laboratory: dairy cattle, dairy goat
http://aipl.arsusda.gov/

Veterinary Genetics Laboratory at the University of California, Davis: horse, cattle, sheep, goat, pig, various other species
http://www.vgl.ucdavis.edu/services/index.php

Because it is difficult for the practitioner to be familiar with all of them, online resources become vital. It is recommended that clinicians use websites produced by reputable institutions to obtain the most accurate and referenced information available (Box 51.2). Alternatively, clinicians are encouraged to contact the Veterinary Genetics services available at many veterinary schools if they are unable to locate the information they require.

Genetic Tests for Large Animals

DANIKA L. BANNASCH, *Consulting Editor*
CARRIE J. FINNO

Genetic testing based on deoxyribonucleic acid (DNA) involves the analysis of an animal's DNA to determine its genotype for an inherited disorder, trait, or anonymous marker. Genetic testing can be used for positive or negative selection in a population, depending on whether it is being used to identify a disease (negative) or a trait (positive). Genetic testing can also be used for permanent individual identification and parentage determination. Many breed registries require parentage verification to ensure the accuracy of their pedigrees.

Using genetic testing results for selection requires an understanding of the mode of inheritance of the disease or trait. Most often, a genetic test will be performed for a recessive disorder to determine if an animal is a carrier. Carriers are asymptomatic but have the potential to produce diseased progeny. Because they have no outward manifestation of disease, a genetic test is extremely valuable for managing their breeding appropriately. Carrier animals can be bred to noncarriers if needed to retain valuable characteristics while not producing diseased offspring. In the case of positive selection for a trait of interest, carrier animals may have higher breeding values because they can produce a trait if bred to other carriers or to animals with the trait. Genetic tests may also be used for dominant disorders if the disease/trait has a late age of onset or if it is inherited in a codominant manner. DNA testing for traits that are controlled by more than one locus (polygenic) may also be used for selection for economically important traits. In these cases, one particular genotype may confer a slight advantage over another and therefore, in a large population, can have a significant effect on production.

Box 52.1 defines key genetic terms; see also Chapter 51.

Individual Identification and Parentage Testing

Researchers use genetic markers distributed along all the chromosomes as tools to identify regions associated with diseases or traits. One type of marker used for individual identification and parentage testing is composed of small nucleotide repeats and is called *microsatellite* markers or *short tandem repeats* (STRs). These markers have a feature that makes them extremely useful to geneticists; the markers have been chosen to be "polymorphic" (show differences) between individuals. In other words, individual animals will have different lengths of the nucleotide repeats for each of these markers. The high level of polymorphism of this type of marker makes them useful for "mapping" (identifying the chromosomal location of diseases and traits).

The microsatellite markers are assayed by polymerase chain reaction (PCR) amplification using fluorescent-labeled primers. Primers are short (20 base pairs), single-strand lengths of DNA that are complementary to a specific region of the genome. PCR is the amplification of a section of DNA contained between two primers designed to complement the unique sequence flanking the STR. The PCR products are then resolved by electrophoresis on the basis of their length. Markers with many different alleles are said to be polymorphic and would be a useful marker for individual identification or parentage. Because the markers show differences between individuals, a collection of these markers can be used as a form of identification of an animal. High statistical significance can be obtained with as few as 10 markers, depending on the species and breed. The DNA type of an animal will not change over its lifetime and can therefore be used as a form of permanent identification.

Many purebred registries require parentage verification for registration purposes. To accomplish parentage verification, a DNA sample must be available from both parents, as well as the offspring. DNA samples are taken in the form of hair, blood, or buccal swabs (depending on the species and registry) and submitted at the time registration is requested. Each animal inherits one copy of each marker from its sire and one copy from its dam, so the markers can also be used to verify parentage. The most useful marker has a high polymorphism rate because that type of marker will be most likely to show differences not only between the sire and the dam but also between the two copies (alleles) of the marker. A set of polymorphic markers (10 to 20) is used to verify parentage to ensure a high probability that the parentage is correct. Table 52.1 shows the allele sizes for a set of markers in a parentage case. For marker *A* the offspring inherited a 122 allele and a 126 allele. The 122 came from its dam, so the 126 came from the sire. Because sire 1 does not have a 126 allele, it has been excluded. In this example, sire 1 is excluded as the sire of the offspring and sire 2 is verified on the basis of the results for all three markers.

Genome Sequence

Whole-genome sequencing and genome assembly of large animal species was completed in the early 2000s (horse September 2007, cow October 2011, sheep February 2010, goat February

VetBooks.ir

2013). The whole-genome sequence of an organism provides the exact base pairs along each chromosome of the individual animal that was sequenced. This "assembly" of DNA sequence then becomes the reference assembly for each organization, and genetic variation is compared with that reference providing a frame of reference for all DNA sequencing. In the horse, a Thoroughbred mare (Twilight) was selected for sequencing because of her low heterozygosity rate (1/1380 base pairs). In 2010, a Quarter Horse mare underwent whole-genome sequencing and was aligned to Twilight.[1] In cattle, a single partially inbred Hereford cow was selected to contribute 6× whole-genome shotgun (WGS) reads and another 1.5× came from individual animals of the Holstein, Angus, Jersey, Limousin, Brahman, and Norwegian Red breeds for detection of single nucleotide polymorphisms (SNPs). Following sequencing of each species, over 20,000 protein-coding genes were annotated on the sequences by virtue of previously sequenced cDNAs and also by prediction software that compared known genome sequences in other species with newly sequenced genomes. Since these initial assemblies, revisions have occurred within species. These initial and updated annotated genome databases are publicly available (Table 52.2).

With the advent of whole-genome sequencing and assemblies, there has been a rapid expansion in the number of SNPs discovered in the genomes of large animal species. SNPs are single base pairs of DNA with differences between individuals. They generally have only two alleles and are therefore less informative than the STR markers mentioned earlier. They have distinct advantages, however, when it comes to ease of genotyping. Very large numbers of SNP markers can be genotyped for a fraction of the cost of microsatellite markers. SNPs are now considered the next generation of markers to conduct breed diversity and to map disease-causing traits. The availability of such a tool as an SNP chip facilitates rapid mapping of diseases to specific chromosomal regions and analysis of candidate genes. SNP arrays are currently available on many large animal species (Table 52.2) and are currently being used in mapping studies of various complex disorders. Haplotype structures are being identified across species with targeted resequencing and, most recently, whole-genome next-generation sequencing, of animals from different breeds.

In addition to genomic mapping, functional genomic tools have become more readily available and affordable to researchers. More recently, sequencing of the transcriptome, through technologies such as RNA-Seq, have allowed researchers to evaluate gene expression differences among tissues and between animals of different disease states.

Identifying Genetic Mutations

Initial genetic mutations in large animal species were discovered through the use of comparative genomics. Genes involved in a specific disease were targeted because of equivalent diseases in other species, namely humans. In the horse, the genetic mutations for many diseases that have genetic tests currently available, including hyperkalemic periodic paralysis (HYPP)[2] and severe combined immunodeficiency (SCID),[3] were uncovered by evaluating candidate genes that had been associated with similar diseases in humans (Table 52.3). With the sequencing and annotation of whole genome maps, other diseases were discovered through whole-genome linkage mapping (hereditary equine regional dermal asthenia [HERDA][4]), genome-wide association studies with microsatellites (Type I polysaccharide storage myopathy [PSSM][5]) and genome-wide association studies using SNP array technology (Lavender foal syndrome[6]).

A similar theme is evident in cattle. Initial genetic mutations were discovered based on sequencing of candidate genes known to cause similar disease in humans (bovine leukocyte adhesion deficiency [BLAD][7]). Later studies used microsatellite markers and performed linkage analysis (complex vertebral malformation[8]) and, most recently, the use of SNP-based genome-wide association studies has identified recessive defects (congenital muscular dystony types 1 and 2[9]). At the time of publication,

BOX 52.1

Definitions of Genetic Terms

Allele One of the variant forms of a gene at a particular locus, or location, on a chromosome.
Base pairs Two bases that form a "rung of the DNA ladder." A DNA nucleotide is made of a molecule of sugar, a molecule of phosphoric acid, and a molecule called a "base." The bases are the "letters" that spell out the genetic code. In DNA the code letters are A, T, G, and C, which stand for the chemicals adenine, thymine, guanine, and cytosine, respectively.
Genotype Genetic makeup, either at a single locus or at all loci.
Genome wide association study A study that uses genome-wide markers, typically microsatellites or single nucleotide polymorphisms (SNPs) to determine an association between a phenotype and region of particular chromosome.
Linked Association of genes and markers that lie near each other on a chromosome; linked genes and markers tend to be inherited together.
Locus Place on a chromosome where a specific gene is located; a type of "address" for the gene.
Marker Segment of DNA with an identifiable physical location on a chromosome, the inheritance of which can be followed. A marker can be a gene or some section of DNA with no known function. Also known as a *genetic marker.*
Microsatellite Repetitive stretches of short sequences of DNA used as genetic markers to track inheritance in families.
Phenotype Observable traits or characteristics of an animal (e.g., coat color, weight, presence or absence of a disease).
Recombination Genetic transmission process by which the combinations of alleles observed at different loci in two parental individuals become shuffled in offspring individuals.
Single nucleotide polymorphism (SNP) Differences in a single base pair of DNA (A, C, T, G) often used as genetic markers for linkage and association studies

[a]Considered a locus and not a gene.

there are 147 genetic tests available in cattle (Table 52.4). It is worth noting that the majority of genetic tests currently available are for diseases/traits that are inherited as autosomal recessive traits. With the current technologies available through SNP-association mapping and next-generation sequencing, we should expect to further our understanding of polygenic traits and diseases.

Disease Testing

Clinicians can use DNA testing in disease diagnosis or to determine an animal's potential for producing diseased progeny. Generally, disease diagnosis is based on clinical signs and other diagnostic tests, but occasionally DNA testing is used, in particular for later-onset diseases or diseases for which diagnosis by traditional methods is difficult or invasive. To offer a genetic test, the gene responsible must be known. Ideally, the actual mutation that causes the disease has been identified. Rather than knowing the exact gene or mutation, only a region of a chromosome may have been implicated in a particular disease. DNA tests can be divided into two categories: mutation tests and linked-marker or haplotype tests. *Mutation* tests are based on an actual mutation that causes disease, whereas the *linked-marker* or *haplotype* test is based on the region of the chromosome that is known to cause disease but not necessarily the actual mutation. Usually, haplotype tests are offered instead of a mutation test because the mutation has not yet been identified. With the current tools available in large animals, the identification of disease causing mutations is so efficient that marker-based tests are rarely used.

Mutations that cause disease appear in many different forms. A change of a single base pair from one base to another can cause a disease by changing an amino acid ("missense" mutation), truncating the amino acid chain ("nonsense" mutation), or altering expression or proper splicing. For example, missense mutations have been shown to cause lethal white foal syndrome in the American Paint horse.[10–12] Insertions or deletions of a single base pair (bp) can cause mutations in the coding sequence by altering the translational frame, which ultimately causes protein truncation. An 11-bp deletion in the myostatin gene causes a frameshift mutation and protein truncation in Belgian blue and Peidmontese cattle with the double-muscle phenotype.[13–15] Large deletions or insertions that remove hundreds and thousands of base pairs can also cause disease. For example, the polled intersexuality mutation in goats is caused by an 11.7-kilobase deletion that removes a regulatory element that controls the expression of two genes.[16] This endless array of possible changes in the DNA that result in disease makes each individual DNA-based genetic test different.

The basis for DNA testing is PCR. Primers can be designed specifically to amplify either the disease-causing allele or the normal allele. Alternatively, the PCR product can be digested with a restriction enzyme that cleaves the DNA at a particular sequence of bases. A restriction enzyme is chosen that shows a different cleavage pattern between the mutant and the normal version of the PCR product. Direct sequencing of a section of DNA can also be used to determine the animal's genotype. Many different methods are available to assay changes in DNA that lead to disease. Each company that offers a test may choose a different type of assay for the same mutation.

There are limits to all genetic testing. For mutation tests, the specific mutation being assayed is the only factor being evaluated. An animal may have a different mutation in that gene or a mutation in a different gene that causes the same phenotype (phenocopy). It is therefore correct to state that an animal has been "DNA tested negative" for this specific mutation rather than "DNA tested clear" of the disease. In addition, more complicated modes of inheritance do not provide a direct disease or trait prediction. For example, some loci have incomplete penetrance and not all animals with the affected genotype will get the disease or trait. Other genetic tests are for susceptibility loci and merely confer a disease risk.

No association or committee evaluates quality control of DNA tests that are available in animals. Most tests are published in the scientific literature not as tests but as articles describing the discovery of the mutation. Because some cases involve patent issues, some tests are offered before publication. Much of the research done to identify the mutations involved in the tests is performed at universities and funded by granting agencies that have both financial and intellectual interest in patenting the tests.

Tables 52.3, 52.4, 52.5, and 52.6 list available genetic tests for traits and diseases other than coat color in horses, cattle, and sheep and goats, respectively. Only tests published in peer-reviewed journals are listed. Additional tests available in cattle for various forms of the milk proteins also are not listed in Table 52.4. The breeds of cattle are not listed because rapid changes in testing mean that tests are always being validated for new breeds. It is therefore recommended that a search be performed for the availability of a test for a particular breed each time the need arises. Coat color genetic tests are listed in Table 52.7, with each particular species in which the genetic mutation has been identified referenced.

The diseases or traits that are tested can be divided into two categories: those that have straightforward Mendelian inheritance patterns (recessive, dominant, and sex-linked) and those that are more complicated because many genes are involved with conferring the phenotype (polygenic). *Quantitative trait loci* (QTL) are the genes that contribute to a polygenic disease. In cattle, a vast number of QTL have been placed in specific regions of chromosome for quantitative traits such as dairy form, milk production, and fertility.[17] Selection for these traits can be done with DNA testing (Table 52.4). Because so

	EDNRA (Goat)	Goat	243

many different QTL exist, however, selection can be challenging, and trade-offs need to be made.

Genetic testing relies on advances made in the field of genomics. Veterinarians and owners are fortunate that large animal species were chosen as economically important species for whole-genome sequencing. With the tools currently available, the number of disease-based or trait-based tests available in the future will markedly increase.

Immunologic Disorders

M. JULIA B. FELIPPE and GEORGE M. BARRINGTON, *Consulting Editors*

LAIS R.R. COSTA, ANGELA I. BORDIN, DEBRA C. SELLON, MELISSA T. HINES, DIANNE MCFARLANE, JILL R. JOHNSON, DAVID J. HURLEY, MUNASHE CHIGERWE, RANA BOZORGMANESH, BARRY J. BRADFORD, and JODI L. MCGILL

Equine Immunologic Disorders

Overview of Immunologic Disorders in Horses*

Lais R.R. Costa

The immune system is composed of primary or central organs (bone marrow and thymus) and secondary or peripheral organs (spleen, lymph nodes, and mucosa-associated lymphoid tissues). Immune cells of myeloid and lymphoid lineages are generated (produced and developed) in central organs, subsequently populating the peripheral organs where they carry out their functions of immunosurveillance and mounting immune responses to defend the body from microbial invasion. Many immune cells are not static; instead, they are constantly circulating, migrating into various tissues, and capable of performing their functions of immunnosurveillance, inflammation, and tissue repair in organs outside the immune system. Functionally, immune cells traditionally have been classified into two branches: innate and adaptive immune cells. Cells of the innate branch of the immune system mostly comprise cells of the myeloid lineages—including granulocytes (neutrophils, eosinophils, basophils, mast cells), monocytes and macrophages, dendritic cells (DCs)—and subsets of cells of the lymphoid lineage—including natural killer (NK) cells, plasmacytoid DCs, B1 cells, and gamma delta T cells. Cells of the adaptive branch of the immune system primarily comprise cells of the lymphoid lineages expressing antigen-specific receptors, including B lymphocytes, T lymphocytes (alpha beta T cells of either CD4 and CD8 subpopulations), and regulatory T cells. The various components of the immune system work in unison to bring about broad defense throughout the body. Detailed review of the cellular and molecular components of the immune system and the mechanisms involved in the immune response of horses can be found elsewhere.[1-3]

Normal Immune Response in Horses

The immune response results from an intricate network of innate mechanisms of resistance and complex adaptive immune defense. The innate immune mechanisms are the first line of defense and do not require previous exposure to the invader. Cell-associated molecules and soluble factors of the innate system are capable of recognizing a number of common microbial structures or patterns and respond quickly to an invasion by promoting inflammatory reaction and chemotactic stimuli for leukocyte trafficking, thus serving as the first immune barrier to invading organisms. Cells and soluble factors of the innate system also provide co-stimulatory signals and antigen presentation to cells of the adaptive lymphoid lineage. Once mounted, the adaptive host defense confers antigen-specific anamnestic response following the initial encounter with an antigen or invader. The adaptive immune response can recognize nearly an infinite array of antigenic determinants or epitopes, distinguishing self from those that are nonself. As well, the adaptive immunity has memory that leads to increased effectiveness upon antigenic reexposure. Thus the innate and adaptive mechanisms work together to identify and eliminate offending molecules and organisms that invade the body.

Innate recognition of invaders involves detection of alarm signals generated exogenously (invader patterns) or endogenously (patterns of damaged cells or tissue). Several cells of the innate immune system, including cells of the macrophage lineage, DCs, mast cells, neutrophils, NK cells, and gamma delta T cells, as well as B cells can recognize exogenous and endogenous alarm signals. Sentinel cells scattered throughout the body, especially at sites likely to be invaded (skin and mucosal surfaces), serve the primary function of invasion recognition. Exogenous invasion signals (called pathogen-associated molecular patterns [PAMPs]) and endogenous markers of danger (called damage-associated molecular patterns [DAMPs]) are recognized by pattern recognition receptors (PRRs) expressed on macrophages, DCs, and mast cells. Typically PAMPs are conserved structural molecules that are abundant and commonly found in different organisms. Examples of extracellular and intracellular PAMPs are depicted in Fig. 53.1, *A*. Alarmins, another name for DAMPs, may be of intracellular origin when released upon cell death or of extracellular origin when released upon damage of connective tissue (Fig. 53.1, *B*). PRRs are generally expressed on cell membranes (for recognition of extracellular pathogens) or within the cytosol and cytoplasmic vesicles (for recognition of intracellular pathogens), but some PRRs circulate in blood as soluble factors (Fig. 53.1, *C*). A number of families of PRRs have been identified, with Toll-like receptors (TLRs) being one of the most important families. The binding of a signature PAMP or DAMP to a particular PRR activates a signaling pathway that results in transcription and translation of specific genes characteristic of an appropriate response against the triggering pathogen. Some of the known PRRs and the corresponding PAMPs and DAMPs

*Contributions to previous editions by Melissa T. Hines, Jill R. Johnson, and Debra C. Sellon are acknowledged.

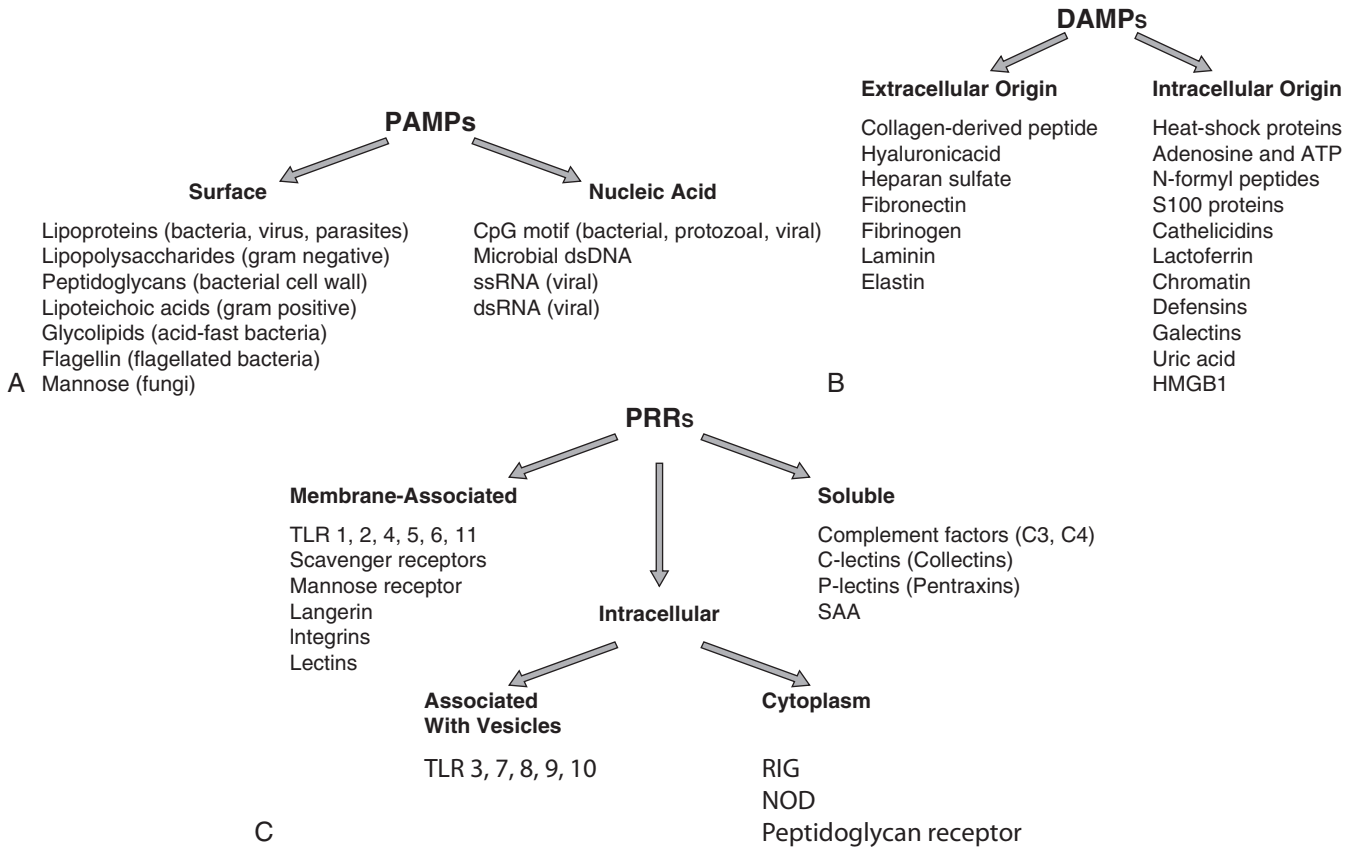

FIG. 53.1 **A,** Pathogen-associated molecular patterns *(PAMPs)* are exogenous invasion signals that comprise conserved and essential molecules abundantly and commonly found in many different organisms. *CpG*, Unmethylated cytosine-phosphate-guanine deoxynucleotide; *dsDNA*, double-stranded deoxyribonucleic acid; *dsRNA*, double-stranded ribonucleic acid; *ssRNA*, single-stranded ribonucleic acid. **B,** Danger-associated molecular patterns *(DAMPs)* are endogenous invasion signals that are released upon cell death or damage of connective tissue. *ATP*, Adenosine triphosphate; *HMGB1*, high mobility group box 1 protein. **C,** Pattern recognition receptors *(PRRs)* recognize pathogen-associated and damage-associated molecular patterns as signals of invasion and danger. *NOD*, Nucleotide-binding oligomerization domain-like receptor; *RIG*, retinoic acid–inducible gene 1 protein; *SAA*, serum amyloid A; *TLR*, Toll-like receptors.

they recognize and their signaling cascade are discussed in Chapter 32 and found elsewhere.[2,4-7]

Once alarm signals are recognized and cell signaling is activated, a cascade of events leads to development of an inflammatory reaction characterized by increased blood flow, increased vascular permeability, and leukocyte migration and activation. Inflammatory response is reviewed in detail in the Endotoxemia and Sepsis section in Chapter 32. Soluble mediators of the innate immune mechanisms include acute-phase proteins, proinflammatory cytokines, chemokines, vasoactive mediators, antimicrobial peptides, and protease systems (Table 53.1). Of note is the complement system activated upon specific immunologic recognition by antibodies (classical pathway), upon association of soluble factor C3b to microbial molecules (alternative pathway), or upon binding of soluble PRRs (lectins) to microbial carbohydrates. Complement activation leads to an amplifying cascade of sequential proteolytic cleavages, resulting in enhancement of phagocytosis (opsonization) and release of potent proinflammatory factors (C3a and C5a) that increase vascular permeability, exert chemoattraction of leucocytes, and amplify inflammation. The final product of the complement sequential proteolytic cleavage is the formation of lytic multiprotein complex, the terminal complement complex, or membrane attack complex.

Neutrophils and macrophages take the center stage in innate immunity, as they are capable of destruction of offending organisms by phagocytosis, oxidative burst activity, and production of lytic enzymes. Neutrophils (polymorphonuclear granulocytes) are abundant and the predominant circulating leukocyte in horses. They are produced in the bone marrow at a very high rate; circulate for a short time (average of 12 hours); exit the bloodstream into capillaries of the liver, spleen, lungs, and bone marrow; and eventually migrate into tissues where they undergo apoptosis. Apoptotic neutrophils are removed by macrophages. Upon inflammatory stimulation, circulating neutrophils are mobilized via diapedesis, and production of new neutrophils in the bone marrow is induced in order to fulfill the recruitment demands, as neutrophils are terminally differentiated and do not divide. Neutrophils have three major types of enzyme-rich granules in their cytosol. Upon stimulation, granules containing complex mixtures of bactericidal molecules are exocytosed. Release of enzymes mediates not only microbial destruction but also tissue damage. Once activated, neutrophils are the most abundant first line of phagocytes at sites of acute inflammation or infection.

Macrophages originate from monocytes and become specialized phagocytic cells resident in various tissues, collectively called the mononuclear phagocyte system (formerly known as the reticuloendothelial system). Macrophages are named according to the tissues they home: microglial cells in the brain, histiocytes in connective tissue, Kupffer cells in the liver, splenic macrophages in the spleen, alveolar macrophages in alveoli of the lungs, pulmonary intravascular macrophages in capillaries of the lungs, and osteoclasts in bones. The mononuclear phagocyte system plays a critical role in removal of bloodborne pathogens and particles and of parasitized and aged red blood cells (RBCs) from the bloodstream when the blood passes through capillary beds lined by macrophages in

TABLE 53.1

Examples of Soluble Mediators of the Innate Immune System and Their Main Functions

Categories of Mediators	Examples of Soluble Mediators	Functions
Acute-phase proteins	C-reactive protein	Opsonization, complement activation, soluble PRRs
	Serum amyloid A	Leukocyte recruitment and activation, soluble PRRs
	Cerulloplasmin	Iron sequester (limiting nutrients required by microorganisms)
	Ferritin	
	Fibrinogen	Hemostasis
	Complement C3b	Factors of complement, involved in activation of leukocytes, soluble PRRs
	Complement C4b	
Protease systems	Complement	Mediate inflammation, opsonization and MAC formation
	Kinins	Mediate inflammation
	Clotting and fibrinolysis proteins	Hemostasis
Host defense peptides and enzyme	Equine beta defensin	Antimicrobial (bacteriostatic and bactericidal) actions
	Equine neutrophil antimicrobial peptide	
	Equine cathelicidin	
	Lysozyme	
	Type I interferons (IFN-α, IFN-β)	Antiviral glycoproteins mainly produced by macrophages, DCs, and fibroblasts
Vasoactive mediators	Biogenic amines (histamine, serotonin)	Vascular smooth muscle relaxation (vasodilation) and endothelial cell contraction (leakage of plasma into tissues)
	Peptides (kinins)	
	Lipids (PGs, TX, PAF, LTRs)	
Proinflammatory cytokines and chemokines	CXCL8 (formerly known as IL-8)	Chemoattractants for cells of both innate and adaptive branches of the immune system
	CCL2 (formerly known as MCP-1)	
	IL-1	Mediate a variety of cellular responses such as chemotaxis of leukocytes, activation of leukocytes (including T and B cells), upregulation of iNOS and COX-2, and induction of fever
	IL-6	
	TNF-α	
Prostanoids	PGs	Mediate and modulate acute inflammation
	LTRs	
	PCs	
Lectins	P-lectins (pentraxin)	Bind microbial glycoproteins and polysaccharides
	S-lectins (galectins)	Mediate binding of leukocytes to extracellular matrix
	C-lectins (dectins)	Surface PRRs

COX, Cyclooxygenase; *DCs*, dendritic cells; *IFN*, interferon; *IL*, interleukin; *iNOS*, inducible nitric oxide synthase; *LTRs*, leukotrienes; *MAC*, membrane attack complex; *MCP1*, monocyte chemoattractant protein-1; *PAF*, platelet-activating factor; *PCs*, prostacyclins; *PGs*, prostaglandins; *PRRs*, pattern recognition receptors; *TNF*, tumor necrosis factor; *TX*, thromboxane.

the liver, spleen, and lungs. The mononuclear phagocyte system is also responsible for the removal of apoptotic cells in tissues. Macrophages also function as sentinel cells responsible for recognition of invaders, release of alarmins, and production of mediators that amplify inflammation and promote neutrophil recruitment. Macrophages serve as a backup to neutrophils, being slower responders with greater phagocytic and antimicrobial abilities, particularly effective against intracellular organisms. Macrophages have other critical immune functions, including antigen processing and presentation to T cells, secretion of cytokines that stimulate lymphocytes and shape the adaptive immunity, and modulation and suppression of the immune response. Hence subpopulations of macrophages exert different immunologic functions. For instance, after exposure to PAMPs and interferon gamma (IFN-γ), macrophages differentiate into M1 cells that are potent amplifiers of inflammation, secreting large quantities of proinflammatory cytokines and producing large amounts of lysosomal enzymes and mediators involved in oxidative burst. In contrast, differentiation into M2 cells occurs after exposure to interleukin (IL)-4, IL-10, and IL-13, leading to anti-inflammatory response characterized by modulation of inflammation and promotion of tissue repair.

DCs comprise a heterogeneous population of immune cells, originating from either myeloid or lymphoid precursors and exerting three main immune functions: serving as sentinel cells for the detection and recognition of invaders; providing antigen presentation to T cells, thus initiating the adaptive immune response; and guiding the type of adaptive response by regulating the milieu of co-stimulatory cytokines. Sentinel DCs are prominent at skin and mucosal surfaces. With respect to their origin, DCs are classified as DC1-type cells, which include myeloid-DC and Langerhans cells, originated from monocytes; or DC2-type cells, the plasmacytoid DCs that originate from lymphoid precursors. Myeloid DCs can convert to macrophages, and vice versa, and are considered part of the mononuclear phagocyte system. Plasmacytoid DCs are specialized in secreting type I interferons (IFN-α and IFN-β) upon viral infections, which activate lymphocytes and NK cells. DCs, along with macrophages, are the principal antigen-processing cells providing stimulation of T cells. Antigen processing and presentation in the context of major histocompatibility complex (MHC) classes I and II are critical functions linking the cells of the innate immune system and those of the adaptive immune system.

NK cells, gamma delta T cells, and B1 cells are lymphoid cells considered to be in the interface between innate and adaptive immunity. NK cells recognize cells under stress, including viral-infected or tumor cells that do not express antigenic epitopes in the context of MHC class I. Many viral-infected and tumor cells actively promote downregulation of MHC class I expression, which allows them to evade detection by cytotoxic T cells, also known as $CD8^+$ alpha beta T lymphocytes (see below). In the absence of MHC class I molecule expression, the NK cells become activated and secrete perforins

VetBooks.ir

and granzymes that destroy the target cells. Another mechanism used by NK cells to destroy viral-infected and tumor cells is called antibody-dependent cell-mediated cytotoxicity (ADCC), which involves binding of receptors for the gamma heavy chain of immunoglobulin G (IgG) (Fc-gamma receptor) on NK cells to IgG bound to viral-infected or tumor molecules expressed on target cells. Once activated, NK cells release cytotoxic granules, containing granzymes and pore-forming protein perforin, onto the surface of the target cell, causing programmed cell death of the target cell. Gamma delta T cells comprise a heterogeneous population of T cells that express gamma delta T-cell receptors (TCRs) and exert a wide range of immune functions, including response to heat shock proteins, cytokine production, activation independent of MHC, and participation in delayed hypersensitivity reaction. In horses, the role of gamma delta T cells has not been well described. A subpopulation of B cells known as B1 cells has been partially described in the horse, and they are abundant during fetal and neonatal periods; with age, these cells concentrate in the peritoneal cavity. Equine B1 cells have diverse immunoglobulin light chain repertoires but more frequently express a receptor that binds to phosphorylcholine commonly present on bacteria, helminths, apoptotic cell membranes, and oxidized lipids; B1 cells are known to become activated, differentiate, and secrete antibodies in a T cell–independent manner but their origin and function still need to be determined in the horse.[8,9]

The adaptive (antigen-specific, clonal) immune response involves two major populations of lymphocytes, B cells and T cells (Fig. 53.2, *A*). B lymphocytes populate germinal centers of the spleen and lymph nodes and comprise 15% to 30% of the peripheral blood lymphocytes. Alpha beta T lymphocytes populate the periarteriolar regions of the spleen and the paracortical regions of lymph nodes and comprise about 70% to 80% of peripheral blood lymphocytes of horses.

In the adaptive immune response, the highly specific antigen recognition is mediated by B-cell immunoglobulin receptors (BCRs) on B lymphocytes and by alpha beta T-cell receptors (TCRs) on T lymphocytes. The diversity of these receptors, both BCRs and TCRs, that allows recognition of an enormous number of antigenic epitopes is generated by several mechanisms, including DNA recombination of different gene segments V, D, and J encoding the antigen-binding region, addition of nucleotides during the recombination process (junctional diversity), and point hypermutations. Both BCRs and TCRs are heterodimers, which in turn provides yet another mechanism to increase antigen-recognition diversity.

The B lymphocytes produce and express antibodies or immunoglobulins (Igs) on the cell surface and are the precursors of plasma cells, which secrete Igs. B cells mediate humoral immunity, which classically provides defense against toxins, extracellular bacterial infections, parasites, and certain viral infections. There are several isotypes of Igs, classified according to their heavy chain constant region—IgA (alpha), IgD (delta), IgE (epsilon), IgG (gamma) and IgM (mu heavy chain)—and each isotype confers special functions.[10] For instance, dimeric IgA (joined by J chain) produced in mucosa-associated lymphoid tissues is the most abundant Ig isotype in body secretions, whereas monomeric IgA is present in serum; the main IgA functions are antigen neutralization and opsonization. IgD is a surface receptor of naive mature B cells, and its function is not well determined. IgE is present in small amounts in serum, and it is mostly found bound to Fc epsilon receptors on the surface of mast cells and basophils; when two or more IgE molecules bind to the antigen or allergen, it promotes cell degranulation. IgM is the original surface receptor of developing B cells and is present in naive and some activated and memory B cells; when secreted by plasma cells, IgM circulates as pentamer, and it promotes antigen neutralization and complement activation. IgG is the main Ig isotype in plasma and serum; IgG's main functions are neutralization and opsonization, and some subclasses promote complement activation. The characteristics and immunologic functions of the equine Ig isotypes and subclasses are summarized in Table 53.2.[11-15] Besides antibody production, B cells function

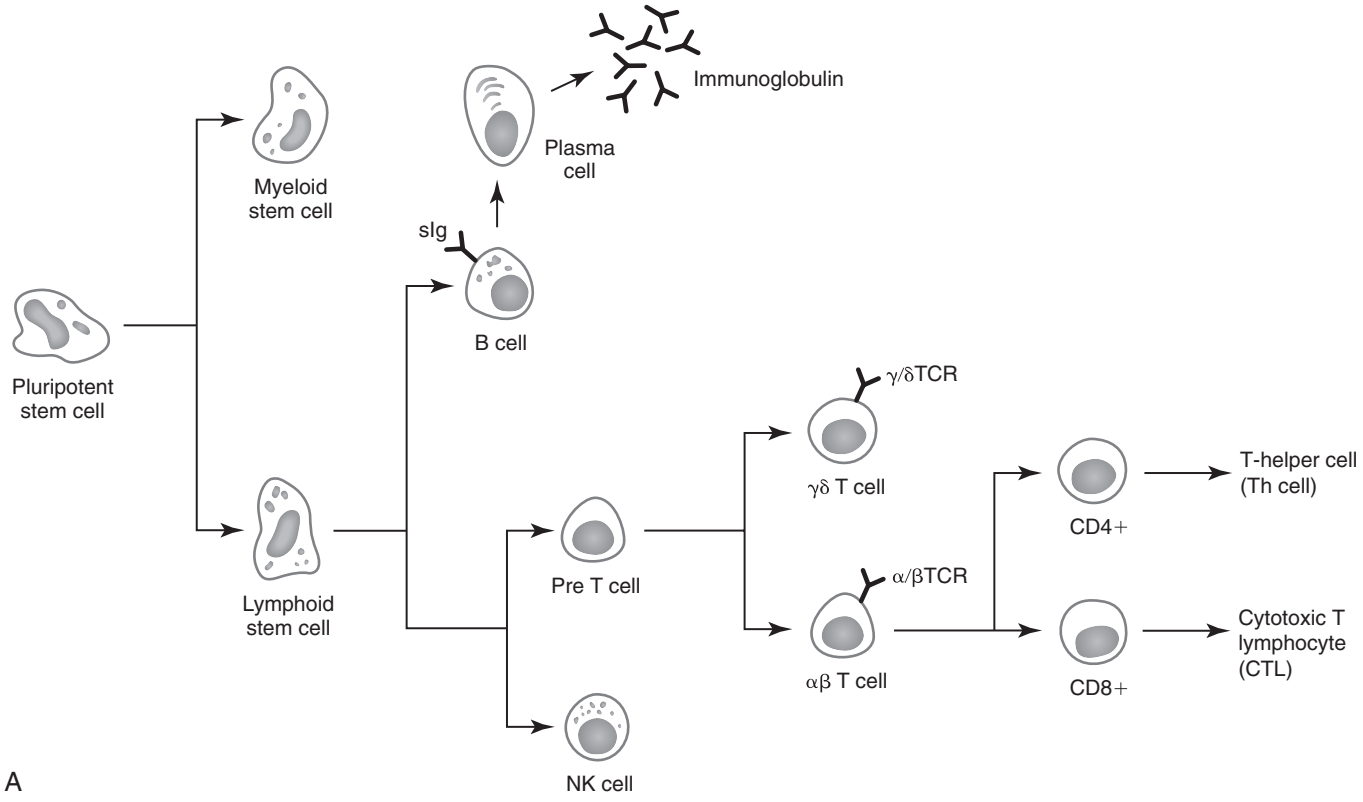

FIG. 53.2 **A,** Ontogeny of the lymphoid cell lineage. *NK cell,* Natural killer cell; *sIg,* surface immunoglobulin; *TCR,* T-cell receptor.

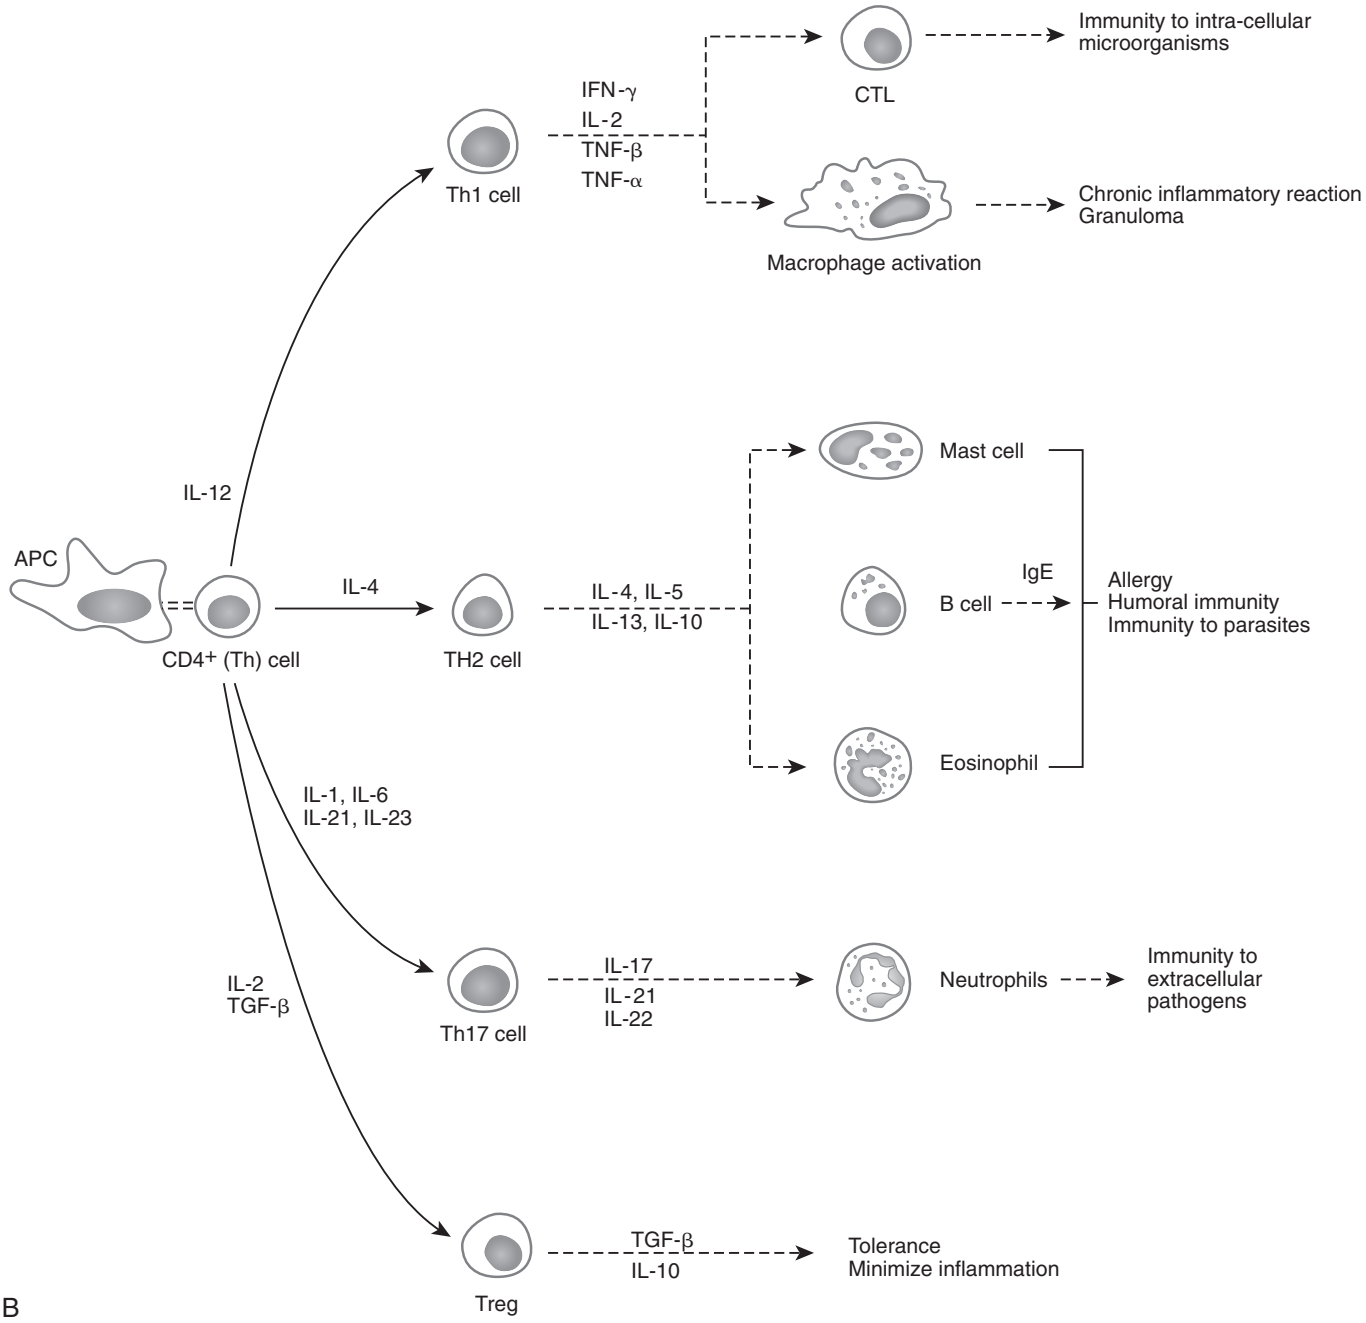

FIG. 53.2, cont'd **B,** Simplified functional differentiation of T-helper *(Th)* cells. CD4+ Th cells can be divided into subsets of Th cells based on their cytokine profile. Antigen-presenting cell *(APC)* interaction with Th cells via antigen presentation, co-stimulatory molecules, and cytokine milieu leads to the functional differentiation of subsets of Th cells. The cytokine milieu by APCs that leads to the functional differentiation of individual Th cells is listed. The known roles of the various functional subtypes of Th cells are also listed. *CTL*, Cytotoxic T cell; *IFN*, interferon; *Ig*, immunoglobulin; *IL*, interleukin; *TGF*, transforming growth factor; *TNF*, tumor necrosis factor; *Treg*, regulatory T cell;

as important antigen-presenting cells (APCs) by recognizing, internalizing, processing, and finally presenting antigens in the context of MHC class II to T cells. A less appreciated function of subsets of B cells is the production of cytokines. Subsets of B cells are now recognized as regulators of the immune responses during inflammation and autoimmunity.

T lymphocytes expressing alpha beta TCRs orchestrate the adaptive immune responses and provide cell-mediated immunity for protection against fungal, protozoal, intracellular bacterial, and viral infections. Unlike B lymphocytes, alpha beta T lymphocytes only recognize antigen fragments associated with the MHC molecule. The alpha beta T lymphocytes are categorized according to the expression of cluster of differentiation (CD) as CD4 or CD8. Functionally, CD4+ T lymphocytes comprise the T-helper (Th) cells, whereas CD8+ T lymphocytes comprise cytotoxic T cells (CTLs). The CD4+ T lymphocytes recognize antigenic epitopes in the context of MHC class II, which means that endocytosed antigens (e.g., extracellular pathogens) are processed and presented by APCs via the exogenous pathway. The CD8+ T lymphocytes recognize antigenic epitopes in the context of MHC class I, which means that the antigens are derived from intracellular proteins (e.g., intracellular pathogens) via the endogenous pathway. Activation of CD8+ T lymphocytes to become effector CTLs requires specialized APCs to be capable of cross-presentation, where antigen peptides that originated from exogenous foreign proteins are presented on MHC class I molecules.[16] Specific subsets of DCs have adapted their endocytic and phagocytic pathways to

acquire exogenous antigens from infectious agents and present them in the context of MHC class I, without being infected by the infectious agent.

Based on the profile of cytokine expression, CD4+ Th cells are classified into distinct functional subsets of Th cells that modulate the humoral and cellular immune responses. Fig. 53.2, *B* illustrates a simplified version of the functional differentiation of Th cells. APC interaction with Th cells via antigen presentation, co-stimulatory molecules, and cytokine milieu leads to the functional differentiation of particular subsets of Th cells. The secretion of IL-12 by APCs leads to the generation of the T-helper type 1 (Th1) cell subset, which produces primarily IFN-γ and functions in cell-mediated immunity, immunity to intracellular organisms, chronic inflammation, and delayed-type hypersensitivity (DTH) reactions. The cytokine IL-4 generates the T-helper type 2 (Th2) cell subset, which secretes IL-4, IL-5, IL-10, and IL-13 and interacts with B cells for the production of antibodies. The subset designated Th17 is induced by a cytokine milieu that includes IL-1, IL-21, IL-23, and IL-6; Th17 cells secrete proinflammatory cytokines IL-17, IL-21, and IL-22, which promote immunity to extracellular pathogens (bacteria and fungi).[17,18] The immunomodulatory cytokine milieu based on IL-2 and transforming growth factor beta (TGF-β) promotes differentiation to the subset designated regulatory T cells (Tregs), which secrete the immunosuppressive cytokines TGF-β and IL-10. A number of other Th subsets have been described in human and animal models of disease, demonstrating the complexity of adaptive immune response.

Factors Associated With Adequacy of the Immune Response

Many factors influence the adequacy of the immune response of an individual animal to potential environmental organisms. Important factors to consider in the horse are age; genetic predisposition; exercise fitness; stress associated with exercise or transportation; state of health, including nutritional status; and the presence of concurrent diseases, including viral infections, tumors, and autoimmunity. Moreover, increased concentrations of corticosteroids can result in varying degrees of immunosuppression and may exacerbate preexisting infectious diseases or decrease resistance to environmental pathogens.[19] The increase in endogenous corticosteroids may be associated with stress or disease; the most common condition in horses is caused by pituitary pars intermedia dysfunction (PPID).[20] In addition, corticosteroid treatment is the most common iatrogenic cause of immunosuppression (see the Drug-Induced Immunosuppression section later in this chapter).[21]

Age has been shown to affect immune function in multiple species. Altered immune function has been identified at both ends of the age spectrum, in foals and older horses. Detailed overviews of the immune responses in young horses and older horses have been reviewed recently, and they are discussed in detail later in this chapter.[22-29] At birth foals have no circulating Igs of their own, and they normally receive maternal transfer of colostral antibodies soon after birth. Colostrum is critical for neonatal immunologic protection. Although foals are immunocompetent at birth, their immune system is naive. Heathy neonatal foals appear to have neutrophilic phagocytocytic ability and killing capacity via oxidative burst activity comparable to that of mature horses.[29-31] Differences in adaptive immune responses between foals and adult horses are not completely understood.[32-35] Despite the apparently adequate preparedness of the immune system in young foals, their ability to develop a humoral immune response is believed to be affected by the maternal-derived antibodies. As the foals age, the maternal antibody levels decline and no longer provide comprehensive protection, but at the same time they may interfere with the foals' ability to mount an immune response. Aging is associated with changes in immunologic status, in particular a decline in the functionality of the immune system characterized by a chronic, low-grade proinflammatory state and a decreased antigen-specific immunity or clonal exhaustion.[20,28] The aging process affecting the immune response is often referred to as immunosenescence.

Nutritional status is well recognized to exert a major impact on immune function, and nutritional deprivation produces impairment of the immune response.[36] Collectively called nutritionally acquired immunodeficiency syndrome (NAIDS), these immunologic dysfunctions include protein-calorie malnutrition and deficiencies of single nutrients. Protein-calorie malnutrition and deficiencies of single nutrients that assist in nucleic acid metabolism lead to dysfunction of the adaptive immune response, especially the T-cell functions, and result in atrophy of lymphoid tissues. In these individuals, the cell-mediated immunity and humoral response to T cell–dependent antigens are subnormal. Deficiency of single nutrients can impair production of key proteins by lymphocytes as well as phagocytic cells. Inadequate nutritional status may result from (1) increased and unmet nutritional requirement, including during growth, pregnancy, lactation, aging, and intense work; (2) disease state associated with altered nutrient intake, such as conditions leading to hypophagia or anorexia; and (3) disease state associated with altered absorption of nutrients.[37] Young, growing animals are most likely to develop NAIDS, followed by geriatric patients, contributing to the greater risk of infections in both age groups.

Exercise represents not only an increased nutritional requirement but also a physiologic stress that can significantly alter the immune response. However, defining the precise effects of exercise on the equine immune system and susceptibility to disease has been difficult because of the complexity of the immune system, host factors (e.g., age, level of fitness), and the variable nature of exercise. In general, it appears that exercise may have both positive and negative effects on the immune response.[38-45] Suppressive effects, such as a decline in the CD4+/CD8+ ratio of T cells, decreased lymphoproliferative responses, and suppression of the innate immune system, have been associated with strenuous high-intensity exercise, prolonged exhaustive exercise, or overtraining. In contrast, moderate exercise tends to have beneficial effects on the host defense mechanisms. Data in horses directly linking exercise-induced immunosuppression and increased susceptibility to infectious disease are limited. However, the potential immunosuppressive effects of exercise need to be recognized. Influenza infection in trained horses subjected to moderate exercise led to increased signs of clinical disease, but the duration of disease was unaffected.[46] Unconditioned ponies vaccinated with a killed influenza vaccine and subjected to 5 days of strenuous exercise had an increased susceptibility to clinical influenza after challenge exposure compared with rested ponies.[47] However, ponies with exercise-induced immunosuppression responded to the administration of an intranasal modified-live equine influenza vaccine and were protected from challenge.[48]

Immunologic Disorders Resulting From Compromised or Deficient Immune Responses

Increased susceptibility to infections, because of recurrence, chronicity, or severity of infectious illness beyond what is considered "normal," raises the suspicion of inadequate immune response. Inadequate immune protection may result from immunodeficiency disorders or a state of immunosuppression.[49-53] General clinical features associated with immunodeficiency disorders or immunosuppression include (1) repeated episodes of infections that respond poorly to standard therapy or return following discontinuation of antibiotic therapy; (2) infections associated with opportunistic or low pathogenicity organisms rarely observed in immunocompetent individuals; (3) systemic illness after administration of attenuated live vaccines; (4) failure

VetBooks.ir

to respond to vaccination; and (5) persistent marked abnormalities in leukocyte numbers. Pathogens most often associated with immunodeficiencies in horses include *Pneumocystis jirovecii*, *Candida* spp., *Aspergillus* spp., adenovirus, *Cryptosporidium*, and *Rhodococcus equi* in adult horses. The type of organism causing infection often suggests the type of defective immunity. When inadequate immune response is suspected, it is important to determine if there is a primary immunodeficiency disorder or a secondary state of immunosuppression.

Primary immunodeficiency disorders recognized in horses are characterized mainly by defects of components of the adaptive immune response and are outlined in Table 53.3. Yet it is possible that many forms of impaired or inadequate immune response in foals and mature horses are not clinically recognized or still poorly defined. Detailed information on the diagnosis and management of immunodeficiency disorders in horses are provided later in this chapter and found elsewhere.[54]

Inherited forms of complement dysfunction or factor deficiency have not been reported in the horse. However, depletion of complement component C3 associated with chronic infections, such as equine infectious anemia, has been reported. Moreover, the foal is born with low serum complement activity, and colostrum is not a significant source of complement. Therefore foals are transiently deficient in serum opsonic capacity and rely on their own production of complement after birth. In sepsis, complement component C3 is rapidly consumed, which delays the physiologic age-dependent increase observed in healthy foals.[51] Neutrophil dysfunction, characterized by decreased neutrophilic phagocytocytic ability and killing capacity via oxidative burst activity is reported in septic neonates.[29-31]

Pelger-Huet anomaly of neutrophils is an inherited disorder described in Arabian horses, characterized by a reduced number of nuclear segmentation and bilobed dumbbell-shaped nuclei, making mature neutrophils resemble band forms.[55,56] Immunophenotyping of Pelger-Huet neutrophils of horses revealed normal expression of myeloid-specific markers and adhesion molecules, and evaluation of phagocytosis and oxidative burst via flow cytometry revealed normal neutrophil function. Despite the morphologic anomaly revealed during the evaluation of blood smears, the functions of Pelger-Huet neutrophils are virtually normal, and clinical signs of immunodeficiency are not observed; however, their inflexible nuclei restrict their ability to emigrate from blood vessels.[53]

Immunologic Disorders Leading to Immune-Mediated Injury

Inappropriate or exaggerated immunologic responses can directly injure bodily tissues. The clinical manifestation of immune-mediated injury depends on the nature and sites of tissue injury. Immune-mediated tissue injury can be from humoral or cell-mediated immune responses, or a combination of both. Immune-mediated tissue or organ damage, often referred to as hypersensitivity reaction, has been classified according to the nature of the immunologic pathway involved. The basic framework of disease mechanisms involving the adaptive immunity proposed by Gell and Coombs consisted of four types of immunopathologic reactions: type I (also referred to as immediate hypersensitivity) encompassing those mediated by IgE; type II encompassing cytotoxic mechanisms mediated by antibodies, generally of the IgG and IgM isotypes; type III encompassing those mediated by immune complexes, which mostly involve IgG and IgM isotypes; and type IV, which are delayed reactions mediated by sensitized T cells. The four types of hypersensitivity reactions are discussed in more detail below. Comprehensive reviews of hypersensitivity disorders may be found elsewhere.[2,3,57,58]

Immediate or type I hypersensitivity reactions are mediated by antibodies of the IgE isotype; hence they manifest after a primary exposure (sensitization) to antigen or allergen and subsequent B-cell differentiation, antibody production, and memory development. These reactions typically occur within 15 minutes to a few hours after the time of exposure to the antigen or allergen, depending on the need for metabolic processing of the triggering molecule. Binding of the antigen or allergen to at least two IgE molecules bound to the surface of mast cells via high-affinity IgE receptors (Fc epsilon RI) leads to degranulation of mast cells and release of mediators such as histamine, serotonin, leukotrienes, prostaglandins, various chemokines, and cytokines. These inflammatory mediators cause vasodilation, edema, smooth muscle contraction, and chemotaxis; this immediate inflammatory reaction occurs locally and potentially systemically. Of clinical significance, localized reactions may propagate to systemic reactions known as anaphylaxis. In horses, anaphylaxis may manifest with fever, hypotension, bronchoconstriction, dyspnea, tachypnea, coughing, sweating, piloerection, diarrhea, and abdominal pain, as the respiratory and gastrointestinal (GI) tracts are the shock organs.

Antibody-mediated hypersensitivities reactions include (1) reactions to self cell-associated antigenic epitopes, referred to as type II hypersensitivity, and (2) reactions involving soluble antigen-antibody (Ag-Ab) complexes, referred to as type III hypersensitivity. Antibodies of the IgG, IgM, and IgA isotypes can trigger severe inflammation via opsonization for enhanced phagocytic function and complement activation with deposition of C3b and iC3b that lead to destruction of antigen-bearing cells. In addition, Igs also mark the cell target for ADCC by NK cells. Activation of C5a potently recruits neutrophils that release proteolytic enzymes (including acid phosphatases, acid hydrolytic enzymes, cathepsins, elastase, collagenase) and oxidative agents with further tissue destruction. Target cells may be circulating or be part of tissues. In type II hypersensitivity, the binding of Ig to antigenic epitopes on cells that are fixed in a tissue or on tissue structural elements, such as basement membrane, results in damage to the respective tissue. For instance, direct antibody binding to self-antigens of the keratinocyte desmosome are responsible for damage that results in acantholysis, blistering, and desquamation in the pemphigus complex. If the antigen-bearing cell is circulating (e.g., erythrocyte, platelet, neutrophil), the cell may be destroyed in circulation but more typically is removed by the mononuclear phagocyte system. Examples of hypersensitivity to antigenic epitopes on circulating cells include alloimmune reactions (such as neonatal isoerythrolysis, neonatal alloimmune thrombocytopenia, and neonatal allogeneic neutropenia) and drug hypersensitivities (such as penicillin-induced hemolytic anemia). In the case of type III hypersensitivity, antibodies bind to soluble antigens (e.g., pathogens) that are not cell associated, resulting in Ag-Ab complexes that deposit in a variety of vascular beds, including lymph nodes, kidneys, joints, and skin.[59] Tissues in the vicinity of the precipitated Ag-Ab complexes are also damaged by the ensuing immune reaction. An important condition characterized by hypersensitivity reaction to soluble antigens in horses is purpura hemorrhagica.

Delayed hypersensitivity reactions, also referred to as type IV hypersensitivity, consist of exaggerated cell-mediated immune responses within 24 to 48 hours from the time of exposure to the antigen. This condition also requires previous sensitization to the antigen, with a previous exposure that leads to APC processing and presentation of the antigens to T cells in the context of MHC and the cytokine milieu. The cytokine milieu, dictated by the APCs, leads to the differentiation of Ag-specific T cells into specific subsets of Th cells or CTLs and development of memory. Classically, the sensitization phase of cell-mediated hypersensitivity involves antigen processing and presentation in the context of MHC accompanied by IL-12 as co-stimulatory signal by the APCs, leading to differentiation of the T cells into Th1 cells. Upon reexposure to the same antigen, APCs activate the antigen-specific Th1 cells that

TABLE 53.3

Features of Immunodeficiency Disorders Affecting the Adaptive Immunity of Horses

Immunodeficiency Disorder	Age of Clinical Onset[b]	Breed and Gender	Peripheral Lymphocyte Count	B cell Count and Function	Serum IgM Concentration	Serum IgG Concentration	Serum IgA Concentration	T cell Count and Function	Response to ID PHA	Response to Vx	Comments
Failure of passive transfer of maternal immunity (partial or total)	Neonate (0 to 3 weeks)	Any	Normal	Normal count; normal function	Low	IgG <800 mg/dL	Low	Normal count; normal function	Normal	Normal	Secondary immunodeficiency; treatable; favorable prognosis if secondary infection is controlled
SCID	1-3 months	Arabian, Arabian cross, Caspian[b]	Severe absolute lymphopenia (< 1000 cells/μL)	Low count; absent function	Undetectable[a]	Only from passive transfer (incapable of producing any Ig)	Undetectable[a]	Low count; absent function	Absent	Absent	Primary immunodeficiency; fatal; genetic testing available; clinical manifestation when maternal antibodies are below protective levels
Foal immunodeficiency syndrome (FIS)	3-5 weeks	Fell pony Dale pony	Normal at birth, then progressive lymphopenia	Count declines over time; no function	Undetectable[a]	Only from passive transfer (incapable of producing any Ig)	Undetectable[a]	Present; questionable function	NR	NR	Severe, progressive nonregenerative anemia; fatal; genetic testing available
X-linked agammaglobulinemia	2-6 months	THB, STB, QH Males only	Normal or low	Absent	Undetectable[a]	Undetectable[a]	Undetectable[a]	Normal count; normal function	Normal	Absent	Fatal; no genetic testing available; clinical manifestation when maternal antibodies are below protective levels
Juvenile selective IgM deficiency	2-18 months	Any; especially Arabian, QH, THB, STB, Paso Fino	Normal	Normal count	Undetectable or low	Normal	Normal	Present	Normal	Normal	Capable of producing Igs of other isotypes (IgG and IgA)
Transient hypogammaglobulinemia of the young	2-18 months	Any; especially Arabian, THB	Normal	Normal	Persistently low (detectable)	Persistently low (delayed onset of Ig synthesis for variable period of time)	Low	Normal count; normal function	Normal	Delayed	Transient condition
Transient CD4+ T cell lymphopenia of the young	2-18 months	Any	Normal to low	Normal count; normal function	Low or normal	Low or normal	Low or normal	Low CD4+ T cells	NR	Delayed	Transient condition
Common variable immunodeficiency	Older than 2 years; average 10 years	Any;especially THB, QH, WB, pony, Arabian, Paint	Normal or low	Low count or absent	Undetectable or low	Low	Normal or low, gradual declines over time	Normal count; normal function	NR	Poor or absent	Poor prognosis; fatal; no genetic test available

Onset of signs listed in this table is in face of adequate colostral transfer of maternal immunity, except for partial or total failure of passive transfer of maternal immunity.

[a]Values depend on concentration of passively transferred maternal antibodies and age.

proliferate and produce large amounts of Th1 cytokines (IFN-γ, IL-2, tumor necrosis factor [TNF]–α, and TNF-β). This cascade of cytokines activates macrophages and recruits nonspecific circulating leukocytes, including monocytes and lymphocytes, to infiltrate the site; there is amplification of the inflammatory reaction and development of epithelioid macrophages and multinucleated giant cells, leading to a chronic inflammatory reaction that mediates tissue damage or granuloma formation. If during sensitization the cytokine milieu by APCs includes IL-4 and IL-5, the T cells differentiate into Th2 cells. Upon reexposure, the sensitized Th2 cells produce large amounts of the Th2 cytokines (IL-4 and IL-5), leading to IgE production and nonspecific eosinophilic activation. If the sensitized T cells differentiate into CTLs, upon reexposure, the sensitized CTLs proliferate and mediate cytotoxicity and tissue damage. Examples of DTH in horses include (1) contact dermatitis to heavy metals and aniline dyes found in tack, bedding, soaps, and blankets; (2) granulomatous diseases; and (3) hypersensitivity to insect bite. Table 53.4 summarizes some disorders caused by immune-mediated injury in the horse; detailed discussion of these and other conditions can be found elsewhere.

Evaluation of Immunologic Response in Horses*

Lais R.R. Costa

Assessment of immune response encompasses in vivo, in vitro, and ex vivo measurements of immune function and can be divided into three categories: (1) assays for characterizing the adequacy of the immune response when an immunodeficiency

*Contributions to previous editions by Melissa T. Hines, Jill R. Johnson, and Debra C. Sellon are acknowledged.

TABLE 53.4

Immune-Mediated Conditions and the Immune Mechanism Mediating Tissue Injury in the Horse

Organ/Tissue	Condition	Proposed Immunologic Mechanism Mediating Injury
Systemic	Systemic anaphylaxis	• Abs of IgE isotype bound to mast cell surface via high-affinity Fc epsilon receptor I lead to degranulation and release of vasoactive and inflammatory mediators. • Type I hypersensitivity reaction.
	Systemic lupus erythematosus (SLE)	• Autoantibodies against nuclear structures, including nucleic acids and ribonucleoproteins, mediate tissue injury. Antinuclear Abs (ANAs), combine with Ags and deposit in basement membranes of skin, glomeruli, synovial membranes, and lymph nodes. • Type II hypersensitivity reaction.
	Multisystemic eosinophilic epitheliotropic disease (MEED)	• Chronic IgE-mediated hypersensitivity reaction against undefined Ags characterized by eosinophilic infiltrate involving multiple tissues/organs, including skin, lungs, GI tract (leading to malabsorption and enteric protein loss), GI-associated lymph nodes, liver, and pancreas (resulting in maldigestion).
	Serum sickness	• Generalized hypersensitivity reaction resulting from formation of large quantities of immune complexes to circulating Ags and deposition in disseminated vascular beds. • Type III hypersensitivity reaction.
	Equine sarcoidosis	• Idiopathic systemic granulomatous disease, affecting most commonly skin, lymph nodes, and lungs, and less commonly spleen, intestinal tract, liver, and endocardium. • Characterized by multifocal infiltrates of macrophages, lymphocytes, plasma cells, multinucleated giant cells, and epithelioid macrophages. • Unknown triggering agent. • Type IV hypersensitivity reaction.
Respiratory system	Recurrent airway obstruction (RAO) or equine asthma	• Hypersensitivity to inhaled organic dusts characterized by neutrophilic infiltrate. • Complex immunopathologic mechanisms: (1) increased expression of IL-4 and IL-5, with development of allergen-specific Th2 response, Ag-specific IgE bound to mast cells and basophils; and (2) concurrent upregulation of cytokines of Th17 and Th1 immune responses.
	Hypersensitivity pneumonitis	• Lymphocytic/plasmacytic bronchiolitis and lymphocytic interstitial pneumonia, sometimes accompanied by granuloma formation and fibrosis, associated with inhalation of organic antigens such as chicken dust and fungi.
Alimentary system	Chronic inflammatory bowel disease	• Malabsorptive and maldigestive disorders characterized by infiltration of the GI mucosa and submucosa with immune cells. • Phenotypic characterization according to infiltrate: (1) predominance of eosinophils (eosinophilic entiritis, MEED, and segmental eosinophilic enteritis), (2) lymphocytes and plasma cells (lymphocytic-plasmacytic enteritis and premalignant lymphoma), and (3) macrophages and epithelioid macrophages (granulomatous enteritis and sarcoidosis).
Renal system	Glomerulonephritis	• Disease resulting from deposition of Abs leading to activation of complement, vasculitis, influx of inflammatory cells (particularly neutrophils), and possibly proliferation of mesangial and endothelial cells. • Mechanisms include: (1) antibodies to the glomerular basement membrane (type II hypersensitivity reaction), or (2) circulating immune complexes in glomerular vascular endothelium (type III hypersensitivity reaction).
Nervous system	Polyneuritis equi (PNE)	• Progressive, insidious radiculoneuritis characterized by granulomatous inflammation of the nerve roots, hemorrhages, demyelination, axonal degeneration, and fibrosis. • Inflammatory infiltrate of the perineurium consists of lymphocytes (including T cells and B cells), plasma cells, macrophages and giant cells, eosinophils, and neutrophils. • Cases of PNE present antibodies to myelin P2 protein.

TABLE 53.4

Immune-Mediated Conditions and the Immune Mechanism Mediating Tissue Injury in the Horse—cont'd

Organ/Tissue	Condition	Proposed Immunologic Mechanism Mediating Injury
Hematopoietic system	Autoimmune hemolytic anemia	• Antibodies directed against autologous RBC Ags activate complement, resulting in rapid destruction of RBCs or removal by phagocytic cells from the mononuclear phagocyte system.
	Neonatal isoerythrolysis	• Alloantibodies of maternal origin (absorbed from colostrum) recognize Ags on the foal RBCs that are inherited from the sire but absent in the mares. • Alloantibodies directed against RBCs' surface glycoproteins or glycolipids, known as alloantigens, mediate RBC damage and destruction.
	Drug-induced immune-mediated hemolytic anemia	• Three mechanisms: (1) drug (e.g., penicillin, sulfonamides, phenylbutazone) binds to RBC surface glycoproteins, is recognized as foreign, and is eliminated; (2) drug and Ab combine, resulting in direct activation of complement with RBCs destroyed as bystanders; (3) drug modifies RBC membranes such that Abs are passively adsorbed and the RBCs are removed by phagocytic cells in the mononuclear phagocyte system.
	Neonatal alloimmune thrombocytopenia	• Alloantibodies of maternal origin (absorbed from colostrum) recognize Ags on the neonate's (horse or mule) platelets. Ig-mediated damage and destruction ensue.
	Immune-mediated thrombocytopenia	• Primary autoimmune disorder in which Igs are directed at autologous platelet Ags, or secondary to infectious disease (e.g., equine infectious anemia) or lymphoma with foreign Ags precipitating on the platelets. Ags are recognized by Igs and Ig-mediated damage and destruction ensue.
	Neonatal allogeneic immune-mediated neutropenia	• Binding of alloantibodies of maternal origin (absorbed from colostrum) lead to destruction of foal's neutrophils.
Vascular system	Hypersensitivity vasculitis	• Immune-mediated vasculopathy, most often affecting small vessels, results from deposition of immune complexes or autoantibodies on the endothelium, leading to inflammation and damage. Vasculitides are most commonly neutrophilic (leukocytoclastic) but may be eosinophilic, lymphocytic, or mixed. • Either type III or type II hypersensitivity reaction. • Generally, lesions involve the skin, typically in dependent and nonpigmented areas.
	Equine purpura hemorrhagica (EPH)	• Hypersensitivity vasculitis, most commonly post *Streptococcus equi* infection or vaccination, resulting from deposit of immune complexes of the IgA isotype in walls of small vessels (venules and arterioles). • Type III hypersensitivity reaction. • Commonly manifested as cutaneous and mucosal involvement, but when severe, EPH leads to extensive edema and hemorrhages of dermis, subcutaneous tissue, skeletal muscles, lungs, kidney, spleen, and intestinal wall.
Eye	Equine recurrent uveitis (ERU)	• Immune-mediated ocular disease characterized by recurrent-remitting episodes of intraocular inflammation, mediated by CD4+ Th1 and Th17 responses directed against several retinal proteins, leading to destruction of intraocular structures.
	Immune-mediated keratopathy (IMK)	• Primary, nonulcerative, noninfectious keratitis (progressive or chronic) characterized by mild to moderate cellular infiltrate (predominantly lymphocytes and plasma cells), corneal vascularization, and corneal edema.
Skin	Pemphigus complex (pemphigus foliaceus and vulgaris)	• Autoimmune vesiculobullous disorders of the skin or mucous membranes mediated by Abs to components of keratinocyte desmosome (i.e., desmogleins), leading to destruction of keratinocyte adhesion (acantholysis). • Horses are commonly systemically ill (depression, anorexia, weight loss, and fever).
	Bullous pemphigoid	• Autoimmune vesiculobullous and ulcerative disorder of the skin and oral mucosa mediated by antibodies to glycoprotein (BPA2 = bullous pemphigoid Ag II and collagen XVII) in the lamina lucida of the cutaneous basement membrane (BM), with complement activation leading to chemotaxis of neutrophils, eosinophils, and mononuclear cells, and consequent damage of the BM. • Horses often appear systemically ill (depression, anorexia, weight loss, and possibly fever).
	Cutaneous (discoid) lupus erythematosus	• Autoantibodies against nuclear structures combine with Ags and attach to keratinocytes, leading to ADCC. Injured keratinocytes release IL-2, resulting in lymphohistiocytic infiltrate. • Lesions may be induced or exacerbated by UV light.
	Erythema multiforme	• Immunologic reaction (triggered by various insults such as infections, drugs, food, neoplasia, or idiopathic) leading to apoptosis of keratinocytes and resulting in formation of macules, papules, urticarial lesions, or vesicular bullous lesions.
	Cutaneous adverse drug reactions	• Immune-mediated condition triggered by a drug (e.g., sulfonamides, penicillins, phenylbutazone, ivermectin, diuretics, phenothiazine, antipyrectics) can be of any of the four types of hypersensitivity reactions. Reaction is typically noted 1 to 3 weeks after beginning of therapy.

TABLE 53.4

Immune-Mediated Conditions and the Immune Mechanism Mediating Tissue Injury in the Horse—cont'd

Organ/Tissue	Condition	Proposed Immunologic Mechanism Mediating Injury
	Hypersensitivity to insect bite	• Salivary Ags are introduced by bites from *Culicoides* spp. (or possibly *Simulium* spp., *Stomoxys calcitrans*, and *Haematobia irritans*), triggering an immediate and delayed responses leading to pruritus. (1) IgE-mediated reaction (type I hypersensitivity). (2) Cell-mediated hypersensitivity reaction associated with Th2 lymphocyte response and nonspecific eosinophilic activation (type IV hypersensitivity).
	Feed-related allergies	• Mixed hypersensitivity reactions mediated by IgE, immune complexes, or cellular responses to foodstuffs (including malt, beet pulp, buckwheat, wheat, alfalfa, red or white clover, barley, bran, oats, etc.).
	Atopic dermatitis	• Genetically predisposed inflammatory and allergic skin reaction mediated by allergen-specific IgE, leading to degranulation of mast cells and release of inflammatory mediators that cause erythema, vascular leakage, and pruritus.
	Allergic urticaria	• Hypersensitivity reaction mediated by one or a combination of (1) IgE, (2) immune complexes, or (3) cytotoxins, leading to activation of tissue mast cells or blood basophils and resulting in release of mediators and formation of wheals.
	Allergic contact dermatitis	• Cutaneous delayed reaction to nonirritant agents (heavy metals and aniline dyes) that alter skin self-proteins, transforming them into antigenic targets. • Type IV hypersensitivity.
	Granulomatous dermatoses	• Chronic inflammatory dermatoses characterized by the presence of macrophages, histiocytic giant cells, and occasionally eosinophils. • Examples of granulomatous dermatoses include noninfectious (equine nodular collangenolytic granuloma, amyloidosis, sterile granuloma) and parasitic/infectious (habronemiasis, bacterial granulomas, pseudomycetoma, fungal granulomas, pythiosis, sporotrichosis).
	Neonatal ulcerative dermatitis, thrombocytopenia, and neutropenia	• Multifocal ulcerative skin disease of neonatal foals associated with profound thrombocytopenia and mild neutropenia suspected to be caused by alloantibodies of maternal origin (absorbed from colostrum). Immunologically mediated damage and destruction ensue.
Muscle	Immune-mediated myositis (IMM)	• Rapid onset of muscle atrophy associated with mononuclear infiltrate of macrophages and lymphocytes (mostly CD4+ cells, lesser CD8+ cells, and clusters of B cells) and no evidence of IgG deposition.
	Infarctive purpura hemorrhagica (IPH)	• Severe infarctive vasculitis associated with deposition of Ag-Ab complexes (i.e., atreptococcal M protein bound to IgM or IgA) along the vessels and activation of complement leading to leukocytoclastic vasculitis and vascular necrosis in skeletal muscles as well as skin, GI tract, and pancreas vessels.
	Rhabdomyolysis associated with *Streptococcus equi*	• Severe, generalized rhabdomyolysis during *S. equi* infection. • Proposed mechanisms: (1) streptococcal superantigen causing nonspecific, polyclonal T-cell activation, massive cytokine release, uncontrolled inflammatory response, tissue necrosis, and multiorgan dysfunction; (2) bacteremia, multiplication of *S. equi* in skeletal muscles, release of bacteria proteases causing myodegeneration.
	Systemic calciniosis or calciphylaxis	• Severe muscle atrophy associated with elevated calcium and phosphorus, leading to fatal systemic dystrophic calcification. • Proposed mechanism: strong systemic inflammatory process and synergistic effect of inflammatory cytokines (TNF-α and IL-6).
Synovial	Immune-mediated polysinovitis/ polyarthritis	• Nonerosive polyarthritis and effusion of other synovial sheaths, such as tendons and bursae, with deposition of immune complexes and mild lymphocytic/plasmacytic infiltrate of synovial tissue: (1) associated with remote infectious processes (*Rhodococcus equi* pneumonia) or (2) without concurrent infectious process.

Ab, Antibody; *ADCC*, antibody-dependent cellular cytotoxicity; *Ag*, antigen; *GI*, gastrointestinal; *Ig*, immunoglobulin; *IL*, interleukin; *RBCs*, red blood cells; *Th*, T-helper cell; *TNF*, tumor necrosis factor; *UV*, ultraviolet.

or immunosuppression is suspected (e.g., assays to assess humoral, cellular, and innate immune responses)[1-5]; (2) assays for identifying inappropriate or exaggerated immunologic responses when immune-mediated injury is suspected (e.g., antinuclear antibody titer, assay for platelet surface–associated IgG, isotype-specific antibodies coating erythrocytes)[6-9]; and (3) assays of immunologic recognition of pathogens (e.g., antibody titer to specific antigens or pathogens) and protection against infectious agents.[10] The aspects of immune response evaluation discussed in this section include only assays for characterizing the adequacy of the immune response when immunodeficiency or immunosuppression is suspected. Assays for identifying inappropriate immunologic responses when an immune-mediated condition is suspected and assays of immunologic recognition of pathogens and protection against infectious agents are discussed in this book under body systems or found elsewhere. Genetic tests are also available to diagnose inheritable conditions, and those are discussed under their respective diseases in this book.[11,12]

Characterizing the Adequacy of the Immune Response

Assessment of the adequacy of a patient's immune response is warranted when there is an increased recurrence, severity, or chronicity of infectious illness above and beyond what is considered normal, especially if the possibility of enhanced

VetBooks.ir

virulence of the pathogen involved has been ruled out. Because true immunodeficiency disorders are uncommon, they should be considered only after more common causes of recurrent infection have been excluded. It is important to remember that inadequate immune response may occur in association with malnutrition, neoplasia (especially leukoproliferative disorders), autoimmune diseases, immunosuppressive therapy, and the presence of underlying diseases such as PPID. In addition, immunosuppression and immune evasion mediated by the infectious agent itself should be considered. Therefore the diagnostic plan should include evaluating the patient's immune response as well as ruling out conditions that may account for the inadequate immune response of the patient.

In case of increased recurrence, severity, or chronicity of infectious illness above and beyond what is considered normal, the type of infectious agent involved may provide clues that will guide the choice of diagnostic plan. For instance, when the recurrent, severe, or chronic infection is caused by encapsulated bacteria such as *Staphylococcus aureus*, *Streptococcus zooepidemicus*, *Klebsiella* spp., or *Actinobacillus equuli*, it raises the suspicion of compromised B-cell function, complement deficiency, or phagocytic dysfunction.[4,13-16] Assays for humoral immunity and phagocytic function should be investigated first. When the recurrent, severe, or chronic infection is caused by an intracellular organism such as *R. equi*, *P. jirovecii*, *Candida albicans*, or *Aspergillus* spp., compromised cellular immunity should be considered.[5]

Evaluation of humoral immunity is assessed readily by measurement of Igs. A comprehensive approach to the evaluation of humoral function in horses can be found elsewhere.[4] Tests to evaluate humoral immunity include (1) determination of total serum concentration of each Ig isotype, namely IgG, IgM, and IgA[17-20]; (2) humoral response to vaccination by measurement of antigen-specific antibody titers prior to and at 15 to 21 days post vaccination[4,10]; (3) evaluation of gamma globulins by serum electrophoresis to determine the nature of gammopathies (monoclonal or polyclonal); (4) characterization of peripheral blood B-cell distribution by immunophenotyping and flow cytometry (FCM)[4,21]; and (5) detection of deficiencies of the CD4+ Th cell function that co-stimulates and helps B-cell differentiation and survival, leading to secondary humoral disorders.

Assessment of cellular immunity is more challenging, and in vitro assays may fail to demonstrate dysfunction in cellular immune response. A comprehensive approach to the evaluation of cellular immune function in horses can be found elsewhere.[5] Tests available to evaluate cellular immunity include (1) immunophenotyping and FCM of circulating lymphocytes, including determination of CD4+ and CD8+ T lymphocytes,[22,23] (2) determination of cytokine profiles,[24,25] (3) mitogen-induced lymphocyte proliferation or blastogenesis,[21] and (4) mitogen-induced cytokines and expression of co-stimulatory markers.[5]

Table 53.5 lists assays used to assess and characterize the adequacy of adaptive (humoral and cell-mediated) and innate immune responses.

TABLE 53.5

Assays to Assess and Characterize the Adequacy of Immune Response in Horses

Assay	Sample	Description	Purpose	Comments
Complete blood cell count (CBC)	Whole blood preserved in EDTA	Standard hemogram, focusing on leukogram and evaluation of cell morphology.	Identification of abnormalities in number and morphologic changes of lymphocytes, monocytes, neutrophils, and eosinophils.	Part of the initial assessment as the minimum database of most patients. Equine CBC can be performed by most clinical pathology laboratories. Absolute, persistent lymphopenias might suggest compromised cellular immune mechanisms.
Serum protein electrophoresis	Serum	Separation of serum proteins by gel electrophoresis.	Evaluation of gamma globulins, which are primarily Igs, and determination if they are monoclonal or polyclonal.	In horses with repeated infections, serum Ig levels are likely to be high and polyclonal in nature. Monoclonal hypergammaglobulinemia is evidence of lymphocyte malignancy. Low levels of gamma globulins are supportive of Ig deficiency. Assay is offered at most clinical pathology laboratories.
Semiquantitation of Igs	Serum	Precipitation of Igs using serial concentrations of specific salts (e.g., zinc sulfate, sodium sulfite precipitation, glutaraldehyde coagulation).	Semiquantitative tests measure IgG to predict failure of transfer of passive immunity after colostrum ingestion.	Tests based on these principles include: (1) Zinc sulfate precipitation (2) Glutaraldehyde coagulation Precipitation of Igs can be used in several species and is quick and easy to perform.
	Serum or whole blood preserved in EDTA or heparin	Species-specific tests based on antigen-antibody (Ag-Ab) reactions, either enzyme-linked-immunosorbent assay (ELISA) or latex bead agglutination.		Examples of commercially available kits include: (1) Species-specific equine IgG ELISA (e.g., SNAP® Foal IgG Test, Idexx) (2) Latex bead agglutination (e.g., FoalChek Kit IgG Level by Centaur)

TABLE 53.5

Assays to Assess and Characterize the Adequacy of Immune Response in Horses—cont'd

Assay	Sample	Description	Purpose	Comments
Radial immunodiffusion (RID) for quantitation of Igs	Serum	RID quantitates Igs of specific isotypes using a precipitation reaction where the diameter of the reaction corresponds to a certain concentration of Ig.	Quantitation of specific classes of equine Igs (e.g., IgG, IgM). RID requires incubation for 24 hours. RID can be used to evaluate foals for failure of transfer of passive immunity after colostrum ingestion or testing humoral competence at any age.	RID is a species-specific quantitative test considered to be the gold standard for Ig quantitation. Kits for equine Ig isotypes are commercially available. RID for IgG and IgM is performed at several veterinary clinical immunology laboratories. A RID kit for equine IgA is not currently available.
IgG turbidimetric immunoassay (TIA) for quantitation of Igs	Serum or plasma (blood collected in EDTA or heparin) harvested after centrifugation	TIA is based on the principles of immunologic agglutination and light scattering of the agglutination products. The automated TIA is performed on chemistry analyzer, and results are available within hours.	Quantitation of equine IgG results are available within less than 15 minutes. TIA can be used to evaluate foals for failure of transfer of passive immunity after colostrum ingestion or to test humoral competence at any age.	TIA is a species-specific quantitative test with high sensitivity and specificity and very good correlation with RID. Kits for equine IgG TIA are commercially available. It requires spectrophotometric equipment.
Equine Ig ELISA kits for quantitation of various Ig isotypes	Serum or plasma (blood collected in EDTA or heparin) harvested after centrifugation	Various platforms of ELISA: sandwich ELISA, competitive ELISA.	Quantitation of specific classes of Igs (e.g., IgG, IgM, IgA, IgE) is considered of reasonable accuracy.	ELISA is a species-specific quantitative test. There are several commercially available ELISA kits for quantification of equine IgG, IgA, IgM, and IgE manufactured by various companies. It requires spectrophotometric equipment and laboratory experience.
Measurement of specific Ab responses pre and post vaccination	Serum	Paired serum samples, pre and 15-20 days post vaccination are tested to measure Ag-specific Abs. Samples can be stored in the refrigerator or frozen.	Determination of B-cell function by evoking an anamnestic response to a protein Ag.	Choice of Ab titers depending on vaccine used (e.g., tetanus toxoid). Several laboratories provide Ab titers to common diseases of horses for which vaccines are used. Results are meaningful when comparing pre- and postvaccination titers using the same test.
Equine cytokine multiplex assay	Serum or body fluid	Detects soluble equine IL-4, IL-10, IL-17, IFN-γ, and IFN-α in biological samples using monoclonal Abs specific for each cytokine and fluorescent bead/microspheres that are color coded.	Quantitation of cytokines as pg/mL of biological sample.	Offered at the Animal Heath Diagnostic Center, Cornell University, http://ahdc.vet.cornell.edu/docs/Equine_Cytokine_5plex_assay.pdf Results may be difficult to interpret.
Equine cytokine ELISA	Serum	Detects soluble cytokines and chemokines in biological samples using various platforms of ELISA.	Quantitation of specific equine cytokines and chemokines.	ELISA is a species-specific quantitative test. There are several commercially available ELISA kits for quantification of various equine cytokines and chemokines manufactured by various companies. It requires spectrophotometric equipment and laboratory experience. Results may be difficult to interpret.

TABLE 53.5

Assays to Assess and Characterize the Adequacy of Immune Response in Horses—cont'd

Assay	Sample	Description	Purpose	Comments
Immunophenotyping of peripheral blood lymphocytes	Whole blood preserved in EDTA or heparin	Enumeration of specific subsets of lymphocytes using fluorescent antibodies to cell surface markers and flow cytometry.	Determination of circulating lymphocyte types—B cells (CD19+-like, CD20+, CD21+, sIgM+), total TCD3+ cells, CD4+ T cells and CD8+ T cells—and determination of CD4/CD8 ratio.	Flow cytometry is a qualitative and quantitative test. In healthy adult horses, about 10% ± 4% of circulating lymphocytes are B cells, about 64% ± 6% are CD4+ T cells and 18% ± 3% CD8+ T cells. Normal CD4/CD8 ratio is 3.5 ± 1.0.
Immunophenotyping of leukocyte populations in body fluids	Body fluid (e.g., CSF, pleural fluid peritoneal fluid) and apirates (e.g., bone marrow, lymph node) preserved in EDTA or heparin	Evaluation of leukocyte types and subsets using fluorescent Abs to cell surface markers and immunocytochemistry.	Determination of B cells (sIgM+), total CD3+ T cells, CD4+ T cells, CD8+ T cells, and myeloid cells (CD172a).	Immunocytochemistry is a qualitative test but can also be quantitative for cell distributions or counts.
Immunophenotyping of leukocyte populations in tissues (e.g., lymph node, spleen, bone marrow)	Biopsy specimen preserved in formalin or fresh frozen	Evaluation of leukocyte types and subsets using Abs to cell surface markers and immunohistochemistry.	Determination of B cells (sIgM+), total CD3+ T cells, CD4+ T cells, CD8+ T cells, and myeloid cells (CD172a).	Immunohistochemistry is a qualitative test. There are limitations in the availability of Ab reagents when using formalin-fixed samples.
Histologic evaluation of lymph node	Biopsy specimen preserved in formalin	Evaluation of lymphoid tissue morphology using histology, histochemistry, and immunohistochemistry with specific antibodies to cell markers.	Determination of the presence or absence of B cells (sIgM+) and germinal centers.	Useful to evaluate humoral deficiencies, particularly for postmortem diagnosis. Offered at most diagnostic laboratories and at the Animal Health Diagnostic Center, Cornell University.
Peripheral blood phagocytic functions of opsonization capacity, phagocytosis, and oxidative burst	Whole blood preserved in heparin	Peripheral blood leukocytes are incubated with oxidative-sensitive dye dihydrorhodamine (DHR), and/or fluorescent-labeled inactivated bacteria (e.g., *Staphylococcus aureus*, *Escherichia coli*). Bacterial opsonization can be performed with pooled or autologous serum; heat-inactivated serum or no serum can be used as controls.	Evaluation of functions of the innate immune response: (1) opsonization capacity by serum complement components and Igs; (2) phagocytosis by neutrophils and monocytes; and (3) oxidative burst by neutrophils and monocytes. Oxidation of DHR generates green-fluorescent rhodamine 123 (rho). Two-color flow cytometric analysis can be performed for oxidative burst and phagocytosis.	Currently performed for research purpose or academic interest by immunology laboratories to further characterize certain immunodeficiencies.

TABLE 53.5

Assays to Assess and Characterize the Adequacy of Immune Response in Horses—cont'd

Assay	Sample	Description	Purpose	Comments
Intradermal skin testing with the plant lectin phytohemagglutinin (PHA)	Direct patient skin testing	Measure the thickness of a skin fold before injection, then intradermal injection of 50 µg of PHA dissolved in 0.5 mL saline. At a different site 10 cm (4 inches) away, 0.5 mL of saline is injected as control. After 24-48 hours, the skin thickness of both injection sites is measured.	Evaluation of lymphocyte response to stimulus in vivo. PHA elicits an immune response without requirement of prior sensitization. Increase in skin thickness should be greater than 0.6 mm, otherwise there is a defect in cell-mediated immunity.	The intradermal testing with PHA might yield false results; therefore confirmation with in vitro assay is recommended.
Mitogen-induced lymphocyte proliferation (blastogenesis) assay	Whole blood preserved in EDTA or heparin	Lymphocytes are isolated, labeled with CFSE, and incubated in vitro with mitogens, including pokeweed mitogen (PWM), phorbol mistrate acetate (PMA), PHA, and concavalin A (ConA).	Measurement of proliferating cells by reduction (division) of fluorescent-labeled cellular proteins using flow cytometry. PWM and PMA stimulate blastogenesis of B and T cells; PHA and ConA stimulate T cells.	Currently performed for research purposes or academic interest by immunology laboratories to further characterize certain immunodeficiencies.
Mitogen-induced cytokine and co-stimulatory cell marker expression	Whole blood preserved in EDTA or heparin	Lymphocytes are isolated and incubated in vitro with mitogens, including PWM, ConA, PHA, and PMA. Measurement of cytokines and cell markers via flow cytometry, multiplex assay, or molecular assay.	Measurement of cell function and response based on cytokine production (e.g., IFN-γ) and expression of co-stimulatory molecules (e.g., CD40 ligand, CD28, MHC class II)	Currently performed for research purposes or academic interest by immunology laboratories to further characterize certain immunodeficiencies.
Severe combined immunodeficiency (SCID) genetic testing	Collect sample from a convenient source of DNA: (1) swab the inside of the mouth with a mucosal brush and submit the brush containing mucosal cells (2) blood sample in EDTA or ACD anticoagulant (3) Pulled mane or tail hair placed in a clean bag	A DNA-based carrier test for the genetic mutation affecting the DNA-dependent protein kinase (DNA-PK) located in chromosome 9.	Genetic tests that detect carriers of the recessive genetic trait; information can be used to select mating pairs and avoid producing affected foals. Recessive genetic traits, requiring two copies of the mutated gene to produce an affected foal. These conditions are fatal, and animals homozygous for the mutation do not survive to reproductive age. Horses that have one copy of the mutated gene are normal.	Laboratories offering SCID testing include: (1) VetGen, Ann Arbor, Mich., http://www.vetgen.com (2) Veterinary Genetics Laboratory, University of California, Davis, https://www.vgl.ucdavis.edu/services/CA.php (3) Animal Genetics, http://www.animalgenetics.com/Equine/Equine_Index.asp
Foal immunodeficiency syndrome (FIS) genetic testing		A DNA-based carrier test for genetic defect affecting the sodium/myo-inositol cotransporter gene *(SLC5A3)* located in chromosome 26.		Laboratories offering FIS testing include: (1) Animal Health Trust, Newmarket, UK, http://www.aht.org.uk/cms-display/genetics_fis.html (2) Animal Genetics, http://www.animalgenetics.com/Equine/Equine_Index.asp (3) LABOKLIN Laboratory for Clinical Diagnostics, Manchester, UK, http://www.laboklin.co.uk/laboklin/showGeneticTest.jsp?testID=8454

ACD, Acid citrate dextrose as anticoagulant; *CFSE*, carboxyfluorescein succinimidyl ester; *CSF*, cerebrospinal fluid; *EDTA*, ethylenediaminetetraacetic acid; *IFN*, interferon; *Ig*, immunoglobulin; *IL*, interleukin; *MHC*, major histocompatibility complex.

Immunity at Birth and the Immune Development of the Foal

Angela I. Bordin

Despite a lengthy development of the innate and adaptive immune systems in the equine fetus, the foal is born with a relatively immature and naive adaptive immune system. In addition, the epitheliochorial placentation in the mare precludes transfer of immunoglobulins in utero, and foals are born hypogammaglobulinemic.[1] At birth they rely heavily on colostral IgG for protection against infection but also on colostral soluble molecules and cells for stimulation of the immune system. In horses, colostrum absorption occurs within the first 24 to 36 hours after birth (with a peak around 8 hours) through specialized enterocytes that allow absorption of macromolecules. After this period, these specialized cells mature, and absorption of immunoglobulins ceases. Consumption of antibody-rich colostrum therefore is essential for protection against pathogens not only immediately after birth but also during the period until foals can produce their own antibodies at protective levels, which may require 2 to 3 months. Therefore in foals with low or inadequate transfer of colostral IgG, hypogammaglobulinemia increases the susceptibility to infections during the first few months of life. The knowledge of the actual (rather than an estimated) IgG concentration in the foal's blood after ingestion of colostrum could be used for clinical planning and monitoring of risk of infection in the initial months of life, and tests are repeated as needed during this phase. Besides antibodies, other factors are possibly transferred to the foal via colostrum, including the cytokines IFN-γ, IL-4, IL-6, and TNF-α.[2-4] Maternal lymphocytes in colostrum can also be absorbed through the GI tract and participate in adaptive immune responses of the equine neonate. Equine colostrum contains primarily CD4+ and CD8+ T cells and few B cells. These cells can express inflammatory cytokines (IFN-γ and IL-17) upon stimulation.[5]

There is evidence that the immune system of foals actively develops during the fetal period. For instance, the detection of Igs in the fetus and presuckle foal, despite their low levels, suggests antibody production in utero.[6] Indeed, antigen-specific antibody production and antigen-specific IgG isotype switching have been measured in the equine vaccinated fetus or potentially in the foal born to naturally infected dams.[7-9] In addition, functional lymphocytes and lymphoid tissue organization have been detected in the fetus by 100 (T cells) and 200 days (B cells), and presence of IL-8 in presuckle foals suggests endogenous production.[2,10] Despite maternal antibodies, foals have been shown to produce endogenous serum IgM and IgG at protective values by 2 ± 3 months of age, regardless of colostrum ingestion.[11-15] Although foals can make their own antibodies despite colostrum consumption, prepartum vaccination of mares is important because Ig levels in mares' serum correlate with levels in mammary secretions, and foals with inadequate transfer of passive immunity through colostrum are more susceptible to infections, particularly to those pathogens that cause septicemia and are challenging in the first few months after birth.[16]

The development of the immune system continues intensively after birth with the exposure to both pathogenic and nonpathogenic microorganisms in the environment. In individuals not exposed to microbes, such as germ-free mice and rabbits, both innate and adaptive immunity are not as well developed as those exposed to environmental microbes and present many immunologic defects.[17] Although research of the microbiome of horses and foals is still a developing area, it has been demonstrated that it changes significantly with age.[18-21] By 1 month of age, the microbiome of foals is significantly more diverse than at birth, and both changes and increases in bacterial communities in the gut likely reflect the replacement of milk diet by available forage and concentrate fed to the mare.[18-21] It has been shown that diversification of the microbiome in neonates of all species influences various developmental processes such as immunity to infection.[22,23]

Absolute peripheral blood lymphocyte counts in healthy equine neonates are somewhat comparable to adult horses, but prematurity or immaturity is often characterized by lymphopenia.[15,24] Therefore a rapid increase in the blood lymphocyte count (at least two times) is expected in the initial few months of life in a normally developing immune system responding to microorganisms.[15] Hence both B and T lymphocyte subpopulations increase with age.[12,15,25] In addition, B-cell markers such as B29A+ and CD21+, as well as MHC class II, also increase with age, whereas the proportion of CD8+ lymphocytes decrease with age.[25]

Innate immune cells are fundamental for protection against infections soon after birth and a crucial link between innate and adaptive immune systems. In foals, phagocytic function by innate immune cells is particularly important for protection against disease because of the lack of developed adaptive immunity.[26] Neutrophils are the most abundant effector cells of innate immunity in blood and the first line of defense by containing the infection via phagocytosis and subsequent killing of invading pathogens, as well as producing both cytokines and chemokines that recruit and activate other effector cells.[27,28] In general, studies report comparable neutrophil function in foals and adult horses; however, some studies showed decreased bactericidal activity in individual foals relative to adults, including during sepsis.[15,29-31] Phagocytosis and killing of yeasts by neutrophils increase with age, being lower in newborns before colostrum ingestion and reaching adult levels by 1 month of age.[32-34] Neutrophil chemotaxis also increases with age.[35] Macrophages are another important type of phagocytic cells: they ingest and kill intracellular pathogens and recruit other phagocytes to the site of infections; in addition, they function as APCs. In a study comparing newborn, 3-month-old foal, and adult alveolar macrophages and monocyte-derived macrophages, the authors observed a similar capacity of *R. equi* intracellular killing in newborn and adult horses.[36]

Opsonization of pathogens with antibodies plays an essential role in their uptake by phagocytes through antibody Fc receptors and subsequent bactericidal capacity; therefore hypogammaglobulinemia markedly limits phagocytic activity and protection.[29,30,32,37,38] The complement system is also important for the defense against pathogens, but colostrum is not a reliable source of this protein, and foals depend on their own production for protection.[39] Complement activity in foals increases with age, being 13%, 64%, and 85% of that in adult horses in the first week after birth, at 1 month, and at 5.5 months of age, respectively.[34]

DCs are APCs to T lymphocytes for the generation of cell-mediated responses. There are functional differences between DCs of adult horses and foals, in which cells from young foals are less able to produce cytokines in response to stimulation (e.g., lipopolysaccharide [LPS], cytosine-phosphate-guanosine oligodeoxynucleotide [CpG-ODN]) and are considered less mature than cells in adult horses.[40] DCs from foals have reduced expression of MHC class II and co-stimulatory molecules, meaning that their potential for interaction and ability to stimulate naive T cells is limited.[15,41] In addition, foals' APCs also express less CD1, which is a surface cell molecule involved in the presentation of lipid antigens to subsets of T cells, in comparison to adult horses' cells.[42]

Under physiologic conditions, serum IgM concentration of 25 mg/dL but less than 20 mg/dL for IgG may be measured in presuckle foals.[10,13] Nevertheless, endogenous synthesis of IgG_b ($IgG_{4/7}$) cannot be detected until 63 days old.[43] IgG_b ($IgG_{4/7}$) is the most common isotype in serum of both adult horses and foals, as well as in colostrum, and IgA is the major

isotype found in nasal secretions of adult horses and milk. In nasal secretions of foals, however, IgG_a and IgG_b are the major isotypes.[43] Maternal antibodies decline within the first 3 months of age, with an IgM half-life of 6 ± 16 days and an IgG half-life of 28 ± 32 days.[11,43] Serum half-lives of Ig isotypes in foals are 17.6, 32, 21, and 3.4 days for IgG_a (IgG_1), IgG_b ($IgG_{4/7}$), IgGT ($IgG_{3/5}$), and IgA, respectively.[43] Yet the equine fetus and newborn can respond to vaccination with antibody production, indicating that the humoral response is in place at early life. Two important studies demonstrate that early intramuscular vaccination of newborns can elicit specific yet modest antibody responses to antigens.[44,45] However, the development of a long-lasting immune response with memory cells is limited at this age. The current recommended age for vaccination of foals born from mares vaccinated in the prepartum period is 4 to 6 months for most vaccines with the exception of botulism, for which the first dose can be administered at 2 to 3 months of age (according to American Association of Equine Practitioners [AAEP] guidelines). This recommendation aims to especially avoid maternal antibody interference, assuming adequate transfer of passive immunity.

CD4+ Th1 responses (or Th1-associated cytokine response) are thought to be essential for protection against intracellular pathogens, whereas Th2 responses with a shift to antibody production are thought to be important for extracellular pathogens and parasites. Foals are known to have reduced IFN-γ responses at birth.[46,47] Although foal peripheral blood lymphocytes respond to nonspecific stimulation with a mitogen, foals produce less cytokine compared to adult horses, and this response increases with age in vivo and in vitro.[48] Bronchial lymph node lymphocytes of foals produce lower levels of IL-4 (a hallmark for Th2 response) than those of adult horses.[49]

Despite being considered partially immature and naive, both innate and adaptive immune systems of foals can be stimulated to generate an immune response. Parapoxvirus ovis (PPVO) and inactivated *Propionibacterium acnes* (PA) were used as immunostimulants in foals: PPVO increased phagocytosis in neutrophils, and PA reduced intracellular replication of *R. equi*.[50] In addition, due to the expression of TLR9 by foal neutrophils, CpG-ODNs have shown to stimulate cytokine as well as reactive oxygen species (ROS) production both in vitro and in vivo.[27,51-53]

Failure of Passive Transfer of Maternal Immunity*

M. Julia B. Felippe • Debra C. Sellon

Definition and Etiology Normal foals are immunocompetent at birth and capable of mounting an immune response. However, they are immunologically naive: they have had no exposure to foreign antigens and have not yet mounted any type of protective immune response or accumulated significant levels of immunoglobulins. Although the equine fetus is capable of producing antibodies, newborn foals are essentially devoid of Ig at birth, with the exception of small amounts of IgM normally produced in utero. Without being able to rely on their acquired immunity in the first encounter with pathogens, foals are indeed more susceptible to infectious diseases during the neonatal period. Foals begin mounting immune responses and producing their own Igs immediately on exposure to antigens after birth, and Igs produced by the foal are detectable within 1 to 2 weeks of life and reach significant levels by 2 to 3 months of age.

Immunologic protection of the newborn foal therefore relies on the transfer of maternal immunity through the colostrum. Under normal circumstances, temporary protection against infection in the first 1 to 2 months of life is provided to the foal in the form of passively transferred antibodies, cytokines, immune mediators, and a small number of mononuclear cells from the dam (Fig. 53.3; Table 53.6). Because of the diffuse epitheliochorial nature of the equine placenta, no transplacental transfer of Igs occurs in horses. Instead, ingestion and absorption of Ig-rich colostrum within the first day after birth are the sole means of passive transfer of immunity in foals. Serum IgG concentration in healthy foals after ingestion of colostrum under natural conditions varies between 500 and 6000 mg/dL.[1-3] In a properly functioning system, maternal antibodies wane as levels of endogenous antibodies increase, and thus the foal should be protected during this transition period (Fig. 53.4; Table 53.7).

Failure of the foal to ingest or absorb sufficient quantities of colostrum to provide adequate absorption of IgG is called *failure of passive transfer* (FPT). *Complete* FPT is defined as a foal with a serum IgG concentration of less than 400 mg/dL at 24 hours of age. *Partial* FPT is defined as a foal with a serum IgG concentration of 400 to 800 mg/dL at 24 hours of age. The reported incidence of complete or partial FPT in

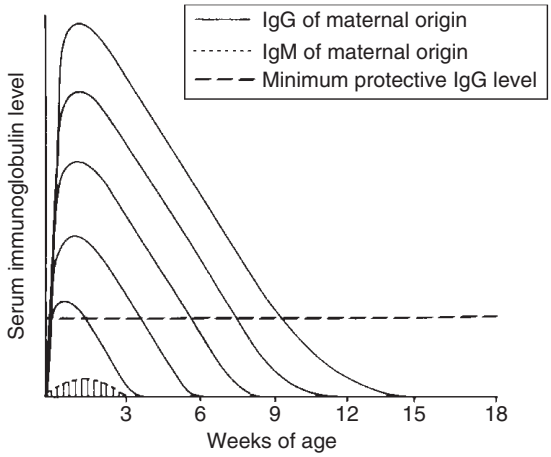

FIG. 53.3 The duration of protection provided by colostral immunoglobulins (Igs) in the foal varies with the isotype of immunoglobulin (e.g., IgG, IgM) and the quantity absorbed during the first 24 hours of age.

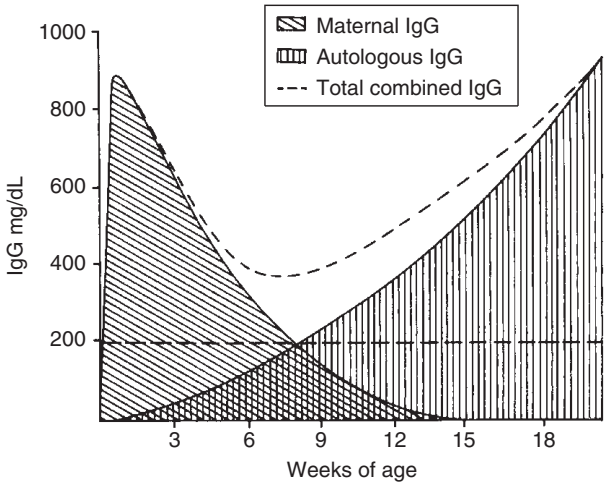

FIG. 53.4 Maternal immunoglobulin *(Ig)* wanes, whereas the production of autologous immunoglobulin increases during the first several months of life. The combined total amount of immunoglobulin ideally remains above the level considered the minimum for maintenance of good health.

foals varies from 3% to 37.8%.[4-11] Risk factors for FPT include month of foaling, adverse health events for mare or foal in the periparturient period, age of the dam, and colostral immunoglobulin content. Low total Ig content in colostrum is associated with breed (e.g., Standardbred), age of dam (e.g., older mares), and low total solar radiation (i.e., shorter days).[5,10,12]

Immunoglobulins are selectively concentrated from the mare's sera into colostrum in response to hormonal changes that occur in the last 2 weeks of pregnancy; local production in the mammary gland is also possible. The predominant Ig isotype in equine colostrum is IgG, followed by IgA and smaller quantities of IgM.[13] The reported amount of total IgG in equine colostrum is variable among different studies (see Table 53.6), but overall a good-quality colostrum should contain 2500 to 5000 mg/dL. The reported amounts of IgA often range between 500 and 1500 mg/dL, whereas IgM generally ranges between 100 and 350 mg/dL. At birth the neonate has specialized enterocytes in the GI tract that can absorb large molecules such as immunoglobulins intact by pinocytosis.[14] Absorbed proteins pass through the intercellular spaces and lacteals into the systemic circulation via the lymph. The window of gut absorptive capacity for Igs is narrow, lasting from birth until about 18 to 24 hours of age. Maximal absorptive efficiency occurs immediately after birth, declining to only 22% efficiency at 3 hours after birth and then to less than 1% by 20 hours.[15,16] The decline in Ig absorption is accompanied by transient proteinuria that peaks at 6 to 12 hours of age and declines by 24 to 36 hours of age. This proteinuria most likely reflects absorption and excretion of low-molecular-weight milk proteins.[16]

Diminished Ig absorption over the first 12 to 24 hours of life is the result of shedding of specialized enterocytes capable of pinocytosis and replacement by more mature cells that are incapable of absorbing immunoglobulins.[15,17] It has been hypothesized that delayed ingestion of macromolecules may prolong the duration of intestinal permeability to Igs. In one study, however, the type of fluid administered to foals before the ingestion of colostrum did not influence subsequent IgG absorption, suggesting that the process of gut closure is not mediated by a finite capacity for the uptake of macromolecules.[18]

The half-life for maternal IgG in the foal's circulation varies between 20 and 30 days.[19-21] Concentrations decline as a result of normal protein catabolism, gradual dilution associated with an increasing plasma volume as the foal grows, and transfer of functional antibody into the mucosa. Most maternal antibodies are present in only negligible concentrations by 6 months of age, although antibodies to some infectious agents have been detected for up to 12 months after birth. As passive antibody concentrations decline, endogenous antibody production increases. There is a nadir in serum Ig concentrations in colostrum-fed foals at approximately 1 to 2 months of age, followed by gradually increasing concentrations until adult levels are reached at 5 to 10 months.[22,23] Serum Ig concentrations are similar in colostrum-fed and colostrum-deprived foals by 3 to 4 months of age.

In addition to antibody, other colostral factors may be important for optimal immune protection of foals. For example, colostrum influences cell-mediated immunity and activates granulocytes. Colostrum contains many constituents of innate immunity and immunomodulating agents, such as cytokines, growth factors, hormones, enzymes, CD4 and CD8 T

VetBooks.ir

lymphocytes, macrophages, neutrophils, and epithelial cells.[24-26] The cellular components of colostrum are likely to play an especially important role in local GI immunity in the neonatal foal. Maternal cells are found in a variety of blood and tissues in the neonate after absorption of colostrum, suggesting that these cells may also play a role in systemic immunity.[24]

In foals, FPT may occur because of ingestion of poor-quality colostrum with a low Ig content, failure to ingest a sufficient quantity of colostrum, or failure to absorb colostral Igs from the GI tract.[27] Colostrum may have an insufficient quantity of Ig because of prelactation (lactation before parturition), premature foaling, a defect in the mare's ability to concentrate Ig in the colostrum, ingestion of endophyte-contaminated fescue grass or hay, or other factors. Premature lactation is most commonly associated with twin pregnancies, placentitis, and premature placental separation but occasionally occurs without any concurrent uterine, placental, or fetal pathology. Mares most likely to produce colostrum with low Ig content are those older than 15 years of age, those that foal early in the year, and Standardbred mares.[3,10,11] Insufficient colostral Ig concentration has also been associated with ingestion of endophyte-contaminated fescue grass or hay.[28,29]

Foals that are orphaned or rejected at birth, too weak to stand, or unable or lack the desire to suckle are unlikely to ingest sufficient colostrum to prevent FPT. Malabsorption is occasionally incriminated as a cause of FPT in foals that are observed to suckle adequate quantities of good-quality colostrum. This most often happens in premature or dysmature foals, possibly as a result of immature GI function but may also occur in otherwise healthy and vigorous full-term foals.[30] Glucocorticoids enhance the maturation of small-intestinal epithelial cells and thus their loss of absorptive capacity, leading to speculation that endogenous corticosteroids released secondary to stress at parturition may impair Ig absorption in foals.[31,32] However, administration of adrenocorticotropic hormone (ACTH) failed to affect absorption in experimental foals, and stress has not been a consistent historical finding in foals with FPT caused by presumptive impaired Ig absorption.[8,33]

Clinical Signs and Differential Diagnoses

The association between FPT and infection has been investigated in numerous studies.[4,5,7,10,11] Although the results have varied somewhat, FPT is generally considered a risk factor for infectious disease. By itself, FPT produces no clinical signs of disease and cannot be detected by physical examination. Clinical presentations that strongly suggest an underlying problem with FPT include onset of bacterial infections within the first 2 weeks of life, particularly septicemia, septic arthritis, pneumonia, and enteritis. Other immunodeficiencies or simply exposure to potent pathogens cannot be ruled out solely based on the time of onset; however, even with other forms of immunodeficiency, clinical signs of infection usually do not show up for several weeks if passive transfer is adequate.

Clinical Pathology

FPT is diagnosed by the demonstration of low serum concentrations of IgG in the foal as early as 6 to 12 hours after birth, typically between 12 and 24 hours after birth, and probably for as long as several weeks after birth (see Table 53.6). The level of IgG considered adequate for protection against infectious disease is poorly defined and probably varies considerably with the environment. A serum IgG concentration greater than 800 mg/dL is considered to provide adequate protection for most foals in their first few weeks of life. In contrast, an IgG concentration of 400 to 800 mg/dL in a foal at high risk for sepsis because of its environment or other factors indicates the need for Ig replacement. Importantly, these figures only address *total* Ig content and not pathogen-specific antibody titers, which also play a critical role in determining risk for certain infectious diseases.

In healthy foals that nurse within 2 hours of birth, serum IgG concentrations become detectable at approximately 6 hours of age and peak at approximately 18 hours. Routine determination of serum IgG concentrations in apparently healthy foals is usually recommended between 12 to 24 hours of age. Foals considered to be at high risk for FPT and sepsis may be assessed as early as 6 to 12 hours of age.[34,35]

Importantly, since endogenous production of Igs in the foal takes an average of 2 to 4 months to reach protective levels, and colostrum-derived IgG concentrations decrease at a half-life of about 20 to 30 days, it is critical to ensure that minimum levels of transfer (>800 mg/dL or perhaps 1000 mg/dL serum IgG concentration) are measured after ingestion of colostrum in the foal's blood; this minimum amount of colostrum-derived IgG is expected to protect the foal beyond the first week of life, bridging this transition period in the first few months of life (see Fig. 53.3).

Described methods for IgG quantitation include turbidimetric immunoassay, radial immunodiffusion (RID), enzyme-linked immunosorbent assay, zinc sulfate turbidity, latex agglutination, and glutaraldehyde coagulation.[34,36-41] Selection of an appropriate screening test for a specific farm or foaling environment should be made after considering overall accuracy based on sensitivity and specificity, time necessary to perform the test, simplicity of the testing procedure, technical skills and knowledge of the attending personnel, and cost. Turbidimetric immunoassay and RID are the most accurate quantitative (actual value) diagnostic tests; turbidimetric tests provide immediate results, whereas RID turnaround is 24 hours, which may be impractical when an at-risk foal needs rapid diagnosis and treatment. Total serum protein is not a reliable indicator of FPT in foals (unlike calves) because of the wide variation in total serum protein in cases of adequate transfer; serum globulin values correlate better with IgG values when using appropriate cutoff points.[41-45] Many veterinarians prefer to use semiquantitative commercial kits based on enzyme-linked immunosorbent assay or glutaraldehyde coagulation technology for stall-side screening of foals.[40-43] Both types of tests have high sensitivity and negative predictive value. False-negative and false-positive results tend to be more common when attempting to accurately identify foals with partial FPT of IgG concentrations between 400 and 800 mg/dL. These tests do not provide actual values above 800 mg/dL, which prevents predicting humoral protection throughout the first few months of life, given the half-life of colostrum-derived IgG (see Fig. 53.3).

No consistent changes in the blood work are seen in foals with FPT; however, a range of abnormalities related to secondary infection (e.g., neutrophilia, neutropenia), hyperfibrinogenemia, and hypoglycemia may be present. The presence and severity of these changes depend on the organisms and systems involved.

Necropsy Findings

No specific necropsy findings are indicative of FPT. Necropsy findings reflect the site and severity of secondary infectious problems that have developed. Lymphoid tissue is normally developed, unless secondary infections have caused lymphoid necrosis or atrophy.

Treatment and Prognosis

Treatment of FPT depends on the degree of FPT, the environment in which the foal is exposed, the foal's age at diagnosis, and the presence of secondary infectious problems. Treatment is aimed at minimizing exposure to pathogens, supplying immunoglobulins, and managing secondary infections, if present.

If FPT can be anticipated within hours of birth because of premature lactation, low-specific-gravity colostrum, or a weak or orphaned foal, treatment can include the provision of an alternative source of colostrum or antibody orally. Foals with complete colostrum deprivation require approximately 1.5 g

VetBooks.ir

IgG/kg body weight to achieve a peak serum IgG concentration of more than 800 mg/dL. In a 45-kg foal, administration of 1 to 3 L of colostrum with a specific gravity greater than 1.060, divided into multiple hourly feedings over the first 6 to 8 hours of life, is desirable. Mares that donate colostrum for feeding should be healthy, checked for blood type, negative for anti-RBC alloantibodies (especially anti-A and anti-Q), and appropriately vaccinated during the last 4 to 6 weeks of gestation.

If equine donor colostrum is not available, bovine colostrum, a commercial colostrum substitute, or equine plasma may be administered orally to the foal.[46-53] Because bovine colostrum is often more readily available than equine colostrum, it may be substituted in emergency situations when equine colostrum is not available. Bovine colostrum is relatively well absorbed in the foal, but bovine immunoglobulins have a much shorter half-life in foals and do not contain antibodies specifically directed against equine pathogens. It is certainly better than no colostrum and, on the basis of a small experimental study, may be used without creating adverse reactions.[4,11,48,49] Approximately 2 to 4 L should be administered orally, and many foals develop transient mild diarrhea; increased colostrum-derived gamma-glutamyl transferase (GGT) values will be measured in the foal's blood for a few weeks.

Concentrated equine serum products such as Seramune Oral (Sera, Inc., Shawnee Mission, Kan.) are available for use in foals with FPT.[54] In one study, however, it failed to increase serum IgG concentrations in colostrum-deprived foals to adequate levels, probably because of the relatively low total IgG dose administered.[53] If the product contains 25 to 30 g of IgG/300-mL bottle, approximately three bottles may be required to increase the serum IgG concentration of a 45-kg colostrum-deprived foal to greater than 400 mg/dL.[53]

If no other sources of immunoglobulin are available for a foal, oral administration of equine plasma or serum may be considered. This is an expensive source of oral Ig, however, and approximately 2 to 4 L are required to treat a colostrum-deprived 45-kg foal.

If the foal is older than 6 hours of age, the absorption of colostral antibody is significantly decreased, although a locally protective effect of the colostrum may still be present in the intestinal tract. If the foal is older than 12 hours of age, it is unlikely that sufficient colostrum will be absorbed; therefore Ig levels should be rechecked at 24 hours and intravenous (IV) plasma transfusion given, if indicated by persistently low serum Ig levels.

Some animals with FPT, particularly partial FPT, do well without treatment if they are systemically healthy, are not heavily exposed to pathogens, and have no preexisting infections. FPT itself is not necessarily fatal. If plasma transfusions are not administered, owners should be made aware of the risks, and these foals should be maintained in an environment with minimal exposure to potential pathogens. Foals with other risk factors for septicemia (e.g., prematurity, dysmaturity, placentitis) should receive IV plasma transfusions if they have blood IgG concentrations of less than 800 mg/dL at 12 to 24 hours of age. Importantly, foals with FPT may develop recurrent infections around 1 to 2 months of age when blood IgG concentrations are below protective levels or until endogenous IgG production reaches protective values. Therefore checking serum IgG concentrations should also be a practice in foals with recurrent infections during this transition time.

If the decision is made to supplement plasma parenterally, equine plasma for transfusions can be collected and processed locally or obtained commercially. Available sources of commercial equine plasma include Plasmune (formerly Foalimmune) and HiGamm-Equi (Lake Immunogenics, Inc., Ontario, N.Y.); Equi-Plas and Polymune (Plasvacc USA, Inc., Templeton, Calif.); and Immuno-Glo Normal Equine Plasma (Mg Biologics, Inc., Ames, Iowa).[55] Commercial sources are convenient, save time, have been screened for anti-RBC antibody, contain minimal amounts of RBCs, are free of diseases such as equine infectious anemia, and originate from animals with known Ig levels. The major disadvantage is that plasma may not contain antibodies specific for the pathogens from the particular environment to which the foal is exposed.

Use of a local donor has the potential benefit of providing antibodies specific to the environmental pathogens to which the foal has been exposed. If a local donor is to be selected, several criteria should be met. First, the horse should be healthy, and results of agar gel immunodiffusion for equine infectious anemia should be negative. Second, no anti-RBC antibody should be detectable in the horse's serum. The donor's plasma should be screened for lysins and agglutinins by a blood-typing laboratory against a panel of cells representing all known blood groups. If plasma evaluated in this way is not available, the presence of anti-RBC antibody in donor plasma can be crudely evaluated with a minor crossmatch for agglutination using donor plasma and recipient blood cells. Lytic antibodies require an external source of complement for activity in vitro and may not be detected using this test.

Ideally, a third criterion is selection of a horse that is negative for blood group factors Aa and Qa. Even though there are dozens of blood group factors, Aa and Qa have been associated with the great majority of cases of neonatal isoerythrolysis (NI).[56-58] If plasma is collected and separated by sedimentation, it is inevitable that some RBC contamination be present. If Aa-positive (Aa+) RBCs are given to an animal that is Aa negative (Aa–) or if Qa+ RBCs are given to an animal that is Qa–, the recipients could become sensitized to these antigens. This sensitization probably would not have any immediate consequences for the recipient foal because the foal's cells would not be affected by the antibodies, but it has potentially sensitized any Aa– and Qa– females for production of a foal with NI later (see the Diseases Caused by Allogeneic Incompatibilities [Horses and Ruminants] section later in this chapter). To avoid these potential complications, the ideal donor should be Aa– and Qa– and possess no anti-RBC antibody in its serum. It is desirable to have identified this type of donor to avoid the need for immediate crossmatching in every case of plasma transfusion.

The volume of plasma needed to correct the measured IgG deficit in a foal can theoretically be calculated on the basis of the blood volume of the foal and the concentration of IgG in the foal's serum and in the donor plasma; however, these calculations do not reliably predict the actual levels of IgG achieved after transfusion.[34,59] A 20-mL volume of plasma per kilogram of body weight administered intravenously in general raises serum IgG levels 200 to 300 mg/dL, and often two to three times this amount is necessary to bring serum IgG levels into the range considered the minimum for protection (e.g., 800 mg/dL).[34,60] If the foal is already clinically ill, additional plasma often will be required to raise IgG levels an equivalent amount.[34,40] In a newborn foal (estimated at 50 kg) with complete FPT, between 2 and 4 L of plasma is frequently necessary.

Plasma should be administered through an IV catheter placed aseptically in one jugular vein. Frozen plasma is thawed and warmed slowly to room temperature in a lukewarm water bath. Microwave thawing or thawing with high temperatures is not recommended because this may denature important plasma proteins. An appropriate in-line blood filter should be used for IV administration of any blood product to remove fibrin clumps and other debris. Initial infusion rates should be slow (0.5 mL/kg over 10 to 20 minutes) to monitor for adverse reactions. Muscle fasciculations, piloerection, increased heart or respiratory rate, fever, respiratory distress, abdominal pain, soft feces, blanching of mucous membranes, and collapse are indicative of transfusion reactions. One dose of flunixin meglumine has been used in cases of adverse reactions, and

VetBooks.ir

plasma transfusion may be attempted again at a slower rate. In the absence of these or other adverse effects, the remainder of the transfusion may be administered in 30 to 40 minutes. Slower infusion rates are recommended for foals that are systemically ill. If other IV fluid therapy is being administered concurrently, slower infusion rates are also indicated to diminish the likelihood of inadvertent fluid overload.

Serum IgG concentrations in the foal should be rechecked 24 hours after plasma transfusion to confirm that the desired increase has been achieved. The delay from transfusion to IgG assessment is necessary to allow for distribution of Ig into extravascular spaces. Healthy foals transfused with plasma at 1 day of age experienced a 30% decrease in serum IgG concentrations by 7 days of age.[59] This decline may be even more marked in septic foals with increased vascular permeability, increased catabolism, and increased demand for use in immune responses.

Although several equine serum-derived products are marketed for IV administration in the treatment of foals with FPT, these products have been associated with significant adverse reactions in some foals. Administration of high-quality equine plasma is preferred for treatment of foals with FPT.

Prevention and Control Evaluation of colostral Ig content has proved to be valuable in predicting the occurrence of FPT and assessing the neonate's risk for FPT.[34,61] Colostrum with high Ig concentration tends to be sticky, yellow, and thick, but these subjective criteria are unreliable in assessing colostral quality. The quantity of Ig in colostrum may be more accurately estimated by single RID, refractometry, glutaraldehyde coagulation, or specific gravity.[62] Because 24 hours are required to read the results of RID, it is more practical in a field situation to assess specific gravity with the other tests. A handheld Brix 0% to 50% sugar refractometer provides a simple and cost-efficient stall-side screening test for assessing colostral quality.[63,64] A Brix reading of 20% to 30% correlates with adequate colostral quality; a reading greater than 30% indicates good-quality colostrum.[65] A commercial kit based on glutaraldehyde coagulation of immunoglobulins is the Gamma-Check-C (Veterinary Dynamics, San Luis Obispo, Calif.). Colostral specific gravity using a colostrometer such as the Equine Colostrometer (Lane Manufacturing Company, Denver, Colo.) should be at a minimum of 1.060, corresponding to an IgG concentration greater than 3000 mg/dL; levels of 6000 mg/dL or higher are desirable. Approximately 75% of foals that ingest colostrum with a specific gravity less than 1.060 will have serum IgG concentrations less than 400 mg/dL; when colostral specific gravity is greater than 1.060, foals usually attain serum IgG concentrations above 500 mg/dL.[62]

Some of the causes of FPT can be alleviated or recognized for early intervention by careful management. These include identification of mares that drip colostrum before parturition, attendance at foaling to ensure that foals suckle within several hours of birth or are supplemented artificially with colostrum, and screening of high-risk foals with doubtful nursing histories. Routine screening of foals between 12 and 24 hours of age allows early identification of FPT and potentially allows for therapy before the onset of infections. Although signs of septicemia secondary to FPT are often first observed on days 3 to 4 of life, a bacteremia may already be present at 24 hours of age or earlier.[62,65]

A colostrum bank can be established by collecting small amounts of colostrum from lactating mares (e.g., 200 to 250 mL) within the first 2 hours after foaling. This is only about 10% of the total colostrum produced by the average mare in the first 24 hours after parturition and therefore does not adversely affect the foal suckling the donor mare. Although the volumes are quite variable, mares produce about 300 mL of colostrum per hour and about 5 L during the first 18 hours. Colostrum can be stored frozen for at least 1 year at standard freezer temperatures, approximately –20° C (–4° F). Although frozen immunoglobulins are stable for much longer, the overall quality of the colostrum may deteriorate. Ideally, banked colostrum should be screened for the presence of anti-RBC antibodies as advised for plasma. Colostrum typically has low titers of agglutinins, which are probably not of significance unless they present a dilution of one eighth or greater.

Transient Hypogammaglobulinemia*

M. Julia B. Felippe

Definition and Etiology Transient hypogammaglobulinemia is a rare disorder characterized by the delayed onset of Ig synthesis in the foal.[1-4] Foals normally produce some IgM and trace amounts of IgG in utero and begin to produce significant amounts of immunoglobulins after birth following exposure to environmental antigens (see Fig. 53.4). Assuming adequate passive transfer, maternal antibody fills the void from birth until the foal has produced sufficient autologous antibody for protection (e.g., first 2 months). For unknown reasons, in transient hypogammaglobulinemia, the onset of endogenous antibody production is delayed in the first 6 months of life, but in some cases, protective levels of IgG (i.e., >800 or 1000 mg/dL) may be reached only by 2 years of age. As maternal immunoglobulins wane, the amount of endogenous antibody is transiently insufficient to be protective, making the foal highly susceptible to infections; recurrent pneumonia is a common presentation.

This disorder has been described in the literature in an Arabian foal and a Thoroughbred foal, but this author has diagnosed the condition in other foals. It is possible that this condition is underdiagnosed because testing serum IgG concentrations in older foals (i.e., beyond the first week of life) is not common practice in equine medicine. Therefore to make a diagnosis, serial samples may be required to document that autologous Ig is not increasing sufficiently as maternal Ig declines. Many cases that are not followed this closely probably occur.

Clinical Signs and Differential Diagnoses Clinical signs occur more often when passively acquired antibodies are catabolized to nonprotective levels, which may happen in the first month of life. As with other Ig deficiencies, signs consistent with the recurrent infections are seen in affected foals. The differential diagnosis list should include FPT and, if the affected animal is male, agammaglobulinemia.

Clinical Pathology The cardinal features are persistently low serum Ig concentrations and recurrent bacterial infections that require antibiotic therapy.[1,2] Determining low levels or nonprotective levels of Ig in young foals is challenging because of variable amounts of passively transferred immunoglobulins, their catabolism, presence of infections in early age, environmental risks, and age-dependent developmental aspects of the immune system, among other factors. In the event of a robust passive transfer of antibodies at birth, colostrum-derived antibody concentrations are expected to wane by 3 to 4 months of age, and foals with normal immune system development will have produced measurable quantities of endogenous antibodies by then. Therefore serum IgG concentration of 500 mg/dL and serum IgM concentration of 50 mg/dL are commonly measured in affected and normal foals between 3 and 6 months of life; however, in foals with transient hypogammaglobulinemia, the concentrations of immunoglobulins,

*Contributions to previous editions by Melissa Hines, Jill R. Johnson, and Debra C. Sellon are acknowledged.

VetBooks.ir

including IgG and IgM, do not increase with age at the same degree when compared with age-matched samples.

Affected foals have normal cell-mediated responses in vitro and in vivo and appear to be able to respond to immunization to some antigens. Normal numbers of B and T lymphocytes are present in blood and lymph nodes. However, some foals may present CD4 T-cell lymphopenia and low CD4/CD8 ratio distribution (<2).[5] In addition, the age-dependent increase in the expression of MHC class II molecules on lymphocytes, but not on monocytes, is delayed.[5]

Differentiation between FPT and transient hypogammaglobulinemia is based on the age of the patient at evaluation. Transient hypogammaglobulinemia must be differentiated from agammaglobulinemia. Both disorders have normal lymphocyte counts and normal responses to PHA skin testing and show waning levels of maternal IgG and IgGT if followed serially. However, transient hypogammaglobulinemia cases usually have low but detectable levels of IgM and IgA, whereas agammaglobulinemia cases usually have no detectable levels of these immunoglobulins. Differentiation between the two may require serial sampling to show that Ig production does ultimately increase in the patient with transient hypogammaglobulinemia. Moreover, B lymphocyte count is absent in cases of agammaglobulinemia and normal in cases of transient hypogammaglobulinemia.

Pathophysiology

The cause of this delayed development of the humoral immune response is currently unknown. A proposed mechanism is inadequate lymphoid tissue milieu to support B-cell differentiation.[5] Immunoglobulin is critical for neutralization and opsonization of pathogens for efficient phagocytosis and killing by phagocytes; therefore recurrent bacterial infections are common and require continued or intermittent antibiotic therapy. A syndrome of transient hypoglobulinemia of infancy has been described in children and is characterized by recurrent infections and one or more reduced serum Ig levels.[6-7] The pathophysiology of this disorder is also not completely understood.

Necropsy Findings

No specific gross or microscopic lymphoid changes have been associated with transient hypogammaglobulinemia. Necropsy findings would reflect the secondary infectious processes that have affected the foal.

Treatment and Prognosis

The goal of therapy is to minimize infections until the foal's immune system begins to function adequately. Treatment should include antimicrobial therapy and plasma transfusions for Ig replacement as needed; periodic (i.e., every 2 months) evaluation of serum IgG and IgM concentrations and distribution of CD4 and CD8 T cells and B cells in peripheral blood document trends in values and resolution of this transient condition and determine the continued need for supportive therapy. With appropriate support the prognosis is good, as the hypogammaglobulinemia resolves with time.

Severe Combined Immunodeficiency*

Melissa T. Hines

Definition and Etiology

Severe combined immunodeficiency (SCID) is a group of disorders in which both T- and B-cell functions are absent.[1-4] SCID has been recognized in several species, including humans, mice, dogs, pigs, and horses.[2-10] In horses, the condition primarily affects Arabians and part-Arabians, although sporadic cases have been described in other breeds, such as Caspians and Appaloosas.[2,3,11,12] Affected foals are highly vulnerable to infections as a result of a stem cell defect that prevents maturation of T and B cells and leads to a complete inability to produce antigen-specific immune responses. In horses of Arabian breeding, the condition is transmitted as an autosomal recessive trait.[13]

Clinical Signs and Differential Diagnoses

Foals clinically affected with SCID are typically normal at birth, but the absence of both specific humoral and cellular immunity renders them susceptible to infections once colostral protection wanes.[2,3] Typically, affected foals develop infectious diseases between birth and 2 months of age and die before 5 months of age. The exact age of onset of infectious disease depends to some degree on the adequacy of passive transfer of maternal immunity and the degree of environmental challenge by organisms. Infections in affected individuals can be caused by a variety of bacterial, viral, parasitic, and fungal agents, some of which rarely affect animals that are not immunocompromised.[2,14-19] Many body systems may be involved, but pneumonia is particularly common. *P. jirovecii* (formerly called *Pneumocystis carinii*) pneumonia and adenoviral pneumonia are often found in SCID foals as compared with other foals. Differential diagnoses include other immunodeficiencies of foals.

SCID in Arabians and Arabian-cross horses has an autosomal recessive mode of inheritance. Thus foals of Arabian breeding that show clinical manifestations of SCID are homozygous for the defective SCID gene. Carriers of the gene are asymptomatic but can be detected by production of an affected offspring or genetic testing.[20,21] A correlation between heterozygosity for the SCID allele and the development of sarcoids has been demonstrated, suggesting that the gene may play a role in tumor suppression.[6]

Clinical Pathology

A consistent finding on the hemogram of affected foals is an absolute lymphopenia, which is less than 1000 lymphocytes/μL and often much lower.[22,23] Depending on the neutrophil response, the total white blood cell (WBC) count may be low, normal, or elevated, making it essential that the absolute number of lymphocytes be determined. Septic and other compromised foals, as well as some normal foals, may have low lymphocyte counts during the first few days of life; therefore persistent lymphopenia should be established before considering a diagnosis of SCID.[24]

Concentrations of autologous serum Ig are low in foals clinically affected with SCID.[22,25-27] The presence of colostral antibody may mask these low levels of autologous Ig; therefore the degree of colostral transfer and the age of the foal should be considered when interpreting the serum Ig values (see Table 53.6). In normal foals, IgM is produced in utero, and thus some IgM should be present in presuckle serum.[28] Although not pathognomonic, the absence of IgM in presuckle serum is a feature of SCID. Also, due to the relatively low concentrations of IgM in colostrum and the short half-life of IgM (see Table 53.7), maternally derived IgM is generally absent from the circulation by about 3 weeks of age. Thus the absence of serum IgM after 3 weeks of age, although also not pathognomonic, is consistent with SCID.

Foals affected with SCID do not respond to intradermal phytohemagglutinin (PHA) by increasing skin thickness as do normal foals, nor do they respond to DTH stimulators, such as dinitrochlorobenzene.[29] In vitro tests such as blastogenesis are depressed with all mitogens.[22,23,26] The definitive diagnosis of SCID in foals of Arabian breeding is based on genetic testing demonstrating that the foal is homozygous for the defective SCID gene.[20,30] Pulled hair, whole blood in ethylenediaminetetraacetic acid (EDTA), or bristle-style cheek swabs may be submitted to VetGen (3728 Plaza Drive, Suite 1, Ann Arbor, Mich., 48108, vetgen@vetgen.com, www.vetgen.com) for DNA

*Contributions to previous editions by Jill R. Johnson and Debra C. Sellon are acknowledged.

testing to determine if a horse is clear, heterozygous, or homozygous for the gene defect. Before the advent of genetic testing, the criteria required to confirm a diagnosis of SCID included (1) persistent lymphopenia (<1000/μL), (2) absence of serum IgM in presuckle samples or samples collected after 3 weeks of age, and (3) thymic hypoplasia along with characteristic histopathologic changes in lymphoid tissue.[27,31] These criteria were used to diagnose SCID in a Caspian filly with pneumonia that was negative for the defective gene of Arabians.[11] Therefore different mutations could be involved in some cases of SCID.

Pathophysiology Foals of Arabian breeding with SCID have a mutation in the gene encoding the catalytic subunit of DNA-dependent protein kinase (DNA-PK) and thus lack activity of this enzyme.[4,7,30,32,33] The mutation results in a five–base pair deletion in the gene on equine chromosome 9. This deletion results in a frameshift and a 967 amino acid deletion from DNA-PK, making the protein unstable. Without functional DNA-PK, lymphocyte precursors are unable to complete gene rearrangement events that lead to the expression of antigen-specific receptors on lymphocyte surfaces, namely T-cell receptor and immunoglobulin. As a result, there is an absence of mature, functional T and B lymphocytes. IFN-γ, which is a cytokine primarily produced by lymphocytes, is deficient.[34]

Neutrophils, monocytes, and NK cells appear to be fully functional, and complement concentrations are normal.[2,35,36] Although these nonspecific protective mechanisms appear to be intact, the absence of both cell-mediated and antibody-mediated immunity leaves the foal vulnerable to even innocuous infectious agents.

Epidemiology SCID has been reported in Arabians in the United States, Canada, Australia, Morocco, and Great Britain.[2,3,37-39] It is believed that the trait originated in a horse in Great Britain and subsequently was imported into other countries. The widespread distribution of this disease provides a significant example of the *founder effect* in population genetics.

The prevalence of SCID at one time was estimated to be 2% to 3% of Arabian foals born in the United States.[40] From this estimate, it was predicted that the numbers of SCID carriers at that time could be as high as 25% of the U.S. Arabian horse population. The number of carriers appears to have decreased. Studies of Arabian horses in 1998 and 2002 found the frequency of SCID gene carriers to be approximately 8%, leading to the prediction that 0.18% of Arabian foals would be affected with SCID, assuming a random breeding population.[6,38] In a study of Arabian foals in South Africa, the carrier prevalence of SCID decreased significantly from 6.4% in the 2004/2005 foals to 3.4% in the 2009/2010 foals, and it was suggested that genetic screening may have played a role in reducing the carrier prevalence.[41] Several hereditary conditions in addition to SCID can affect Arabians, and while studies are limited, it is suspected that these are most likely distinct conditions. A study of ten Egyptian Arabian horses with juvenile idiopathic epilepsy found no association between this disorder and SCID.[42]

Necropsy Findings Lymphoid tissues should be evaluated both grossly and histologically in cases of suspected immunodeficiencies. In SCID, the thymus is small and has a fatty appearance on gross examination.[26,31,43] Because the thymus may be difficult to identify, mediastinal tissue often must be collected "blindly" for subsequent histologic evaluation and identification of thymic remnants. Histologically, the thymus is largely replaced with adipose tissue, with only islands of lymphoid cells and partially formed Hassall's corpuscles present.

The spleen and lymph nodes may not be significantly abnormal on gross examination, but they generally have microscopic abnormalities, including the absence of germinal centers and periarteriolar lymphocytic sheaths in the spleen, as well as absence of germinal centers with scarcity of lymphocytes in other areas of lymph nodes (Fig. 53.5, *A*).

Foals with SCID typically have evidence of infectious disease on necropsy, with bronchopneumonia being particularly common (Fig. 53.5, *B*). Infectious lesions in other systems, such as colitis and hepatitis, are also frequently found.

Treatment and Prognosis Affected foals invariably die by about 5 months of age, despite intensive conventional therapy (e.g., antimicrobials, plasma transfusion, isolation).[44] There is no practical method of curing affected foals at this time. Successful bone marrow transplants have been performed between histocompatible full siblings in a research setting, but this option remains impractical.[45-47]

Prevention and Control SCID in horses of Arabian breeding is an autosomal recessive trait, and therefore production of an affected foal identifies both sire and dam as carriers of the SCID gene.[13] Mating of two carriers is expected to

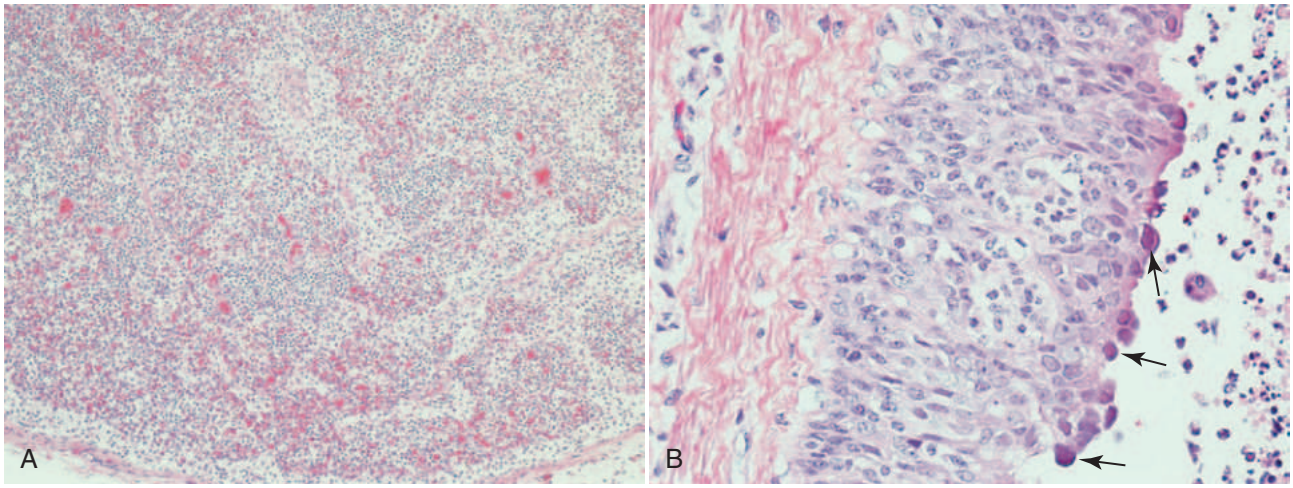

FIG. 53.5 Tissue from an Arabian foal with severe combined immunodeficiency (SCID). The foal presented at 1 month of age for evaluation of persistent pneumonia. **A,** 200× mediastinal lymph node with extensive lymphoid atrophy. The node is poorly populated with lymphocytes that fail to form lymphoid follicles, and active germinal centers are lacking. The node is predominantly composed of loosely scattered mononuclear cells and edema. **B,** 400× tracheal epithelium with adenovirus inclusion *(black arrows)*, epithelial hyperplasia, and suppurative tracheitis. *(Photos courtesy Sushan Han.)*

result in 1 in 4 foals affected with SCID, 1 in 4 completely normal and not a carrier, and 2 in 4 asymptomatic carriers of the SCID trait. Mating of a carrier and a normal horse (noncarrier) does not produce any affected foals, but half the offspring would be expected to be carriers.

The disease can be controlled in horses of Arabian breeding by avoiding the production of affected foals, which has been simplified now that carriers can be identified by genetic testing. Mares and stallions intended for breeding should be tested to determine whether they are free or heterozygous for the defective SCID gene. Under no circumstances should two heterozygotes be mated to each other. If an owner decides to continue breeding a heterozygote, the breeding partner should be confirmed homozygous normal. All foals from such matings should be tested to determine if they are clear of or heterozygous for the defective gene (50/50 probability). Only homozygous normal foals should be selected for future breeding purposes, whereas heterozygous foals should be used for nonreproductive purposes. The decreasing prevalence of SCID provides support for the positive effect of genetic screening.[6,38,41]

Foal Immunodeficiency Syndrome

M. Julia B. Felippe

Definition and Etiology Foal immunodeficiency syndrome (FIS), previously known as *Fell Pony syndrome* and also referred to as "anemia, immunodeficiency, and peripheral ganglionopathy," is an inheritable and fatal condition characterized by profound anemia and septicemia, the latter due to a primary immunodeficiency. A genomewide study identified a mutation in the gene *SLC5A3* on chromosome ECA26 associated with the syndrome.[1] The mechanistic implications of this mutation have not been fully resolved, and a causal relationship between the *SLC5A3* mutation and FIS requires further studies to date. The presence of other mutations in that genomic region has not been ruled out as being responsible for the phenotype of the immunodeficiency syndrome.

Clinical Findings, Clinical Signs, and Differential Diagnoses FIS-affected foals are born apparently healthy but rapidly fail to thrive. The fatal illness becomes clinically apparent in foals within 1 month, and death occurs generally by 3 months of life due to a primary, profound, nonregenerative anemia and B-cell lymphopenia, with increased susceptibility to opportunistic infections and septicemia.

The foals present with weight loss and dullness, pale mucous membranes, and signs of infection, including diarrhea and pneumonia.[2-4] Enterocolitis, bronchopneumonia, pancreatitis, and glossal hyperkeratosis are often caused by opportunistic infections (e.g., *Escherichia coli*, *Cryptosporidium* spp., adenovirus). The severe, progressive anemia results from lack of erythrocyte production in the bone marrow (nonregenerative), and it is not associated with hemorrhage or hemolysis.[2,3,5]

Clinical Pathology At birth, blood work may be normal, with normal or borderline low erythrocyte counts and hemoglobin values and normal distribution of neutrophils and lymphocytes.[5] When infections are present, abnormalities in the leukogram, including regenerative neutropenia or neutrophilia, toxic changes in neutrophils, and lymphopenia, may be present, and values vary depending on the type and phase of infection. Thrombocytes are often present in the blood at normal values unless disseminated intravascular coagulopathy secondary to septicemia is present.

Severe normocytic or macrocytic anemia develops rapidly. Based on bone marrow cytology, FIS-affected foals may be born with erythroid precursors but rapidly evolve to erythrocyte hypoplasia. At birth, hemoglobin and hematocrit values may be measured in the low end of the normal reference range, and peripheral blood B-cell distribution may be equivalent to that of healthy, unaffected foals. In a few weeks, profound anemia and B-cell lymphopenia develop. In time, cytologic evaluation of the marrow reveals differentiating myeloid precursors, megakaryocytes, and/or paucity of hematopoietic precursors. When present, proerythroblasts have been described to be binucleate.[4]

Immunologic Findings Absolute lymphopenia in FIS-affected foals likely reflects poor lymphocyte development in primary and secondary lymphoid tissues, as well as failure of lymphocyte population expansion with age.[6,7] B-cell distribution in blood may be within normal or low-normal values at birth but rapidly declines in the first few weeks of life.[5,8] Although CD4+ and CD8+ T-cell distributions have been reported as normal in affected foals, T-cell dysfunction is suggested by the small thymus and opportunistic infections with cryptosporidia and adenovirus.[7,9] The expression of MHC class II molecules in peripheral blood lymphocytes may be decreased and/or fail to increase with age in FIS-affected foals when compared with healthy foals, also supporting abnormal lymphocyte development.[10] Nevertheless, when stimulated in vitro, the peripheral blood lymphocytes of affected foals respond normally to mitogens PHA, concanavalin A (ConA), and pokeweed mitogen (PWM).[4,7]

Although the B-cell lymphopenia limits the ability of FIS-affected foals to produce immunoglobulins, serum IgG concentrations are often normal when clinical signs are detected due to the presence of circulating colostrum-derived antibodies.[2-4,11] Nevertheless, serum IgM concentration (a parameter not confounded by colostrum-derived antibodies at this age) is low or not detectable in affected FIS-affected foals and strongly suggests impaired primary humoral immune response.[5,11,12] FIS-affected foals develop septicemia despite normal (colostrum-derived) serum IgG concentrations, suggesting a broad lymphocytic dysfunction.[4,5]

The distribution and function of neutrophils have been reported as normal, including the presence of bands and normal oxidative burst activity.[4]

Pathophysiology Bone marrow cytologic studies performed prospectively in affected foals immediately after birth and before clinical signs became evident at a later age revealed evidence of initial erythroid hyperplasia with dysplasia, followed by a rapid and progressive hypoplasia and aplasia, as well as marked anemia.[5] In addition, a concomitant mild myeloid dysplasia could be observed, which questions the involvement of further types of cells.

The presence of erythrocytes and B cells in peripheral blood at birth suggests a limited hematopoiesis during fetal life. Nevertheless, this cell production is not sustained after birth, leading to a marked and progressive anemia and B-cell lymphopenia in the perinatal phase, corresponding clinical signs, and death. Erythrocytes and B lymphocytes are the most severely affected cell populations in FIS, and both undergo critical developmental stages in the bone marrow. The condition may be caused by independent or common genetic abnormalities that affect both cell lines. Most early B-cell differentiation essential genes and genes associated with erythropoiesis are expressed in the affected foals, and a potential common hematopoietic genetic defect is still under investigation.

Epidemiology FIS is a genetic and inheritable fatal immunodeficiency condition that occurs in male and female young foals of the Fell and Dales breeds and potentially in other breeds that include common ancestors.[13,14]

The Fell Pony breed experienced loss of genetic diversity due to the small numbers of animals and overuse of prominent

VetBooks.ir

stallions, which likely led to the spread of the genetic defect. Pedigree analysis of the Fell Pony breed suggests that FIS may have an autosomal recessive inheritance. Carriers are phenotypically normal. FIS was initially described in the United Kingdom and subsequently in Fell Pony foals in the United States, Czech Republic, and Netherlands.[2,4,15,16]

Necropsy Findings In the postmortem, abnormal gross findings include generalized tissue pallor, thymic hypoplasia, and inflammation and lymphadenopathy associated with infections of many organs (e.g., necrotizing enteritis, pyogranulomatous bronchopneumonia, pancreatitis, myocarditis). The medullary cavities of bones often do not contain marrow but instead pale, tan, fatty tissue, a striking finding in early age. Histopathology reveals severe erythroid hypoplasia, with small numbers or absent late erythroid precursors in the bone marrow, and high myeloid-to-erythroid ratio (ranging from 16 to 32:1, compared with the normal myeloid-to-erythroid ratio of 0.5 to 1.5:1).

Despite lymphadenopathy, there is severe lymphocytic hypoplasia and lack of secondary lymphoid follicles in the lymphoid tissues; in addition, plasma cells are absent. Immunohistochemical staining detects no B lymphocytes in the bone marrow and rare or few B cells in the lymph nodes and spleen, dispersed in the tissues without forming germinal centers. In addition, peripheral ganglionopathy characterized by neuronal chromatolysis involving trigeminal, cranial mesenteric, and dorsal root ganglia has been reported.[2]

Treatment and Prognosis FIS is a fatal disease, and foals die or are submitted to euthanasia soon after the initial clinical signs. Management of infections and septicemia may be temporarily possible with antibiotic therapy; however, the combination of infectious organisms, commonly viruses and bacteria, prevents a sustained protection. The severe, progressive anemia is a major challenge for treatment.

Prevention and Control A DNA-based carrier test was developed by the Animal Health Trust (Newmarket, United Kingdom).[1,14] The genetic test offers powerful herd management planning to avoid the mating of two carriers with the genetic defect and consequently to decrease the incidence of FIS, a fatal disease to date. The use of the genetic test has been shown to reduce the number of births of affected foals.[17]

Agammaglobulinemia*

Melissa T. Hines

Definition and Etiology Agammaglobulinemia in horses is a rare primary immunodeficiency characterized by complete B-cell dysfunction with an intact cell-mediated response. The disorder is associated with a failure of B-lymphocyte maturation, absent or very low serum Ig concentrations, and failure of specific antibody production. It has been described in Thoroughbreds, Quarter Horses, and Standardbreds, and thus far it has been reported only in males, suggesting that the trait may be X-linked.[1-4] Although this linkage has not been proven in the horse, the disorder is sometimes referred to as X-linked agammaglobulinemia. The first report of an immunodeficiency in any species was agammaglobulinemia in a young boy, and it was subsequently established that the most common form of agammaglobulinemia in humans is X-linked.[5-11]

Clinical Signs and Differential Diagnoses Horses with agammaglobulinemia typically develop signs around 2 to 6 months of age as transferred maternal antibodies decline. The specific signs reflect the infections that develop. Pneumonia and septic arthritis, as well as dermatitis and enteritis, have been reported. Infections often respond poorly to therapy. The differential diagnosis list should include transient hypogammaglobulinemia and common variable immunodeficiency (CVID).

Clinical Pathology Total peripheral blood lymphocyte counts are within the normal range, but lymphocyte phenotyping reveals a lack of circulating B cells with normal numbers of T cells. Changes on routine laboratory evaluation are nonspecific and may reflect chronic infection. Depending on the response to infection, neutrophil counts may be normal, low, or high.

Serum concentrations of IgM, IgA, and all subisotypes of IgG are persistently low or absent. Depending on the age at evaluation, the assessment of antibody concentrations may be complicated by the presence of maternal antibody. Considering that the half-life of IgG is longer than that of IgM, serial sampling will demonstrate a decline in antibody concentrations, with IgM and IgA typically decreasing first, followed by a decrease in all subisotypes of IgG. In some foals, low levels of Ig may persist, possibly due to either a prolonged catabolism of antibody or some residual B-cell activity, which has been identified in human patients with X-linked agammaglobulinemia.[1-5]

Horses affected with agammaglobulinemia do not produce specific antibody in response to immunization regardless of the antigen. Cell-mediated responses are essentially normal, including lymphocyte proliferation in response to T-cell mitogens (PHA and PWM) and DTH skin testing by intradermal (ID) injection of PHA. In contrast, lymphocyte proliferation and DTH skin testing by ID injection of ConA is blunted, but the reason for this response to ConA remains unclear.[4] Total hemolytic complement activity is also normal.

Pathophysiology The molecular basis of agammaglobulinemia in horses is unknown, but a defect at the stem cell level that blocks early B-cell differentiation is suspected because all classes of Ig are affected. In human patients with X-linked agammaglobulinemia, a mutation in *Btk*, a gene encoding Bruton's tyrosine kinase, accounts for the disease.[7,8] Assessment of the *Btk* gene in horses may help in understanding this disorder.

Necropsy Findings Gross and histologic changes in the lymph nodes, spleen, and thymus have been observed in horses with agammaglobulinemia.[1-4] Lymph nodes are small and microscopically show as being devoid of germinal centers and follicles. Grossly, the spleen may be small and contracted and microscopically shows lack of germinal centers, periarteriolar lymphocytic sheaths, and plasma cells. The thymus may be small and difficult to locate, making it necessary in some cases to blindly sample tissue from the mediastinal region. Histologically, the thymus does not show recognizable epithelial structure and lacks defined nodules. The reason for cell-mediated functions to be normal while the architecture of the thymus is so abnormal remains unexplained.

Treatment and Prognosis In the absence of production of autologous antibody, affected horses develop recurrent infections. Although antimicrobial therapy and administration of plasma may temporarily control infections, the long-term prognosis is poor. In human patients with X-linked agammaglobulinemia, early diagnosis along with well-controlled Ig replacement therapy have allowed patients to survive well into adulthood.[9]

Horses with agammaglobulinemia illustrate that T cells make a significant contribution to immunity along with B cells. Horses with defects in both B- and T-cell functions (e.g., SCID) seldom survive to 5 months of age, whereas horses with a pure B-cell defect such as agammaglobulinemia may survive between 1 and 2 years. Agammaglobulinemia with a lack of

*Contributions to previous editions by Jill R. Johnson and Debra C. Sellon are acknowledged.

VetBooks.ir

circulating B cells was identified in a Pinto gelding that did not exhibit recurrent pyogenic infections until 3 years of age.[12] It is not certain whether this horse had agammaglobulinemia or a form of common variable immunodeficiency. Although it could not be established whether the immunodeficiency was primary or secondary, an underlying disease process was not identified.

Selective IgM Deficiency*

M. Julia B. Felippe

Definition and Etiology Selective IgM deficiency is a very rare, poorly characterized immunologic disorder described based on absent or markedly decreased serum IgM concentrations with normal or elevated levels of other Ig isotypes.[1] Three presentations of the disorder have been described in horses.[2-6] The most common involves foals that have severe infectious pneumonia, arthritis, or enteritis, resulting in death before 10 months of age. The second involves foals with a history of repeated episodes of infections that respond to antimicrobial therapy but recur when treatment is stopped. These foals tend to do poorly and are stunted, although they may survive for 1 to 2 years. The third involves older horses that are usually 2 to 5 years of age at initial diagnosis. These horses do not necessarily have problems with recurrent infections, but about half ultimately have lymphosarcoma.[6] Selective IgM deficiency has been most frequently reported in Arabians and American Quarter Horses, although it affects other breeds.

It is unclear whether the selective IgM deficiencies reported in foals are primary or secondary or are a feature of other immunodeficiencies. The levels of endogenous IgM present before the onset of infections have not been measured. The occurrence of multiple cases within groups of related horses suggests a genetic basis. However, to date, breeding trials have been inconclusive regarding the heritability of this condition. In humans, there is no described genetic or molecular mechanism as the cause of selective IgM deficiency, and this condition has been shown to manifest with infections, atopy, autoimmunity, and cancer, although it can also be asymptomatic.[7-9] Recent literature points out the importance of ruling out other humoral deficiencies and performing clinical case follow-up to confirm persistence of selective IgM deficiency.

Clinical Signs and Differential Diagnoses Foals with selective IgM deficiency tend to have frequent respiratory infections, and *Klebsiella* spp. are commonly isolated. Other infections, such as enteritis and septic arthritis, have also been reported. The age of onset of clinical signs may be slightly later than in foals with SCID, and the condition may be difficult to diagnose when colostrum-derived antibodies are still circulating. The most important differential diagnosis is delayed hypogammaglobulinemia of the young, which may take several months (i.e., 6 to 24 months) to resolve.

Although low serum IgM concentration has been shown to have a low specificity, sensitivity, and positive predictive value for the diagnosis of lymphoma, older horses with IgM deficiency should be carefully evaluated for neoplasia using definitive diagnostic tests (e.g., lymph node biopsy, cytology, and histology), since the clinical signs and hematologic features of lymphoma in horses are often nonspecific[10] (see Chapter 37).

Clinical Pathology Selective IgM deficiency is defined by a persistently low or absent serum IgM concentration, whereas levels for other classes of Ig are normal or elevated for age. Serum IgM concentrations are more than two standard deviations below the age-specific mean (see Table 53.6). In one study, serum IgM concentrations in adult healthy horses during a period of 5 months ranged from 50 to 242 mg/dL, and 20% of these horses had values below 60 mg/dL; based on these data, IgM deficiency was suggested at values lower than 23 mg/dL.[10] Serum IgM concentration of 10 to 22 mg/dL may be measured beyond 185 days of gestation in the equine fetus, and levels of 25 mg/dL may be measured in presuckle foals; however, there is marked individual variation in how serum IgM concentration increases with age.[11-13] Because IgM levels may transiently decrease, especially in critically ill foals, it is essential to document that IgM levels are persistently low rather than to base a diagnosis on a single sample. Lymphocyte counts and other in vitro immunologic tests, such as lymphocyte proliferation to mitogens (including PHA, ConA, PWM, and LPS), are generally normal.[2,4] However, in one horse with selective IgM deficiency, lymphocytes failed to respond to the B-cell mitogen LPS, whereas responses to the T-cell mitogens ConA and PHA were normal.[5] The hemogram and biochemical profile may reflect infection or inflammation, depending on the underlying infectious process (e.g., neutrophilia, hyperfibrinogenemia, anemia) and the organ system involved, but no diagnostically specific changes occur.

Pathophysiology The pathophysiology of selective IgM deficiency is difficult to explain when B-cell development in the bone marrow depends on IgM expression on the cell surface, as part of the B-cell receptor, and patients have normal numbers of IgM-expressing B cells.[1,7,8] Exclusive impaired secretion of IgM could be caused by intrinsic B-cell dysfunction or dysfunction of T cells during B cell–T cell interaction in lymphoid tissues, but it is curious why such deficiencies do not affect more elaborated B-cell differentiation into other isotype (e.g., IgG, IgA)–secreting plasma cells. Whether IgM is low because of decreased production, hypercatabolism, or loss is not known. In one case with lymphosarcoma, suppressor activity was identified in the neoplastic cells, suggesting that the low IgM may be a result of suppression of B-cell function by neoplastic cells.[5,14] IgM plays a role in complement activation and neutralization of antigens, but such functions can also be accomplished by IgG or IgA, which are generally within normal levels.

Necropsy Findings Lymphoid tissue in affected foals is grossly and histologically normal. Other findings reflect secondary infections. Pneumonia is frequently present and is often caused by infections with encapsulated bacteria (e.g., *S. aureus*, *S. zooepidemicus*, *A. equuli*, *Klebsiella* spp., and *E. coli*).[2,4]

Treatment and Prognosis For the clinical cases diagnosed in the literature, selective IgM deficiency has an unfavorable long-term prognosis. Most horses eventually succumbed to infection despite appropriate antimicrobial therapy. However, some of the reported foals recovered IgM and IgG productions when yearlings.[2,4] Plasma therapy may provide transient benefit not for IgM replacement (because only small amounts of IgM are present in plasma and the half-life of transfused IgM is short) but for expansion of IgG concentration and potentially coverage (neutralization, opsonization, complement activation) against pathogens.[7] No concentrated IgM preparations are commercially available for parenteral use. If persistently low IgM levels can be documented, a poor to grave prognosis can be expected.

Prevention and Control Some cases of selective IgM deficiency may be hereditary, and therefore it may be advisable to avoid repeating matings that produced an affected offspring. However, no firm recommendations can be made.

Common Variable Immunodeficiency

M. Julia B. Felippe

VetBooks.ir

Definition and Etiology Common variable immunodeficiency (CVID) in the horse is a rare, late-onset, clinically relevant immunologic disorder of inadequate antibody production due to impaired B-cell differentiation in the bone marrow and consequent B-cell depletion from lymphoid tissues and blood. The cause of impaired B-cell development in the bone marrow is under investigation, and a primary or secondary cause has not been resolved.

Clinical Findings, Clinical Signs, and Differential Diagnoses Most patients are reported to have had a healthy life until the signs of disease manifest as late-onset recurrent bacterial infections and fevers, hypogammaglobulinemia or agammaglobulinemia, progressive B-cell lymphopenia or depletion, and poor response to protein vaccination (e.g., tetanus toxoid).[1] The most common clinical signs include recurrent pneumonia, sinusitis, meningitis and/or neurologic disorders, abnormal gait (ataxia), peritonitis, gingivitis, hepatitis, diarrhea, susceptibility to GI parasites, uveitis, conjunctivitis, and skin abscesses.[2-4] Meningitis may clinically present with marked depression, alternated by periods of normal appetite. Weight loss and muscle atrophy are common.

The humoral feature of this immunodeficiency predisposes to infections and diseases caused by encapsulated bacteria, which requires opsonization with both antibody and complement for effective phagocytosis and bacterial killing. Therefore common pathogens involved in infections include *Staphylococcus* spp., *Streptococcus* spp., *Actinobacillus* spp., and *Klebsiella* spp. Occasionally, fungal infections, such as *Aspergillus* spp., *Bipolaris* spp., *P. jirovecii* (formerly *P. carinii*), or *R. equi* infections, have been diagnosed in a small number of CVID-affected horses that were treated with glucocorticoids or presented with a concomitant CD4+ T-cell lymphopenia.[1,5] In addition, *Borrelia burgdorferi* meningitis, cranial neuritis, and radiculoneuritis have been described in horses with B-cell lymphopenia and hypogammaglobulinemia.[6-8]

A differential diagnosis is lymphoma because some forms of this type of cancer may alter lymphocyte distribution and function, including B-cell lymphopenia and hypogammaglobulinemia. If the disease manifests before the yearling phase, differential diagnoses would include transitory hypogammaglobulinemia (in which B cells are normally present) of the young and X-linked agammaglobulinemia (in which B cells are absent).

Clinical Pathology During bacterial infections, blood work may reveal leukocytosis with neutrophilia, often mature, although a left shift and toxic changes may be present. Intermittent lymphopenia (<1200 cells/μL) is common. During the period when infections respond to antibiotic therapy, both neutrophil and lymphocyte counts may be within normal reference values.

Hyperfibrinogenemia is present accordingly to active infections. An important feature is the presence of low-normal or low globulin levels despite severe bacterial infections and hyperfibrinogenemia; the hypoglobulinemia results from the hypogammaglobulinemia. Abnormal liver enzymes may also be measured when there is septicemia.[3]

In the case of meningitis, spinal fluid analysis reveals increased protein values and pleocytosis, often with nondegenerate neutrophils, lymphocytes, and monocytes.[3] Blood culture has not been routinely performed in these patients but has resulted in bacterial growth in some cases; culture of spinal fluid may or may not result in bacterial growth.

Immunologic Findings Peripheral blood lymphocyte immunophenotyping reveals persistent, severe B-cell lymphopenia (<2%) in most patients. In a subpopulation of affected horses, B cells may be persistently measured at a distribution of less than 10%. A relative increase in the percentage of circulating CD8+ T cells and occasionally in CD4+ T cells has been observed in most patients. The parameter that defines a humoral dysfunction is serum IgG concentration, which is markedly and persistently low (<800 mg/dL) in *all* affected horses. Serum IgM concentrations are markedly reduced (<25 mg/dL) in all patients, suggesting the inability to elaborate primary immune response. Serum IgA concentrations are often within low-normal values (≈60 mg/dL) in early diagnosis in most patients despite severely low serum IgM and IgG concentrations, but levels reduce with progression of clinical disease, severity of clinical condition, and proximity to euthanasia. Affected horses do not respond to tetanus toxoid vaccination with an increase in serum antibody titers, and prevaccination values are often low or undetectable. It is recommended that these values be interpreted in the context of clinical presentation (i.e., recurrent bacterial infections, infections caused by opportunistic microorganisms, septicemia in adult horse) and subsequently measured after 2 to 3 months to confirm a persistent rather than transitory immunologic condition.

Lymphocyte proliferation assays reveal normal or subnormal responses to PWM, PHA, and ConA mitogens and therefore are not useful in the diagnosis.[1] Upon stimulation with mitogens, the expression of IFN-γ and CD40 ligand in isolated lymphocytes of affected horses is comparable with control healthy horses, suggesting normal T-cell function and capacity for co-stimulation of B cells, which is required for B-cell differentiation and antibody production.

Besides the B-cell lymphopenia, a small number of CVID-affected horses may also present a concomitant CD4+ T-cell lymphopenia, leading to a low CD4/CD8 ratio (<2). In these cases, infection with intracellular organisms that require cellular immunity may be observed, characterizing a clinical relevance for this finding.

The in vitro phagocytosis and oxidative burst activity are normal and often increased in these patients, reflecting in vivo activation.

Postmortem diagnosis can be based on the presence of infections in tissues plus the absence of germinal centers in the lymph nodes and spleen, with paucity or absence of B cells and plasma cells and no evidence of lymphoma.

Pathophysiology By the time of clinical diagnosis in horses, B cells are markedly rare in primary and secondary lymphoid tissues, leading to peripheral blood B-cell lymphopenia or depletion.[3,9] It is likely that B-cell production was sustained in the affected patients for a period of time before the diagnosis of CVID, and secondary lymphoid tissues were then populated with B cells, including memory cell development; this possibility is based on the clinical evidence that all patients diagnosed to date had a normal development and no obvious susceptibility to infections prior to diagnosis. A late-onset event impairs B-cell development in the bone marrow, and the continuous population of peripheral tissues could not be sustained.[10] B cells must be continuously generated over an individual's lifetime from hematopoietic stem cells in the bone marrow to maintain adequate population and humoral function in the lymphoid tissues.

B-cell differentiation and development is regulated by a network of transcription factors and demethylation of dinucleotides at promoter sites.[11] In the bone marrow of affected horses, the expression of key early B-cell commitment genes, including *E2A* and *PAX5*, is significantly decreased in comparison with healthy horses; in addition, *PAX5* downstream target genes

VetBooks.ir

are also significantly reduced in CVID-affected horses, including *CD19*, *IGHM*, and *IGHD*.[12] Immunohistochemical studies confirm the absence of PAX5-BSAP protein in the bone marrow of affected horses. Through a hierarchical dependence, *PAX5* directly promotes the expression of B lymphoid–specific genes while it represses the transcription of non–B lineage genes.[13] Hence CVID in horses may be caused by impairment of B-cell development in the bone marrow at the transition between pre-pro-B cells and pro-B cells; current studies investigate epigenetic mechanisms that lead to gene silencing in earlier stages of B-cell differentiation.

Epidemiology Affected patients are unrelated adult horses and ponies (average age 10 years, range 2 to 23 years) of both sexes and many different breeds (e.g., Thoroughbred, Quarter Horse, Arabian, Warmblood, Paint) living in distinct parts of the United States.[1] Cases elsewhere in the world have not been reported but are likely; their identification may be limited by the lack of knowledge of differential diagnosis for immunodeficiency diseases and availability of immunologic testing for the horse.

By the time the diagnosis of CVID is obtained, several months of recurrent infections and fevers may have been observed in some cases. The recurrent character of clinical signs is the most common factor that triggers the suspicion of an underlying immunodeficiency. Affected horses have been euthanized for financial reasons or due to poor quality of life either soon after the diagnosis or after a few years of antimicrobial management. Survival for several years after diagnosis is extremely rare but has been documented in a patient with marked B-cell lymphopenia (<2%) that maintained serum IgG concentrations between 500 and 900 mg/dL.

Necropsy Findings Necropsy findings include organ lesions according to the infectious processes. In addition, histopathology confirms the lack of germinal cells, which affects the lymph node typical cortical-paracortical distribution and the primary and secondary follicles in the cortex.[1,3] In general, lymph nodes are small. In addition, there is absence or marked paucity of plasma cells in various lymphoid and mucosal tissues. Immunohistochemical analysis may identify occasional positive B cells dispersed or in small groups in the lymph nodes but absent B cells in the bone marrow and spleen (Fig. 53.6).

Treatment and Prognosis Most affected horses are subjected to euthanasia due to severe pneumonia, meningitis, and/or septicemia. When affordable, a few horses have been managed for 1 to 5 years on continuous or intermittent antibiotic and Ig therapies. Commercial equine plasma is the current available source of Ig for clinical use, and its low concentration prevents it from being a cost-effective treatment. Frequent Ig replacement therapy in human patients is possible due to the availability of IgG concentrate products, which improves quality of life. Hematopoietic stem cell transplantation has been attempted in a horse with CVID, but no replacement of B-cell population with function has been successful to date; the costs involved with the procedure discourage clinical application. When the mechanism of disease is revealed, gene therapy may be a more feasible treatment if appropriate.

Prevention and Control Current studies investigate the possibility of epigenetic mechanisms that lead to the impaired B-cell differentiation in the bone marrow. Epigenetic regulation can be affected by environmental or infectious elements, yet to date, common factors have not been identified in the horse patients. At this time, prevention and control measures are not known.

Immunosenescence in Horses

M. Julia B. Felippe • Dianne McFarlane

Definition *Immunosenescence* is the term used to describe a multitude of changes in the immune system associated with aging. Reported age-associated changes in the immune system in people include alterations in cell population composition, as well as inadequate or inappropriate immune responses.[1] Immunosenescence is considered an important risk factor for the infectious, neoplastic, and inflammatory diseases that accompany aging. However, a balanced (successful) or detrimental (pathologic) effect of aging can result in different outcomes (e.g., immunity) in different individuals depending on how biological resources are individually maintained or exhausted, respectively.[2] Although there are limited available data, evidence suggests that horses experience age-related changes in the immune function, some of them in agreement with and some of them contrary to elderly humans.[3]

An important consideration when investigating age-related changes of immune function is how to define "aged," including chronologic versus biological aging.[4,5] A study population that is too old may cause one to miss age-related immune defects because the selected population may have survived to extreme old age due to exceptional immune function. It is likely that aging biomarkers may differ between very old horse populations (e.g., horses older than 30 years of age) and less old horse populations, such as horses around 20 years of age. Risk of certain diseases, frailty, or other impairments differs along the spectrum of aging. It is also important that the comparisons are made between fully mature horses and aged horses. Finally, marked variations in leukocyte composition, cell morphology, and inflammatory and anti-inflammatory cytokine release ex vivo were shown to be influenced by age, sex, breed, and individual factors, highlighting the importance of study design, analyses, and comparisons that account for this variability.[6]

Clinical Findings Several important factors must be considered when evaluating age-induced changes in the immune system. First, it is important to separate age-associated functional changes from disease-induced changes. In an aged population, this can be difficult due to the high prevalence of comorbidities that contribute to chronic, low-grade, or occult inflammatory disease. Ideally, strict evaluation criteria should be used. In human immunologic research, a screening procedure known as the SENIEUR protocol has been developed.[7] This protocol combines a clinical examination, medical and lifestyle history, diagnostic blood analyses, and urinalysis to identify healthy aged individuals for study inclusion. No such standardized protocols have been adopted in veterinary gerontology. In aged horse studies, important additional factors to consider include endoparasite load and hormone profiles. The high prevalence of PPID in the aged equine population and the immunosuppressive effects of pars intermedia–derived pituitary hormones make it absolutely critical that endocrine status be reported when evaluating immunosenescence in horses and ponies.[8,9] Other important considerations when assessing immune function in aged horses include diet, medications, nutritional supplements, exercise, season, and environmental conditions of the study participants.

Clinical Pathology Hematologic changes associated with aging in horses and ponies include a lower total WBC count due to a lower total lymphocyte count compared with younger counterparts.[10-13] In addition, there is a decrease in total monocyte and eosinophil counts in aged ponies.[11] The implications of these hematologic changes remain unclear.

VetBooks.ir

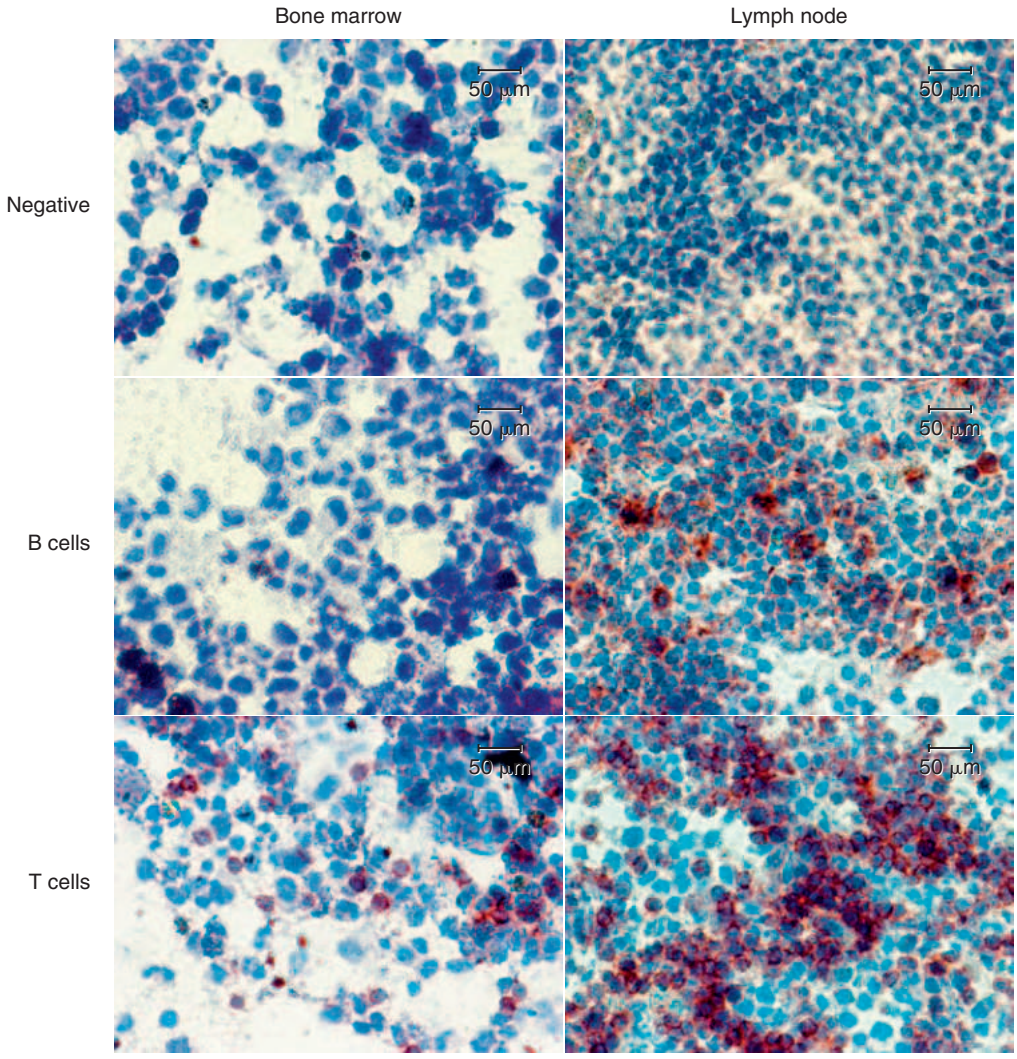

FIG. 53.6 Immunohistochemical analysis of bone marrow and lymph node microsections from a horse with common variable immunodeficiency (CVID). Bone marrow and mesenteric lymph node microsections from a horse with CVID were stained using monoclonal antibodies against equine B-cell (CD19-like) and T-cell (CD3) markers, irrelevant control (negative), and 3-amino-9-ethylcarbazole (AEC) chromogen. Note the lack of germinal centers and paucity of lymphocytes in the lymph node. B cells are not detected in the bone marrow; numerous B cells are detected dispersed in the lymph node. T cells are present in the bone marrow and lymph nodes; however, the typical cortical-paracortical regions in the lymph node are lost with the lack of germinal centers. *(Photos courtesy Julia Felippe.)*

Immunologic Findings Age-associated alterations in lymphocyte subset populations have been documented in several species, including people, dogs, and rodents, although inconsistencies in outcomes exist among the various studies.[14-17] Aging has been associated with alterations in subsets of circulating lymphocytes (i.e., CD4+, CD8+, and B cells) in horses and ponies.[10-13,18] The consistent decrease in total circulating lymphocyte populations in aged horses results from a decrease in total number of CD4+ and CD8+ T cells and B cells,[10-12] although another study reported an increase in the percentage of CD4+ lymphocyte population.[18] The CD4/CD8 ratio is an indicator of whether lymphocyte populations favor an inflammatory or immunosuppressive reponse. The CD4/CD8 ratio has been reported to increase, decrease, or remain unchanged in geriatric human populations.[19-21] CD4/CD8 ratio has been reported to be increased in aged horses, suggesting a proinflammatory state known as *inflammaging*.[12] A robust decrease in peripheral naive T cells has been a consistent finding in numerous studies in people and rodents.[22-25] Thymic involution is considered a likely major contributor to the failure to maintain a naive T-cell pool. In addition, it has been suggested that the loss of naive T cells may be the result of lifelong infection by viruses, especially cytomegalovirus or other chronic antigenic stimulants that promote a bias toward the frequency of memory cells.[26,27] The effect of age on naive T-cell populations has not been explored in the horse.

Serum cytokine profiles in the aged are typically those of a proinflammatory phenotype.[28,29] Aged horses show similar cytokine profiles with increased gene expression of TNF-α, IL-6, IL-1β, IL-8, IFN-γ, IL-15, and IL-18.[12,18] In addition, there are increased proinflammatory-to–anti-inflammatory cytokine ratios such as IL6/IL10 and TNF-α/IL-10.[25] Serum cytokine concentration of TNF-α was found to be increased in aged horses in one study but not another.[18,30] Obesity also increases the frequency of mononuclear cells expressing inflammatory cytokines.[31] Confounding factors that might affect serum TNF-α concentration in these and other studies include concurrent illness, inflammation, or season of sample collection. A chronic, controlled, low-grade inflammation seems to play a role in improving immunity and counterbalancing the inevitable immunosenescence; however, uncontrolled inflammation leads to decreased adaptive immunity, cellular dysfunction, and

increased immunosenescence.[2] Indeed, in human medicine, balanced inflammaging seems to play a role in longevity.

One of the most consistent findings in immunosenescence is a decrease in the ability of lymphocytes to proliferate. Studies in rodents and people have shown impaired lymphocyte proliferation possibly involving a decrease in serum IL-2 concentration or IL-2 receptor expression.[23,32,33] However, a decrease in lymphocyte proliferation has also been reported independent of these two factors, suggesting that defects in intracellular signal transduction may also be a consequence of aging.[34] Horses also experience an age-associated decrease in lymphocyte proliferation, which is not responsive to IL-2 supplementation and not associated with a change in lymphocyte IL-2 receptor expression.[11,18,35] This suggests that, similar to what has been observed in people, the age-associated defect in lymphocyte division in horses may be in intracellular signaling. In addition, progressive age-associated telomere shortening in equine peripheral blood mononuclear cells has been associated with decreased proliferation potential.[36]

Several studies have assessed the ability of peripheral blood mononuclear cells (PBMCs) to respond to immune stimulation. Inflammatory response after stimulation of whole blood or PBMCs from healthy aged people results in a greater release of proinflammatory cytokines than that observed in nonaged adults, a condition known as "trained innate immunity."[2,37-39] Similar studies in aged horses have revealed an increase in TNF-α and IFN-γ production from PBMCs following stimulation.[23,37]

Although immunosenescence affects primarily adaptive immunity, changes in innate immunity occur as well. Innate immunity includes the response of neutrophils and macrophages as a first-line defense against pathogens. Age-associated changes in neutrophil function that have been reported in people and rodents include decreases in phagocytosis, oxidative burst, chemokinesis, and chemotaxis, whereas neutrophil numbers appear to be maintained.[40-43] In healthy aged horses, neutrophil adhesion, oxidative burst, and phagocytosis were all found to be unchanged, whereas chemotaxis was increased compared with that observed in healthy adult horses.[44]

One of the major health concerns regarding immunosenescence in people is a failure of the geriatric population to develop an adequate protective titer following vaccination, particularly after influenza virus immunization.[45] As a result, morbidity and mortality due to influenza infection is greatest in the very old. The response of aged horses to influenza vaccines has also been reported to be less robust than that of young or adult horses in several studies.[11,46] Muirhead and colleagues[46] reported a decrease in Ig subisotypes IgG1 (formerly IgG_a) and $IgG_{4/7}$ (formerly IgG_b) in aged horses, although single radial hemolysis titers suggested that both adults and aged horses had adequate response that was protective. Using a different vaccine, Horohov and colleagues[11] reported a tenfold decrease in resultant titers in aged ponies compared with nonaged adults, but it is not clear if adequate titers were achieved in either group. Another study using canarypox recombinant virus vector expressing the hemagglutinin antigen of influenza in older horses slightly enhanced antibody responses but did not affect cell-mediated immune responses.[47]

Response to naive antigenic challenge has also been examined in horses older than 20 years of age. Contrary to what has been reported in primates, the magnitude of a primary antibody response did not decline with age.[46,48-50] When a rabies vaccine was administered to aged horses naive to rabies vaccine, the antibody titer after both the initial and the second immunization did not differ from that of nonaged adult horses. Nutritional factors may affect immune responses, and vitamin E supplementation of older horses enhanced humoral response to vaccination and improved phagocytic bacterial killing.[51] Further studies are necessary to clarify the ability of aged horses to respond to naive and anamnestic vaccinations, including to different types of vaccines, and to assist in the development of ideal vaccination protocols for geriatric horses.

Finally, given the importance of the gut microbiota in the function of the immune system, dysbiosis or microbiota remodeling with age may somehow affect immunosenescence and inflammaging, and the balance between proinflammatory and anti-inflammatory mediators.

Drug-Induced Immunosuppression

M. Julia B. Felippe

Immunosuppressive therapy is required when an immune response causes excessive damage to tissues or autoimmunity develops. On the basis of their primary mechanism of action, immunosuppressants may be classified as inhibitors of gene expression or transcription (e.g., glucocorticoids); inhibitors of nucleotide synthesis (e.g., azathioprine); inhibitors of calcineurin phosphatase (e.g., cyclosporine, tacrolimus, rapamycin) and kinase (e.g., leflunomide); alkylating agents (e.g., cyclophosphamide, chlorambucil); and monoclonal antibodies (e.g., against T-cell receptor IL-2R).[1-4] In the horse, only a few of these drugs have been studied and are used clinically.

Autoimmunity results from the production of self-reactive antibodies and/or T lymphocytes. The potential mechanisms involved include lack of central negative selection of autoreactive cells; molecular mimicry of microbes and self-epitopes; or the development of new epitopes on self-proteins secondary to tissue injury caused by viruses, bacterial exotoxins, chemicals, or tumors.

The type of mechanism involved in autoimmunity (e.g., antibody-mediated and/or cellular-mediated) may require immunosuppressive therapy with corresponding cellular metabolism targets. In addition, the combination of drugs may increase the success and decrease the necessary course of immunosuppressive therapy; nevertheless, this approach has been empirical in large animals and still lacks scientific evidence. Although the goal for immunosuppressive therapy is to decrease tissue damage caused by exacerbated immune response, systemic susceptibility to infections, particularly to fungal and viral organisms, is a risk in patients under therapy.[5,6]

Glucocorticoids are potent immunosuppressant drugs.[7] The lipophilic glucocorticoids pass freely through cell membranes and bind to a cytosolic glucocorticoid receptor (GR).[8,9] This interaction allows the GR transcription factor to translocate into the nucleus; bind to glucocorticoid-responsive elements; and regulate gene transcription that promotes or represses synthesis of cytokines, chemokines, inflammatory enzymes, and adhesion molecules. Frequently used glucocorticoids in horses include hydrocortisone, dexamethasone, prednisolone, methylprednisolone, isoflupredone, triamcinolone, beclomethasone, fluticasone, and budesonide. Oral prednisolone has better bioavailability than prednisone in the horse.[10] In general, therapeutic doses are high and frequent in the initial phase of treatment, and dosage is subsequently tailored to the clinical condition. Glucocorticoids in horses have been used for the treatment of a broad range of diseases that directly involve the immune system, including atopy or skin hypersensitivity reactions, contact dermatitis, immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, immune-mediated myositis, uveitis, purpura hemorrhagica, vasculopathy, pemphigus foliaceus, inflammatory airway disease, recurrent airway obstruction, and lymphomas or lymphosarcomas, many times with limited efficacy.[11-24]

Glucocorticoids cause immunosuppression mainly by sequestration of CD4+ T lymphocytes in the mononuclear phagocyte system and by inhibition of the transcription of cytokines.[3] A single IV dose (any of 0.05, 0.1, or 0.2 mg/kg

VetBooks.ir

body weight) of dexamethasone has shown to induce neutrophilia and lymphopenia, a decrease in the peripheral blood CD4+ T-cell population with a concomitant increase in the CD8+ T cells, and a consequent decrease of CD4/CD8 ratio; these effects are observed at 4 and 12 hours after the drug administration and gradually decrease over time in the first 48 hours.[25] Chronic treatment with glucocorticoids may lead to susceptibility to infection, hyperglycemia, hypokalemia (particularly isoflupredone), GI ulceration, delayed wound healing, osteoporosis, growth suppression, myopathy, and hypertension.[3,22] Parenteral, oral, and aerosolized corticoids reversibly suppress adrenocortical function, while the response to ACTH stimulation remains intact.[22,26]

Aerosolized glucocorticoids have been used for the prevention and treatment of recurrent airway obstruction and inflammatory airway disease in the horse, and they were shown to decrease airway hypersensitivity, neutrophilic pulmonary inflammation, and the expression of IL-1β and IL-8 in isolated alveolar macrophages.[18,19,22,23,27,28]

Aerosolized fluticasone proprionate may be detected in plasma for a minimum of 72 hours post administration.[29] The treatment of heaves-affected horses with inhaled fluticasone at therapeutic dosages for 11 months had no significant or detectable effect on innate and adaptive (both humoral and cell-mediated) immune function assays, including response to vaccinations.[30]

Inhaled budesonide may be detected in the plasma of horses with recurrent airway obstruction at higher concentrations and at longer time points (beyond 96 hours) after administration in comparison with healthy horses.[31]

Azathioprine inhibits the de novo pathway of purine synthesis, which is essential for DNA and RNA production and consequently lymphocyte activation and proliferation. Azathioprine has been used in horse patients for the treatment of immune-mediated anemia, immune-mediated thrombocytopenia, vasculopathy, and pemphigus foliaceus.[32] The use of azathioprine allows reduction in the glucocorticoid dose when the two are combined in therapy. Because proliferation of many cell types can also be inhibited, adverse effects associated with azathioprine treatment include leukopenia, alopecia, and hepatotoxicity. A single IV dose (1.5 mg/kg) of azathioprine resulted in a rapid decrease in plasma drug concentration with a half-life of 1.8 minutes.[33] Oral bioavailability at 3 mg/kg was low and varied from 1% to 7%. When given daily for 30 days, and subsequently every other day for another 30 days, that oral dose did not cause clinical adverse effects or abnormal hemogram, leukogram, and serum biochemical analysis in most horses. Lymphopenia and immunosuppression were observed in one horse during the experiment.

Cyclosporine is a cyclic polypeptide that binds to the cytoplasmic receptor cyclophilin and subsequently to the catalytic domain of the cytoplasmic phosphatase calcineurin.[34] This binding inhibits dephosphorylation of transcription factors, most importantly the nuclear factor of activated T lymphocyte (NFAT), which prevents their translocation to the nucleus. Therefore the production of key elements of T-cell activation and proliferation (IL-2, IL-4, CD40L, TNF-α, IFN-γ, *c-myc*) is suppressed. Cyclosporine has been used in the horse for intravitreal treatment of recurrent uveitis and immune-mediated keratitis.[35] Potential adverse effects of cyclosporine include vasoconstriction, hypertension, nephrotoxicity, hepatotoxicity, and potential susceptibility to infectious organisms that require cell-mediated protection.

Rapamycin and tacrolimus are macrolide antibiotics that bind to the cytoplasmic FK binding protein (FKBP), and the resultant protein complex inhibits calcineurin. The effect includes cell-cycle arrest and decrease in the expression of inflammatory cytokines. Rapamycin ocular toxicity and distribution have been studied for potential clinical use in the horse.[36]

Cyclophosphamide (phosphoramide and acrolein) and chlorambucil (phenylacetic acid mustard) metabolizes alkylate DNA bases, resulting in mutagenic, cytotoxic, antiproliferative, and chemotherapeutic effects. Cyclophosphamide affects B cells and has been used in the treatment of autoantibody-mediated diseases. In horses, these drugs have been used for the treatment of lymphosarcoma.[37] Adverse effects associated with cyclophosphamide and chlorambucil therapies include anemia, leukopenia, alopecia, and secondary malignancies.

Vincristine is a vinca alkaloid that binds to tubulin in the mitotic spindle and prevents purine synthesis. Consequently it inhibits cell proliferation, resulting in antitumor and immunosuppressive effects. In horses, vincristine has been used for the treatment of immune-mediated thrombocytopenia, pemphigus foliaceus, and lymphosarcoma.[38] Mild neurologic adverse effects (proprioceptive deficits) and ileus may occur in the horse.

The development of species-specific monoclonal antibodies and the identification of appropriate antigenic targets have contributed to the advance of their use in medicine.[39] The great advantage of monoclonal antibodies is the specificity of response, which may minimize adverse effects. Examples of use include treatment of inflammation (targeting inflammatory cytokines) and cancer.[40]

Immunosuppression Associated With Immune-Mediated Disorders*

M. Julia B. Felippe • Debra C. Sellon

Immune-mediated disorders often cause tissue or cellular damage. One of the outcomes is the potential for immunosuppression and increased risk of secondary infection through a variety of mechanisms, including loss of epithelial barriers, loss of critical immune cellular elements, hormonal imbalances, and dysregulation of immune responses. Autoimmune disorders comprise a subset of immune-mediated conditions, and self-molecules become a target in the context of an immune response. The etiology of most autoimmune diseases is uncertain but appears to be related to exposure to an antigen (e.g., infectious organism, tumoral proteins, drugs) and/or an environmental trigger (e.g., chemicals) in an individual animal or human that is genetically susceptible.

Aplastic anemia and myelodysplastic syndrome, both associated with autoimmune syndromes in humans, have been reported rarely in the horse.[1,2,3] Severe panleukopenia is seen peripherally, whereas significant bone marrow hypocellularity and myeloid maturation arrest are seen in aplastic anemia and myelodysplastic syndrome, respectively. Profound immunosuppression would be expected to occur with such pathology because immune cells involved in all aspects of innate and adaptive immunity are affected.

Autoimmune neutropenia may occur from hypersensitivity mediated by autoantibodies (or isoantibodies) that destroy circulating neutrophils or neutrophil precursors in the bone marrow. These antibodies may be produced as a primary autoimmune disorder secondary to drug administration, infectious disease, or neoplasia. Adult immune-mediated neutropenia has been reported in the dog, generally occurring concurrently with immune-mediated thrombocytopenia and/or immune-mediated hemolytic anemia, but no similar reports have been described in the horse.[4] Destruction of neutrophils has also been reported in alloimmune neonatal neutropenia with the absorption from colostrum of alloantibodies (produced by the dam). These alloantibodies, once in the foal's circulation, promote opsonization of neonatal neutrophils and enhanced clearance from circulation. The impaired immunity associated

*Contributions to previous editions by Sidra Hines are acknowledged.

VetBooks.ir

with profound neutropenia places these foals at significant risk for sepsis and other serious infections and must be identified early to allow successful intervention. Administration of exogenous granulocyte colony-stimulating factor (G-CSF) is usually necessary because affected foals often do not produce adequate levels of endogenous G-CSF.[5] Alloimmune neonatal neutropenia causes moderate to severe neutropenia in neonatal foals and has been reported in conjunction with alloimmune neonatal isoerythrolysis, ulcerative dermatitis, and thrombocytopenia.[5-7]

Reported occasionally in horses, immune-mediated thrombocytopenia has the potential to negatively affect immune responses.[8,9] Platelets can play both indirect and direct roles in protecting an animal from infection. They promote antiviral cytotoxic T lymphocyte–mediated responses and contain important antibacterial proteins that when released promote rapid microbial killing.[10] Diminished levels of platelet-derived cytokines may affect Th polarization and have a negative impact on bone marrow function.[11] Importantly, RBCs from thrombocytopenic mice have demonstrated an increased susceptibility to hemoparasite infection, indicating that thrombocytopenia can have an important in vivo effect on immunocompetency.[10]

Autoimmune skin disorders causing lesions that impair the skin barrier can predispose affected areas to secondary infection.[12] This is primarily a concern with the large bullae and ulceration occurring in pemphigus vulgaris or bullous pemphigoid, but the risk exists for any skin disease that breaches this important physical barrier to infection. Pemphigus foliaceus, paraneoplastic pemphigus, cutaneous (discoid) lupus erythematosus, and systemic lupus erythematosus (SLE) can all cause lesions that may predispose to secondary infection. This risk may be amplified if the lesions are painful or pruritic, leading to excoriation or self-mutilation. Hence *Culicoides* hypersensitivity, urticaria, and vasculitis are autoimmune conditions of the skin that can also predispose to secondary infections.

In cutaneous vasculitis, most commonly seen in the horse as purpura hemorrhagica, Ag-Ab complexes are deposited in the walls of small blood vessels, and the resultant inflammation is manifested as severe edema, tissue necrosis, and ulceration. Penetration of the skin barrier under this condition may result in a secondary bacterial infection, particularly cellulitis and pneumonia. Therefore prophylactic antimicrobial therapy is often warranted in the treatment of purpura hemorrhagica.[13]

Systemic lupus erythematosus, rarely reported in horses,[14] may impair cutaneous defense to infection and compromise the adaptive immune system. In humans, SLE causes dysregulation of apoptosis that leads to premature death of PBMCs, resulting in leukopenia, particularly lymphopenia.[15] The functionality of T cells in patients with SLE is impaired, with decreased IL-2 secretion and other factors leading to weakened antiviral immunity.[15]

Most reports of diabetes mellitus (DM) in the horse have described type 2 (noninsulin-dependent) DM secondary to PPID or equine metabolic syndrome. However, type 1 DM resulting from autoimmune destruction of pancreatic beta cells and subsequent decreased insulin production has been reported.[16] In humans, DM is associated with an increased risk of lower respiratory infections, urinary tract infections, and infections of the skin or mucous membranes.[17] Abnormal function has been documented in neutrophils, monocytes, and lymphocytes, including decreased adherence, chemotaxis, and intracellular killing, as well as impaired phagocytosis and diminished lymphocyte proliferative response.[18] These negative effects have largely been attributed to the impact of poor glycemic control, and it is therefore likely that similar effects could occur with equine DM.

Immunosuppression Associated With Leukoproliferative Disorders*

M. Julia B. Felippe • Debra C. Sellon

Neoplastic disease can impair cell-mediated and humoral immune responses as a result of an abnormal bone marrow environment, altered patterns of cytokine production or release, or impaired proliferative responses (anergy). In horses, immunodeficiency has most often been described in association with lymphosarcoma or plasma cell myeloma.

Lymphosarcoma

Immunodeficiency has been identified in some horses with equine lymphosarcoma. The immunologic abnormality most often described is a decrease in the concentrations of serum immunoglobulins, especially IgM.[1-5] Recurrent or persistent infections may occur and complicate recognition of the underlying neoplastic disorder. Neoplastic cells were suggested to be T-suppressor cells in one horse, indicating a possible mechanism for the IgM deficiency.[1] Diminished lymphocyte blastogenesis responses indicative of impaired T-cell function have been described in two horses with lymphosarcoma, one of which had concurrent IgM deficiency.[5] Some horses with lymphosarcoma have been diagnosed with concurrent bacterial infections, which may be related to immunosuppression.[4,5] Lymphosarcoma has been associated with bone marrow necrosis in people and horses, leading to pancytopenia and sepsis, presumably due to profound neutropenia.[6] Similarly, myelophthisis secondary to tumor cell infiltration of bone marrow may lead to pancytopenia and immunosuppression in horses.[7,8]

Plasma Cell Myeloma

Plasma cell myeloma has been reported in horses of several breeds.[9] Although reports of the condition are limited, there appears to be no gender predilection. Horses have ranged in age from 3 months to 22 years (median is 11 years) at diagnosis. Common clinical signs include weight loss, anorexia, fever, pneumonia, and limb edema. Both equine and human patients with plasma cell myelomas have an increased susceptibility to bacterial infections, probably as a result of a secondary immunodeficiency.[9-11] Immune suppression in human patients with myeloma is well documented and can lead to severe infection.[12] Mechanisms include abnormal Ig production, abnormal cytokine production, and dysfunctional NK cell and DC populations.[12] As a malignancy of plasma cells or lymphocytoid plasma cells, plasma cell myelomas typically produce large quantities of a homogeneous immunoglobulin or immunoglobulin fragment, resulting in a monoclonal gammopathy. In both equine and human cases of myeloma, the predominant serum globulins are generally subclasses of IgG.[9,10] Hyperglobulinemia is a characteristic but not invariable finding. Monoclonal gammopathies in the horse have also been reported with lymphoma and benign disorders.[13,14] The concentrations of normal polyclonal immunoglobulins are generally decreased in myeloma patients as a result of several mechanisms, including decreased synthesis and accelerated catabolism of antibody and suppressed clonal expansion of B cells.[9-11] Similar to plasma cell myeloma, certain types of B-cell lymphoma and/or leukemia can produce monoclonal gammopathies and decreased relative numbers of normal B cells and polyclonal immunoglubulins.[15] Decreased numbers and dysfunction of neutrophils and defective complement activation may also contribute to the impaired immune function.

Other Leukoproliferative Disorders

A wide variety of other leukoproliferative disorders have been described in horses, including acute and chronic granulocytic

*Contributions to previous editions by Sidra Hines are acknowledged.

leukemia,[16-18] myeloblastic leukemia,[19] myelomonocytic leukemia,[20,21] monocytic leukemia,[22] eosinophilic myeloproliferative disorder,[23] and malignant histiocytosis.[24] Regardless of the primary cell line of origin, the end result is often myelophthisis and pancytopenia with the potential for significant immunosuppression. A horse with myelomonocytic leukemia was diagnosed with pulmonary aspergillosis.[25]

Immunosuppression Associated With Infectious Agents or Processes

M. Julia B. Felippe • Debra C. Sellon

The interrelationship between infectious agents and the host immune system is complicated. Infection, regardless of etiology, initiates a cascade of complex reactions intended to assist the host in control and elimination of the infectious agent. When the immune system is compromised, infectious agents have an increased opportunity to become established and cause significant disease in the host. This may happen because external factors suppress immune function in the host before encountering a pathogen or because the pathogen suppresses immune responses in the host.

Common Infections in the Immunocompromised Host

Immunocompromised horses are incapable of developing a normal immune response, usually as a result of an immunodeficiency disorder, immunosuppressive therapy or endocrine dysregulation, underlying disease, or malnutrition. When an equine host has impaired immune responses for any reason, infectious agents have an increased opportunity to establish persistent infection or cause significant harm to the host. For many immunocompromised horses, the result is persistent or unusually severe disease secondary to infection with common equine pathogens. In some situations, however, the immune capabilities of the horse are so impaired as to enable normally nonpathogenic infectious agents to cause disease. Identification of such pathogens or patterns of infection in an equine patient should lead the clinician to suspect underlying immunodeficiency.

Undoubtedly, primary immunodeficiency disorders (including SCID, agammaglobulinemia, FIS, and CVID), described in detail earlier in this chapter, represent the principal cause of immunocompromise in horses.[1-8] The most commonly described pathogens in horses with severe primary immunodeficiency include adenoviruses, *Cryptosporidium parvum*, *Candida* spp., *P. jirovecii* (formerly *P. carinii*), and *R. equi* (in adult horses). These are generally considered to be pathogens of the respiratory and GI tracts, and most affected horses present with persistent or severe clinical signs associated with these body systems. Horses with less severe primary or secondary immune deficiency (e.g., selective IgM deficiency) may present with recurrent respiratory tract infections associated with a variety of bacterial pathogens.[4] The most common secondary immunodeficiency disorder of horses is FPT of immunity.[9] Affected foals commonly develop bacterial septicemia with or without localized bacterial infections.

Some foals with FPT or other forms of immunosuppression develop localized or systemic candidiasis.[10,11] This disorder appears to be most common in foals with FPT that have been treated with broad-spectrum antimicrobials for treatment of bacterial septicemia. This syndrome has some similarities to mucocutaneous candidiasis in people, which has been associated with several different subtle T-cell defects. Oral lesions range from discrete, focal, white, plaquelike lesions on the margins of the tongue to a generalized, thick, white, pseudomembranous coating covering the tongue and gingival mucosa. Most foals exhibit bruxism, ptyalism, fever, and depression. Other significant clinical problems include pneumonia, septic arthritis, and diarrhea. This syndrome should be distinguished from the glossitis caused by *Candida* infection seen in inappetent or debilitated neonatal foals, which is fairly common and generally resolves with amelioration of the primary disease.[12] Regardless of cause or underlying nature of the immunodeficiency, the prognosis for foals with oral candidiasis and associated bacterial septicemia is guarded to poor.

Immunosuppression may also occur secondary to corticosteroid administration, which is discussed in detail earlier in this chapter. Corticosteroid therapy results in lymphopenia, suppression of macrophage phagocytic function, impaired killing of ingested organisms, impaired secretion of monokines, and inhibited antigen processing and presentation.[13,14] Cell-mediated immunity is impaired through T-cell lymphopenia, altered cytokine production, and decreased antigen presentation, and it is reflected in the suppression of mitogen stimulation responses. Humoral immunity is impaired indirectly through altered T-cell responses, enhanced Ig catabolism, and decreased antigen presentation.[13] Horses receiving high or prolonged therapy with corticosteroids have been reported to experience exacerbations of preexisting infections or decreased resistance to newly encountered pathogens.[15,16] This may manifest as bacterial pneumonia or pleuropneumonia, candidiasis and other fungal infections, equine protozoal myeloencephalitis, or a variety of other infectious disorders.[11,16]

Infections That Cause Immune Suppression

Some infectious agents have developed strategies to elude immune defenses in hosts with otherwise normal, functioning immune systems. These strategies may downregulate immune responses to the extent that the host becomes vulnerable to secondary infection. Many viral, fungal, and bacterial infections transiently suppress specific and nonspecific immune responses, predisposing animals to secondary bacterial infections.[17] Severe endotoxemia or septicemia may suppress neutrophil numbers and bactericidal function, predisposing to secondary infection.

EQUINE INFLUENZA. Although little work has been done to specifically examine the effects of equine influenza viruses on the equine immune system, it is widely acknowledged that this viral infection predisposes horses to secondary bacterial infection.[18,19] Proposed mechanisms for increased susceptibility to bacterial infection after influenza infection include disruption of the barrier function of respiratory epithelium, exposing bacterial adhesion molecules; desensitization of alveolar macrophages to bacterial Toll-like receptor ligands; and alteration of immune functions in the alveolar microenvironment.[20,21]

PERINATAL EQUINE HERPESVIRUS TYPE 1 INFECTION. Infection of the fetus with equine herpesvirus type 1 (EHV-1, rhinopneumonitis) late in gestation has been associated with death or postnatal development of interstitial pneumonia, lymphopenia, marked necrosis and atrophy of the thymus and splenic lymphoid tissue, and increased susceptibility to bacterial infections.[22] Despite apparently adequate passive transfer of maternal antibody, affected foals contract a variety of infectious bacterial diseases, including colibacillosis, streptococcal septicemia, salmonellosis, and Tyzzer's disease. EHV-1 is isolated from nasal passages in about 30% of the cases. The spleen and thymus are grossly small at necropsy. Bilateral adrenocortical hyperplasia is noted in most foals. Histologically, splenic periarteriolar lymphocytic sheaths are depleted of lymphocytes, and no lymphoid follicles are detectable. Thymic alterations vary from extreme diminutions of thymocyte numbers to complete necrosis of thymic lymphocytes with disappearance of Hassall's corpuscles and disruption of the epithelial matrix. Lymph nodes also show lymphoid necrosis. An immunodeficiency secondary to the marked lymphoid damage induced by

VetBooks.ir

the virus is credited with allowing secondary bacterial infections to become established. Immunization of broodmares against EHV-1 would seem to be the most appropriate approach to prevention.

EQUINE HERPESVIRUS TYPE 5 INFECTION. Equine herpesvirus type 5 (EHV-5) is an emerging pathogen linked to equine multinodular pulmonary fibrosis (EMPF).[23-26] This gammaherpesvirus has been found in bone marrow of infected horses, contributing to speculation that the virus may be immunosuppressive.[25,26] Many affected horses are lymphopenic for undetermined reasons, most are anemic and thrombocytopenic, and at least one affected horse was profoundly pancytopenic, leading to speculation that immune-mediated or direct viral destruction of mature cells and/or hematopoietic precursors in the bone marrow may play a role in diminished cell counts in peripheral blood.[23-25] Transient improvement in cell counts after initiation of corticosteroid therapy supports the possibility of immune-mediated mechanisms for destruction of hematopoietic cells.[25] One case of EMPF presented with primary lymphocytic leukemia, generalized lymphadenopathy, and infiltration of neoplastic lymphocytes in bone marrow, lymph nodes, and spleen.[26] Infiltrating cells were almost exclusively T lymphocytes, whereas B lymphocytes could not be detected. Depletion of B-cell lines was accompanied by hypogammaglobulinemia.[26] EHV-5 infection was demonstrated in lung, bone marrow, and lymph nodes.[26] A link between the T-cell leukemia and infection by EHV-5 was suggested.

Diseases Caused by Allogeneic Incompatibilities (Horses and Ruminants)

M. Julia B. Felippe • Jill R. Johnson

The surfaces of cells are covered with molecular structures, the presence or absence of which is determined by genes and cell function. Some of these molecules have limited heterogeneity within a species, and all members of the species share identical forms (monomorphic). In other cases, a spectrum of minor structural variations or polymorphisms of a particular molecule occur within the population; therefore some members of the species will have one form of the molecule, whereas others will have another. If the structural variations are such that the immune system of one individual can recognize the differences in the molecules from another individual, these are known as alloantigens. Antibodies produced against these antigens are alloantibodies. Examples of alloantigens include certain molecules of RBCs, platelets, and WBCs.

In nature, because there are few situations in which tissues are exchanged, there are relatively few naturally occurring diseases that involve allogeneic incompatibilities. Neonatal isoerythrolysis (NI), neonatal alloimmune thrombocytopenia (NAIT), and alloimmune neonatal neutropenia (ANN) are three examples of such naturally occurring diseases. Blood transfusion reactions and organ transplant rejection are examples of iatrogenic diseases associated with allogeneic incompatibilities.

The same alloantibodies that mediate disease are also useful in vitro as reagents for the detection of the presence of alloantigens and serve as the basis for blood typing, for instance.

Blood Typing and DNA Profiling

The blood type of an individual is the actual composite of genetic codes determined by codominant alleles (i.e., the pair of one maternal and one paternal alleles). Several kinds of genetic markers have been used in blood typing, including RBC alloantigens, major histocompatibility complex molecules, and electrophoretic markers. Polymorphisms of the DNA have emerged as useful genetic markers and essentially replaced other genetic tests for parentage verification.

Red Blood Cell Antigens

The blood group genes produce surface molecules that contain antigenic sites known as *factors*. More than 30 different factors have been identified. Each factor is associated with only one system, although the same factor may be associated with more than one allele within the system. The factors are named with an uppercase letter to denote the system and a lowercase letter to designate the factor within that system. Groups of factors that are produced by a single allele are called *phenogroups*.

The presence of RBC antigens is detected primarily by either agglutination or complement-mediated lysis of test cells using antibodies directed against *specific* RBC alloantigens. In some systems, antigens are detected with antiglobulin tests.

Seven independent RBC groups or systems have been internationally defined in horses under the auspices of the International Society for Animal Genetics[1-4] (Tables 53.8 and 53.9). These systems are named A, C, D, K, P, Q, and U. Additional systems are recognized by individual laboratories. Each system corresponds to a particular gene for which two or more alleles exist. Some blood groups are relatively simple and contain only two alleles, whereas other systems may have more than two dozen different alleles.

Eleven blood groups have been identified in cattle[5] (Tables 53.8 and 53.10). In cattle, groups B and J have the greatest clinical relevance. The B group is a complex system with more than 60 different antigens.[6] This complexity has been used to advantage for individual animal identification and parentage studies in the past, but it makes it difficult to closely match donor and recipient blood for transfusions. The J antigen, a lipid found in body fluid, is adsorbed to erythrocytes; thus it is not a true erythrocyte antigen. Newborn calves do not have this antigen but usually acquire it during the first 6 months of life. After acquiring it, some groups of cattle have high amounts of J antigen both in the serum and adsorbed to erythrocytes, whereas other groups have small amounts found only on erythrocytes. These latter groups, often referred to as *J negative*, actually may have anti-J antibodies and develop transfusion reactions when transfused with blood from J-positive donors.[1]

Seven blood groups have been identified in sheep (see Table 53.8). The B system is analogous to the B system in cattle and is extremely polymorphic, with more than 52 different alleles. The R system is similar to the J system in cattle in that the antigens are soluble and are passively adsorbed to erythrocytes.[5] The M-L system is involved in the genetically determined RBC potassium polymorphism found in sheep.[7]

Blood groups of goats appear to be similar to those of sheep, and many of the reagents used for typing sheep blood have been used to type goats' blood. Reagents used to detect antigens

of the J system of cattle have been used to detect differences in a similar system in goats.[8]

The biological function of RBC antigens is not known for any system in any species with the exception of the M-L blood group system in sheep, which is involved in active potassium transport across RBC membranes.

Electrophoretic Markers

Many plasma and intracellular proteins have polymorphic forms. These variants have subtle biochemical differences, which for the most part do not alter the major characteristics of the molecules but can be detected using electrophoretic methods. These are not technically alloantigens because the differences are not detected immunologically. The various forms of the molecules are detected based on their different rates of migration in electrophoresis. The specific forms of any particular protein that an individual possesses are determined genetically, and those used in blood typing are usually expressed codominantly. Currently, no diseases are clearly associated with the presence or absence of particular alleles of polymorphic proteins; however, they are useful genetic markers for identification and parentage studies commonly included in the blood type (Table 53.11).[3,8-10] Electrophoretic markers were used extensively in horses because RBC antigens did not provide the same degree of discrimination among individuals in this species as they do, for example, in cattle. The current application is limited to legacy parentage verification when parental DNA is not available for testing.

Major Histocompatibility Complex

Three systems of equine alloantigens tested using lymphocytes have been described: ELA, ELY-1, and ELY-2.[11-15] ELA is the major histocompatibility complex (MHC) of the horse. ELA is a complex system that includes several genes, each of which is polymorphic (e.g., has many different alleles). Because the MHC regulates the interactions of many cells in the immune response, a potential for the association of disease susceptibility or resistance with ELA exists. An association between a particular ELA allele and equine sarcoid has been described.[16,17] ELY-1 and ELY-2 have limited polymorphism and appear to be two allele systems.

The MHC of cattle is called BoLA, for bovine lymphocyte antigen. In sheep the MHC is called OLA, for ovine lymphocyte

antigen, and is also known as SH-LA. In goats the comparable system is GLA.[18]

DNA Polymorphisms

A wide variety of approaches has been developed for detecting genetic variation using DNA. Certainly, DNA sequencing is the most sensitive approach, but other approaches have been used to detect DNA variants. Genetic variation of DNA can be detected among individuals based on differences in length for a section of DNA or even for differences in base composition at specific sites. DNA length variants are usually referred to as *minisatellite* or *microsatellite markers*. Minisatellite DNA markers are based on sequences, often 15 to 100 bases long, that may be repeated hundreds of times on a chromosome. The number of repetitions can vary dramatically among individuals and collectively is referred to as *DNA fingerprinting*. Although they are powerful, these tests are costly and time consuming. More recently, another type of DNA length variant has been discovered. Microsatellite DNA markers are short repetitions of nucleotides, usually ranging from 1 to 9 bases long, which may be repeated 15 to 40 times. As with minisatellites, the number of repetitions may vary among chromosomes. More than 100,000 of these markers are thought to exist in each species and to contribute to the development of genetic maps in diverse species. These markers currently form the basis for most parentage analysis.

Variation recognizable as a change in a single base of DNA is more subtle but can be detected through a variety of techniques. Single-nucleotide polymorphisms (SNPs) are variations in single nucleotides at specific positions in the genome, such as coding or noncoding sequences of genes, or between genes (intergenic). These variations may not change (synonymous SNPs) the protein sequence; however, they may change (nonsynonymous SNPs) the protein sequence or alter its expression. SNPs are used to determine haplotypes (linkage of SNPs) in a population, as well as in association studies for individual genetic background and susceptibility to certain diseases, disease severity, and effective treatments.[19,20] Examples described for horses include susceptibility to insect bite hypersensitivity, uveitis, *R. equi* pneumonia, and papillomavirus-induced sarcoids in horses, as well as variations in the immune system.[21-28] Examples described for ruminants include susceptibility to mastitis, ketosis, tuberculosis, paratuberculosis, as well as variations in the immune system.[29-35]

DNA sequence variation is often detectable using restriction enzymes. Restriction enzymes are isolated from bacteria and will cleave DNA when the sequence is specific for the enzyme. For example, the method to detect the gene defect causing hyperkalemic periodic paralysis (HYPP) in horses is based on polymerase chain reaction (PCR) amplification of the gene and then detection of sequence differences that occur between the normal and mutant gene using restriction enzyme digestion of the DNA. Other approaches to identifying DNA sequence differences include single-strand conformational polymorphism (SSCP), allele-specific PCR amplification, and ligase chain reaction. DNA-based testing has essentially replaced blood typing for purposes of parentage analysis.

Blood Typing and DNA Genotyping Applications

To determine an animal's blood type or DNA genotype, a battery of different tests is run on the blood or tissue to check for the presence or absence of each recognized allele in each of several genetic systems. Each system is controlled by a separate autosomal gene. These genes are inherited independently of one another.[4,15] Most genetic markers used in blood typing are expressed codominantly, which means that the alleles on both chromosomes are expressed. This often allows determination of genotype (the actual genes present) from the phenotype (the antigens actually detected). Some systems have null alleles with no detectable products that would allow inference of genotype (e.g., C, K, and U blood group systems in horses). An individual can have only two of the possible different alleles for any given gene (one on each chromosome of a pair).

Blood typing based on RBC antigens and electrophoretic markers has been used for animal identification and pedigree analysis, but currently RBC typing is used primarily for prediction of potential for NI and crossmatching for blood transfusion.

The use of genetic markers for parentage verification is based on exclusion (i.e., markers are tested until a discrepancy is found). If no discrepancy is observed after a statistically acceptable amount of testing, the probability of a match is determined.

Because genetic testing is a composite mosaic of a large number of different, largely independent genetic markers, the odds of two individuals sharing exactly the same pattern of markers, whether RBC antigens, electrophoretic markers, or DNA polymorphisms, are remote. Thus once an animal's genetic type is on record, it can be a powerful identifier of an individual animal. In this sense it is an unalterable form of identification that is present from birth to death.

These markers can be used to support or refute parentage claims because the presence or absence of markers is genetically determined and because the markers contributed by both parents are expressed in a codominant fashion (unless "blank" alleles exist). Blood typing and DNA profiling cannot prove that one horse is the parent of another; however, in certain instances it can exclude with certainty a stated parent as the true parent. Two types of parentage exclusions can occur: type I and type II[36] (Fig. 53.7). With type I, the foal possesses a dominant or codominant marker that is not present in either parent; this result indicates that at least one of the stated parents is incorrect. If one parent (usually the dam) is known with certainty based on circumstances other than genetic type, the error lies with the other stated parent. With type II exclusions, the foal does not possess either of the dominant or codominant markers of a stated parent. Because a foal must inherit one of the two markers expressed by each parent, exclusion can be made if neither of the two markers present on the stated parent is detected in the foal. In parentage cases, each genetic system is evaluated for type I and type II exclusions. A parent can be excluded based on an inconsistency in one system. For this reason, the more systems that are used, the better genetic typing becomes as a tool for solution of parentage disputes. The calculated effectiveness of blood typing for detecting incorrect paternity using 20 internationally defined systems in horses is as high as 96%.[3,9,37] With DNA genotyping, effectiveness is as high as 99.998%.[38-40]

Laboratories that provide DNA genotyping in North America are listed in Box 53.1.

Neonatal Isoerythrolysis

Equine

Definition and Etiology

Neonatal isoerythrolysis (NI) is a condition characterized by the destruction of RBCs in the circulation of a foal by alloantibodies of maternal origin absorbed from colostrum.[2,41,42]

Production of alloantibodies can be stimulated in mares in several ways, including transfusion, exposure to blood from the foal during parturition, or as a result of placental pathology during gestation. Incompatibilities of at least some blood groups between the dam and foal are the rule rather than the exception, and yet the incidence of sensitization of the dam and occurrence of NI is relatively low. Most blood groups are not strongly antigenic under the conditions of exposure via previous

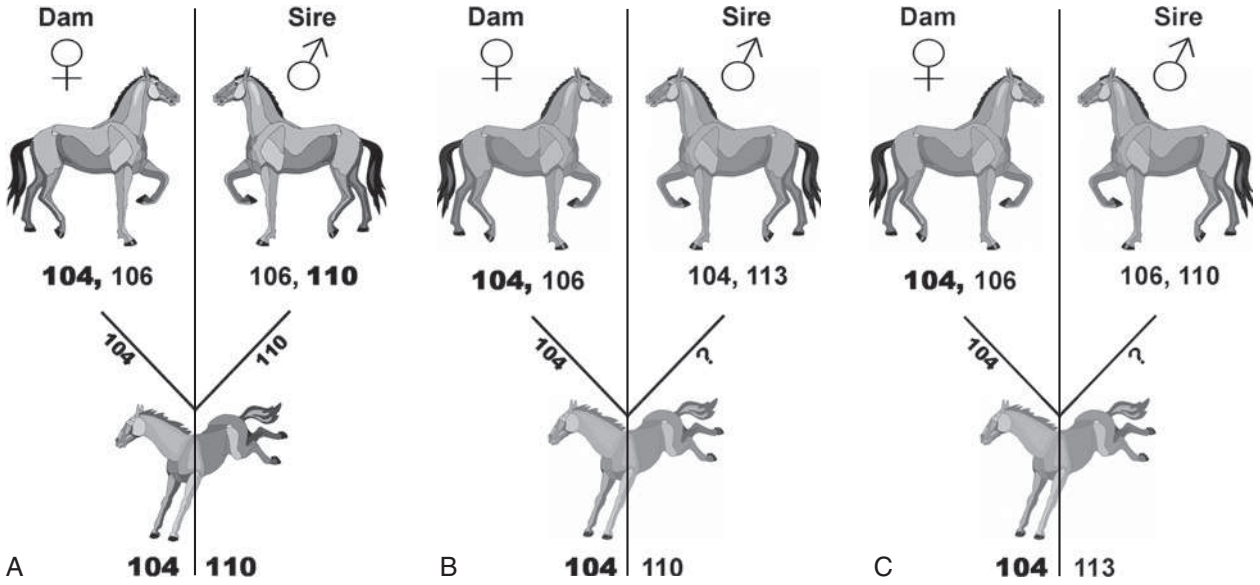

FIG. 53.7 **A,** The sire of this foal cannot be excluded as the sire of the foal based on the results for the DNA marker VHL20. **B,** The sire of this foal is excluded by a type I exclusion. The foal possesses an allele for the DNA marker VHL20 not present on either parent. Assuming that the dam of the foal is known to be correct and therefore would have contributed the 104 allele to the foal, the sire must be incorrectly stated. **C,** The sire of this foal is excluded by both a type I and a type II exclusion. The foal possesses an allele not present on either parent and also does not possess either allele expressed by the putative sire.

parturition or placental leakage. Several blood group factors, however, are particularly immunogenic, and antibodies against these antigens have been reported to cause nearly all cases of NI. These include factor Aa in the A system and factor Qa in the Q system. In mules, a unique donkey RBC antigen called donkey factor has been associated with NI.[43,44] Antibodies to these antigens develop after the exposure of the mare to RBCs and are not naturally occurring. In humans, the absence of certain RBC antigens results in the production of natural antibodies against that antigen, presumably because of exposure to cross-reacting antigens in the diet. This does not occur in horses, with a few exceptions, and has not been associated with NI. Ca-negative (Ca–) horses frequently make anti-Ca antibody of low titer without known RBC exposure. However, anti-Ca antibody is generally not associated with NI, and mares with anti-Ca antibody appear less likely to develop certain antibodies responsible for NI.

For NI to occur, several things must happen (Figs. 53.8 and 53.9). First, the dam must be negative for the antigen in question. Mares that are Aa–, Qa–, or both are considered at risk because most cases of NI in horses are associated with either anti-Aa or anti-Qa antibodies. All horses appear to lack donkey factor; thus all mule pregnancies are considered at risk. Second, the mare must become sensitized and produce antibody to the offending antigen. Sensitization can be caused by exposure during a previous pregnancy, blood transfusion, or transplacental contamination with fetal RBCs earlier in the current pregnancy (rare). Third, the foal from the current pregnancy must have inherited from its sire the antigens to which the mare has been sensitized. When these conditions are met, there is a significant potential that maternal antibody directed against the foal's RBC antigens will appear in the colostrum and, if subsequently ingested and absorbed by the foal, could cause loss of RBCs. The higher the anti-RBC titer is at foaling, the higher the risk. The highest titers are likely to be produced in a previously sensitized mare that is reexposed to the same RBC antigens shortly before parturition.

Clinical Signs and Differential Diagnoses

Foals are born healthy and usually begin to develop signs of NI at 24 to 36 hours of age, after suckling. Progressive lethargy and weakness are early signs. In acute cases, mucous membranes show initial pallor that is followed by icterus. In severe cases, hemoglobinemia and hemoglobinuria may be pronounced. In peracute cases, death may precede the development of icterus. Breathing becomes rapid and shallow, followed by labored breathing as the disease progresses. The foals may yawn repeatedly. Heart rate is elevated. Seizure-like activity may occur as the anemia becomes more severe.

Clinical Pathology

Affected foals are anemic. All indicators of RBC concentration (packed cell volume [PCV] hemoglobin, RBC count) show significant decreases. PCV values often decline into the teens, and values as low as 5% have been observed. Hemoglobinemia and hemoglobinuria may be present. Bilirubin (mainly unconjugated) levels will be increased as a result of accelerated RBC destruction. Total bilirubin levels may be close to 20 mg/dL in severe cases. Affected foals, especially mule foals, may also be thrombocytopenic.[4]

Demonstration of significant amounts of alloantibodies in the colostrum (or serum from the mare) that are directed against the RBC antigens expressed by the foal provides a definitive diagnosis of NI. These antibodies are most commonly demonstrated by lytic and agglutinating tests.[45,46] Lytic tests are believed to be more reliable indicators of the presence of offending antibody.[45] The presence of antibodies attached to the foal's RBCs can also be demonstrated with a direct antiglobulin test (Coombs test). The presence of antibodies in the mare's serum that attach to RBCs can be demonstrated with an indirect antiglobulin test.[2]

Pathophysiology

In mares sensitized to RBC antigens, most commonly Aa or Qa, alloantibodies are concentrated in the colostrum late in gestation. These antibodies are passed to the foal through passive transfer. If the foal's RBCs carry the antigen that the antibody recognizes, the cells become antibody coated. Subsequently, they are removed prematurely by the mononuclear phagocyte system (reticuloendothelial system) or lysed intravascularly by complement. A distinction has been made between antibodies that are lysins as opposed

to agglutinins; however, this distinction is based on in vitro testing and may be somewhat artificial. Under appropriate laboratory conditions, offending antibodies may exhibit both abilities.[43] However, when using certain conventional agglutination tests, some alloantibodies capable of producing NI may go undetected.[10]

Epidemiology The percentages of mares at risk for sensitization against the common offending antigens (Aa and Qa) vary among breeds, depending on the frequency in the population of each gene involved (Table 53.12). In Thoroughbreds the prevalence is about 1%, and in Standardbreds the incidence is about 2%.[42] The prevalence in mules (donkey sire, horse dam) has been reported to be as high as 10%.[2] Increased numbers of mares at risk in a breed do not necessarily translate to higher numbers of NI cases. A corresponding number of stallions lack the factors in question and are therefore unable to sire foals with the offending antigen.[42] Virtually all mule pregnancies are incompatible with regard to donkey factor.[44]

Although the disease is more common in multiparous mares, NI can occur with the first pregnancy.

Necropsy Findings Liver failure, kernicterus, and complications related to bacterial sepsis are the most important causes of death in foals dying from NI.[47] Pale tissues with or without icterus and splenomegaly are characteristic necropsy findings. Lesions associated with RBC destruction and anemia,

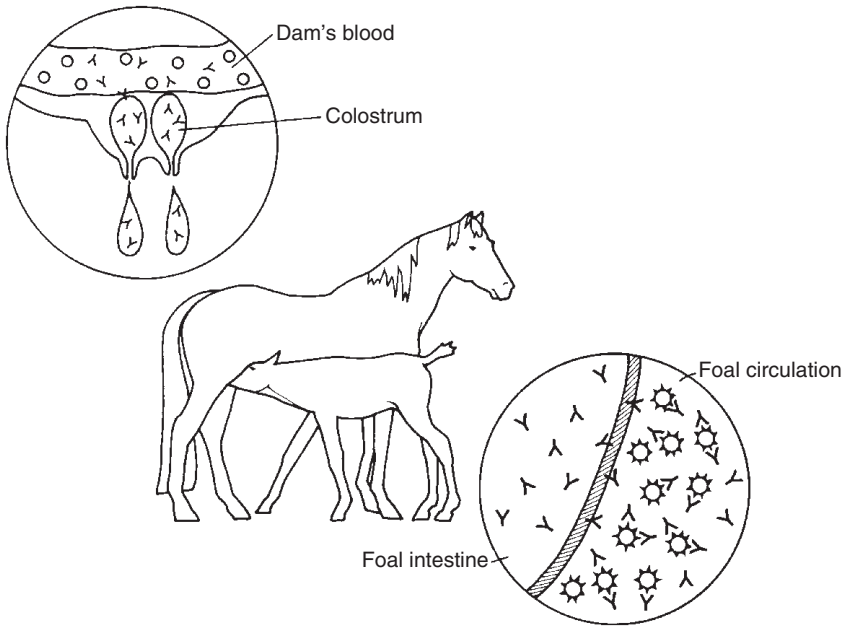

FIG. 53.9 Alloantibody in the mare's serum is concentrated in colostrum at the end of gestation. Through passive transfer, the foal absorbs immunoglobulins, including alloantibodies. The absorbed antibodies attach to the foal's red blood cells and cause either premature removal from circulation or intravascular lysis.

TABLE 53.12

Estimate of the Percentage of Mares in Selected Breeds That Are "At Risk" for Producing a Foal With Neonatal Isoerythrolysis[a]

Breed	At Risk for Aa	At Risk for Qa
Thoroughbred	2%	16%
Standardbred—pacer	22%	[b]
Standardbred—trotter	3%	[b]
American Saddlebred	25%	88%
Quarter Horse	25%	68%
Arabian	3%	72%

[a]Based on the lack of all alleles that include factors Aa or Qa.

[b]Mares all lack factor Qa and are technically "at risk," but all Standardbred stallions also lack the factor.

such as nephrosis and centrilobular hepatic necrosis, may also be present.

Treatment and Prognosis In most cases, by the time the problem is recognized clinically (e.g., when the foal is about 24 hours of age), the bulk of colostral antibody will have been depleted from the mare's milk and the absorptive ability of the foal's gut will have diminished. Withholding milk at this point is of questionable benefit.

Stress should be minimized and exercise restricted. Affected foals have decreased exercise tolerance and can collapse and die if forced to follow their dams. Generalized supportive care should be administered as indicated by clinical parameters. Intravenous fluids are frequently indicated to promote diuresis to minimize the effects of the large hemoglobin load presented to the kidneys. Acid-base balance should be monitored and corrected if indicated.

If the anemia becomes severe (e.g., PCV = 10% to 15%), transfusions that provide RBCs should be considered. Unless the PCV drops below this level, transfusion may not be necessary if rest is enforced. The object of transfusion is to provide the affected foal with RBCs that will not be destroyed by the maternal alloantibodies that were absorbed from colostrum. The foal is immunologically naive and will not have autologous alloantibody directed against any RBCs that would have an immediate effect on transfused RBCs. Thus the key is to select an RBC donor whose cells will not be destroyed by the maternal antibody derived from colostrum. Selection of a donor with cells that will not be destroyed by the maternal antibody can be based on the results of crossmatching using mare serum, colostrum, and/or foal serum (all contain the same antibody) and the donor RBCs.

Washed RBCs from the dam are obviously the perfect choice in terms of cells that will not react with the alloantibodies present in the foal. Therefore, to avoid administering additional harmful antibody to the foal, the mare's serum (containing antibody against the foal's cells) must be removed by washing before administration. Up to 6 to 8 L of blood can be collected from the mare into containers with acid-citrate-dextrose (ACD) or sodium citrate (3.8% NaCitrate solution; 1 part NaCitrate/9 parts blood), although 3 to 4 L usually provide sufficient RBCs. The preparation of large volumes of washed cells is aided by a large-volume centrifuge, but the procedure can be accomplished by serial sedimentations. Anticoagulated blood from the mare is allowed to settle for 1 to 2 hours. The plasma is aseptically drawn off, a similar or greater volume of sterile isotonic saline (0.9% NaCI) is added to the RBCs and mixed, and the RBCs are again allowed to settle. The saline is then drawn off and discarded. At this point the RBCs can be resuspended in an equal volume of isotonic saline for administration, or the washing procedure can be repeated. The sedimentation method is less desirable than centrifugation because it is slower and does not remove as much of the offending antibody. The aim is to dilute any harmful antibody to insignificant levels.

If it is not possible to use the dam's RBCs, alternative donors can be selected. The donor should lack the antigen to which the alloantibody is directed. Because it is generally not possible to blood type donors on short notice, a previously identified horse that has been determined by blood typing to be Aa–, Qa–, and free of alloantibody is a good choice for a donor

VetBooks.ir

because most cases of NI are associated with these two antigens. The odds of randomly selecting a donor that lacks the offending type (e g., Aa–, Qa–, or both) and would therefore be a suitable donor vary significantly with the breed and would mirror the percentage of the population of mares at risk. For example, the odds of finding an Aa– Thoroughbred to serve as an RBC donor would be about 1 in 50 (2%), whereas in Quarter Horses the odds would be about 1 in 4 (25%) (see Table 53.12). The sire of the foal is not the donor of choice. He shares the same RBC antigens as the foal, and his cells will react with the maternal alloantibody present, adding more of a load to the foal's mononyclear phagocyte system as they are destroyed.

In the case of mules, the same considerations in the use of washed cells would be necessary if the dam's cells were used. However, because the offending antibody is generally directed against a unique donkey antigen, it appears that RBCs from any horse would be satisfactory. Horses do not appear to make naturally occurring antibodies against donkey factor; therefore in most cases it is not necessary to wash the cells from horses that would not be likely to have been immunized by pregnancy against donkey factor.

Transfusion of RBCs that will not react with maternal alloantibody results in the introduction of an obviously incompatible cell into the foal. Transfused cells may sensitize the foal to future transfusions, causing reactions (perhaps not within hours or a few days but potentially within a week). The RBCs will probably not survive for long periods in the circulation, and such transfusions should be considered temporary measures. These possibilities must be considered when weighing the potential good versus potential harm of such transfusions.

To produce clinical improvement, 1 to 4 L of washed RBCs or whole blood are usually adequate, although some cases may require repeated transfusion if the anemia progresses. Exchange transfusions can be done whereby blood is administered via one jugular and withdrawn simultaneously from the opposite jugular and discarded, allowing administration of large volumes of blood without overloading the vascular system. There is no good evidence to suggest that this is more effective than simply providing a source of RBCs that are unaffected by the maternal antibody.

Limited transfusion studies in adult horses have suggested that transfused RBCs do not survive long in circulation (e.g., 2 to 4 days), whereas in foals cells survived slightly longer (e.g., 4 to 6 days).[48,49] PCVs in foals with NI commonly increase following transfusion and then gradually decline. This decline is probably not great cause for concern if it is gradual because the PCV of the foal generally levels off as the offending maternal antibody is metabolized. However, even short-term survival of cells may be of benefit in severely affected foals and may allow them to survive until the titer of maternal anti-RBC immunoglobulin has declined in the circulation. Hepatic failure in foals administered blood transfusions may be the result of iron intoxication. Administration of drugs that increase iron excretion, such as deferoxamine mesylate, are of potential value.[50]

The prognosis varies depending on the quantity of antibody ingested, the rapidity of onset of signs, and the degree of anemia. Peracute cases may die before the problem is recognized, with no chance for administration of therapy. Foals that develop the condition more slowly may respond to supportive care or transfusion if the PCV continues to fall.

Prevention and Control Several strategies are available for prevention of NI.[51,52] First, identify broodmares at risk for development of NI by testing them for the presence of Aa and Qa. Mares negative for either antigen, which means they could potentially make antibodies against them, should be considered at risk. One subsequent strategy would be to breed at-risk mares to Aa-negative and Qa-negative stallions, thus eliminating the possibility of the foal inheriting the offending antigens. However, in breeds in which a relatively small part of the population is negative for these antigens, identifying a stallion that is negative for both antigens and suitable based on other criteria may be difficult. The percentage of at-risk females based on the presence or absence of Aa or Qa is somewhat balanced by the number of males able to transmit the offending antigen. For example, all Standardbred mares would be considered at risk because of the absence of Qa; however, because the antigen Qa is not present in the Standardbred population, no stallions have the Qa antigen to pass on to foals.

In the circumstance of unknown or incompatible matings, sera from at-risk mares should be screened for the presence of anti-RBC antibodies within 30 days before foaling. This can be done by submitting a serum sample and an anticoagulated sample to a screening laboratory. A panel of 10 to 12 different RBCs selected to represent all major blood groups is adequate to screen for anti-RBC antibody in the absence of blood from the sire. If results of serum testing are equivocal (e.g., low but positive titer, especially if there is anti-Aa or anti-Qa activity), the test should be repeated closer to the time of parturition because the levels of offending antibody can rise quickly late in gestation.

If anti-RBC antibody is detected in the mare before parturition, the colostrum should be checked for reactivity against the foal's RBCs before allowing the foal to ingest colostrum. An alternative source of colostrum should be provided to the foal. Most field screening tests of colostrum have not proved to be satisfactory for practical use; however, the jaundiced foal agglutination (JFA) test described in Box 53.2 has been shown to correlate well with the standard hemolytic assay, and it may detect antibody that does not react on the standard agglutination tests.[7]

Horses negative for Ca frequently make anti-Ca antibody; however, this antibody is not known to produce adverse effects in the foal. It has clouded the issue of field screening tests for NI because it commonly causes positive reactions in most screening tests at low dilutions. Because these tests do not differentiate between antibody to Aa, Qa, Ca, or any other blood group, anti-Ca antibody, when present in low dilutions, is responsible for many false-positive reactions. This antibody actually appears to play a protective role in the prevention of sensitization of mares to NI through a mechanism of antibody-mediated immune suppression. Aa– and Qa– mares that are also Ca– (and thus often produce anti-Ca antibody) become sensitized to Aa and Qa at a significantly lower rate than mares that are Ca+.[53] This is attributed to the fact that anti-Ca antibody is produced by Ca– mares. The anti-Ca antibody may more rapidly remove potentially sensitizing cells from the circulation before they stimulate production of antibody against Aa or Qa.

Uncommonly, other antigens have been associated with NI in foals. These include factors Db, Dc, Dg, Ua, Pa, Qc, and Ab.[2,4,53-58] Two other factors, R and S, have been described to be associated with NI, but they are not detected by routine hemolytic or agglutinating methods and are detected only using an antiglobulin test (direct Coombs test).[41] Because of the difficulty in testing for these antigens, there has never been sufficient agreement among laboratories to allow international designation. These antigens may not be detected using the JFA test.[25] Estimates are that 1 in 2000 pregnancies may result in sensitization against some other antigen besides Aa or Qa. Because these cases occur so infrequently, it is not practical to consider mares without these antigens to be at risk for NI. A blood-type evaluation of mares with a history of production of foals with NI should be done to identify the offending antibody or antigen.

A list of laboratories providing NI screening tests (e.g., Aa, Qa, and Ca typing and screening of sera for alloantibody) is provided in Box 53.3. Routine agglutinating crossmatch tests using mare serum or colostrum and foal or sire cells

VetBooks.ir

BOX 53.2

Jaundiced Foal Agglutination (JFA) Test

Materials

1. Centrifuge capable of spinning 300× to 600× gravity
2. Test tube rack
3. Test tubes: 13- × 100-mm disposable or blood collection tubes
4. Pasteur pipettes and rubber bulbs or other pipette system to deliver 1-mL volumes
5. Isotonic (0.9%) saline at room temperature
6. Serum or colostrum from the mare; RBCs from mare and foal, preferably in EDTA anticoagulant

Methods

1. Collect colostrum from the mare.
2. Collect an EDTA-anticoagulated blood sample from the foal before nursing.
3. Set up six tubes and add 1 mL of saline to each tube. Label the tubes Control, 1:2, 1:4, 1:8, 1:16, and 1:32.
4. Make serial dilutions of the colostrum at 1:2, 1:4, 1:8, 1:16, and 1:32 in five of the tubes. Add 1 mL of colostrum (or serum) to the tube labeled 1:2 and mix. Then take 1 mL from that tube and add it to the second tube labeled 1:4 and mix. Take 1 mL from that tube and add it to the third tube labeled 1:8, and so on, until all five dilution tubes have been filled. Discard 1 mL from the last tube labeled 1:32.
5. Add 1 drop of the foal's whole blood to each of the six tubes and mix.
6. Centrifuge the tubes for 2 to 3 minutes at a medium speed (300× to 500× gravity).
7. Invert each tube, pouring out the liquid contents; observe the status of the button of RBCs at the bottom of the tube. Complete agglutination causes the cells to remain tightly packed in the button; strong agglutination causes the cells to remain in large clumps; for weaker agglutination the cells are in smaller clumps as they run down the side of the tube. When there is no agglutination, the cells easily flow down the side of the tube. This should be the case in the control tube. If the cells in the control tube are clumped, they may be autoagglutinating and the results will have questionable validity.
8. If there is a positive reaction with the foal's cells, the test should be run with the dam's own RBCs to be certain that neither the conditions of the test nor the viscosity of the colostrum is causing the agglutination.
9. Positive reactions at 1:16 or greater are considered significant. At levels of 1:16 or greater, this test correlates well with the standard hemolytic assay. At dilutions of less than 1:16, the correlation is not as good, and more false-positive results will be recorded. Also, other factors such as the viscosity of colostrum make less diluted samples more difficult to read.

EDTA, Ethylenediaminetetraacetic acid; *RBCs*, red blood cells.

can be performed by most veterinary or human hematology laboratories.

Ruminants

NI is not a naturally occurring disease in cattle, sheep, or goats. Its occurrence in cattle has been associated with administration of vaccines derived from blood origin, such as certain anaplasmosis and babesiosis vaccines.[2] When these vaccines are used on breeding females, they may sensitize the dam to certain blood groups, most commonly in the A and F systems. Under chance circumstances, if the blood types of the sire and offspring reflect these systems and the dam has produced alloantibodies, an isoimmune hemolytic crisis may appear in the calf associated with successful passive transfer.

[a]Serum or colostrum from the suspect mare is required to screen for the presence of alloantibody. Acid-citrate-dextrose anticoagulated blood is generally preferred for screening for red blood cell antigens.

Hemolytic crises are rare in sheep and are even difficult to induce experimentally.[2]

Bovine neonatal pancytopenia (BNP) is a fatal condition reported in Europe and New Zealand in a subset of neonatal calves born to cows vaccinated with a certain vaccine product (Pregsure® BVD [Pfizer, New York, N.Y.]); the vaccine has been withdrawn from the market.[59] Nevertheless, cases of BNP continue to be seen in calves born to dams that have been historically vaccinated. This vaccination-induced alloimmune condition is characterized by marked anemia, thrombocytopenia, lymphopenia, and bone marrow hypoplasia, causing severe internal and external hemorrhage. The involvement of colostrum was identified by inducing the disease in newborn calves (about 10 days when offering colostrum from vaccinated cows) and by preventing disease by colostrum substitution.[60] Studies demonstrated that the alloantibodies produced by vaccinated cows reacted with proteins from the cell line used to manufacture the vaccine. One study demonstrated that the development of BNP involves a heritable trait (19%) determined by the dams; that is, genetic differences between dams explain in part why the colostrum of some but not all vaccinated dams cause BNP in the calf or cause subclinical disease.[61] Genetic inheritable differences do not seem to involve major histocompatibility complex classes I and II genes or differences in Ig isotypes but rather unknown genes that control the amount of alloantibody produced by the vaccinated dams.[62,63]

Neonatal Alloimmune Thrombocytopenia

Equine

Definition and Etiology

Neonatal alloimmune thrombocytopenia (NAIT) is a condition characterized by the destruction of platelets in the circulation of a foal by alloantibodies of maternal origin absorbed from colostrum.[63] The syndrome has been observed in horse and

VetBooks.ir

mule foals.[44,64,65] The prevalence of this condition is unknown. Some cases may be asymptomatic, and the condition may be self-limiting as alloantibody is metabolized.

Clinical Signs and Differential Diagnoses Few clinical signs may appear unless foals are traumatized. Affected foals may have prolonged bleeding from venipuncture sites. Petechial hemorrhages may or may not be present.[64] Other conditions often associated with thrombocytopenia in neonates include sepsis, disseminated intravascular coagulation, equine infectious anemia, drug-induced thrombocytopenias, and angiopathies. The challenge is to determine whether the thrombocytopenia is primarily due to allogeneic antibodies or secondary to some other disease process.

Clinical Pathology Profound thrombocytopenia in the absence of other hematologic changes typifies uncomplicated NAIT. Evidence of successful passive transfer is present based on quantification of serum IgG. Affected foals are thrombocytopenic. Thrombocyte counts less than 10,000 cells/μL have been observed.[64]

Demonstration of significant amounts of antibody in the colostrum (or serum from the mare) that are directed against platelet antigens expressed by the foal provides a definitive diagnosis of NAIT; however, assays for equine platelet-bindable and platelet-associated immunoglobulins are not routinely available.

Pathophysiology The pathophysiology is believed to mirror that of NI. In mares sensitized to platelet antigens, alloantibodies are concentrated in the colostrum late in gestation. These antibodies are passively transferred to the foal. If the foal's platelets carry the antigen that the antibody recognizes, the platelets become antibody coated. Subsequently they are removed prematurely by the mononuclear phagocyte system. Platelet antigens have not been characterized in horses, although platelet-associated antibodies have been recognized in affected foals. Circulating antibody is removed by attachment to platelets and rapid clearance by the mononuclear phagocyte system.

Treatment and Prognosis Circulating antibody is removed relatively quickly, and treatment may not be necessary. Platelet-rich plasma may be indicated in cases of severe thrombocytopenia accompanied by clinical signs of bleeding complications; however, as offending antibody is removed, the problem will tend to be self-limiting.

Prevention and Control Currently there are no screening tests to predict NAIT. Following production of an affected foal by a mare, it would be prudent to provide an alternate source of colostrum to foals born in subsequent pregnancies.

A rare condition of severe thrombocytopenia, neutropenia, and ulcerative dermatitis has been described in equine neonates, and clinical signs suggest an association with passively transferred colostral antibodies or other factors.[66]

Alloimmune Neonatal Neutropenia

Equine

Definition and Etiology

Alloimmune neonatal neutropenia (ANN) is a condition characterized by the destruction of neutrophils in the circulation of a foal by alloantibodies of maternal origin absorbed from colostrum.[67,68]

Clinical Signs and Differential Diagnoses In the absence of secondary bacterial infections, no clinical signs are observed. Diagnosis depends on the presence of persistent neutropenia in the absence of evidence of increased consumption or decreased production of neutrophils.

Clinical Pathology Persistent neutropenia in the face of normal clinical conditions has characterized reported cases.

Pathophysiology The pathophysiology is believed to mirror that of NI. In mares sensitized to granulocyte antigens, alloantibodies are concentrated in the colostrum late in gestation. These antibodies are passed to the foal through passive transfer. If the foal's neutrophils carry the antigen that the antibody recognizes, the neutrophils become antibody coated. Subsequently they are removed prematurely by the mononuclear phagocyte system. Neutrophil antigens have not been characterized in horses, but neutrophil-associated antibodies have been recognized in affected foals. Circulating antibody is removed by attachment to neutrophils and rapid clearance by the mononuclear phagocyte system.

Treatment and Prognosis ANN is self-limiting in infants and typically resolves over several weeks as maternal antibodies diminish. Administration of antimicrobial drugs may provide protection against bacterial infections. Corticosteroids are not currently recommended for treatment of the condition in human infants and have not been used in equine cases. Administration of recombinant human granulocyte colony-stimulating factor (rhG-CSF) was associated with increases in neutrophil counts in one affected foal.[67]

Prevention and Control Demonstration of agglutinating neutrophil antibodies or immunoglobulin coating of neutrophils using flow cytometry from the foal may be used to confirm a diagnosis.[67] Following production of an affected foal by a mare, it would be prudent to provide an alternate source of colostrum to foals born in subsequent pregnancies.

Ruminant Immunologic Disorders

George M. Barrington, *Consulting Editor*

Immunity at Birth and the Immune Development of the Calf

David J. Hurley

At birth, calves possess the appropriate immune components needed for a protective response; however, these components lack maturity and require time to become as functional as those in adults. Although calves that do not receive colostrum within the appropriate time can still mount innate responses, they have a much greater risk of disease during the neonatal period and beyond.[1] For more on closotrum management in ruminants, see Chapter 19.

Prior to receiving colostrum, calves rely on macrophages located in tissues to manage tissue-level immune homeostasis. This includes mounting and managing the response to environmental microbes that share common antigenic determinants. The ability of macrophages to recruit monocytes, neutrophils, and other innate cells from neonatal circulation is a core component of the immediate innate immune response. Finally, in addition to macrophage activation and recruitment of circulatory innate cells, the activities of antimicrobial peptides combine to form the functional limit of immunity in calves at birth.

The earliest production of antibody by neonatal calves is reported in circulation at approximately 4 days of age. IgM can regularly be measured at 8 to 10 days of age.[2] T cell–dependent IgG is not usually observed in the circulation of calves until at least two half-life decays of maternal antibody. A large volume of research supports the role of IgG1 in the health and immune development of calves and its importance in providing protection from invading microbes. In addition,

VetBooks.ir

IgA in colostrum and milk play an important role in managing the colonization of the GI tract by microbes and the management of GI disease. Maternal antibody, directed against local microbes, helps protect calves during development and growth.

In calves, some B cells can be found in the neonatal organized lymphoid tissue both before and immediately after birth. These cells are widely distributed and are not organized into germinal centers (organized B-cell areas following immune activation). Their exact function and origin are not clear. After ingestion of colostrum containing viable maternal cells and IgG, or noncellular maternal factors and IgG, an almost complete depletion of the IgG-bearing cells in organized lymphoid tissues of the neonatal calf is observed. A small number of IgM- and IgA-positive cells are also present in these organized lymphoid tissues, and these are not affected by feeding whole colostrum or maternal colostrum without live cells.[3] Tracking of B cells in the peripheral blood of calves indicates that at birth about 5% of circulating mononuclear cells are B cells and that the number increases to about 20% by 20 weeks of age.[4] Fetal B cells are rapidly deleted from organized lymphoid tissues of very young calves. B cells are found in low numbers in the blood of young calves but are not likely to represent a sufficient pool of naive B cells to produce all the antibody required to resist pathogens early in life. Thus antibody transferred from colostrum (or whey antibody in colostrum substitutes) is required to adequately protect the calf.

Colostrum has a significant effect on the development of the neonatal GI tract.[5] Critical nutrients, vitamins, minerals and trace elements, and nonnutrient factors (Ig, growth factors, hormones, and cytokines) affect several processes, including the function of microbes; mucosal epithelial cell proliferation, migration, and differentiation; recruitment and function of innate immune cells; production of immune-active molecules; development of vascular beds and normal vascular tone; and mechanisms necessary for efficient transfer of nutrients and other components to the body. Serial microbial colonization of neonatal mucosal surfaces is critical for the development of both the innate and the adaptive immune networks.[6-8]

Norrman and colleagues compared the effects on B- and T-cell production of feeding newborn calves either colostrum or milk replacer.[9] They demonstrated that colostrum intake decreased neonatal adaptive immune responses compared with colostrum-deprived calves that lacked immune-priming assistance. The model also indicated that calves receiving colostrum were protected from the immune-suppressive effects of glucocorticoids and thus were less susceptible to infection.

Once calves ingest colostrum, immunoglobulin (primarily IgG1) rapidly crosses the gut epithelial cells and enters the circulation. Once in circulation, IgG1is distributed to the tissues by mass action, where it acts as a key element in immediate immune protection against microbial agents. Because of its structural flexibility, IgG1 readily enters tissues and enhances the response by macrophages, monocytes, and neutrophils.

In addition to circulating innate immune cells, both T and B lymphocytes are present as part of the adaptive response, though both are considered naive, having never been activated. Core structures such as the spleen and lymph nodes will eventually serve as foci for lymphoid maturation.

There is evidence in calves that lymphocytes can be activated as early as 2 days after birth.[10,11] Both colostrum-deprived and colostrum-fed calves produced antibody- (primarily IgM) and antigen-responsive T cells after exposure to bacille Calmette-Guerin (BCG) and ovalbumin antigens, and calves receiving colostrum had less evidence of disease over the course of the study. Both groups showed the capacity to mount adaptive responses to test antigens. Thus it appears that a full complement of experienced B and T cells and an adult-like organization of lymphoid tissues are not absolute requirements for successful production of at least some adaptive responses. However, this limited capacity is not sufficient to protect calves from disease.

It has long been established that maternal leukocytes present in colostrum successfully pass from the neonatal intestine into circulation. The exact function of these maternal cells is only beginning to be understood and is a topic of much debate. Nonetheless, while it is clear that calves can develop without the transfer of viable maternal cells, there are many reports of specific enhancements in immune function seen over the first 7 to 28 days after ingestion of colostrum with viable maternal cells.[12-24]

The induction of the adaptive response strongly depends on expression of antigen in the context of MHC antigens. At birth, calves have very low levels of MHC classes I and II antigen expression on circulating cells. However, rapid enhancement in expression of MHC classes I and II antigens is observed after ingestion of colostrum containing viable maternal cells (within 12 to 24 hours). A similar increase in cells expressing MHC classes I and II antigen requires at least 7 days in calves receiving colostrum without viable maternal cells.[25] The role of MHC class II in transmitting antigen information from tissues to lymphocytes in secondary lymphoid tissues and activating local lymphocyte and NK cell populations has been clearly established.

Maternal cells originating from colostrum appear to home to lymph nodes and mucosal lymphoid structures of calves.[26] Circulating leukocytes in calves receiving maternal colostral cells showed enhanced capacity to respond to viral and bacterial antigens that the dam had exposure to for 12 to 48 hours after colostrum feeding.[16-18,21,27] Calves not receiving viable maternal cells from colostrum showed no response to viral antigens and suffered more severe GI disease.[16,22-24] The innate and adaptive immune responses are clearly enhanced by ingestion of viable maternal cells in colostrum.[12-15,19,20,24]

In calves the number of circulating leukocytes declines rapidly beginning around day 2 after birth and reaching a minimum between days 7 and 11.[28,29] At birth, the predominant leukocyte in neonatal circulation is the segmented neutrophil, making up about two thirds of circulating WBCs. The other third includes lymphocytes, primarily T cells. As the total number of circulating leukocytes declines and then recovers over the first 2 weeks of life, the proportion of cell types also shifts. By day 14, neutrophils make up one third of total cells, and lymphocytes (including NK and gamma-delta cells) make up more than half of total cells. In the neonate, both NK and gamma-delta cells can leave the circulation and participate in immune protection within tissues.

Once DCs and neutrophils populate organized lymphoid tissues, the lymphoid environment changes to provide enhanced capacity for homing of lymphocytes and the structural development of germinal centers in these tissues. Although lymphoid germinal centers are rarely observed in mammals younger than 21 days of age, the seeds of the network required for their development begin in the first week of life. B cells, located in functional germinal centers, are under the influence of imbedded follicular DCs and surrounded by supporting Th cells. B cells and neutrophils (carrying whole antigen) provide important components for the development of an antibody response. Slowing development are low levels of MHC class II antigen expression by B cells, monocytes, DCs, and macrophages during the first 10 days to 2 weeks of life. Expression of MHC class II antigen is a limiting factor in the development of a rapid adaptive response.[25]

The process of calf immune development to adult levels takes time. Many potential pathways can lead to successful protection. The path a calf takes will be influenced primarily by the management strategies of the farm or ranch. For example, dairy calves can have a range of contact time with the dam (0 to 4 days) and may receive fresh, frozen, or processed colostrum,

VetBooks.ir

which is single-source or pooled. Dairy calves may be fed waste milk or milk replacer that may not possess populations of local microbes. In contrast, most beef calves are exposed to a number of herdmates and remain with their dam and herd during development. Beef calves are typically more aggressive than dairy calves, usually stand and nurse within 1 to 2 hours after birth, and continue to nurse ad libitum. In dairy calves the primary reason for FPT of maternal immunity involves poor-quality colostrum (low IgG1), whereas in beef calves FPT typically results from conditions that adversely affect the timely ingestion and absorption of colostral immune components.

Lethal Trait A46

Munashe Chigerwe

Lethal trait A46, also known as bovine hereditary zinc deficiency, Adema disease, hereditary thymus hypoplasia, and hereditary hyperkeratosis, is an autosomal-recessive immunodeficiency disorder with clinical presentation similar to acrodermatitis enteropathica (AE) in humans. The disease was first described in 1964 in Black Pied Friesian cattle.[1] Black Pied Friesian is a cross breed between Black Pied Jutlands from Denmark and Friesians from the Netherlands. A similar disorder has been reported in Shorthorn cattle in the United States[2] and Angus cattle in Australia.[3]

Zinc is an essential nutrient for several physiologic processes as a cofactor of many enzymes and transcription factors.[4] The molecular basis in AE in humans has been linked to an identification of a defect in a solute carrier (SLC), referred to as *SLC39A4*. A defect in a bovine ortholog of *SLC39A4* has been identified in cattle with lethal trait A46.[5] The defect has been postulated to negatively affect a pore responsible for zinc transport, leading to impaired zinc absorption.[5] Zinc is required for normal lymphocyte function. In a zinc-deficient state, lymphocyte numbers and function are reduced, and antibody responses are reduced.[6] Clinical signs associated with lethal trait A46 include skin lesions, diarrhea, and bronchopneumonia. Calves appear normal at birth but develop skin lesions at 4 to 8 weeks of age. The skin lesions are characterized by alopecia, hyperkeratosis, and exanthema. The distribution of the skin lesions includes the perineum, lower legs, head, and neck. Skin lesions of the entire body of the animal may be observed in advanced cases. Death occurs at approximately 4 months, secondary to bronchopneumonia or complicated diarrhea. Necropsy findings in affected animals include acanthosis, hyperkeratosis, thymus atrophy, gut-associated lymphoid tissue, spleen, and lymph nodes. The disease is responsive to zinc supplementation. Doses of 0.5 to 1 g/day zinc oxide[7] or 1 g/day of zinc acetate in cattle younger than 2 years of age[8] and of 45 g/day of zinc acetate in cattle older than 2 years have been recommended.[5]

Bovine Leukocyte Adhesion Deficiency

Bovine leukocyte adhesion deficiency (BLAD) is an autosomal-recessive congenital disease of Holstein calves characterized by chronic, recurrent bacterial infections and death. Leukocytes express cell surface glycoproteins called β_2 integrins, which mediate cell–extracellular matrix and cell-cell interactions.[9-11] The β_2 integrins include lymphocyte function-associated antigen-1 (LFA-1), complement receptor type 3 (CR3), and p150,95, and the family of these proteins is referred to as CD11/CD18 adhesion molecule.[9-11] The β_2 integrins LFA-1, CR3, and p150,95 consist of unique subunits—CD11a, CD11b, and CD11c, respectivelyand a common subunit CD18.[9,11] The CD11/CD18 adhesion molecules are essential for host defense against infections.[9-11] LFA-1 is expressed on all leukocytes and is essential for leukocyte adhesion and lymphocyte cytotoxicity.[9-11] CR3 and p150,95 are present on the surfaces of neutrophils, monocytes, macrophages, and NK cells.[9,12] Binding of CR3 and LFA-1 on the neutrophil surface with intercellular adhesion molecule 1 expressed on the vascular endothelium is required for neutrophil emigration into sites of inflammation.[12] Calves affected by BLAD lack expression of adhesion molecules of the CD11/CD18 family on the leukocyte surface.[13] The molecular basis for BLAD is a single point mutation (adenine to guanine) of the *CD18* gene, resulting in aspartic acid to glycine substitution at amino acid 128 (D128G) in the glycoprotein.[14] Calves with BLAD are homozygous to the D128G allele, whereas β_2 integrin expression in heterozygotes occurs in 56% to 90% of cattle not affected by BLAD.[15]

Clinical signs in calves appear within a couple of weeks after birth and include anorexia, fever, chronic pneumonia, chronic diarrhea, severe ulcers on oral mucosal membranes, ulcerative stomatitis, gingivitis, periodontitis, loss of teeth, impaired wound healing, chronic dermatitis, decreased growth rate, and death.[16,17] Marked and persistent neutrophilia is a consistent hematologic finding in calves with BLAD due to lack of emigration of neutrophils out of the vessels.[16] Consistent serum biochemical abnormalities include hypoalbuminemia, hyperglobulinemia, and hypoglycemia, consistent with chronic infections.[17] In the United States, 14% of bulls and 6% of cows were reported to be carriers of the D128G allele.[18] Diagnostic tests are available to detect heterozygotes and homozygotes. The information is available from the Holstein Association USA in Brattleboro, Vermont.

Selective IgG2 Deficiency

Rana Bozorgmanesh

IgG subclass deficiencies have been reported in ruminants. Primary (partial or complete) IgG2 deficiency in Red Danish milk cattle increases their susceptibility to gangrenous mastitis, bronchopneumonia, peritonitis, and abomasoenteritis.[1-3] There is also a report of IgG2 deficiency with transient hypogammaglobulinemia and chronic respiratory disease in a 6-month-old Holstein heifer that was eventually euthanized due to lack of improvement with therapy and a poor prognosis.[4] A transient IgG2 deficiency (with no adverse consequences) has been reported in neonatal lambs that ingested colostrum resulting in delayed synthesis of IgG2 to 5 to 6 weeks of age.[2]

Chediak-Higashi Syndrome

Chediak-Higashi syndrome is an inherited disorder resulting in partial oculocutaneous albinism, photophobia, increased susceptibility to infection, and coagulopathies. The condition affects cattle, mink, cats, mice, killer whales, and humans.[5,6] The condition is characterized by enlarged cytoplasmic granules (often lysosomes) in most types of granule-containing cells and defects in the function of leukocytes, renal tubular cells, and platelets. Neutrophils demonstrate abnormal intracellular killing due to a defect in the hexose monophosphate shunt as well as defective degranulation.[6] The condition is well documented in Japanese Black cattle, where inheritance has been identified as a simple autosomal recessive trait as it is in other animals and humans.[5,7]

Combined Immunodeficiency

Both T- and B-cell deficiencies due to genetic failure result in combined immunodeficiency. This may go unnoticed until maternal antibodies wane at several weeks of age, leaving the animal susceptible to infections. There is one report of a 6-week-old Angus embryo-transfer calf that died as a result of generalized systemic mycosis. This calf was hypogammaglobulinemic

and lymphopenic and had an absence of serum IgM. Necropsy confirmed the absence of lymphoid tissues and the diagnosis of combined immunodeficiency. Interestingly, the full sibling from the same embryo flush was healthy at 6 months.[8]

Viral and Bacterial-Induced Immunodeficiency

Bovine viral diarrhea (BVD) infection has been associated with altered immune function in infected calves and lambs.[9-11] Evidence suggests that the virus may have immunosuppressive effects on both the innate and the adaptive immune systems, making animals more susceptible to secondary infections and resulting in the establishment of persistent infection and immunotolerance.[9-10] Cattle infected with Johne's disease may show an inability to mount cell-mediated immune responses as well as the presence of humoral immunosuppressive factors contributing to chronic intracellular infection.[12] Furthermore, a state of tolerance may exist in the intestine of cows subclinically infected with Johne's disease organisms, in part due to proliferation of regulatory T cells that suppress mucosal immune responsiveness.[13]

Immunosuppression in the Periparturient Period

Barry J. Bradford • Jodi L. McGill

Introduction

In dairy cattle, the period 3 weeks prior to calving through 3 weeks after parturition, referred to as the transition period, is marked by dramatic changes in physiology, metabolism, and immunity.[1] The transition period is associated with a sharply increased incidence of metabolic and immunologic diseases, including endometriosis, mastitis, ketosis, and dystocia.[1-3] Further, the occurrence of health problems in the first few weeks postpartum is a major risk factor for continued production and reproductive performance problems.[4] It is now widely accepted that the increased incidence of both metabolic and production-related diseases is directly related to a temporary state of immunosuppression, which is known to affect the transition cow for at least 3 to 5 weeks following parturition.[2]

IMMUNOLOGIC DISORDERS OF THE INNATE IMMUNE SYSTEM. The innate immune system responds rapidly and nonspecifically to insults and thus plays a critical role in protecting the cow during the early days following parturition. Neutrophil function is particularly affected during transition, demonstrating reductions in chemotaxis, phagocytosis, oxidative burst capacity,[5-9] and downregulated expression of pathogen recognition receptors.[10,11] Changes in glucocorticoid levels at or around the time of calving are thought to be a prime factor leading to impaired neutrophil functions,[12,13] and a number of studies have shown that increased circulating cortisol levels downregulate neutrophil adhesion molecules, leading to reduced neutrophil surveillance activity and immune response.[13-15] However, glucocorticoid levels are increased for only a short period post calving[16-18]; thus additional factors likely contribute to the prolonged state of immunosuppression observed during transition. The final stages of fetal development and colostrogenesis require significant quantities of calcium, causing most cows to develop either subclinical or clinical hypocalcaemia in the transition period.[19] Hypocalcemia is linked to elevated cortisol plasma concentrations,[20] and cows with decreased serum calcium concentrations have decreased neutrophil activity, delayed pathogen recognition by peripheral blood mononuclear cells, and increased susceptibility to several periparturient conditions.[21-24] Due to the high demands of early lactogenesis, transition cows also regularly enter a state of negative energy balance and mobilize adipose and other tissues for energy.[2,4,18] Increased mobilization leads to increased concentrations of non-esterified fatty acids (NEFAs) and ketone bodies, such as beta-hydroxybutyrate (BHB). BHB is clearly shown to negatively affect neutrophil functions, including formation of neutrophil extracellular traps (NETs), chemotaxis, and phagocytosis.[25-27] High circulating NEFA concentrations are associated with diseases such as hepatic lipidosis,[28] retained placenta,[29] and mastitis.[30,31] High circulating NEFA concentrations in vivo are associated with reduced neutrophil and mononuclear cell functions,[32,33] and a study by Scalia and colleagues showed in vitro that high levels of NEFAs were associated with increased neutrophil oxidative burst activity but severely reduced viability.[34]

IMMUNOLOGIC DISORDERS OF THE ADAPTIVE IMMUNE SYSTEM. Like the innate immune system, the adaptive immune system of the transition cow is altered both qualitatively and quantitatively. Numbers of circulating lymphocytes and monocytes are reduced during the postpartum period.[35,36] Large quantities of serum IgG are transported into the mammary gland during colostrogenesis,[37] and physiologic reductions in serum IgM and IgG have been reported well into the postpartum period.[38] High levels of glucocorticoids are thought to be a primary factor in suppression of the adaptive immune system,[12] although lymphocyte blastogenesis and cytokine secretion are also adversely affected by metabolic factors such as hypocalcaemia,[22] ketosis,[39,40] and high circulating NEFA levels.[32,41]

Epidemiology

Impaired immune function during the periparturient period likely contributes to increased risk of infectious disease at that time. It is well established that mastitis incidence is greater in the first 5 weeks of lactation than during the remainder of the lactation,[41] along with high prevalence of metritis at this time.[42] Although numerous possible mechanisms could explain increased infectious disease incidence in early lactation, there is now strong evidence that impaired innate immunity is at least a contributing factor.[43]

Several functional attributes of neutrophils, including chemotaxis, phagocytosis, oxidative burst, and bacterial killing were found to be impaired prior to disease onset in cows that experienced retained placenta, mastitis, or metritis compared to healthy herdmates.[5,33,44] Mastitis and retained placenta were also associated with an increase in the proportion of immature neutrophils in circulation,[44] perhaps due to extravasion of the more mature, functional neutrophils. Shifts in monocyte populations were recently linked to postpartum disease; a high ratio of CD14+ to CD14– monocytes in the 6 weeks before parturition was associated with substantially greater risk of mastitis or metritis in early lactation.[45] Although there have been fewer studies linking adaptive immune function to transition success, a pilot study showed that cows with a weak lymphocyte proliferation response to LPS 3 weeks prior to parturition subsequently suffered from clinical infections postpartum, and this functional classification was associated with a genetic polymorphism.[46]

Interventions

A variety of approaches are being advanced to attempt to counteract periparturient immunosuppression and decrease disease incidence during this critical period.[19] Among the most widely adopted methods is vaccination against the J5 component of *E. coli* endotoxin, which decreases the incidence of coliform mastitis.[47] Although not commercially available, early trials are also showing promise for a multitarget metritis vaccine strategy.[48] A longer-term approach already in use by dairies is genetic selection for superior immune response, with reported benefits for periparturient disease incidence.[49]

VetBooks.ir

An innate immune stimulant is now available to substantially increase circulating neutrophil populations and enhance their functionality.[50] This modified bovine G-CSF, when administered 7 days prior to and immediately after calving, decreases clinical incidence of mastitis in early lactation,[51,52] although the potential impacts on other infectious conditions are not yet known. Feed additives are increasingly investigated for impacts on immune function. Beyond the benefits of better understanding and meeting requirements for nutrients like vitamin E[53] and chromium,[54] some yeast-containing products may stimulate innate and adaptive immunity in ways that are not completely understood.[55-58] Another line of research is investigating the immune benefits of decreasing milk yield through decreased milking frequency or partial milking in the first week of lactation.[59] Ultimately, the practices with the most impact for supporting immunity during the periparturient period are likely to be already established best management practices: appropriate stocking density,[60] prevention of heat stress[61] and hypocalcemia,[62] and body condition management.[63]

Disorders Caused by Toxicants*

LYNN R. HOVDA, *Consulting Editor*

TAM GARLAND, BIRGIT PUSCHNER, TIMOTHY J. EVANS, C. LANGDON FIELDING, ROBERT H. POPPENGA, DIONNE BENSON, MICHELLE MOSTROM, and BENJAMIN R. LANDERS

Poison cases in large animals occur less often than in other species but are usually more time consuming and frustrating to manage. Generally, an animal is found dead in the stall or pasture, or a sudden outbreak of illness occurs in a herd of animals. A rapid response is necessary, especially in herd cases, to eliminate the toxicant, treat affected animals appropriately, and prevent the development of further cases. The initial history is frequently limited, yet owners, trainers, barn managers, elevator owners, and others may demand an immediate answer. Emotions often run high, especially with the death of a beloved horse or when legal and media-related issues arise. The veterinarian is left to provide immediate answers to many complicated issues while attempting to undertake a diagnostic investigation.

The simple act of finding a toxicant does not necessarily mean it is the causative agent or that it is even related to the problem at hand. Concluding thus without further evidence could skew the investigation and result in an inaccurate diagnosis and further illness in or death of other animals. A complete toxicologic investigation, including a thorough history, clinical signs, clinicopathologic testing (including necropsy if available), and analytic testing, should be undertaken in a careful and systemic manner. Internet websites can be used to provide accurate and rapid sources of toxicologic information to aid in the investigation and provide treatment options[1,2] (Table 54.1). An established working relationship with a diagnostic laboratory providing advanced testing and access to a board-certified toxicologist specializing in large animals will increase the likelihood of a positive diagnosis.

History

An accurate history is the starting point of any toxicologic investigation and, when done correctly, ensures that you have obtained the appropriate samples for further analysis. The investigation may vary from simple to complex but should always be done in a calm and ordered manner so that nothing is overlooked. The history should be used to provide information on circumstances surrounding the problem and may or may not identify the toxicant itself. Again, the presence of a toxicant in the environment does not necessarily mean that it is the source of the problem. Finding a toxicant is simply a starting point, as it may or may not support the clinical findings. Many other factors, including the dose and degree of exposure, need to be considered because exposure to a nontoxic dose generally does not result in a worthwhile diagnosis.

Species, breed, age, sex, body weight, and body condition are important pieces of information that should be collected for all involved animals. Current and past medications used, vaccination history, reproductive status, and illnesses in other animals are other pieces of useful data. Species identification is particularly important because some toxins are species specific or have different toxicologic profiles for different species. In addition, absorption of some toxins in ruminants, horses, and swine varies due to their specific gastrointestinal (GI) tracts. Some individual breeds may have different metabolic pathways, resulting in delayed metabolism and excretion. The presence of a P-glycoprotein transporter in the *MRD1* gene was recently identified in horses, and this may play a role in the development of breed-related toxicosis.[3,4,5] Very young and very old animals are often at increased risk for developing signs of poisoning at much lower doses. Neonatal animals absorb some metals and chemicals more readily than adults do, and nursing animals may receive toxic substances in the milk. Geriatric animals often have underlying deficiencies in liver metabolism and renal excretion that affect their ability to clear potential toxicants in a timely manner.

Initial questions often revolve around whether a known toxicant is present in the animals' environment. There are literally hundreds of toxicants, but many people, when questioned appropriately, often know or are suspicious of which one(s) may be playing a role. Common questions include whether medications, pesticides, herbicides, or fertilizers have recently been used or are present on the property. Is rodent control used in barns and outbuildings? Are there old junk piles on the property? What farm equipment and automotive products have been used recently? Have any old buildings been moved or torn down? Are there any known poisonous plants on the property?

Recent changes in animal management should be investigated in detail. Animal handlers should be questioned about the introduction of any new feeds, either new bags or fresh batches from a feed mill, or a complete change in feed. Feed should be examined closely for mold and the presence of any foreign bodies. Samples of feed, both as purchased and as fed, should be obtained and stored for further analysis. Hay and pasture should be examined for the presence of blister beetles, clippings from plants such as yew or oleander, other poisonous plants and weeds, foreign bodies, and mold. Again, samples should be taken and saved for analysis. Water samples from the original

source and at the trough or stock tank should be taken and conserved in preserving jars for analysis if needed.

Clinical Signs

Live animals should have a complete physical examination performed and be closely examined for the presence of any unusual clinical signs. Ultimately, the conclusion of the physical examination may help to narrow the list of toxicants. Both the nature of the signs and the sequence of events should be documented. Specific abnormalities such as the color and consistency of mucous membranes, mouth lesions, blistering on pink skin areas, loss of hair around the eyes or tail, horizontal lines on hoof walls, presence of bite marks, and other abnormal findings may help determine whether the process is specific to an organ system or more generalized in nature. It is important to remember that in some instances this may not actually be an intoxication because other diseases or illnesses may result in similar generalized, nonspecific clinical signs.

The time frame from when the animal was last noted to be normal to the onset of signs should be determined, as should cessation, continuation, and duration of signs. Much of this information may need to be obtained in a historical manner from the animal caregiver because the veterinarian is often examining the animal at a single time point in the progression of signs and may otherwise miss valuable information.

Clinicopathologic Testing

The results of clinicopathologic tests often shorten the list of potential toxicants and may point toward a specific organ system and toxicant.[3] It is invaluable to obtain and either test or store appropriate samples at the time of the physical examination or postmortem. Blood should be examined for electrolytes, complete blood cell count (CBC), liver enzymes, blood urea nitrogen (BUN), and creatinine. Urine should be examined for specific gravity and discoloration, as well as crystals, casts, red blood cells, hemoglobin, and methemoglobin. Other body fluids (e.g., ocular, cerebrospinal), hair, and ingesta should be obtained as needed. All samples except blood and central nervous system (CNS) fluid can be frozen.[3,6,7] Blood should be centrifuged, the clot removed, and the sample stored in the refrigerator. It is important to remember that zinc and many of the trace minerals must be collected in a special tube for analysis.[6]

If possible, animals should be referred to the appropriate diagnostic laboratory for a postmortem completed by a board-certified pathologist. This is especially important if the animal is insured or legal issues are looming on the horizon. Animals sent to the diagnostic laboratory should be identified by tattoo, microchip, ear tag, or other means. Digital pictures taken before shipment can be used as a further source of identification. If a field necropsy is performed, extra samples should be taken because it is far wiser to take more samples than needed and discard them later rather than not have them at all. Often necropsy results will show specific lesions that may confirm a working diagnosis or point the veterinarian in another direction. Sometimes, the postmortem shows only generalized lesions or no lesions at all.

Analytic Testing

Analytic testing can be used to provide a definitive answer, but it must be used correctly and the results analyzed judiciously. Samples should not be sent to an analytic laboratory without some knowledge and forethought. The analytic laboratory will need guidance in terms of what they are testing for, as well as a history including the time since intoxication, dose of toxicant, and postmortem changes. Urine is the gold standard, especially for drug identification, but serum and plasma can also be used for analysis. Different forms of instrumentation and analyses are used for specific substances. For example, metals such as lead, zinc, arsenic, and others are analyzed with atomic absorption and spectrometry.[6] Enzyme-linked immunosorbent assay screens are generally sensitive, but the risk of cross-reaction with other substances may be large.[6] Drugs, many pesticides, and plant toxins are analyzed using gas or liquid chromatography–mass spectrometry, but unless specifically requested, the results are generally not quantitated and only demonstrate the presence of a toxicant.[3,5,6]

In summary, poisoning cases can vary from simple and direct to highly complex. It is important to investigate each one using a systematic approach, including history, clinical signs, clinicopathologic findings, and the results of analytic testing. As the veterinarian works through the investigation, each step may narrow the list of toxicants until a final answer is found. Alternatively, some investigations do not come to a conclusion, and the veterinarian is left to wonder what actually occurred. In many of these cases, environmental and management changes eliminated the toxicant before the investigation, leaving only the after effects.

Poisonous Plants

Tam Garland

VetBooks.ir

Plant Poisoning Considerations

The need for forage and therefore risk of toxicosis in both ruminants and Equidae is well established. Significant economic losses have been attributed to poisonous plants in regions and countries that rely on grasslands for raising livestock. Studies in the western United States suggest that plant poisonings adversely affect 3% to 5% of rangeland cattle, sheep, goats, and horses.[1] In China, poisonous grassland species of plants are responsible for an estimated $12.3 million of all livestock losses, including loss of performance and mortality from 2000 to 2006.[2] The estimated price of plant poisonings in Australia is $100 million (Australian dollars) per year.[3,4]

Based on these statics, poisonous plants pose significant dangers to all large animal species. Poisonings can occur for a variety of reasons. Toxic plants may be consumed inadvertently when baled into hay or processed into silage. Consequently, the animal may be unable to avoid the plant. However, hungry or thirsty animals are much more prone to eat plants that may otherwise be avoided. Naive animals, those unaccustomed to the surroundings, are more likely to consume plants that are unfamiliar to them.

The severity of toxicity may be affected by a variety of factors acting on the plant, such as season (summer versus winter) or moisture (either excessive or drought conditions). Severe heat may affect the toxicity of plants. The type of soil may be an influencing factor in the toxicity of the plants as well as the micronutrient levels in the soil. For example, some soils may be high in such nutrients as selenium, and some plants are selenium accumulators.

Investigation of possible plant poisoning on the affected premises include limited availability of forage as evidenced by animal observation and body condition scores; drought affecting plant growth, availability, and potentially high concentrations of toxins such as nitrates; recent storms having downed trees or fences or even a lightning strike; feed changes; inappropriate disposal of garden, shrub, or tree trimmings; and administration of herbal products for medicinal value. The level of toxins within a given plant species is often variable, even in samples obtained from the same pasture. Toxicity may be more pronounced in specific growth phases of the plant species, during times of stress or rapid growth, or after drying. Endophyte or fungal infections of the plant may also be important, either as the sole or an additional source of toxicity. These factors can be important in the timing and choice of plant specimens to identify, as well as assay for toxicity.

Individual animal factors play a role in both quantity of plant consumed and expression of clinical signs, thus making investigations more challenging. More than one type of toxic plant may have been ingested, which may lead to a wider variety of clinical signs. An individual animal may develop a taste for a plant being avoided by others in their herd or flock or be forced to eat it due to feed competition and low social order. Herbicide application may also enhance the palatability of plant species such as water hemlock.[5] Recent fertilizer application may increase nitrate concentrations in both plants and water supplies. Some plants can create a wide range of clinical signs depending on the amount consumed, either acutely or chronically. Research done on specific plants and toxins, and applied to feeding trials, has demonstrated that differences in metabolism, GI flora, and genetics may have a role in disease expression. Yet another variable is interaction between plant toxins and medications. Consumption of hay with two separate species of nightshade (*Solanum* spp.) has recently been identified as a factor in the development of clinical signs of ivermectin toxicosis in horses.[6]

Any suspicion of plant poisoning in an individual or group of individuals in a herd or flock should trigger a diligent investigation. The first step is a complete history of the affected individuals, the herd or flock, and the premises. In addition to routine health questions, emphasis should be placed on current feed, and whether any changes have been instituted; weather factors possibly affecting feed and water access or quality; fertilizer use on forage sources; differences in the management of affected and unaffected animals; and the potential for feeding errors or inadvertent exposure to garden refuse.[7] If the history yields evidence to strengthen the suspicion of plant poisoning, it may be necessary to immediately remove access to the suspected source of the clinical problems. If multiple animals have been affected, determining a timeline of events and cases may be helpful in evaluating the history and determining the cause.

The second step in the investigation should be thorough examination of affected animals to identify and characterize clinical abnormalities and lesions. Low body condition scores, particularly if accompanied by a strong appetite, should raise clinical suspicion of consumption of normally unpalatable plants, or lack of appropriate nutrition. Pregnant animals should be evaluated for signs of potential abortion. Quick access to a veterinary diagnostic laboratory, an animal poison control center, or an available online database where clinical signs are entered to yield potential diagnoses may help veterinarians quickly sort through potential differential diagnoses for the animal(s).[8] Symptomatic treatment is often the first line of medical response if the etiology has not been determined or a specific antidote is not available or approved for use in a particular species, especially a food animal species. Stress of treatment, particularly for ruminants, must be weighed against the benefits. Activated charcoal administration remains advisable for most acute toxicoses, if the animal can withstand the stress of administration. In monogastrics, stomach lavage followed by instillation of a slurry of activated charcoal in water may be the best option for acute cases. However, in ruminants this may be more challenging, and a rumenotomy for evacuation of contents and instillation of activated charcoal could be considered. In herd situations, rumenotomies on multiple animals may not be feasible or affordable. The cost of treatment of an animal may exceed the value of the animal, and treatment considerations for large animals and the associated cost should be discussed with owners or caregivers prior to treatment. A limited number of specific antidotes are described for a few plant poisonings, but their use may be restricted by cost and the need to avoid food residues. Enhanced excretion of toxins through laxatives or manipulation of urine or rumen pH may be applicable in specific situations where the toxic plant or principle has been confirmed.

Postmortem examination of affected animals should take place as soon after death as possible to maximize the opportunities to identify lesions and an etiology. In some plant poisonings, a specific odor may be noted, such as a bitter almond smell in cyanide poisoning (e.g., *Prunus* spp.), an acetone smell with white snakeroot poisoning, and a mousy aroma due to poison hemlock ingestion.[5]

Samples should be taken of rumen or stomach contents to look grossly and microscopically for recognizable plant fragments or seeds. An aliquot of the ingesta should be collected and labeled and a second sample frozen as soon as possible for toxicologic analysis. This is especially necessary when the possible toxin is unknown. Depending on the history and the timeline, more ingesta samples may be warranted from other segments of the digestive tract, especially the abomasums of calves. If the animal is a calf, collect contents of the abomasum in a similar fashion. Intact seeds may be identifiable in the distal intestinal tract or manure.

VetBooks.ir

Samples of aqueous humor, amniotic fluid, and fetal stomach fluid for nitrate concentrations should be considered if clinical signs are compatible with a particular etiology. If the animal has died within a few hours, blood samples for hematologic, chemistry, and toxin profiling may be rewarding. Tissue samples are important for characterizing histologic lesions to confirm a plant toxicity or alternative etiology. All grossly affected tissues should be sampled and a piece of liver, both fresh and frozen, submitted for toxicologic analysis. If neurologic signs were observed, the brain should be removed with proper barrier precautions.[7]

Identification of the plants, foodstuffs, or water responsible for clinical signs or deaths is important for guiding treatment and further control of an offending agent. Inspection of the feed, including grain, hay, and pasture, may be necessary when dealing with suspected plant intoxications or suspected mycotoxins. Mycotoxins may be visible as moldy bits in the feed. However, the presence of mold does not ensure a mycotoxin, just as the absence of mold does not ensure the absence of mycotoxins (see the Mycotoxins section later). Several samples of the feed should be obtained for both toxic plant and mycotoxin testing. Remember as well that grasses can contain mycotoxins such as ergot. Walking the fence line looking for known toxic plants and evidence of grazing them is necessary for completeness. Samples of plants in question or unknown to you should be collected, especially if there is evidence of grazing.[8] Fresh plants may be placed in plastic bags, chilled, and shipped chilled overnight to a diagnostic lab. Additional samples can be pressed between newspaper sheets or brown paper with a board or heavy cardboard with some type of weight (e.g., books, gym weights) on top to keep them flat. The plants should remain under the weight for several days. Modern technology (smart phone) can be used to take photos of the plants and email or text them immediately to the toxicologist at the diagnostic lab. A telephone conversation with the toxicologist may assist you in finding the offending plant more quickly, perhaps even while you are on site. For identified plants known to have variable toxicity, such as larkspur (Color Plate 54.1) or selenium-accumulating plants, multiple samples should be taken of the same species, concentrating on areas where the plants have been visibly browsed or grazed.[9] Resources for plant identification include toxicology texts, the U.S. Department of Agriculture (USDA) plant identification website, the USDA Poisonous Plant Research Laboratory website and its publications, other country-specific websites, and university or extension service plant experts.[10-16] In the United States, plant samples can be sent to the USDA Poisonous Plant Research Laboratory or Texas A&M's Veterinary Medical Diagnostic Laboratory. Other veterinary diagnostic laboratories may be able to identify the plants. Your diagnostic laboratory of choice may send the sample to one of these other labs, or you may need to request that it be sent to one of these laboratories.

Common plant poisonings often trigger a recognizable pattern of clinical signs and disease progression. These are reviewed below in more detail, with emphasis on diagnostic features, treatment options, and preventive measures. Less frequent causes of livestock morbidity and mortality are listed in tables, grouped by predominant clinical signs. Highlights of newly described toxicities that have the potential to harm multiple animals are presented in this chapter section.

Sudden Death

Poisonous plants, chemical toxins, lightning strikes, and infectious diseases are causes to consider when investigating sudden death in multiple animals. Numerous plant species have the potential to kill multiple animals within minutes to hours (Table 54.2).

TABLE 54.2

Plants With Potential to Cause Sudden Death in Large Animals[a]

Common Name	Scientific Name	Species Affected[b]	Toxin(s)	Plant Habitat	Clinical Signs	Specific Therapy
Cyanogenic plants[1,10]	Many	O, B, C, E, P	Hydrogen cyanide	Worldwide	Cyanosis, dyspnea, muscle twitching, staggering, convulsions, coma	Sodium thiosulfate, sodium nitrite
Nitrate-accumulating plants[10]	Many	B, O, C, E	Nitrates	Worldwide	Weakness, drowsiness, chocolate mucous membranes, muscle tremors, tachycardia, tachypnea, staggering gait	Methylene blue
Copperweed[10]	*Oxytenia acerosa*	B, O	Unknown	Southwest U.S.	Appetite loss, weakness, coma, death in 1-3 days (longer in sheep)	
Death camas[10,17]	*Zigadenus* spp.	O, B, E	Zygacine	U.S., Canada	Salivation, bloody frothing, vomiting, muscle weakness, staggering, tachycardia, coma	Atropine
Dogbane[1]	*Apocynum* spp.	O, B, E	Cymarin	North America	Blue mucous membranes, tachycardia, mydriasis, progressive weakness, coma	
Easter (Atamasco) lily[10]	*Zephyranthes atamasca*	B, E	Unknown	Southern U.S., Mexico	Staggering, diarrhea, collapse

[a]Plant names in bold are discussed in more detail in the text.

[b]Species listed in relative order of toxicity importance: *B*, Bovine; *C*, caprine; *E*, equine; *O*, ovine; *P*, porcine.

Several groups of plants deserve greater discussion because of the frequency with which they are incriminated in the death of livestock and horses. All produce a range of clinical signs influenced by the amount consumed, time period of consumption, concentration of toxins, animal species, and in some instances, accommodation of ruminal microbes.

Larkspur (*Delphinium* spp.)

Larkspur (Color Plate 54.1) is considered one of the most important plant poisonings of range animals in the United States, second only to locoweed in its impact.[10] Cattle are most susceptible, but sheep and horses can be affected. The toxicity varies with the specific plant, stage of growth, amount eaten, and time period over which it is consumed. Numerous toxic diterpenoid alkaloids have been identified in the nine *Delphinium* spp., the most often cause of poisoning in cattle. Tall larkspur *(Delphinium barbeyi)* is considered the most problematic.[1] These alkaloids cause a curare-like blockade of neuromuscular junctions, by reversibly binding to nicotinic acetylcholine receptors. Larkspur consumption may also enhance the toxicity of another range plant, death camas (*Zigadenus* spp.).[17]

Death varies from sudden to 3 hours post larkspur consumption. Clinical signs include excitability, muscle tremors, stiffness, staggering, and a basewide stance.[10] Cattle may assume a kneeling position before collapsing. Bloat, regurgitation (ruminants), constipation, mild GI irritation, venous congestion, and aspiration pneumonia may be observed. There are no pathognomonic postmortem changes. A definitive diagnosis is

usually reached by identifying pieces of larkspur in the upper GI tract.

If treatment is possible, bloat should be immediately addressed to relieve thoracic compression and reduce the chances of aspiration; however, the stress of treatment may hasten death. Intravenous (IV) physostigmine has been advocated at dosages of 0.04 to 0.08 mg/kg, repeated as needed over several hours.[10] Neostigmine at 0.04 mg/kg is slightly less effective. Neither drug is approved for use in food animals. An affected animal may be mistaken for a grass tetany case; however, treatment with magnesium exacerbates the effect of larkspur's toxins at the neuromuscular junction and should be avoided.

Prevention of larkspur toxicity in range cattle is challenging and requires knowledge of when the plants are most toxic and most palatable, particularly if other forage is limited. For example, early spring grazing of cattle in pastures with tall larkspur should be curtailed as soon as the flower stalks begin to elongate. Sheep are more tolerant and can be used to reduce the plant's density. Aversion to eating larkspur has been created with lithium chloride administration, a strategy that may be worthwhile on some ranches.[22] Larkspur reduction may not be cost-effective with herbicides, leading investigators to use insect control with the larkspur myrid *(Hoplomachus affiguratus)*.[10]

Cyanogenic Plants

Toxicity induced by consumption of cyanogenic plants produces sudden death, along with the characteristic signs of bright red mucous membranes and bright red venous blood.

Clinical signs are rarely observed but include obvious respiratory distress, rapid breathing, bloat, salivation, muscle twitching, staggering, mydriasis, cardiac arrhythmias, and convulsions.[10] Cyanide blocks molecular oxygen transfer in cytochrome oxidase systems in mitochondria causing tissue anoxia.[23] Ruminants are more susceptible than monogastrics because rumen microorganisms readily release cyanide from the cyanogenic glycosides. Acute, sublethal cases generally recover within an hour. Toxicities have also been reported in alpacas.[24] Chronic cyanide toxicity has been associated with sorghum consumption in pregnant horses and cattle. The foals and calves are born with arthrogryposis. Animals may also develop neurologic damage to the brain and spinal cord resulting in weakness, ataxia, and urinary incontinence. Low doses of cyanogenic glycosides can be goitrogenic.[10]

Cherry red venous blood may be observed in fresh postmortem examinations. In ruminants, a bitter almond odor may be detected in rumen contents.[10] Tracheal, pulmonary, and muscle congestion may be observed, along with hemorrhages in multiple organs. Cyanide ion content may be measured in refrigerated samples of heart, brain, or skeletal muscle or rumen contents. Blood samples for analysis should be kept in airtight containers at 4° C until analyzed. A sensitive field test for use on forage samples or rumen content has been developed using alkaline picrate–treated filter paper strips.[11]

A number of plants have varying levels of cyanogenic glycosides, including the following trees, shrubs, crops, and grasses: acacia, African star grass, apple, arrow grass, Bahia grass, bamboo, Bermuda grass, birdsfoot trefoil, bracken fern (Color Plate 54.2), cassava, chokecherry, Christmas berry vetch, corn, elderberry, eucalyptus, flax, flowering quince, hydrangea, Indian grass, Johnson grass, lima bean, mountain mahogany, poison suckleya, reed canary grass, service berry, sorghum, South African daisy, star grass, Sudan grass (*Sorgum* spp.), tall manna grass, Texas queen's delight, and white clover.[10,23] Seeds of apples and crabapples (*Malus* spp.) and the seeds, as well as leaves of the *Prunus* spp. (bitter almond, cherry, chokecherry, apricot, peach, nectarine, plum, mock orange), may have large amounts of cyanide. Drying as hay or incorporation into silage generally decreases the toxic potential of the forage plants; most are not routinely grazed or browsed. Early growth phases of the plants are the most toxic. Poisoning is most likely if animals eat a large quantity in a short period of time. Wilting, frost, drought, or other damage to the plant enhances toxicity.[1] Toxicity is measured as cyanogenic potential. Plant material containing more than 20 mg per 100 g (200 ppm) cyanide potential is reason for concern, but this varies between species.[23] Cyanogenic potential is significantly reduced by properly curing forages for hay or ensilage.

If the diagnosis is made rapidly, some cattle and sheep may be saved by IV or intraperitoneal (IP) injection of 20 mL of a 10% solution of sodium thiosulfate mixed with 10 mL of a 10% solution of sodium nitrite.[1] However, this treatment is not approved for use in food animals. An alternative treatment has been described for ruminants using only a 30% to 40% thiosulfate solution IV at a dose of 25 to 50 g/100 kg of body weight.[11] Administration of a gallon of vinegar diluted in 3 to 5 gallons of water administered by stomach tube to help acidify the rumen has also been recommended.[10] Preventive measures are largely focused on limiting access to highly cyanogenic plants and trees, particularly during rapid early-growth phases, and planting varieties with lower cyanogenic potential.

Nitrate Toxicity

Many plants and some water sources contain harmful concentrations of nitrates, which can cause a wide range of clinical signs from sudden death to congenital defects in ruminants, camelids, and monogastrics. Examples of plants known to accumulate nitrates are listed in Table 54.3. When photosynthesis is impaired by shade or prolonged cloudiness or excessive nitrogen is applied to plants (e.g., fertilizer), nitrate accumulation may reach dangerous levels. Other triggers for nitrate accumulation include drought, frost, hail, and herbicide application. Nitrates are water soluble and can leach from harvested forages, occasionally causing toxicosis by elevating concentrations in the lowest bales of a rained-on haystack.[25]

In ruminants, ingested nitrates are converted to nitrites and ammonium in the forestomachs. Nitrates can cross the placenta. If excessive nitrates are ingested, absorbed nitrites can trigger oxidation of the ferrous iron in hemoglobin, producing methemoglobin. Chocolate brown mucous membranes and blood are characteristic findings. Vasodilation and hypotension may result, leading to hypoxia, dyspnea, exercise intolerance, death, fetal stress and subsequent abortion, stillbirths, and/or weak neonates.[27] In bulls, sperm abnormalities and degenerative changes within the testes have been reported.[28] If the animals are anemic or hypoxic for any other reason, methemoglobinemia will have even greater consequences. At postmortem examination, a brownish cast of the tissues due to the methemoglobinemia may be apparent.

Congenital hypothyroidism in equine neonates is most often caused by insufficient iodine intake by the broodmare but can also be caused by excessive nitrate intake. Multiple animals in the herd may be affected.[29,30] Signs of high nitrate intake may not be observed in the broodmare. Abortion may result, or more commonly a dysmature foal is produced after prolonged gestation. The affected neonates have varying degrees of signs but classically include mandibular prognathism, flexural deformities of the forelimbs, secondary rupture of the common digital extensor tendon just above the carpus, poorly ossified cuboidal bones, and poor immune function. If recognized at birth, these foals can survive to be useful animals if treated intensively with splints to address the flexural deformity, very limited weight-bearing until the cuboidal bones ossify, and measures to reduce the likelihood of infection. If an affected foal is allowed to bear weight before full ossification of the cuboidal bones in the hocks and carpi, angular limb deformities will likely result. The syndrome can be prevented by avoiding high nitrate forage or water sources and ensuring that there is adequate iodine in

TABLE 54.3

Plants With Potential to Accumulate Nitrates

Type	Common Name	Scientific Name	Reference(s)
Crops	Barley	*Hordeum* spp.	25
	Beets	*Beta vulgaris*	10
	Corn	*Zea mays*	10, 25
	Flax	*Linum* spp.	10
	Kale	*Brassica oleracea*	10
	Oats	*Avena* spp.	24, 25
	Pearl millet	*Pennisetum typhoides*	10, 25
	Rape	*Brassica napus*	10
	Rye	*Secale cereale*	10, 25
	Soybeans	*Glycine max*	10, 25
	Sunflower	*Helianthus annuus*	10
	Turnips	*Brassica rapa*	10
	Wheat	*Triticum aestivum*	10, 25
Forages	Alfalfa	*Medicago sativa*	10, 25
	Barnyard grass	*Echinochloa* spp.	10
	Button grass	*Dactyloctenium radulans*	26
	Johnson grass	*Sorghum halepense*	10, 25
	Sudan grass	*Sorghum vulgare*	10, 25
	Sweet clover	*Melilotus* spp.	10
	Tall fescue	*Lolium arundinaceum*	25
Weeds	Canada thistle	*Cirsium arvense*	10
	Cheese weed, mallow	*Malva* spp.	10
	Dock	*Rumex* spp.	10, 25
	Field bindweed	*Convolvulus arvensis*	10
	Fireweed	*Kochia* spp.	25
	Goldenrod	*Solidago* spp.	10
	Jimsonweed	*Datura stramonium*	10
	Kochia (summer cypress)	*Kochia scoparia*	10, 25
	Lambsquarters	*Chenopodium* spp.	10, 25
	Nightshades	*Solanum* spp.	10, 25
	Pigweed	*Amaranthus* spp.	10, 25
	Ragweed	*Ambrosia* spp.	10
	Russian thistle	*Salsola kali*	10
	Smart weed	*Polygonum* spp.	10

the mare's diet. Confirmation of nitrate toxicity is based on demonstration of elevated levels in forages, weeds, water, or body fluids such as aqueous humor, fetal stomach fluid, and amniotic fluid.[1,10] In ruminants, plants containing more than 1.5% nitrates (measured as KNO_3) dry weight may be lethal. Sublethal effects are seen from feed containing 0.5% to 1.5% nitrates. Seeds are usually unaffected by high nitrates in other plant parts. Ruminants can adapt to higher nitrate feeds if their introduction is gradual. Reproductive effects in ruminants are linked to forage concentrations greater than 5000 ppm on a dry matter basis.[27] In adult ruminants, signs of methemoglobinemia are seen with forages containing 2000 to 10,000 ppm nitrates on a dry matter basis. Water with more than 200 ppm is excessive for pregnant ruminants; 30 ppm is the recommended limit for broodmares.[10,29,30] In nonpregnant animals, a range of 445 to 1000 ppm in water is considered dangerous for livestock.[10,26]

Treatment of nitrate toxicity in ruminants is restricted by the paucity of approved drugs. Methylene blue administration is prohibited in food animals in the United States for at least 180 days before slaughter but, if permitted in other areas, may be given IV at a rate of 4 to 15 mg/kg body weight as a 2% to 4% solution.[10] In acute ruminant cases, the adjunct therapy of the administration of either cold water or vinegar to slow nitrate reduction, and mineral oil to hasten passage of the ingested source has been used, provided the animal can withstand the stress of intubation.[10]

Forages known to have high nitrate potential should be tested prior to feeding livestock, particularly if fertilizer or poultry litter has been used on the forage. High-nitrate forages can potentially be ensiled to reduce the nitrate content by as much as 30%.[26] Nitrate levels are highest at night and in early morning, and this knowledge can be applied to the timing of pasture access and hay cutting. If high-nitrate forage is harvested, the nitrate content will not dissipate on curing. Gradual introduction of high-nitrate forage into the ruminants' diet will permit rumen microflora to adapt, but this should preferentially begin with nonpregnant adult animals to minimize the reproductive effects. Monensin in the diet may change the threshold for toxicity[31] and probiotics containing *Propionibacterium* spp. reduce nitrates, which may also be useful.[10]

Neurologic Signs

Many plant ingestions result in neurologic signs exclusively or as part of an array of signs. Plants linked to neurologic deficits are listed in Table 54.4. Many other plants found in Australia and New Zealand also can produce neurologic signs.[3] Abnormal behavior, seizures, coma, ataxia, weakness, and muscle tremors may be associated with ingestion of poisonous plants or other medical conditions such as rabies, encephalitis, and electrolyte disorders. Perennial ryegrass infected with an endophyte, *Neotyphodium lolii*, causes perennial ryegrass staggers in all herbivores. The syndrome, caused by lolitrem B, was recently reproduced in horses demonstrating varying degrees of muscle fasciculations, tremors, truncal swaying, basewide stance, and limb edema.[35] Signs abate when the forage is changed.

Locoweed and Milkvetch

Locoweed and milkvetch (*Astragalus* spp. and *Oxytropis* spp.) (Color Plate 54.3) are the most important plant-related toxicoses in the western United States and significantly affect animals in other areas of the world.[10] A review of poisonous plants affecting livestock in China suggested locoweeds were responsible for an estimated 80% of all livestock losses due to plant toxicoses.[2] Many species in these genera can cause four different toxic syndromes: sudden death from methemoglobinemia due to nitro compounds in cattle and sheep (milkvetch [*Astragalus* spp.]); respiratory syndrome with emphysema-like signs, most often seen in sheep (milkvetch [*Astragalus* spp.]); neurologic signs (*Astragalus* spp. and *Oxytropis* spp.); and selenium toxicosis (*Astragalus* spp.). Recent investigations have shown that the toxin swainsonine, responsible for the signs of nervous system dysfunction, is produced by an endophyte *(Undilum oxytropis)* in the plant seeds rather than by the plants themselves.[39] Swainsonine triggers clinical signs after chronic locoweed ingestion in horses and ruminants. This same toxin poisons horses and cattle consuming swainsona or darling pea (*Swainsona* spp.) in Australia.[3] The toxin creates a lysosomal storage disease in which α-mannosidase is inhibited, resulting in swelling of axonal hillocks and growth of new dendrites and synapses in severe locoweed cases, a nonreversible change.[36]

Clinical neurologic signs of locoweed intoxication begin with depression and incoordination and progress to aberrant behavior, aggression, circling, weight loss, and eventually death if locoweed consumption continues. In affected horses, this leads to unpredictable behavior, endangering riders and handlers, so these animals are often euthanized or perhaps salvaged for breeding. Similar signs may be seen in horses forced to eat

TABLE 54.4

Plants Associated With Neurologic Signs[a]

Common Name	Scientific Name	Species Affected[b]	Toxin(s)	Plant Habitat	Clinical Signs	Specific Therapy
Blown grass, Pacific bent grass[3]	*Agrostis avenacea*	B, O	Corynetoxins in nematode	Australia, New Zealand, southwest U.S.	Incoordination, weakness, muscle weakness, rocking stance, high-stepping, collapse, seizures, abortion	
Bracken fern[10]	*Pteridium aquilinum*	E, P, B, O	Ptaquiloside	Worldwide	Weight loss, progressive incoordination, depression, tremors, crouching stance with arched neck (equine), blindness (sheep), aplastic anemia (ruminants), thrombocytopenia, bladder and gastrointestinal cancer	Thiamine
Buttercup[10]	*Ranunculus* spp.	B, E	Ranunculin	North America, Europe	Salivation, depression, blindness, hematuria, oral ulcers, diarrhea, colic	
Caltrop or carpetweed[10]	*Kallstroemia* spp.	B, O, C	Unknown	Southwest U.S.	Hindlimb weakness, knuckling, seizures, posterior paralysis	
Castor bean[19]	*Ricinus communis*	E, B, O, C, P	Ricin	Worldwide	Bloody diarrhea, tenesmus, colic, trembling, incoordination, seizures	
Coyotillo[10]	*Karwinskia humboldtiana*	B, O, C, E, P	Unknown	Southwest U.S.	Hypersensitivity, muscle tremors, abnormal high-stepping gait, diminished reflexes, progressive paralysis	
Fitweed[10]	*Corydalis* spp.	B, E	Isoquinolone alkaloid	U.S., Canada	Tachypnea, seizures, staggering, snapping at objects, muscle tremors, depression	
Golden chain tree[10]	*Laburnum anagyroides*	E, B	Cystisine	Southern U.S.	Incoordination, muscle tremors, mydriasis, excitement, seizures, coma, vomiting, diarrhea, paralysis	
Hairy cat's ear, flatweed[32]	*Hypochaeris radicata*	E	Unknown	U.S., Europe, Australia	Bilateral stringhalt, depression, aggression	Phenytoin
Hairy vetch[10]	*Vicia villosa*	B, E	Unknown	U.S., Europe	Excitement, slobbering, oral ulcers, nasal discharge, cough, stiffness, anorexia, weakness, seizures, swelling of the head and neck, pruritic dermatitis, diarrhea, abortion, myocardial necrosis	
Halimium[33]	*Halimium brasiliense*	O	Unknown	Brazil, Uruguay	Transient seizures when excited, muscle tremors, ventroflexion of neck or opisthotonus, nystagmus, tetanic spasms, postictal ataxia	
Horse chestnut, buckeye[10]	*Aesculus hippocastanum*	B, O, C, E	Aesculin, fraxin, alkaloids	U.S., Europe	Muscle tremors, incoordination, depression or excitability, hopping gait, dorsomedial strabismus (ruminants), gastroenteritis (monogastrics)	
Horse nettle[10]	*Solanum carolinense*	B, E	Solanine	U.S., Canada	Falling when excited, incoordination, anorexia, emaciation, rough coat, constipation, mouth inflammation	Physostigmine
Horsetail or scouring rush[10]	*Equisetum* spp.	E, B, O	Aconitic acid, palustrine, thiaminase	Worldwide	Weight loss, staggering, muscle tremors or rigidity, paraparesis, tachycardia, diarrhea, coma	Thiamine
Jamaican nettle tree[34]	*Trema micrantha*	B, C, E	Trema toxin, ammonia	Americas	Apathy, blindness, recumbency, paddling, coma (hepatic encephalopathy)	
Jimmyweed[10]	*Haplopappus heterophyllus*	B, E	Tremetol	Western U.S., Mexico	Depression, trembling, weakness, knuckling, seizures, paralysis, congestive heart failure, acetone breath smell	

TABLE 54.4

Plants Associated With Neurologic Signs—cont'd

Common Name	Scientific Name	Species Affected[b]	Toxin(s)	Plant Habitat	Clinical Signs	Specific Therapy
Jimsonweed, thornapple[35]	*Datura* spp.	E, P, B	Tropane alkaloids	Worldwide	Colic, ileus, diarrhea, mydriasis, tachycardia, anorexia, muscle spasms, seizures, polyuria	
Johnson grass[10]	*Sorghum halepense*	B, O, E	Hydrocyanide	Worldwide	Posterior ataxia, urinary incontinence, cystitis, weight loss	
Kochia[1]	*Kochia scoparia*	B, O, E	Thiaminase, nitrates, oxalates	Worldwide	Ataxia, muscle spasms, depression, blindness, photosensitization	Thiamine
Locoweed[36]	*Astragalus* and *Oxytropis* spp.	E, B, O, C	Swainsonine (endophyte produced)	Worldwide	Abnormal behavior, abortion, reduced fertility, skeletal malformations, weight loss	
Locust trees[19]	*Robinia* spp.	E, B, O, C	Robinin, robitin	North America, Europe	Diarrhea, anorexia, weakness, posterior paralysis, mydriasis, dyspnea, arrhythmias	
Lupines[1]	*Lupinus* spp.	O, B	Piperidine, quinolizidine	U.S., Canada	Salivation, frothing, depression, dyspnea, loss of muscle control, convulsions, coma, birth defects	
Mescal bean, Eve's necklace	*Sophora* spp.	B, O, C, E	Cystisine	Southwest U.S., Mexico	Incoordination, violent muscle tremors, falling, stiffness, respiratory paralysis	
Milkvetches[10,36]	*Astragalus* spp.	B, O, E	Miserotoxin	North America	Acute and chronic—acute: respiratory distress, muscle weakness, emphysema; chronic: goose-stepping, knuckling, wheezing, drooling, posterior paresis, collapse	
Milkweed[36]	*Asclepias* spp.	E, B, O, C	Glycosidic cardenolides	North America	Depression, weakness, dyspnea, ataxia, seizures, arrhythmias	
Morning glory[3]	*Ipomoea* spp.	B, O, C, E	Calystegines	Worldwide	Ataxia of hindlimbs, staggering	
Nightshade[10]	*Solanum* spp.	B, O, C, E	Solanine	Worldwide	Fatigue, muscle tremors, head tremors, seizures, bloat, congestion of lungs, heart, spleen	Physostigmine
Oak[10]	*Quercus* spp.	B, E, O, P	Gallotannins	North America, Europe	Incoordination in horses along with weakness, ileus, mouth ulcers, mucosal discoloration, patchy sweating, abnormal feces, colic, dark urine	
Paspalum grasses[37]	*Paspalum* spp.	B, E	Ergot alkaloids	Worldwide	Staggers, muscle tremors, seizures, abortion, gangrene	
Poison hemlock[1]	*Conium maculatum*	O, B, P, E	Coniine, γ-coniceine	North America, Europe	Trembling, ataxia, salivation, incoordination, mydriasis, tachycardia, respiratory paralysis, coma, convulsions, birth defects	Atropine
Russian knapweed[1]	*Centaurea repens*	E	Sesquiterpene lactones	Western U.S.	Twitching of lips, tongue flicking, involuntary chewing, weight loss, emaciation, poor prehension, incoordination, muscle tremors, facial paralysis	
Ryegrass[38]	*Lolium perenne*	B, O, E	Lolitrem B	Worldwide	Muscle tremors, fasciculations, truncal swaying, basewide stance, slowed movement, limb edema	
Sagebrush[10]	*Artemisia* spp.	E	Unknown	Western U.S., Mexico	Abnormal behavior, ataxia, sage aroma in breath and manure	
Sneezeweed[1]	*Hymenoxys* spp.	O, B, E	Sesquiterpene lactones	North America	Equine: weakness, incoordination, foaming at the mouth, seizures; ruminants: chronic vomiting, emaciation, stiffness	
Squirrel corn, Dutchman's breeches[10]	*Dicentra* spp.	B, E	Isoquinoline alkaloid	North America	Muscle tremors, seizures, extensor rigidity, dyspnea, pain

TABLE 54.4

Plants Associated With Neurologic Signs—cont'd

Common Name	Scientific Name	Species Affected[b]	Toxin(s)	Plant Habitat	Clinical Signs	Specific Therapy
Sudan grass[10]	*Sorghum sudanense*	B, O	Hydrocyanide, nitrates	Worldwide	Posterior ataxia, urinary incontinence, cystitis, weight loss	
Yellow jessamine[10]	*Gelsemium sempervirens*	E, B, O, C, P	Gelsemine, gelseminine	Eastern U.S., Mexico	Weakness, hypothermia, mydriasis, seizures, extensor rigidity, coma	
Yellow star thistle[1]	*Centaurea solstitialis*	E	Sesquiterpene lactones	U.S., Argentina, Australia	Twitching of lips, tongue flicking, involuntary chewing, weight loss, emaciation, poor prehension, incoordination, muscle tremors, facial paralysis	

[a]Plant names in bold are discussed in more detail in the text.

[b]Species listed in relative order of toxicity importance: *B*, Bovine; *C*, caprine; *E*, equine; *O*, ovine; *P*, porcine.

sagebrush.[10] Pregnant animals may abort or give birth to neonates with neurologic signs. In cattle and sheep, swainsonine-induced damage to the lungs and hearts may contribute to high mountain disease, characterized by right-sided heart failure.[10]

Nitro-toxins are the most common toxins found in the milkvetch species of *Astragalus* and are primarily responsible for ruminant herd and flock problems. The toxic principles are β-D-glycosides converted to 3-nitro-1-propanol (miserotoxin) in the rumen and subsequently changed to the toxic compound 3-nitropropionic acid in the liver.[36] Signs of acute toxicosis include weakness, tachycardia, respiratory distress, coma, and death. Chronic consumption results in neurologic signs beginning with weakness, incoordination, fetlock knuckling, and goose stepping, progressing to paralysis and death. Respiratory emphysema, as well as incoordination and weakness, may be observed in both acute and chronic cases, particularly in sheep.

Chronic ill-thrift is attributed to chronic locoweed consumption. Research in food animals has demonstrated a number of effects attributed to swainsonine, including reduced production of growth hormone and thyroxine, decreased intestinal absorption of nutrients, and reduced immune response to vaccinations. These can lead to poor weight gain and increased frequency of infections.[10]

Diagnosis of locoism is based on clinical signs and confirmed by measurement of swainsonine and/or α-mannosidase in serum. Vacuolation of peripheral lymphocytes may be evident in some cases. Vacuolation of many tissues, particularly brain and liver, may be seen histologically after finding little gross change at necropsy. Treatment is removal from locoweed forage.[10]

Locoweed is usually not palatable but will be eaten if more enticing forage is not available. For example, many locoweed species start growth early in the spring, attracting livestock less interested in dormant grasses. This period of preference is influenced by rainfall, so the impact of locoweed and milkvetch species will vary from year to year even within a region. Prevention is challenging if alternative forages are not available in the spring. One innovative approach is a conditioned food aversion model that combines feeding fresh-picked locoweed to naive animals with lithium chloride administration by stomach tube. The treated animals form a strong and lasting (>3 years) aversion to locoweed following a single dose but must be pastured separate from nonaverted animals on locoweed areas to prevent social facilitation from extinguishing the aversion.[22]

Musculoskeletal Disease Attributed to Plant Poisoning

Plant poisonings may affect the skeletal system, resulting in abnormal bone growth or remodeling. Day-blooming jasmine *(Cestrum diurnum)* induces calcinosis in horses and cattle by means of calcinogenic glycosides converted to vitamin D–like compounds.[10,40] This plant is found in the southeastern United States and tropical countries. Other plants with this potential include *Solanum malacoxylon*, *Solanum sodomaeum*, *Solanum linnaeanum*, *Trisetum flavescens*, and *Nierembergia veitchii*.[10] Those affecting the fetus are discussed in the Reproductive and Neonatal Effect of Poisonous Plants section later.

Signs of muscle dysfunction in livestock and horses have been attributed to ingestion of a number of plants, often as part of a larger panoply of signs. Muscle tremors may be manifestations of muscle or nervous system dysfunction, as well as electrolyte disturbances or pain. The toxin tremetol (tremetone and other compounds) affects all species of livestock and horses consuming it. The effects of the toxin are cumulative and affect both skeletal and cardiac muscle. Important plants include white snakeroot *(Eupatorium rugosum)*, rayless goldenrod *(Haplopappus heterophyllus)*, and burrow weed *(Isocoma pluriflora)*.[10] Adult cattle are relatively unaffected by consumption of white snakeroot but pass the toxin through the milk, causing clinical signs in milk-fed calves. Rayless goldenrod produces myonecrosis and cardiomyopathy at higher doses in goats.[41] Horses, cattle, and pigs may be affected by this plant. The effect of tremetol on myocardial tissue may lead to arrhythmias and congestive heart failure. Tremorgenic mycotoxins should also be considered in cases with muscle tremors, particularly in livestock grazing perennial ryegrass or *Paspalum* species such as dallisgrass or bahiagrass.[42]

Senna (previously *Cassia*) species such as coffee weed (Color Plate 54.4) and sickle pod are an important source of skeletal and cardiac muscle degeneration and gastroenteritis in cattle, sheep, goats, horses, and pigs.[10] Renal and hepatic failure may be observed in severe cases. Gossypol poisoning attributed to feeding cottonseed or its products containing a high level of gossypol is a source of muscle degeneration and significant morbidity and mortality in livestock.[10]

Summer Pasture-Associated Myositis and Equine Atypical Myopathy

Recent research defined ingestion of box elder seeds from female trees *(Acer negundo)* (Color Plate 54.5) as a cause of

acute, nonexertional, severe, often fatal rhabdomyolysis in pastured horses and a donkey in the United States and Canada.[43] The syndrome of atypical myopathy seen in horses, donkeys, and zebras in Europe may also have this underlying cause because outbreaks have been linked to ingestion of maple leaves *(Acer pseudoplantanus)* covered with European tar spot *(Rhytisma acerinum)*.[44] Box elder trees are also found in Europe. In addition, European researchers have demonstrated a link between atypical myopathy and *Clostridium sordellii* toxin.[45] In both syndromes, one or multiple animals may be affected, typically on a premises having the equids for a portion of the day on a pasture with sparse grass surrounded by or with trees, which, along with any seeds or fruiting bodies, are often knocked down after a storm or high winds.[43,46] The toxic principle identified in box elder seeds is hypoglycin A, a branched-chain amino acid, which is metabolized to methylene cyclopropyl acetic acid (MCPA), a potent inhibitor of multiple acyl-CoA dehydrogenases. Lack of these enzymes damages mitochondria and impairs lipid metabolism within muscle cells, leading to lipid accumulation, thus limiting the muscle cell's energy supply and causing cell death.[43]

Clinical signs include muscle weakness, recumbency, and myoglobinuria.[43] Other reported signs include dysphagia, esophageal obstruction, or colic-like signs. In atypical myopathy, myocardial damage may be detected with electrocardiography (ventricular premature depolarizations, prolonged QT intervals); echocardiography (abnormal ventricular wall motion); and elevated serum troponin concentrations.[47] Histologically, the change in both diseases is marked myofibril degeneration with intramyofiber lipid accumulation in skeletal, respiratory, and cardiac muscles. Additional confirmation of this etiology for rhabdomyolysis can be obtained at specialized laboratories by demonstration of increased urinary organic acids (specifically ethylmalonic and methyl succinic acids and glycine conjugates) and abnormal patterns of serum acylcarnitines.[48] Other toxic etiologies to be considered for muscle disease are white snakeroot, rayless larkspur, and monensin toxicity.

Treatment of affected cases is symptomatic but should include attention to establishing a positive energy balance. Case fatality rate is high despite treatment.[43] Preventive measures should focus on provision of sufficient forage to deter horses from consuming box elder seeds, rapid removal of downed box elder branches after high winds, and planting less toxic trees as windbreaks.

Cardiovascular and Hematologic Plant Toxicities

Ingestion of plants containing toxins affecting myocardial function may result in a wide variety of signs, including sudden death. Consumed plants most noted for producing myocardial effects are those containing cardiac glycosides. Cattle are most frequently affected. These include the pasture plants milkweed (*Asclepias* spp.), dogbane or Indian hemp *(Apocynum cannabinum)*, blue-eyed grasses (*Sisyrinchium* spp.), and a number of plants possibly more likely to be found in gardens than pastures: foxglove (*Digitalis* spp.), hellebores (*Helleborus* spp.), hyacinth (*Hyacinthium* spp.), kalanchoe (*Bryophyllum* spp.), lily of the valley *(Convallaria majalis)*, oleander (*Nerium* spp.), periwinkle *(Vinca major)*, pheasant's eye *(Adonis microcarpa)*, spindle tree (*Euonymus* spp.), squill (*Drimia* or *Urginea* spp.), and star of Bethlehem (*Ornithogalum* spp.). Digestive signs of hemorrhagic enteritis with colic may also be seen.[10] Gousiekte is a syndrome of heart failure and sudden death affecting sheep and cattle in South Africa 4 to 6 weeks after ingestion of the pavetamine-containing Rubiaceae (coffee) family of plants. Six plants in the genera *Fadogia*, *Pavetta*, and *Vangueria* have been implicated in significant losses. New research suggests that toxin production in the plants may be linked to their infection by *Burkholderia* spp. of endophytic bacteria.[49] The toxin inhibits myocardial protein synthesis, resulting terminally in dilated cardiomyopathy and congestive heart failure.[50]

Four important plants with toxins that damage the myocardium and cause mortality in large animals are yew (*Taxus* spp.), avocado *(Persea americana)*, death camas (*Zigadenus* spp.), and summer pheasant eye (*Adonis* spp.). Avocado poisoning in horses produces edematous swelling of the head and neck and subsequent respiratory distress, which may progress to congestive heart failure. Likewise, goats may develop signs of heart failure. The udder is affected by avocados in female horses, cattle, and goats, creating a noninfectious mastitis.[10] Summer pheasant eye consumed in hay caused signs of colic and death in horses, and pigs have died after consuming a diet containing *Adonis* seeds.[51]

Signs of anemia and hemorrhage are linked to ingestion of several groups of plants that cause methemoglobinemia, hemolysis, or thrombocytopenia. Ingestion of wilted maple leaves or bark (*Acer* spp.) (Color Plate 54.6), most often red maple, results in oxidative damage to erythrocytes and acute Heinz body anemia or methemoglobinemia in horses and zebras. Weakness, tachycardia, tachypnea, icterus, and hemoglobinuria may occur. In severe cases, laminitis, colic, or abortion may occur.[52] In ruminants, nitrate-accumulating plants that cause methemoglobinemia should be considered (see Table 54.3). Wild onions and garlic can produce hemolytic anemia, most often observed as a clinical problem in cattle.[10]

Plants containing coumarin, such as sweet clover (*Melilotus* spp.), have the potential for endogenous coumarin to be converted to dicoumarol if cut plants become moldy. Signs ranging from subtle to death may be observed, particularly in cattle, depending on the amount of dicoumarol present and any trauma to the animal causing bleeding. Transfusion and vitamin K_1 administration may be necessary in moderate to severe cases.[10]

Thiaminase enzymes in bracken fern *(Pteridium aquilinum)* and horsetail (*Equisetum* spp.) produce a thiamine deficiency most often causing neurologic signs in horses. Other signs associated with bracken fern ingestion are due to alternate toxins, particularly ptaquiloside, a sesquiterpene glycoside responsible for detrimental effects on the bone marrow and neoplastic changes in the bladder and upper GI tract. The cancerous changes in the urinary tract may manifest as enzootic hematuria in cattle. Retinal changes resulting in blindness are reported in sheep. The toxins are transmitted through milk. Protamine sulfate administration may counteract the effects on blood coagulation. In horses, bracken fern may also produce colic.[10,36]

Digestive and Hepatic Plant Poisonings

A plethora of plants have the potential to induce pathology in the digestive tract and liver. Plants causing significant impact in large animals are listed in Table 54.5. The effects of a plant may be mechanical or chemical irritation, altered motility, or altered cell function. Depending on the toxin, plant species, animal species, and stage of intoxication, a single species of plant may produce a wide range of signs, even within the same animal. Clinical signs may include excessive salivation or slobbering, anorexia, dysphagia, colic, vomiting or regurgitation in ruminants, bloat, constipation, diarrhea, and melena. Excessive salivation may result from injury due to plant awns, irritant substances in the plant, mold infection of the plant (e.g., red clover and slaframine production), and inability to swallow. Sources of plant awns include grasses (e.g., foxtail, needle, squirrel tail, bristle, sandbur, medusahead rye, prairie threeawn, tanglehead, tickle grass), cacti (e.g., prickly pear), nettles, and many seed pods.[10,55] Substances irritating to mucous membranes are found in a number of plants and may also produce signs of diarrhea in the more distal digestive tract.

TABLE 54.5

Plants Producing Gastrointestinal (GI) Clinical Signs[a]

Common Name	Scientific Name	Species Affected[b]	Toxin(s)	Plant Habitat	Clinical Signs	Specific Therapy
Pyrrolizidine alkaloid plants[10]	See Table 54.6	P, B, E, C, O	Pyrrolizidine alkaloids	Worldwide	Loss of appetite, lethargy, diarrhea, constipation, icterus, photosensitization	
Autumn crocus[10,16]	*Colchicum autumnale*	B, E, P	Colchicine, colchiceine	Europe	Salivation, dysphagia, colic, abdominal pain, diarrhea, tenesmus, melena, cardiorespiratory failure, congenital defects	
Bitterweed[1]	*Hymenoxys odorata*	O, B	Sesquiterpene lactone	Southwest U.S.	Weight loss, poor appetite, vomiting, bloat, abdominal pain, stiff gait (lambs)	
Box or boxwood[10]	*Buxus sempervirens*	E, B, O,	Alkaloids	Worldwide	Colic, melena, respiratory failure	
Broomweed, snakeweed[1]	*Gutierrezia* spp.	O, C, E, B	Saponins	Western U.S., Mexico	Diarrhea, constipation, rough hair coat, anorexia, abortion, photosensitization	
Buffalo bur[10]	*Solanum rostratum*	E, B, O, C	Solanine alkaloids and glycoalkaloids	U.S.	Trauma to mucosal surfaces; tiredness; muscle tremors; bloat; congestion of lungs, heart, liver, spleen	Physostigmine
Buttercup[10]	*Ranunculus* spp.	B, E	Ranunculin	North America, Europe	Salivation, depression, blindness, hematuria, oral ulcers, diarrhea, melena, colic	
Castor bean[10]	*Ricinus communis*	E, B	Ricin	Worldwide	Bloody diarrhea, tenesmus, colic, trembling, incoordination, seizures	
Chinaberry[10]	*Melia azedarach*	P, B, O, C, E	Alkaloids, saponin	China, southeast U.S.	Colic, vomiting, constipation, hemorrhagic diarrhea or muscle tremors, ataxia, seizures, tetraparesis	
Coffeeweed[10]	*Cassia* spp.	B, O, C, E, P	N-methylmorpholine and anthraquinone glycoside	Eastern, southern U.S.	Diarrhea, anorexia, staggering gait, myoglobinuria, renal failure, liver failure (horse)	
Colorado rubberweed (Pingue)[1]	*Hymenoxys richardsonii* var. *floribunda*	O, B	Sesquiterpene lactone	Western U.S.	Weight loss, poor appetite, vomiting, salivation, GI stasis, bloat, abdominal pain, weakness, depression, stiff gait	
Corn cockle[10]	*Agrostemma githago*	B, O, P, E	Githagenin	U.S., Europe	Colic, diarrhea	
False hellebore, skunk cabbage[10]	*Veratrum* spp.	O, B, C	Steroids	U.S., Canada	Salivation, colic, diarrhea, respiratory failure, abortion, malformed neonates	
Foxtail grass[10]	*Hordeum jubatum*	E	None	U.S., Canada	Foreign body–induced ulceration in ears, eyes, neck, face, mouth; colic; impaction	

TABLE 54.5

Plants Producing Gastrointestinal (GI) Clinical Signs—cont'd

Common Name	Scientific Name	Species Affected[b]	Toxin(s)	Plant Habitat	Clinical Signs	Specific Therapy
Hairy vetch[10]	*Vicia villosa*	B, E	Unknown	U.S., Europe	Excitement, slobbering, nasal discharge, cough, stiffness, anorexia, weakness, seizures, swelling of the head and neck, pruritic dermatitis, hair loss, diarrhea, abortion, photosensitivity	
Horse nettle[10]	*Solanum carolinense*	B, E	Solanine	U.S., Canada	Anorexia, emaciation, rough coat, constipation, mouth inflammation, falling when excited	Physostigmine
Jimsonweed, thornapple[35,53]	*Datura* spp.	E, P, B	Tropane alkaloids	Worldwide	Colic, ileus, diarrhea, mydriasis, tachycardia, anorexia, muscle spasms, seizures, polyuria	
Kentucky coffee tree[10]	*Gymnocladus dioica*	B, O, E	Cystisine	Eastern U.S., Canada	Vomiting, colic, diarrhea, hypotension, bradycardia, seizures, muscle paralysis	
Lantana[10]	*Lantana camara*	B, O, C, E	Lantadene A and B	Worldwide	Photosensitization, anorexia, constipation, gastroenteritis	
Laurel[10]	*Kalmia* spp.	E, O, B, C	Andromedotoxin	Northern U.S., Canada	Colic, nasal discharge, salivation, odontoprisis, bloat, bradyarrhythmias, collapse, coma	
Leafy spurge[10]	*Euphorbia* spp.	B, E	Unknown	North America	Blistering of lips, tongue, skin, GI irritation, photosensitization	
Lobelia[10]	*Lobelia* spp.	B, O, C	Lobeline	U.S., Mexico	Excessive salivation, vomiting, diarrhea, mydriasis, coma, ± oral and corneal ulcers	
Locust trees[36]	*Robinia* spp.	E, B, O, C	Robinin, robitin	North America, Europe	Diarrhea, anorexia, weakness, posterior paralysis, mydriasis, dyspnea, arrhythmias	
Marsh marigold[10]	*Caltha palustris*	B, O, E	Anemonin	Northern U.S., Canada	Ulceration of skin, oral cavity, salivation, diarrhea, colic, nervousness	
Mesquite[10]	*Prosopis glandulosa*	E, B	Arabinose	Western U.S.	Colic, salivation, rumen or intestinal obstruction (phytobezoars), tremors, anemia, emaciation	
Nightshade[10]	*Solanum* spp.	B, O, C, E, P	Solanine	U.S.	Fatigue, muscle tremors, mydrasis, bloat, colic, watery diarrhea, congestion of lungs, heart, spleen	Physostigmine
Oak[10]	*Quercus* spp.	B, E, O, P	Gallotannins	North America, Europe	Incoordination in horses along with weakness, ileus, mouth ulcers, mucosal discoloration, patchy sweating, abnormal feces, colic, dark urine	

Continued

TABLE 54.5

Plants Producing Gastrointestinal (GI) Clinical Signs—cont'd

Common Name	Scientific Name	Species Affected[b]	Toxin(s)	Plant Habitat	Clinical Signs	Specific Therapy
Oleander[10]	*Nerium oleander*	B, E	Oleandrin, neriine	Southern U.S., Mexico, Mediterranean	Tachycardia, severe gastroenteritis, diarrhea, abdominal pain, sweating, weakness	
Persimmon[10]	*Diospyros virginiana*	E	Tannins	Southern U.S.	Obstruction due to phytobezoars, colic, weight loss	
Pokeweed[10]	*Phytolacca americana*	B, O, C, P, E	Saponins, oxalates, alkaloids	Eastern U.S.	Oral irritation, excessive salivation, vomiting, colic, bloody diarrhea, depression	
Privet[10]	*Ligustrum vulgare*	E, B	Ligustrin, ligustron	U.S., Canada	Diarrhea, severe colic, hypotension, renal failure	
Rape[10]	*Brassica napus*	B, E	Glucosinolates	North America	Colic, bloat, diarrhea, pulmonary emphysema (cattle), icterus, anemia, goiter	
Red clover[10]	*Trifolium pratense*		Slaframine from mold infection	U.S.	Slobbers, bloat, stiffness, diarrhea, blindness, abortion, laminitis	
Rhododendron[10]	*Rhododendron maximum*	B, O, C, E	Andromedotoxin	U.S., Canada	Colic, nasal discharge, salivation, odontoprisis, bloat, bradyarrhythmias, collapse, coma	
Rosary pea[10]	*Abrus precatorius*	E, C	Abrin	Southeast U.S.	Anorexia, abnormal temperature, ulcers, incoordination, lung congestion, liver and urinary damage	
Sesbania or bladderpod[10]	*Sesbania* spp.	B, O, C	Saponins	North America	Severe hemorrhagic diarrhea, abomasitis, renal and hepatic necrosis	
Sneezeweed[1]	*Hymenoxys hoopesii*	O, B, E	Sesquiterpene lactone	North America	Vomiting, stiff gait, poor appetite, weakness, coughing ± aspiration, pneumonia, emaciation, ascites	
Tobacco[10]	*Nicotiana* spp.	E, B	Nicotine	Southern U.S., Mexico	Muscle tremors, tachyarrhythmias, colic, dyspnea, diarrhea, congenital defects (blindness, staggering, forelimb collapse, coma at high doses)	
Tung or candle nut tree[10]	*Aleurites* spp.	B	Saponins	China, southeast U.S.	Anorexia, atonic rumen, watery diarrhea, emaciation	
Yellow wood[3]	*Terminalia oblongata*	B, O	Tannins	Australia	Nervous signs (sheep). Colic, photosensitization, icterus, dark urine, stiffness, nephrosis (cattle)	
Yellow bristle grass[10]	*Setaria lutescens*	E	None	U.S., Canada	Ulcers in mouth, digestive tract	
Yerba de pasmo[54]	*Baccharis pteronioides*	B, O, E	Trichothecenes	Southwest U.S., South America	Anorexia, hemorrhagic enteritis	

[a]Plant names in bold are discussed in more detail in the text.

[b]Species listed in relative order of toxicity importance: *B*, Bovine; *C*, caprine; *E*, equine; *O*, ovine; *P*, porcine.

VetBooks.ir

Bracken fern *(P. aquilinum)* (Color Plate 54.2) has long been recognized as a cause of enzootic hematuria and bladder cancer but more recently has been linked to upper digestive tract squamous cell carcinoma in cattle grazing pastures with high bracken content in conjunction with bovine papillomavirus type 4. In a study reviewing 40 tumors in cattle, metastasis was common (56%), predominately to regional lymph nodes.[56]

Hepatic Disease

Absorption of toxins from the digestive tract results in subsequent exposure of liver tissue where further pathologic changes may be induced. Depending on the toxin and disease syndrome, signs of liver disease may be only subtle weight loss or failure to grow but more often include icterus, photosensitization, and/or hepatic encephalopathy. For example, alsike clover can produce two syndromes in horses, either hepatic encephalopathy or photosensitization. (Plants causing primary photosensitization are listed in the Poisonous Plants Affecting Skin and Hooves section later.) A variety of plants damage biliary cells, leading to secondary photosensitization as the primary clinical sign, including agave *(Agave lechuguilla)*, bear grass or sacahuista *(Nolina texana)*, bog asphodel *(Narthecium ossifragum)*, kleingrass and switchgrass (*Panicum* spp.), and puncture vine *(Tribulus terrestris)*.[10] Mycotoxins can also produce biliary damage leading to photosensitization. Photosensitization is one of many systemic effects often seen with consumption of plants, such as black sage *(Artemisia nova)* consumed concurrently with horsebrush (*Tetradymia* spp.), *Brassica* spp., Dutchman's breeches *(Thamnosma texana)*, hairy vetch *(Vicia villosa)*, inkweed *(Phytolacca octandra)*, *Kochia* spp., *Lantana* spp. (Color Plate 54.7), and yellow wood *(Terminalia oblongata)*.[3,10,36,57] Plants containing pyrrolizidine alkaloids also produce photosensitization and are the most important source of widespread liver problems to both livestock and horses (see the Pyrrolizidine Alkaloids section below).

Severe hepatic disease may lead to signs of liver failure, including hepatic encephalopathy and sudden death. The pyrrolizidine alkaloid plants are the foremost plants associated with this. *Senna* (formerly *Cassia)* spp., in particular the seeds, are very toxic to multiple species. Sixty percent of a herd of broodmares died with signs of hepatic encephalopathy with histologic lesions of pericentrolobular necrosis after ingesting seeds of *Senna occidentalis* (formerly *Cassia occidentalis*) in ground corn.[58] Cocklebur (*Xanthium* spp.) and blue-green algae should also be considered. Cocklebur most often produces signs in calves and cattle, but pigs and horses have also been affected.[10]

Pyrrolizidine Alkaloids

This large group of plants is a common source of adverse effects in livestock in many areas of the world, particularly in the southern United States, Australia, and South Africa. Plants in this category of toxins are listed in Table 54.6. Frequently the clinical syndromes are chronic, with clinical signs of liver damage observed months after the plant is eaten. Cattle and horses are most susceptible, with younger animals more easily affected. Poisoning typically occurs in overgrazed pastures but may develop when plants such as houndstongue *(Cynoglossum officinale)*, tansy ragwort *(Senecio jacobaea)*, or rattlebox (*Crotalaria* spp.) (Color Plate 54.8) are incorporated in hay or accidentally harvested with small grains.[1] In cattle, chronic consumption usually occurs for an extended time before the onset of signs. Consumption of mature pyrrolizidine alkaloid forage at a rate of 5% or more of their total daily diet for more than 15 days usually results in death in 1 to 6 months.[1] Young plant growth tends to be even more toxic. Those animals consuming less may become chronic poor doers. In horses, consumption of *Crotalaria* spp. causes liver failure and fibrosing pulmonary alveolitis.[10] Pigs are most prone to development of extrahepatic lesions.[36] There is some evidence that pyrrolizidine alkaloids pass through the placental membranes to affect the fetus. In humans, carcinogenicity is reported.[1] The pyrroles are powerful alkylating agents reacting with cellular proteins, crosslink DNA, and cause cell necrosis and abnormal mitosis.

Clinical signs are variable but originate from hepatic damage induced by the ingested pyrrolizidine alkaloids. Other stressors may trigger expression of clinical signs. Photosensitization of areas of white skin, particularly on the animal's dorsum and face, may be the first sign of illness. Crusting around the muzzle and eyes may be observed. In cattle, an unpleasant sweetish odor may be noted. Lethargy, loss of appetite, and weight loss are common. Weakness is observed when the animal tries to walk. In the terminal stages, signs of hepatic encephalopathy such as blindness and belligerent or compulsive behavior may be reported. Mucous membranes and sclera can be markedly icteric. Ascites, diarrhea, or constipation may be present as well.[1] Serum chemistry analysis confirms hepatocellular and biliary cell damage. The characteristic lesion on postmortem examination or biopsy is liver cirrhosis with necrosis and fibrosis, accompanied by bile duct proliferation. Varying degrees of hepatic megalocystosis may be observed in liver tissue.[36] Gastroenteritis may also be evident.

There is no specific treatment for pyrrolizidine alkaloid poisoning. Livestock may frequently graze these plants with seeming impunity if there is abundant high-quality forage available. If pastures with these plants are unavoidable, the use of herbicides should be considered. Biological control measures have been developed for some plants, such as tansy ragwort, and may be considered as preventive measures.

Reproductive and Neonatal Effect of Poisonous Plants

Poisonous plants affecting fertility, pregnancy, fetal development, and lactation can have a large economic impact, as can plants

TABLE 54.6

Plants Containing Pyrrolizidine Alkaloids

Common Name	Scientific Name	Plant Habitat	Reference(s)
Groundsel	*Senecio* spp.	Western U.S., Australia	1, 3
Heliotrope	*Heliotropium* spp.	Worldwide	3
Houndstongue	*Cynoglossum officinale*	Southwest U.S.	1
Kochia	*Kochia scoparia*	Western U.S.	1
Paterson's curse	*Echium plantagineum*	Australia	3
Rattlebox, rattlepod	*Crotalaria* spp.	U.S., Australia	1, 3
Tansy ragwort	*Senecio jacobaea*	North America, Europe	10, 19
Tarweed, fiddleneck	*Amsinckia* spp.	U.S., Mexico, Australia	10
Viper's bugloss	*Echium vulgare*	Australia, California	3

VetBooks.ir

infected with ergot or endophytes. Significant management challenges exist when livestock on pasture or on a range are affected. The effects may be as subtle as reduced conception rates or as apparent as abortion storms and multiple neonates with congenital defects. Any severe plant poisoning in a pregnant animal has the potential to precipitate an abortion. Toxins from a few plants may pass into the udder in an active form, harming the neonate or human who drinks the milk.

Ponderosa pine *(Pinus ponderosa)* needles and bark, when consumed in the last trimester, are a significant cause of abortion and premature delivery in cattle in the western United States and Canada.[1] Junipers, lodgepole pine, and Monterey cypress evergreens and perennial broomweed (*Gutierrezia* spp.) may produce similar syndromes. A few cows or even the whole herd may be affected. Isocupressic acid, the abortifacient compound, is rapidly metabolized to agathic acid in the rumen, a process accelerated by conditioning of the cattle to pine needle consumption, thereby reducing its effect.[59] Other toxic compounds such as diterpene abietane acids are also present. A vasoconstrictive effect on uterine vessels leads to uterine inertia, abortion, and frequently dystocia and/or retained placenta. Edematous swelling of the udder and vulva may be observed before abortion. Calves are typically weak, and lactation from the dam may be impaired.[1,10] Many other plants have been identified as sources of significant abortion in other parts of the world.[3,25,60]

Phytoestrogens may accumulate in a number of commonly consumed forages, adversely affecting reproductive performance. Examples include alfalfa and some types of clovers, which can produce coumestrol, and soybeans, which may contain isoflavones. Phytoestrogen concentrations may increase in stressed or diseased legumes. Fungal infections of feed may provide an additional source of xenoestrogens such as zearalenone. These phytoestrogens interact with endogenous estrogen receptors. In swine this can create a syndrome of hyperestrogenism characterized by precocious sexual development in females and preputial swelling and testicular atrophy in immature males. Goats and sheep may be more susceptible to this syndrome than cattle. Disruption of cyclic estrogen changes in older animals has more subtle effects, resulting in reduced fertility.[25]

A number of plants with significant reproductive effects, including locoweed and those accumulating nitrates, are discussed earlier in this chapter. Locoweed is particularly dangerous to range animals, as the plant may contain excessive selenium and/or endophyte infection. Reduced fertility, abortion, fetal defects, abnormal placentas, hydrops, and weak neonates may be observed. Sperm quality is also affected.[10] Nitrate-accumulating plants (see Table 54.3) can be responsible for sudden death, abortions, stillbirths, congenital defects, and weak neonates.

Congenital defects resulting from ingestion of specific plants during pregnancy may trigger abortion or result in nonviable neonates. Skeletal deformities such as arthrogryposis, kyphosis, scoliosis, torticollis, and cleft palate can be the result of lupine ingestion during early gestation to midgestation in ruminants, a syndrome called "crooked calf disease," a significant problem in range cattle. The two specific teratogens identified and studied are anagyrine, a quinolizidine alkaloid, and ammodendrine, a piperadine alkaloid, both of which reduce uterine motility. Toxin absorption and the likelihood of ingestion are affected by body condition score.[61] Anagyrine is also present in mountain thermopsis. Other plants with similar effects include locoweed, poison hemlock, and tobacco. The teratogenic effects of poison hemlock are greatest in cattle and pigs. In sheep, false hellebore and skunk cabbage (*Veratrum* spp.) ingestion in early gestation may result in abortion or birth of cyclopic lambs.[10] Cattle, goats, and llamas are also susceptible.

Congenital hypothyroidism in equine neonates can be caused by ingestion of high nitrate forages or plants with goitrogenic effect. Goitrogenic effects may be observed from plants providing excessive iodine (e.g., seaweed) or compounds such as thiocyanates (white clover) or glucosinolates (*Brassica* spp., kale, turnips, and canola seeds) interfering with iodine use. Horses are particularly susceptible to excessive iodine, as well as iodine deficiency. Excessive iodine consumption in a seaweed-based supplement led to abortion in 27 of 39 mares, goiters, and signs of congenital hypothyroidism in many of the neonates, including pathologic changes in the long bones.[62] Diagnosis is most readily based on histologic evaluation of the thyroid gland or changes of the skeletal system characteristic of congenital hypothyroidism. More commonly, this syndrome is attributable to iodine deficiency or excessive nitrate in forages or water.

Poisonous plants ingested by their dam, which may or may not show signs of toxicity, may affect milk-fed neonates depending on the chemistry of the toxin and/or its metabolites. If plant poisoning is suspected in a sick dam, an alternative milk source for the neonate should be considered, particularly if the toxin is an alkaloid. Plants affecting milk flavor, such as onions, may diminish neonatal consumption. More significant toxic plants to consider in this category include those with pyrrolizidine alkaloids (see Table 54.6), white snakeroot, rayless goldenrod, locoweed, lupines, mountain thermopsis, poison hemlock, tobacco, *Cassia* spp., and lobelia. A number of plants in the Brassica family (mustards, kale, rape, turnips, horseradish, radish, and watercress) can adversely affect thyroid function, as well as impart a bitter flavor to the milk.[10]

Ergot Alkaloids and Endophytes

Clinical syndromes ascribed to plants affected by ergot and endophytes are often included in veterinarians' thought processes when considering poisonous plant etiologies. For this reason, plants with this potential are included in the charts of predominant clinical signs. Two categories primarily affecting reproductive functions are discussed here: ergot alkaloids (ergopeptines) from ergot and those from endophyte infections. Neurologic signs and other syndromes associated with endophyte-infected locoweed are discussed in the Neurologic Signs section earlier.

Ergot-infected forages and grains have much higher concentrations of ergot alkaloids than are found in endophyte-infected forages.[25] Ergot infection (*Claviceps* spp.) of many grasses and cereal grains produces dark fungal sclerotia (ergot bodies) shaped like seeds readily visible in the plant's seed head in pasture, hay, or contaminated grains.[63] Similarly, many grass species can be infected with endophytes; the most economically important is fescue (*Lolium* spp.) infected with *Neotyphodium coenophialum.* Ergovaline is the most prevalent ergopeptine in endophyte-infected tall fescue and considered responsible for most signs associated with fescue toxicosis.[64] Infection provides fescue the advantages of increased resistance to drought, insects, parasitic nematodes, and herbivores. In contrast to ergot infections, endophyte infections are not visible to the naked eye and require microscopy for confirmation. The endophyte infects the plant's seed, ensuring its survival to germination in subsequent seasons.[64] Tall fescue can be infected with both *Claviceps* spp. and the endophyte simultaneously.[25]

Ergot alkaloids affect all livestock and horses. Species susceptibility is highest in horses, followed by cattle, then sheep, goats, and finally camelids. Different disease syndromes may be present, depending on the affected species and type of ergot alkaloids ingested. In ruminants and horses, ergot alkaloids, particularly ergovaline, have vasoconstrictive effects (α_2-adrenergic agonist) and/or depress secretion of prolactin via effects on lactotropic dopamine D_2 receptors in the adenohypophysis of the pituitary. There is a reduction in steroid genesis, including progesterone production by corpora lutea, and relaxin. Diminished relaxin production has less impact on readiness for parturition in ruminants because it is also produced

by the placenta. Thermoregulatory centers are affected by diminutions in prolactin and dopamine receptor perturbation, leading to clinical problems in extreme temperatures.[64] *Claviceps cyperi* has produced signs of severe ergotism in dairy cows in the heat of South Africa.[65] In contrast, infection of grasses with another form of ergot, *Claviceps paspali*, produces predominately neurologic signs associated with γ-aminobutyric acid inhibition.[25]

Clinical abnormalities attributable to ergot and endophyte infections of grasses are often detected in regions with warm, wet climates conducive to fungal infections, such as found in the southern portions of the United States (endophytes) and the cool, wet springs of the northwestern United States (ergot).[66] Prevalence of toxicosis will vary by season and from year to year. Deciphering toxicity attributable to these fungal infections is complicated by the fact that some species of grasses can be infected with both simultaneously and have dangerous levels of nitrates.[25] In addition, concurrent copper deficiency may augment reproductive system clinical signs, as ergopeptine alkaloids impair copper homeostasis. Heavy parasitic loads may have a similar effect.[25]

Depending on environmental conditions, the vasoconstrictive effects of the ergot alkaloids can be costly to livestock. Cold weather can result in gangrene of the distal extremities and lameness. The tongue may also be affected in sheep. Lameness can lead to decreased feed consumption and diminished natural mating. In ruminants experiencing heat stress, hyperthermia can occur due to failure of heat dissipation through the skin. Sheep with full fleeces are particularly susceptible to this syndrome. Other signs include a dull, rough hair coat and unthrifty condition. Nervousness, increased salivation, tachypnea, and delayed puberty may be seen. In some regions, this condition is referred to as "summer slump." Ergot alkaloids should also be considered in alpacas and llamas that develop heat stroke.[64] Fat necrosis or lipomatosis in cattle and goats is associated with consumption of ergot alkaloids in fescue grasses. Masses of necrotic fat in the pelvic canal can lead to dystocia.[25] Because the ruminant placenta can produce a placental lactogen during pregnancy, the suppression of prolactin and hence milk production is minor in comparison to horses. Bulls grazing endophyte-infected pastures during the summer may have altered sperm motility parameters. Cows may have changes in ovarian follicular dynamics, as well as diminished embryo quality. Reduced fertility in both unshorn ewes and rams has been reported during the summer.[25] Diminished immune function may make animals more susceptible to infectious diseases and cases with dry gangrene more susceptible to wound infections. In swine, agalactia and abortion have been reported in association with ergot consumption.[63]

Ergot *(Claviceps purpurea)* and endophytes of forages such as fescue (*Lolium* infested with *N. coenophialum*) have been extensively studied in horses. Broodmares eating ergot or endophyte-infected tall fescue pasture or hay may exhibit failure of udder development, agalactia, prolonged gestation, placental abnormalities, dystocia, decreased milk production, and subfertility.[66] Foals may show signs of dysmaturity despite prolonged gestation and frequently suffer failure of passive transfer and secondary septicemia due to the failure of udder and colostrum development. Early embryonic death and abortion are also possible, with a higher risk of abortion associated with ergot infections than endophyte infections.[67] Ergot alkaloids may stimulate the myometrium and probably impair placental circulation.[66] Gangrene of the extremities has been seen in horses exposed to ergot, as has a syndrome characterized by staggering following consumption of *Paspalum* grass seeds infected with *C. paspali*.[68] A slightly different syndrome characterized by peripheral edema has been described in horses grazing Mediterranean tall fescue intentionally infected with a genetically modified, nontoxigenic form of endophyte, suggesting other factors may be involved and should be considered if reseeding of pastures is desired.[69]

Diagnosis of ergot alkaloid or endophyte-induced toxicity is based on recognition of clinical signs and consumption of infected feed. Diagnostic testing of suspect forages, hay, grain, or processed forages is based on observation of *C. purpurea* sclerotia or intercellular endophyte infection via feed microscopy and testing of the forages. High-performance liquid chromatography (HPLC) can confirm the presence of ergopeptine alkaloid toxins: ergovaline, ergotamine, ergocristine, ergosine, ergocornine, and/or ergocryptine.[25,64] Adverse effects are linked to total dietary concentrations greater than 100 to 200 ppb. Affected broodmares' calcium concentrations in the mammary secretions rarely exceed 50 ppm at parturition.[70]

Treatment is most effective if signs are recognized in the early stages and suspect feed is removed. If pasture is the source, and alternative grazing is not available, mowing to remove seed heads and possible ergot bodies may be helpful. Foaling should be attended due to the risk of dystocia, placental problems, and likely dysmaturity of the neonate. Domperidone (1.1 mg/kg PO q24h) can be used successfully in pregnant mares suspected of ergot alkaloid toxicosis if use is begun 10 to 14 days before expected foaling. Reserpine (2.5 to 5 mg/450 kg PO q24h) may be helpful to induce lactation if administered postpartum.[66]

Prevention focuses on replacing contaminated feed sources with safer alternatives such as legumes or endophyte-free fescue grass. Ammoniation to degrade ergovaline in contaminated hay may be economically feasible on large cattle operations.[71] Pregnant broodmares should be removed from fescue pastures no later than day 300 of gestation. Domperidone can be used as described earlier in broodmares. Attention to mineral nutrition and other additive stressors is advised.[66]

Respiratory Syndromes Following Poisonous Plant Ingestion

Few plants are associated with the development of predominately respiratory signs in large animals. Perilla mint *(Perilla frutescens)* (Color Plate 54.9) causes significant morbidity and mortality in ruminants. Perilla contains ketones and related furan compounds. These are bioactivated in the lung, causing atypical interstitial pneumonia and acute respiratory distress. A similar syndrome is seen in cattle following ingestion of sweet potatoes *(Ipomoea batatas)* damaged by *Fusarium* spp. molds.[72] Acute bovine pulmonary emphysema and edema may occur following ingestion of forages high in tryptophan, typically immature summer grasses. Rumen bacteria convert tryptophan to 3-methylindole, a furan further metabolized to a lung toxicant. Gradually introducing cattle to these grasses or using monensin or tetracycline in the feed for a week before and 2 weeks after turnout on pasture can prevent this syndrome. However, use of antibiotics with claims not on the label may be prohibited by regulations. Also, recall the regulations regarding the Veterinary Feed Directive if considering adding an antibiotic to the feed. Peanut hay *(Arachis hypogaea)* has been linked to acute respiratory distress in beef cattle.[72]

Poisonous Plants Affecting Skin and Hooves

Skin and hooves may be adversely affected by plants causing physical trauma or those containing toxins or excessive selenium. Plants with awns or barbs capable of damaging skin may also damage the digestive tract and adjacent tissues if migration occurs.

Photosensitization and laminitis are chief complaints requiring further investigation. Photosensitization may be a primary effect of the ingested toxin or a secondary effect due to liver

VetBooks.ir

damage. Sunlight triggers an oxidative reaction with photoreactive, polyphenolic compounds absorbed from the digestive tract in areas of unpigmented skin, leading to inflammation, cellular necrosis, and sloughing of affected skin, particularly in horses and cattle. Lesions are typically most severe on the face and dorsum of the animal. Common plant sources of primary photosensitization are St. John's wort *(Hypericum perforatum)*, buckwheat *(Fagopyrum esculentum)*, Dutchman's breeches *(Thamnosma texana)*, bishop's weed *(Ammi majus)*, rain lily *(Cooperia pedunculata)*, spring parsley *(Cymopterus watsonii)*, giant hog weed *(Heracleum mantegazzianum)*, and cow parsnip (*Heracleum* spp.).[10] Wild parsnips *(Pastinaca sativa)* contain furanocoumarins, which can result in contact blisters and photosensitization following ingestion.[55]

Hoary alyssum *(Berteroa incana)* (Color Plate 54.10) ingestion and black walnut *(Juglans nigra)* shavings used for bedding are known triggers of laminitis in horses.[10] Hoary alyssum, a weed often growing on the periphery of hayfields in Europe and North America, is usually avoided at pasture but remains toxic in hay for months. Clinical signs of toxicosis include limb edema, fever, and laminitis. In severe cases, intravascular hemolysis, endotoxemia, hypovolemic shock, diarrhea, abortion, and death may occur.[73,74] Black walnut shavings need not be ingested to cause limb swelling and laminitis in horses. Black walnut extracts containing the tree's heartwood and administered by nasogastric tube have been used to create a model for studying laminitis in horses. These studies suggest that oxidative stress to laminar tissues with subsequent inflammation is responsible for the predominant clinical sign, as well as a systemic inflammatory response.[75]

Selenium Toxicosis

Chronic excessive selenium ingestion produces skin and hoof abnormalities, known as "alkali disease." It is problematic for livestock in areas with seleniferous soils, such as the Great Plains of the United States and Canada, as well as in many areas in Russia, Israel, and China.[76] Common seleniferous plant species with this potential include primary selenium accumulator plants, such as milkvetch (*Astragalus* spp.), woody aster *(Machaeranthera*, section *Xylorrhiza)*, goldenweed *(Haplopappus*, section *Conopsis)*, and prince's plume *(Stanleya pinnata)*.[1,10] Selenium can reach levels of approximately 3000 ppm, remaining water soluble and not incorporated into plant protein. Secondary selenium accumulator plants may contain up to several hundred ppm and, rarely, several thousand ppm selenium. This group includes acacia, other asters (*Aster* spp.), beard tongue (*Penstemon* spp.), gumweed *(Grindelia)*, Indian paintbrush *(Castilleja)*, some milkvetch (*Astragulus* spp.), sage (*Artemesia* spp.), saltbush *(Atriplex patula)*, snakeweed *(Gutierrezia)*, stickleaf *(Mentzelia)*, and toadflax *(Comandra)*.[1,10] A third group of plants possibly endangering livestock do not accumulate selenium compounds but do incorporate it into readily absorbed plant proteins, rarely presenting with more than 50 ppm. This latter group is the most problematic because it includes grasses (e.g., Western wheatgrass), small grains, and alfalfa.[1]

Toxicity is difficult to predict because palatability and tolerance vary with animal species, individual genotype, the form of selenium in the plant, duration of consumption, and amount consumed. Ruminants tend to be more tolerant of high selenium in the forage than horses. Water sources in seleniferous areas may also contribute to excessive selenium intake.[77]

Three syndromes are ascribed to excessive selenium intake: acute toxicosis, blind staggers, and chronic alkali disease. Signs of acute selenium toxicosis are most often described after iatrogenic overdosage of selenium and rarely occur from plant ingestion. In horses, the first signs of selenium toxicity may be vesicles on oral and nasal mucosa and a straw-colored exudate at mucocutaneous junctions, followed by coronary band separation from the hooves and hair loss in the mane and tail. In the tail, the hairs tend to break at the same level, leaving a "bob" tail.[10] In cattle, abnormal posture, unsteady gait, diarrhea, abdominal pain, and elevated pulse and respiratory rate are seen. Sheep do not show the typical signs of poisoning; rather, depression, increased respiration, and sudden death are observed.[10] At necropsy, in acute cases, endocardial petechial hemorrhage, acute congestion and hemorrhage of the lungs, enteritis, and passive congestion of the liver are reported.

Animals that chronically ingest high selenium forages show signs of emaciation, rough hair coat, lack of vitality, and lameness. Reproductive efficiency diminishes. Hooves may become overgrown or cracked (including swine), and long hair may fall out. At postmortem, cardiac atrophy, hepatic cirrhosis, anemia, and erosion of the long bones may be noted.[1,78]

Serum selenium provides an accurate reflection of the body's current selenium pool, whereas whole blood selenium (glutathione peroxidase) reflects a longer period of selenium intake. Both can be useful in antemortem diagnosis. Hair and liver selenium are other options, particularly for more chronic cases and postmortem determination. Laboratories used for selenium determinations should provide ranges for normal values by species and sample type because these vary. Investigation of a herd or flock problem should ideally include samples from multiple animals to reduce the risk of misinterpretation based on the values of one or two individuals.

Once a selenium toxicosis is identified, producers and owners need to find alternative grazing and water sources for their animals, particularly breeding horses and cows. Consultation of soil maps may be useful, as may be looking for primary selenium accumulator species serving as indicators. Animals relocated from high-selenium areas often recover when fed lower selenium rations. Producers should also check that diets contain sufficient copper and protein to avoid enhancement of selenium's toxic effects.[10]

Plant Toxicity in the Urinary System

Urinary system damage may be the result of direct toxin damage or secondary to the toxin's effects on other systems, leading to dehydration, pigmenturia, or hypoxia. Renal damage is an important determinant of case outcome for many intoxications. This fact should focus clinical attention on hydration, urinary output, and other measures of renal function. Among common plant toxicities, renal dysfunction can be significant following consumption of bracken fern *(P. aquilinum)*, cocklebur (*Xanthium* spp.), inkweed *(P. octandra)*, oak (*Quercus* spp.), pigweed *(Amaranthus retroflexus)* (Color Plate 54.11), jimsonweed (Color Plate 54.12), and all plants rich in oxalates.[36,57,72,79] Bracken fern's toxin, ptaquiloside, is carcinogenic to bladder epithelium and responsible for the syndrome of enzootic hematuria in cattle.[36] In oak poisoning, nephritis with necrosis and renal tubular casts is observed, possibly leading to acute renal failure. Inkweed has caused acute renal tubular necrosis in calves, along with signs of photosensitization and cholangiohepatopathy.[57]

Oxalate Toxicity

Consumption of plants with high concentrations of sodium oxalate and/or potassium oxalate damages renal tissue if a large amount of plant is consumed over a short period. In addition, some contain insoluble oxalate crystals in the form of complexes called *raphides*, which cause direct damage and irritation to the mucosal surfaces of the mouth and pharynx.[80]

Clinical manifestations of oxalate poisoning are variable and depend on factors such as the form of oxalate in the consumed plant, the animal species, and the rate of consumption. Plants capable of causing oxalate toxicity are listed in Table 54.7. The balance between soluble (oxalic acid) and insoluble forms of oxalate in plants varies and is affected by GI tract pH following ingestion. Binding of calcium can occur in the GI tract lumen.

	Soybean	*Glycine max*	80
	Spinach	*Spinacia oleracea*	80
Grass	Beardgrass	*Brachiaria brizantha*	80
	Birdwoodgrass	*Cenchrus setigerus*	80
	Buffel grass	*Cenchrus ciliaris*	10
	Bristlegrass	*Setaria* spp.	10, 80
	Elephant grass	*Panicum* spp.	10
	Kikuyu grass	*Pennisetum clandestinum*	10
	Napier grass	*Pennisetum purpureum*	80
	Pangolagrass	*Digitaria decumbens*	80
Weed	Dock	*Rumex acetosa*	10
	Greasewood	*Sarcobatus vermiculatus*	10
	Halogeton	*Halogeton* spp.	10
	Kochia	*Kochia scoparia*	10
	Lambsquarters	*Chenopodium* spp.	10
	Nettleleaf	*Tragia urticifolia*	80
	Noseburn	*Tragia ramosa*	80
	Pigweed	*Amaranthus retroflexus*	10
	Pokeweed, pokeberry	*Phytolacca americana*	10
	Russian thistle	*Salsola* spp.	10
	Slenderleaf ice plant	*Mesembryanthemum nodiflorum*	80
	Sorrel	*Oxalis* spp.	10

Once absorbed from the GI tract, oxalates precipitate calcium from the blood, producing hypocalcemia, which may be most notable in lactating animals.[81] Oxalate crystals damage the microvasculature of the GI tract and may precipitate out on the wall of the rumen. Poorly soluble calcium oxalate crystals precipitate out in the renal tubules, causing acute nephrosis, tubular obstruction, and acute renal failure. At a cellular level, citric acid cycle of energy metabolism is inhibited, leading to cell death. In renal tubular cells, other pathways have been suggested, such as the production of phosphatidylserine, which promotes attachment of oxalates to the cell membrane, and phospholipase A2, with subsequent mitochondrial damage and cell death.[82]

Oxalate poisoning in multiple animals is most often reported in sheep. Acute toxicosis is usually evident within 24 hours. The largest outbreaks are attributed to *Halogeton* spp. consumption. Other plants blamed for multiple deaths include slenderleaf ice plant *(Mesembryanthemum nodiflorum)* and golden bristlegrass *(Setaria sphacelata)* in Australia.[80] Muscle tetany or flaccid paralysis may be observed. These clinical signs pertain to hypocalcemia and hypomagnesemia, which result from sequestration of calcium and magnesium ions. Other reported signs include anorexia, ruminal stasis, mouth froth, weakness, stiffness, tachypnea, ataxia with jerky extensor rigidity, coma, and death. At necropsy, severe rumenitis may be evident. Kidneys are pale, edematous, and enlarged. Calcium oxalate crystals are readily identified in the rumen wall and kidneys. Less commonly, chronic toxicity has been reported with signs typical of chronic renal damage: anemia, weight loss, and poor appetite. Clinical signs of oxalate poisoning in cattle are similar to those in sheep but typically less acute and attributable to hypocalcemia. These include incoordination, belligerence, excessive salivation, bloat, recumbency, coma, and death. In calves, hypersensitivity to stimulation and seizures are possible.[11]

In horses, secondary nutritional hyperparathyroidism has been attributed to chronic high oxalate consumption, resulting in calcium binding in the hindgut and therefore deficiency. This leads to signs of osteodystrophia fibrosa.[80] Acute toxicosis with oxalate nephrosis failure is less common but associated with grass species with high oxalate content.

Treatment should be symptomatic with attention to electrolyte balance and renal function, but it may be insufficient in severely affected animals. Activated charcoal may help bind oxalates remaining in the GI tract. Prevention requires recognition of the toxic potential of oxalate-bearing plants and management of livestock to avoid consumption of large amounts in a short period. Gradual introduction to the plants, ample alternative forage, and water are necessary to avoid deaths. In sheep, slow introduction (≈10 days) of sheep to grazing areas with high proportions of oxalate-bearing plants can result in better tolerance to the toxic effects. In contrast, a sheep acclimated to grazing other forage can be killed with as little as 12 oz (340 g) of halogeton.[1]

warm months when water temperatures exceed 20° C and water is stagnant.[1] High nutrient concentrations, especially phosphorus and nitrogen, increase the presence of cyanobacteria and cyanotoxins.[2] Cyanobacteria are suspended in the water column and easily visible or are attached to the surfaces of stones and sediments along the bottom of lakes or rivers.[3] Currently, of the 2000 species identified worldwide, more than 80 are categorized as toxigenic. Toxigenic and nontoxigenic species and strains coexist in water; thus the potential toxicity of a given water source must be carefully evaluated not only by identification of the actual cyanobacteria population but also by measuring toxin concentrations.[4,5] George Francis first reported in *Nature* in 1878 a toxigenic bloom of a "poisonous Australian lake" with "a thick scum like green oil paint" and vividly described acute intoxications of sheep, horses, dogs, and pigs.[6] Since Francis's publication in 1878, numerous case reports describing morbidity and mortality in animals exposed to cyanotoxins have been published.[7-13]

The most commonly reported cyanotoxin poisoning in large animals is acute hepatotoxicosis subsequent to microcystin exposure. Microcystins are produced by multiple cyanobacteria and detected in fresh and coastal waters worldwide.[14] They present a realistic threat to pastured animals because of their presence in ponds and streams and because animals readily consume contaminated water (Fig. 54.1). Acute neurotoxicosis resulting from anatoxin-a or anatoxin-a(S) can occur in large animals, but reports are rare.

The frequency of cyanotoxin poisoning in animals is likely underreported due to absent diagnostic work-up of large animal mortalities and the current lack of well-established confirmatory methods in biological specimens. Diagnostic confirmation of suspect cyanotoxin poisoning cases of humans and animals requires extensive efforts from both toxicologists and clinicians, and resources are often not readily available. New cyanotoxins and expansion of existing cyanotoxins into new regions are discovered continuously, and oral bioavailability and toxicity data are often unavailable. It is probable that cyanotoxins poisonings are more common in animals than humans due to increased dependence and contact with surface waters.

Hepatotoxic Microcystins

Microcystin-poisoned animals typically die within a few hours after exposure. Severe destruction of the hepatocytes leads to hypovolemia and shock secondary to blood loss into the disintegrated liver lobules and embolism of hepatocytes into the lung. Clinical signs of nervousness, reluctance to move, recumbency, diarrhea, and pale mucous membranes are seen within 30 minutes to several hours of exposure.[15,16] Many die within hours to days, but animals exposed to nonlethal doses may survive and develop hepatogenous photosensitization (Fig. 54.2).

Clinical chemistry changes of animals with microcystin toxicosis include elevated serum gamma-glutamyl transpeptidase (GGT), aspartate aminotransferase (AST), bile acids, alkaline phosphatase (ALP), hypoglycemia, and hyperkalemia. Acute hepatic damage results in a grossly enlarged and friable liver from intrahepatic hemorrhage and, histopathologically, in hepatocyte dissociation, degeneration, and necrosis. Pathologic findings should quickly lead to an environmental assessment for possible microcystin-contaminated water.[17] Necrotic hepatocytes can also be seen in the pulmonary vasculature.

Microcystis, *Anabaena*, *Planktothrix*, *Nostoc*, *Oscillatoria*, and *Anabaenopsis* genera are among the known microcystin producers.[18,19] Toxins are retained inside the cyanobacteria and released only upon cell damage, lysis, and death; of note, destruction of algal mats (either naturally or through the application of herbicides) may result in a pulse of microcystin release following destruction of the individual cell walls. Microcystins are cyclic heptapeptides that inhibit protein phosphatases; currently, more than 80 different structural variants have been identified. The most extensively studied congener, microcystin-LR, is found worldwide and causes acute, lethal hepatotoxicoses in farm animals.[2,16,20] Most natural outbreaks are a result of oral exposure through drinking water; microcystin-containing algae release microcystins in the acidic environment of the stomach. Recently, the risk for microcystin exposure through blue-green algae–containing dietary supplements led to deaths in horses.[21] Inhalation exposure to microcystins has been documented in humans recreationally using certain waters.[22,23] All animal species, including fish and reptiles, and humans are considered susceptible to the toxic effects.

Animals with acute microcystin poisoning may have algal material in the GI tract (Fig. 54.3) or on the skin, especially the legs. Although identification of algae material in water and gastric contents is an important component of the diagnostic work-up, it does not confirm intoxication. As mentioned, the toxicity of cyanobacteria is strain specific, and morphologic observations alone cannot predict the hazard level. Detection of microcystins in gastric contents is confirmatory, but these tests are not routinely available at diagnostic laboratories and are limited to a few structural variants.[24-26] Commercially available methods for microcystin analysis of liver and other tissues are not yet available. Consumption of milk, meat, or liver is unlikely to pose a significant health risk to humans.[27,28] However, as a

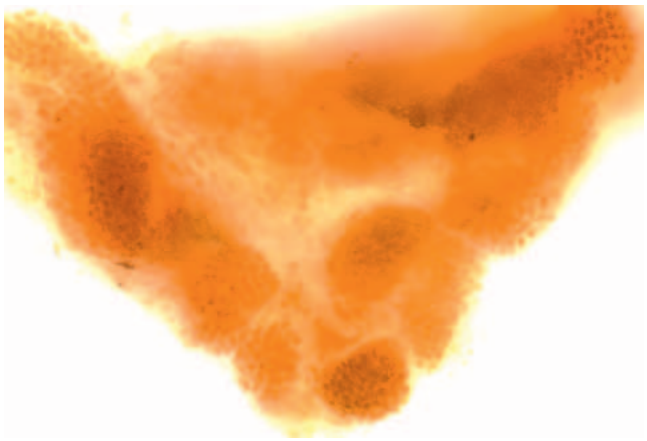

FIG. 54.3 Characteristic algal cell aggregates in rumen content of a heifer formed by *Microcystis* spp. Direct microscopic examination of rumen content in formalin (1:1; v/v). 60×. Rumen content was confirmed to contain microcystin-LR.

tumor promoter, microcystins may pose a cumulative health risk as they become more ubiquitous.

Neurotoxic Anatoxins

Anatoxins are produced by many cyanobacteria genera, such as *Anabaena*, *Aphanizomenon*, *Planktothrix*, *Oscillatoria*, *Microcystis*, *Cylindrospermum*, and *Phormidium*. Reports of anatoxin-a poisoning in livestock are extremely rare; most cases are documented in dogs. However, all animals are considered susceptible. Anatoxin-a poisoning leads to muscle tremor, rigidity, respiratory failure, collapse, and death within minutes to a few hours.[29-31] This is a result of anatoxin-a being a potent cholinergic agonist at nicotinic receptors.[32] Animals poisoned with anatoxin-a(S) develop acute signs of excessive salivation, lacrimation, diarrhea, and urination (SLUD) because anatoxin-a(S) is a naturally occurring, irreversible acetylcholinesterase inhibitor.[33] Animals often die of respiratory arrest within 30 minutes.

Because of the acute onset, CBC and chemistry profiles of animals with anatoxin poisoning are generally unremarkable. Furthermore, other than the possible presence of algae material in GI contents, there are no specific gross or microscopic lesions. Confirmation of anatoxin-a poisoning is by analytic detection of the toxin in urine, bile, or GI contents.[31] Diagnosis of anatoxin-a(S) toxicosis is aided by the determination of blood acetylcholinesterase activity. In any suspect cases, environmental samples should undergo a toxicologic and phycologic analysis.

Other Cyanotoxins

Other freshwater cyanotoxins of concern to livestock include neurotoxic saxitoxins, hepatotoxic nodularins, and cylindrospermopsin, which targets multiple organs (liver, kidneys, lung, heart, GI tract).

Treatment for cyanotoxin poisoning is supportive but often unsuccessful. Efficacy of decontamination with activated charcoal is limited.[34,35] Symptomatic and supportive care to treat hypovolemia and electrolyte imbalances, as well as antioxidants such as vitamin E and selenium, may aid in the therapeutic regimen for large animals poisoned with microcystins. Animals that develop photosensitization must be protected from sun exposure. Because of the rapid onset of clinical signs in anatoxin-a poisonings, therapeutic options are even less pertinent; artificial respiration may be of benefit along with general supportive care. Administration of activated charcoal is suggested, but scientific evidence on its adsorptive capacity for anatoxin-a is lacking. Atropine can revert excessive muscarinic receptor activation in animals poisoned with anatoxin-a(S). It is important to note that pralidoxime (2-PAM) is not recommended.[36]

The frequency and extent of harmful cyanotoxins have increased with the addition of nutrients to surface freshwater ecosystems around the world. Steps must be taken to reduce fertilizer runoff and applications in fields surrounding ponds used for drinking water. Prevention of blooms is key to protecting animal and human health.

Mycotoxins

Timothy J. Evans • George E. Rottinghaus • Benjamin R. Landers

Importance of Mycotoxins

Mycotoxins are secondary fungal metabolites, which, if consumed in sufficient amounts, cause adverse health effects in animal species, including humans.[1] They can be detected in various matrices, including cereal grains and forage, and are a major concern to international agricultural production and a threat to food safety worldwide.[1-3] Individuals working within the United States swine and poultry industries are particularly cognizant of the potential for mycotoxin exposures, given the dietary dependency of those monogastric species on cultivated cereal grains. However, the globalization of agricultural commodities, climate change–related weather conditions favoring fungal growth and/or mycotoxin production, subsequent reductions in the availability of foodstuffs not contaminated by mycotoxins, and economic pressures from higher costs of better-quality foodstuffs all underscore the need for individuals participating in other aspects of animal agriculture in the United States to have a greater awareness of the potential for mycotoxin contamination.

In addition, the increasing risk to human and animal health posed by mycotoxins means that the veterinary profession must be vigilant in the surveillance of domesticated large animal populations as sentinels for mycotoxin contamination of agricultural products. Veterinary practitioners, regardless of whether their practices involve small companion animals or livestock, will need to be familiar with the "major" mycotoxins and the wide range of clinical signs, including subtle reductions in livestock production and food residues associated with these fungal toxins.[4] It is only through an increased awareness of these toxins that mycotoxin-related illness in food animals can be minimized and companion animal and human exposure to mycotoxins limited or prevented.

General Principles of Mycotoxin Production and Detection

Many fungi are capable of producing toxins (i.e., are toxigenic), and a given mycotoxin could be synthesized by more than one fungal species.[3] Some fungi produce more than one toxin or even multiple classes of toxins.[1,3] Although a number of relatively common mycotoxins have already been identified, it is likely that many more potentially toxic, secondary fungal metabolites have yet to be isolated and characterized.[2,3,5] Fungal colonization does not necessarily mean that a given mycotoxin is being produced.[1,3] The substrate, moisture content, pH, ambient temperature, relative humidity, and other requirements for toxin synthesis are often more stringent than those for fungal growth.[1,2] The "ideal" toxigenic conditions for the production of specific mycotoxins have been characterized, and some mycotoxins are more likely to be produced in a "field" or "storage" setting.[1-3] The mere presence of fungal growth does not necessarily correlate with toxin production, and some mycotoxin-contaminated foodstuffs might not even be visibly moldy.[3]

From a clinical perspective, the inability to accurately predict whether mycotoxins will be present in a specific foodstuff means that fungal identification and spore counts are not adequate for identifying livestock diets contaminated with mycotoxins.[1-3] High-performance liquid chromatography (HPLC), liquid chromatography–tandem mass spectrometry (LC-MS/MS),

VetBooks.ir

and/or enzyme-linked immunosorbent assay (ELISA) are some of the more common analytic techniques used to directly measure mycotoxin concentrations in grains or processed foodstuffs. The use of an ultraviolet light to detect fluorescence associated with kojic acid, as an indirect indicator of aflatoxins, is outdated as the sole means of detecting these toxins.[1,6] Likewise, use of semiquantitative methods, such as thin layer chromatography (TLC), as standalone evidence of fungal toxin contamination, is also less than optimal. The consistent use of appropriate sampling techniques ensures the detection of suspected mycotoxins and guarantees that detected mycotoxin concentrations are representative of actual livestock exposure.[3,7,8] Grain "screenings" or "fines" are the grain by-products most likely to contain the highest concentrations of mycotoxins.[1,3]

One of the biggest challenges pertaining to mycotoxin contamination in livestock rations is the accurate interpretation of analytic results, especially now, when low concentrations of mycotoxins are detected by increasingly sensitive laboratory methods.[4] Table 54.8 shows "action levels" established by the U.S. Food and Drug Administration (FDA) for some mycotoxin-contaminated commodities fed to different species of livestock. These action levels (more specifically, "advisory levels" for deoxynivalenol and "guidance levels" for fumonisins) were originally intended as guidelines for "acceptable" concentrations of individual mycotoxins in common substrates being transported between states.[6,9] The mycotoxin concentrations have often been interpreted as the highest dietary concentrations of these mycotoxins considered "safe" in the denoted species. However, the definition of "safe" is a relative term that depends on the end point being measured. Some concern has recently been expressed as to whether these action levels are low enough to prevent adverse health effects, especially with respect to carcinogenesis in humans.[10]

Mycotoxicoses

In discussing mycotoxin-related diseases, it is important to differentiate "mycosis" from "mycotoxicoses." The term *mycosis* refers to a disease caused by fungal growth, rather than by the adverse effects of any toxins produced by that fungi.[3] *Mycotoxicoses*, on the other hand, are diseases caused by the adverse health effects of mycotoxins, which in most cases have been ingested.[1-3] For a specific mycotoxicosis to occur, growth conditions in substrates colonized by the appropriate fungal species must favor production of a specific toxin, and sufficient

TABLE 54.8

Summary of Mycotoxins Important to Livestock

Mycotoxins	Fungal Sources Substrates	Primary Toxic Effects	Dietary U.S. Food and Drug Administration Action Levels
Aflatoxins B_1, B_2, G_1, G_2	*Aspergillus flavus* and *Aspergillus parasiticus* Corn, nuts, cottonseed+	Macromolecular binding enzymatic inhibition DNA adducts formed → hepatic insult/failure cancer (1° hepatic) All species	Total aflatoxins[a] Immature 20 ppb Dairy/horse 20 ppb 100+ lb pigs 200 ppb Feedlot beef 300 ppb Breeding 100 ppb

amounts of that toxin-contaminated substrate must be consumed by a susceptible animal species.

The higher the dietary concentration of a given mycotoxin, the more likely and severe are the observed adverse effects.[1-3] Similarly, the duration of exposure to a mycotoxin affects the likelihood and severity of the observed clinical signs, with longer exposures increasing the probability of more severe intoxications.[2,3] Peracute and acute intoxications generally occur over a short period (usually days) and involve one or several "large" doses (orders of magnitude greater than "allowable" quantities) of a specific mycotoxin. In these instances, the diagnosis is often straightforward because contaminated feed is more likely available for testing. However, clinically recognized mycotoxicoses more often than not involve subacute (weeks) to chronic (months) dietary exposures to fungal toxins.[1] Depending on the dietary concentration of a given mycotoxin, clinical signs in these types of exposures may be "classic" for a mycotoxin's typical target organ (e.g., moderate to severe hepatocellular damage with sufficient amounts of aflatoxins) or more subtle in nature (e.g., immunosuppression, suboptimal growth, reproductive inefficiency, and/or carcinogenesis), reflecting impaired hepatic function.[3,4] In subacute to chronic mycotoxin exposures, affected animals could still be ingesting specific toxins, with contaminated foodstuffs readily available for testing, or the consumption of specific mycotoxins may have already ceased, especially if the observed clinical signs are more subtle in nature and/or took some time to develop. Under these circumstances, analyses of representative samples of grains or forages harvested at the same time as the suspect foodstuffs or analyses of samples of prepared rations retained by the supplier or manufacturer might be the only way to establish the definitive cause of a suspected mycotoxicosis.

Another aspect of a potential mycotoxicosis, as illustrated in Fig. 54.4, using reproduction as an example of monitored animal performance, is the role that mycotoxins may play in diminished livestock performance, such as decreased feed consumption, growth rates, and fertility. In these instances, there may not be a single, definitive "cause" but rather a multifactorial etiology. It is probably overly convenient to hold feed manufacturers and distributors wholly responsible in these instances and to forget the important role of other factors, such as environmental stressors, infectious agents, and suboptimal management. In fact, the mention of this type of diagnostic conundrum can increase the overdiagnosis or misdiagnosis of a mycotoxicosis, especially when the detected concentrations are well below established levels of concern, and should not be misconstrued as an effort to indict trace amounts of some mycotoxins as the primary cause of clinical abnormalities in livestock.[4,6] However, although it is not practical or even possible to eliminate all measurable fungal toxins from livestock diets,

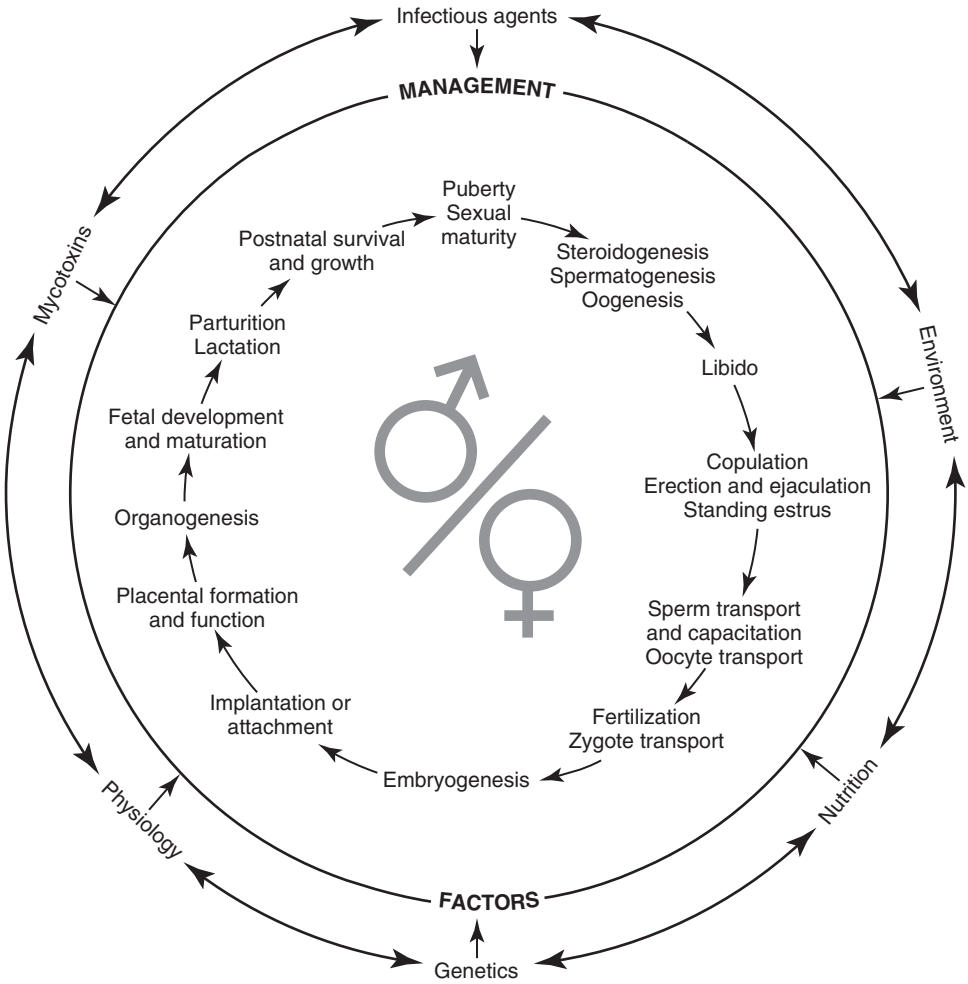

FIG. 54.4 The continuum of developmental stages and reproductive functions taking place in males and/or females, as well as the embryo and fetus, is shown schematically and illustrates the complexity of reproduction in ruminant species. The possible influences of genetic and physiologic predispositions, as well as nutritional, environmental, infectious, and especially mycotoxin stressors, on decreased reproductive performance are also represented, along with the role "management" can play in modulating those influences on reproductive function. *(Modified with permission from Evans TJ: Diminished reproductive performance and selected toxicants in forages and grains. Vet Clin North Am Food Anim Pract 27:345, 2011. Modifications and artwork courtesy Don Connor and Howard Wilson.)*

VetBooks.ir

one should also recognize that there is no nutritional requirement or benefit related to dietary mycotoxins. It is critical, therefore, when no clear-cut, single cause of diminished performance is evident, to take an integrated approach and objectively evaluate the relative contributions of a wide variety of enzootic variables or "stressors" to the clinical problems being observed.[4]

Major Mycotoxins of Veterinary Importance

AFLATOXINS. Aflatoxins arguably pose the most clinically relevant, mycotoxin-related threat to the worldwide health and well-being of humans and domestic animals. A number of fungal species, in particular *Aspergillus flavus* (*A+fla*+toxin) and *Aspergillus parasiticus*, can produce aflatoxins under appropriate growth conditions in a variety of nuts and grains, including cottonseed, peanuts, and especially corn.[1-3] The major aflatoxins found in contaminated grains include aflatoxins B_1, B_2, G_1, and G_2 (B or G = fluorescence color), with aflatoxin B_1 (AB_1) generally being present in the highest concentrations.[3] Although aflatoxins are sometimes described as "storage" mycotoxins, there are certainly instances when they are produced under "field" conditions.[1,6] Drought and/or insect damage to corn or other susceptible plants, followed by warm (>25°C), humid (>70% humidity), ambient weather conditions, is the "classic" scenario that facilitates initial fungal invasion of compromised kernels and seeds and subsequent fungal growth with aflatoxin production.[1-3,6] In fact, drought conditions are often associated with increased scrutiny on the part of grain elevator operators, livestock producers, and regulators, with respect to possible aflatoxin contamination, particularly in corn and corn by-products.

Ingested AB_1 is metabolized by multiple cytochrome P450 subfamilies in the liver to produce several metabolites, including AB_1-8,9-epoxide and AB_1-dihydrodiol, which are toxic, and aflatoxin M_1 (AM_1), which can be found in meat as well as in milk.[1] AB_1-8,9-epoxide and other toxic metabolites bind to biologically important molecules, such as essential proteins, including enzymes involved in carbohydrate and lipid metabolism and protein synthesis.[1,3] These AB_1 metabolites also bind to macromolecular nucleic acids, inhibiting transcription and forming DNA adducts, which can be associated with carcinogenesis, especially hepatic tumors.[1-3,8] In addition, toxic metabolites of AB_1 can bind to subcellular organelles, such as mitochondria and ribosomes.[1]

Although excretion of violative AM_1 residues (>0.5 ppb or 0.0005 ppm) in the milk is the first observed "abnormality" associated with AB_1 exposure in lactating dairy animals, the liver is considered the major target organ of toxic AB_1 metabolites in all species.[1-3,6] Clinical signs of aflatoxicosis range from prolonged prothrombin time (PT), hemorrhage, bloody diarrhea, and rapid death in peracute and acute intoxication, to anorexia, slow rumen motility, weakness, tremors, ataxia, and reproductive failure (abortion), to hepatic failure with icterus, coma, and death in subacute aflatoxicoses.[1-3,6,8,11-16] Aflatoxin-induced hepatic insult and failure are usually accompanied by many of the typical clinical pathologic abnormalities expected with hepatocellular necrosis and/or hepatic failure, and elevations in the detected activities of liver-specific enzymes in serum often precede other clinical signs.[6] Suppression of immune function, particularly those aspects related to cell-mediated immunity, have also been reported in animals following repeated exposure to moderately high dietary concentrations of AB_1.[1,6,8,15] Chronic exposure to dietary aflatoxins can be associated with decreased growth rates and feed efficiency, roughened hair coats and ill-thrift, impaired resistance to infectious disease, and hepatic fibrosis with regenerative nodules.[1,3,6] Spermatogenesis can also be adversely affected by chronic exposures of male animals to AB_1.[17] Low-level subacute to chronic exposures to AB_1 and its toxic metabolites also have the potential to be associated with teratogenesis, mutagenesis, and/or carcinogenesis, and experimentally, AB_1 in grain dusts can be present in sufficient quantities to be converted to carcinogens by pulmonary cytochromes.[3,18]

Attempts to estimate the dosages or dietary concentrations of total aflatoxins likely to be "safe" or, conversely, the concentrations that will probably be associated with clinical disease can be challenging. Anecdotal evidence and reports of clinical cases of aflatoxicosis, which provide some dose-related data, may require additional scrutiny because some of the factors known to influence the toxicity of aflatoxins might be unaccounted for or unknown.[6] However, such reports are still of value because they represent "real" clinical situations. An animal's plane of nutrition, rate of hepatic metabolism, age, and species, as well as the level and duration of aflatoxin exposure, are all important determinants as to whether and what signs of aflatoxicosis are likely to be observed.[1,3,6,8] Animals fed a diet deficient in protein, selenium, and/or vitamin E and those with enhanced rates of hepatic metabolism are more likely to experience hepatic insult associated with dietary aflatoxin contamination.[6,8] Immature animals, particularly young swine, are the livestock populations considered most susceptible to adverse health effects associated with aflatoxins.[3,6] Weeks of exposure to total dietary aflatoxin concentrations of 200 ppb (0.2 ppm) have been associated with mild hepatic insult and suboptimal growth of piglets and decreased performance in calves.[3,6,8] Horses and more mature cattle and swine have experienced toxic insult to the liver following weeks to months of exposure to aflatoxin concentrations exceeding 400 and 600 ppb (0.4 and 0.6 ppm), respectively, and hepatic failure and death are possible in animals consuming foodstuffs that contain a flatoxin concentration exceeding 1000 ppb or 1 ppm.[3,6,8,11,12,14,15,19]

The "threshold" AB_1-induced "abnormality" usually first observed at the lowest dietary concentrations in livestock species is an actionable level of AM_1 detected in milk obtained from exposed lactating dairy animals.[3,6] The concentrations of AB_1 causing short-term, minimally violative AM_1 residues in milk are much lower than those likely to cause any liver-related adverse health effects, especially in ruminants.[3,6,8,11-16,19] The ratio of the concentration of AB_1 in the diet to the AM_1 concentration detected in the milk varies widely from less than 50:1 to almost 2000:1 (average of 300:1), and the proportion of dietary AB_1 excreted as AM_1 can range between 0% and 4% (average of 1%).[6] Excretion of AM_1 in the milk generally continues for 2 to 7 days after withdrawal from an AB_1-contaminated diet.[3,6]

The accurate diagnosis of clinical aflatoxicosis usually involves the detection of high AB_1 concentrations in the feed or, less optimally, the gastric contents of animals exhibiting appropriate clinical signs.[3,6,8] The detection of AB_1 and/or AM_1 in the liver and kidney, in particular, can also be indicative of recent AB_1 exposure (usually within 7 days) and may help establish the consumption of dietary AB_1 by a deceased animal, when foodstuffs are unavailable for analyses.[3,8]

Treatment of aflatoxicosis in large animals is often cost prohibitive, especially in food-producing animals, and limited to therapy for hepatic insult and/or failure; provision of a balanced, AB_1-free diet; possible supplementation with trace minerals and vitamins (selenium and vitamin E); and most importantly prevention of further exposure.[3,6,8] Growth conditions are not conducive to AB_1 production in *Aspergillus*-infected stored grains when the moisture content is reduced to less than 15%.[8] Ammoniation has been reported to prevent fungal colonization and growth and to facilitate detoxification of aflatoxins.[1,3,8] In "emergency" situations where it is difficult to find affordable, alternative foodstuffs free of AB_1 contamination, producers may consider dilution of feeds to "safe" concentrations of AB_1.[3] However, this approach has some attendant risk, including the species of animal involved, exposure to enzootic stressors other than aflatoxins (e.g., infectious disease, poor nutrition),

level of animal management and husbandry skills, willingness of the producer to thoroughly "blend" the feeds and collect frequent representative samples for AB_1 analyses, and the targeted "safe" concentration of AB_1.[3,4] One possible approach to the dilemma of which targeted AB_1 concentrations are likely to be "safe" is for producers to aim for total aflatoxin concentrations approximately one half of that shown in Table 54.8 for total dietary aflatoxin action levels, particularly in diets intended for lactating dairy cows, immature livestock, or animals used for breeding purposes.[4,9] This approach can also be used for other mycotoxins for which there are action levels.[4] Another consideration, especially for aflatoxins, may be the incorporation of clay binders in rations to prevent the absorption of fungal toxins.[3,4,6,8] Hydrated sodium calcium aluminosilicates (HSCASs) have been shown to effectively prevent violative AM_1 residues in milk and meat and to reduce livestock production indices, especially those parameters (e.g., growth and reproductive performance) likely to be affected by low-level chronic exposure to dietary aflatoxins.[3,4,6,8,20-24] Before using a given binder, there should be in vivo evidence that the binder in question is effective at reducing AB_1 absorption in live animals.[1,3,4,6]

DEOXYNIVALENOL (DON OR VOMITOXIN). Deoxynivalenol (DON or vomitoxin) is classified as a trichothecene mycotoxin and is produced in grains such as corn, wheat, and barley by toxigenic *Fusarium* species, especially *Fusarium graminearum* (formerly *Fusarium roseum*). This species is also the conidial stage of *Gibberella zeae* and associated with "head blight" and "scab" in wheat and "Gibberella ear rot" in corn.[1-3,25] Although growth of this toxigenic fungal species occurs in the field when temperatures are warmer (20° to 25°C), DON production is favored under storage conditions when it is cooler (0° to 15°C).[1,3] Rising and falling (undulating) temperatures, especially when associated with a cool, wet fall and delayed harvest, facilitate production of DON.[1,3,26] Trichothecenes are stable compounds that persist much longer than the fungi producing them.[1] Deoxynivalenol can also be found in forages (such as corn stover and wheat straw) associated with the grains most frequently contaminated by this mycotoxin.[1,27] In addition, grains contaminated with vomitoxin are often contaminated with zearalenone (see below), which is also produced by *F. graminearum* (see Table 54.8) under similar fungal growth conditions.[1,3,25]

Deoxynivalenol is an extremely important trichothecene mycotoxin, from an agricultural perspective, because of its impact on indices of animal performance and the frequency with which it is detected in livestock diets, especially those intended for consumption by swine and dairy cattle.[1-3,8,26] This particular fungal toxin inhibits protein synthesis and induces emesis by crossing the blood-brain barrier and directly stimulating the chemoreceptor trigger zone in the medulla oblongata, hence the alternative name of "vomitoxin."[3,25] Immunosuppression has been reported in some animal species, but feed refusal and gastroenteritis are the most common clinical signs, particularly in swine.[1-3,25] Clinical pathologic abnormalities include those associated with decreased feed intake, impaired absorption of nutrients, vomiting, and diarrhea.[8,25]

Table 54.8 shows the guidance levels for DON in various species of livestock. Clinical signs of dietary exposure to DON, such as feed refusal, generally begin within 1 day of ingestion.[3,25] Dietary concentrations of DON associated with clinical disease range from 1 ppm (feed refusal) to 5 to 10 ppm (vomiting and possible gastroenteritis) in swine; ruminants have been reported to refuse eating contaminated foodstuffs containing more than 10 to 20 ppm of DON.[8,25] One dilemma often associated with DON occurs because of the low concentration frequently found in grains and their related forages. It is difficult to differentiate the direct adverse effects of the mycotoxin itself from clinical signs related primarily to reduced palatability and/or the decreased nutritional value of poorer quality foodstuffs, particularly when feed refusal and abnormalities arising from reduced feed intake are the only observed clinical signs.[4] Similarly, any deviations from optimal dairy cattle performance should not necessarily be attributed solely to low-level mycotoxin contamination (<0.5 ppm) without taking into account the reduced palatability and nutritional value of contaminated grains and forages. Evaluation of overall diet quality, rather than just the presence or absence of low concentrations of mycotoxins such as DON, remains an important aspect of the management of livestock production systems, even when experimental data indicate improvement following the addition of "binders."[28,29] Such products may have benefits related to nutrient uptake that are completely independent of interactions with DON or any other mycotoxins.[30]

As with AB_1, appropriate clinical signs and analyses of foodstuffs and, less desirably, gastric contents can be used to determine whether there has been dietary exposure to DON.[3,8,25] However, unlike AB_1, consumption of DON is not associated with residues in milk or meat.[3,25] Treatment of DON intoxication is limited to supportive care and prevention of further exposure to foodstuffs contaminated by DON and related mycotoxins. There has been limited in vivo success in developing binders that are effective in preventing the absorption of DON in experiments involving susceptible species.[31,32]

ZEARALENONE. Like DON, zearalenone (ZEA) is produced in corn and other grains and their corresponding forages by *F. graminearum* (formerly *F. roseum*) and other *Fusarium* species.[1-3,8,33] The synthesis of ZEA is facilitated by a drop in temperature to 12° to 14°C with greater than 23% relative humidity.[1,3,8,33] Under certain growth conditions, both DON and ZEA can be detected in some contaminated foodstuffs, and the diagnosis, treatment, and prevention of dietary exposures to ZEA is essentially the same as outlined for DON.[1,3,25,33]

Zearalenone is a naturally occurring, nonsteroidal xenoestrogen that binds to both the α and β estrogen receptors (ERα and ERβ). Swine, especially sexually immature, prepubertal gilts, clearly is the species most susceptible to the xenoestrogenic effects of ZEA. The enhanced sensitivity of swine to the xenoestrogenic effects of ZEA is based on several factors. The slow detoxification and enterohepatic recirculation of ZEA and its metabolites in swine certainly play important roles in the ZEA susceptibility observed in this species.[1,3,33] However, it also important to note that the porcine liver preferentially metabolizes a greater portion of ZEA into the potent xenoestrogenic metabolite, α-zearalenol, than other animal species.[1,3,33,34] Anecdotally and perhaps more controversially, dairy heifers have also been reported to be particularly susceptible to the xenoestrogenic effects of ZEA, especially when they are being bred to produce their first calf and after entering their first lactation.[3,4,33]

Within a few days to a week after exposure to dietary concentrations of ZEA as low as 1 ppm (possibly even lower concentrations, depending on the clinical or experimental circumstances), classic hyperestrogenism, as evidenced by vulvar swelling (one of the earliest and most dramatic signs), enlarged mammary glands, possibly prolapsed rectum, and increased size and weight of the tubular portions of the female reproductive tract, can be observed in prepubertal gilts.[1,3,8,33] Nymphomania in females and feminization and decreased testicular weights in males can also be observed, especially in gilts and young boars.[33] Dietary concentrations of 3 to 10 ppm of ZEA can be associated with anestrus and pseudopregnancy in postpubertal gilts and sexually mature sows, due to the unique luteotrophic effect of estrogens in swine.[8,34] Exposure of recently bred sows (7 to 10 days after breeding or insemination) to concentrations of ZEA, exceeding 15 ppm, can result in early embryonic death and prolonged interestrous intervals.[8,33]

VetBooks.ir

Although it is clear that postpubertal dairy heifers are more susceptible than mature dairy cows (>10 ppm versus >25 ppm ZEA, respectively) to adverse reproductive effects associated with ZEA, there still remains doubt as to how often ZEA-related problems are observed in dairy cattle in "real-world" situations.[4,8,33] There are reports that cattle are insensitive to ZEA, while others report a 25% lower pregnancy rate in postpubertal heifers fed 12.5 ppm of ZEA.[4,33,35,36] The disparity between these reports attests to the significance of the stage of sexual maturity, concurrent exposure to other enzootic stressors, and sensitivity of the criteria used to evaluate impaired reproductive performance in determining how ZEA affects dairy cattle fertility.[4]

FUMONISINS. Fumonisins, especially fumonisin B_1 and B_2 (FB_1 and FB_2), are produced primarily by the ubiquitous fungal species *Fusarium verticillioides* (formerly *Fusarium moniliforme*).[1-3] *F. verticillioides* grows primarily on corn, and the highest concentrations of FB_1, which is the most common and clinically important fumonisin, are most often found in association with corn "screenings" or "fines."[8,37,38] Although growth conditions facilitating FB_1 production are not as well defined as those for AB_1, DON, and ZEA, drought conditions during the growing season and subsequent cool, wet weather during ear development seem to correspond to higher FB_1 concentrations.[8,37]

Fumonisins structurally resemble sphingolipids, which are found in highest concentrations in the brain and liver and are essential for cell growth and differentiation, as well as vascular integrity.[1,3,8,37] One primary toxic mechanism of action proposed for fumonisins, in particular FB_1, is inhibition of the conversion of sphinganine to sphingosine, resulting in a disruption of sphingolipid biosynthesis.[3,8,37,39] Horses and swine are the two livestock species most susceptible to fumonisin intoxication.[1,3,37] The brain is generally considered the major target organ in horses, especially following more chronic, low-level exposures, but centrilobular hepatocellular necrosis, with clinical pathologic changes in the serum typical of toxic hepatic insult, can be observed in the absence of brain lesions when horses are acutely exposed to high FB_1 concentrations.[1,3,37] Subacute to chronic consumption of dietary concentrations of FB_1 exceeding 8 to 10 ppm have been associated with the sudden onset of the clinical syndrome referred to as *equine leukoencephalomalacia* (ELEM) or "moldy corn poisoning."[1,3,8,37,40-42] Horses affected by ELEM (also see Chapter 35) exhibit altered mentation, ranging from depression to neuroexcitation, sometimes accompanied by head pressing; incoordination and apparent blindness; and finally recumbency and death, often within 5 to 7 days of the onset of clinical signs.[1,3,37,40-42] The pathognomonic lesion of ELEM is *leukoencephalomalacia*, or degeneration of the white matter of the brain, which can be grossly visible involving one or both cerebral hemispheres or subtle and difficult to detect in stained sections of brain.[1,3,37,40-42] Hepatosis of varying severity can also be observed in cases of ELEM, and transient increases in the activities of enzymes specific for hepatocellular damage might be observed under those circumstances.[37,41]

The primary clinical abnormalities associated with FB_1 exposure in swine include porcine pulmonary edema (PPE), which is thought to be secondary to left-sided heart failure, and toxic insult to the liver.[1,3,8,37] However, unlike ELEM, it is difficult to pinpoint any consistent "threshold" dietary concentrations of FB_1 likely to cause heart failure and the resulting PPE in swine or, alternatively, histopathologic changes restricted to only the liver.[8,37,38,43,44] Some authors have suggested that FB_1 concentrations in contaminated corn or especially in contaminated corn screenings, ranging from the dietary action level of 10 ppm of FB_1 (see Table 54.8), should be considered actionable. Conversely, it is interesting to note that swine have been chronically exposed to dietary FB_1 concentrations in excess of 100 ppm, without the development of signs consistent with PPE and with hepatic fibrosis being the only observed histopathologic finding.[44] It appears that if PPE is going to develop, it will almost certainly do so within the first week of consumption of FB_1-contaminated diets.[37,43] This consistent observation suggests the role of various stressors, such as recent transport, excessive animal handling, and/or the presence of respiratory pathogens.[44,45]

The diagnosis of ELEM and PPE involves the observation of the appropriate, species-specific clinical syndromes, as well as the detection of sufficiently high enough concentrations of FB_1 in corn-based rations, especially those diets prepared using screenings from homegrown corn.[3,37] An elevated sphinganine–to–sphingosine ratio (SA/SO ratio) in the serum, urine, or tissues of animals suspected of being exposed to FB_1 can also be an accurate indication of recent (<7 days) exposure to FB_1.[3,8,37] As with DON and ZEA, treatment of fumonisin intoxication is limited to stabilization and supportive care, withdrawal from FB_1-contaminated rations, and, most importantly, prevention.[47] Unless absolutely unavoidable and only if there is concurrent and vigilant FB_1 surveillance to ensure that FB_1 concentrations remain below 1 ppm (see Table 54.8), horses should not be fed diets containing homegrown corn and/or, especially, corn screenings. A similar approach could also be used to prevent FB_1-related PPE and hepatic disease in swine.[3]

ERGOT ALKALOIDS. Ergot alkaloids (EAs) are a complex class of mycotoxins that play a role in several financially devastating livestock diseases (i.e., "fescue toxicosis," "perennial ryegrass staggers," and "ergotism").[1,46,47] However, unlike the other "major" mycotoxins discussed in this chapter, EAs are not found in corn and the most commonly occurring intoxications involving EAs are restricted to forages (i.e., fescue toxicosis and perennial ryegrass staggers). Unfortunately, the economic impact of these two mycotoxicoses is thought by many to be restricted to certain geographic regions.[46,47] Ergotism, on the other hand, which can be associated with the ingestion of contaminated forages or grains, has mistakenly been relegated to history because of its sporadic occurrence and is almost exclusively limited to livestock species.[46-48] Although there are several separate systems of nomenclature for EAs, an easy way to view these compounds is to divide them into clavine alkaloids, ergopeptine alkaloids (ergopeptines, ergopeptides, or EPs), and lysergic acid and its derivatives (LA+).[46,47] The LA+ have also been referred to as "ergoline alkaloids"; however, this terminology has the potential to be confused with the ergoline ring structure present in all EAs.[46-48,50,51] The most clinically relevant EAs to livestock species are EPs, which include ergovaline, ergotamine, ergocristine, ergosine, ergocryptine, and ergocornine, and LA+, such as lysergol, lysergic acid amide, and ergonovine or ergometrine (see Table 54.8).[46,47,51,52]

Most of the naturally occurring EAs have been isolated from fungal species within the *Epichlöe* and *Claviceps* genera.[46-51] *Epichlöe coenophiala* (formerly *Neotyphodium* or *Acremonium coenophialum* or *Epichlöe typhina*) is the endophyte that can grow, as part of a symbiotic grass-endophyte relationship, within the intercellular spaces of tall fescue grass, a long-lived perennial, cool-season grass most simply referred to as *Festuca arundinacea* or, more recently, *Lolium arundinaceum*. Toxigenic endophyte-infected (E+) tall fescue grass grows in humid temperate areas worldwide, including the upper southeastern and lower midwestern United States.[1,48-51] The EP present in highest concentrations in E+ tall fescue is ergovaline (≈0.2 to 0.6 ppm ergovaline in the vegetative parts of the plant and >1 ppm ergovaline in the seed heads), and LA+ are also present in this grass.[50,51-53] The livestock species most likely to consume E+ forages are ruminants, especially cattle, and horses. The primary sources of the EP compounds—ergotamine, ergocristine, ergosine, ergocornine, and ergocryptine—are the dark-colored

ergot bodies or sclerotia of *C. purpurea*. Ergot sclerotia, unlike endophytic mycelia, are externally visible and replace the individual seeds of many common pasture grasses, including E+ tall fescue and small cereal grains, such as oats, barley, wheat, and especially rye and triticale, but *not* corn.[47,48,50] The cool, wet springs in the northwestern United States, the northern Great Plains, and parts of western Canada facilitate the germination and growth of *C. purpurea*.[47,48,50] Those animal species likely to consume E+ tall fescue will also be exposed to the EAs produced by *C. purpurea*, if the E+ tall fescue or other nearby grasses are infected by this fungal species ("ergotized"). On the other hand, when small cereal grains are contaminated by ergot bodies, not only ruminants and horses but also swine, poultry, and even humans are likely to be exposed to EAs. The total concentration of EPs in *C. purpurea* sclerotia are extremely high, generally ranging from 2000 to 10,000 ppm, with LA+ also likely to be present.[47,48,50,54-57]

Although there is some overlap, the pathogenesis of clinical signs associated with dietary exposures to EAs can generally be explained in terms of vasoconstriction and/or hypoprolactinemia. Vasoconstriction involving interactions with dopaminergic, adrenergic, serotonergic, and glutamate receptors is responsible for many of the clinical signs observed in ruminants, especially cattle, and possibly in South American camelids.[46,47,51] Hypoprolactinemia-induced agalactia in late gestational mares is the most sensitive indicator of dietary exposure to EAs.[47,50,51] The stimulation of dopamine D_2 receptors by EAs dramatically reduces prolactin secretion by lactotropes in the adenohypophysis.[8,46-51,58] Abdominal fat necrosis in cattle is associated with chronic exposure to EAs in E+ tall fescue and arises from both vasoconstriction and the effects of hypoprolactinemia on lipid metabolism.[46,51] The higher the dietary concentrations of EAs, the more likely horses are to exhibit vasoconstrictive effects and the more likely agalactia will be observed in ruminants, in which a placental lactogen helps prevent abnormal lactation from the amounts of EAs often present in E+ tall fescue.[1,34,47,51] Swine exhibit vasoconstrictive effects and suboptimal reproductive performance, including agalactia, when exposed to sufficient concentrations of EAs.[1,47]

When trying to define levels of exposure to EAs, the most readily available data pertain to concentrations of EPs measured using HPLC. If animals ingest total dietary concentrations of EPs between 0.1 and 1.0 ppm, regardless of the sources, this is equivalent to low-level exposures involving only E+ tall fescue without seed heads, plus or minus other grasses.[50,51,53] Low to moderately high total dietary concentrations of EPs between 1 and 5 ppm correspond to what would be expected in pastures consisting entirely of E+ tall fescue in the seed head stage.[51,53] Moderately high dietary concentrations of total EP ranging between 5 and 10 ppm and very high dietary EP concentrations, exceeding 10 ppm, would involve contamination of foodstuffs by ergotized grains.[47,54-57,59]

Due to vasoconstriction, the toxicity of EAs can be extremely dependent on ambient weather conditions (see Table 54.8), especially with lower dietary concentrations of EAs (0.1 to 1.0 ppm total concentration of EP), which are typical of E+ tall fescue.[51] When it is hot, a syndrome referred to as "summer slump" or "summer syndrome" is observed in ruminants, in particular cattle, grazing E+ tall fescue.[1,51] This condition is thought to arise from the limited peripheral dissipation of heat associated with vasoconstriction.[1,3,48,49,51] Regardless of the source of toxins, EA-related "heat stress" is characterized by hyperthermia, rapid breathing, lethargy, an unthrifty appearance, and reductions in feed intake and average daily gain, as well as suboptimal male and female reproductive performance.[1,3,4,46-49,60-63] When it is colder, peripheral vasoconstriction in ruminants impairs the circulation to the distal extremities, resulting in cow discomfort, lameness, and eventually dry gangrene with sloughing of ear tips, switches, and hooves referred to as "fescue foot" or "gangrenous ergotism," depending on the source of the EAs.[1,3,8,46,47,51] Controlled experiments indicated that dietary concentrations of ergovaline between 0.4 and 0.8 ppm produced gangrenous effects in ruminants.[64] However, the ambient temperatures in those specific experiments were not below freezing, so, considering the impact of ambient temperature on the vasoconstrictive effects of EAs, lower ergovaline concentrations could be expected to possibly cause "fescue foot" at temperatures below freezing.[47,51,64] Given "average" ergovaline concentrations in E+ tall fescue and clinical signs in cattle eating other forages "free" of EAs, along with E+ tall fescue, it appears that adverse effects on production parameters can be observed in cattle, when total dietary concentrations of EP exceed 0.1 to 0.2 ppm, especially under extreme weather conditions.[47,51,53,54] In areas where cattle are commonly affected by fescue toxicosis, it stands to reason that suspected "fescue foot" or dry gangrene affecting the lower portions of the tail ("switch") observed during the late spring or early summer tends to be more likely associated with the higher concentrations of EPs in ergotized grains or grasses (especially ergotized E+ tall fescue) rather than the lower EP concentrations in tall fescue infected only with endophyte.[51,55-57,64]

Exposure to EAs during the last month of pregnancy is the most common cause of agalactia in mares.[47,50,51,58] Hypoprolactinemia, with minimal udder development, was consistently induced in pregnant ponies treated with a semisynthetic EP, and lactational abnormalities will invariably be the first signs observed in late gestational mares consuming EAs.[50,58] Anecdotal reports suggest that dietary concentrations of ergovaline as low as 0.05 ppm can cause agalactia in some susceptible late gestational mares.[50] Prolonged gestation, dystocia, and abortion, as well as fetal and placental abnormalities, are additional adverse effects observed in pregnant mares consuming higher dietary ergovaline concentrations (generally ≥0.1 ppm).[47,50,51] Pellets containing screenings of ergotized grains or grasses can also be associated with EA intoxication in pregnant mares.[50] The absence of normal changes in udder development ("waxing"), on which horse breeders and veterinarians are dependent to predict imminent parturition, results in unexpected and unsupervised parturition.[58]

The diagnosis of intoxications involving EAs requires the observation of appropriate clinical signs, identification of a source of EAs, and determination of EA concentrations in that source, as well as in the total diet.[1,3,46] The accurate interpretation of those analytic results necessitates a thorough understanding of the analyses being performed and the pathogenesis of EA intoxications in different species.[1,46] Using reproductive performance as an example of a monitored parameter, management factors and the stressors shown in Fig. 54.4, particularly those related to environment, should be considered when interpreting analytic results.[3]

The basic principles for the treatment and prevention of intoxications related to EA are no different than those outlined for other mycotoxicoses (i.e., removal from the source, stabilization, and supportive care). Incorporation of pasture management practices, including frequent mowing with removal of seed heads, careful use of nitrogen-containing fertilizers, dilution with legumes, production of hay, and pasture replacement with genetically modified varieties of continental tall fescue free from EAs, can provide added benefits to cattle producers and horse breeders living in enzootic areas.[47,51] Drying and ammoniation of E+ tall fescue hay, manipulation of stocking rates, physical manipulation of ergotized grasses during the haying process, use of stockpiled E+ tall fescue during the fall, and copper supplementation can also help to further minimize EA-induced effects and maximize performance parameters in cattle.[3,48,65,66] Veterinarians should also be aware of "fescue-associated edema syndrome" recently observed in horses consuming a genetically modified Mediterranean tall fescue in Australia.[67]

VetBooks.ir

Provision of ample shade (also, possibly pond access) and plenty of potable water to cattle consuming low concentrations of EAs during the summer can help prevent "summer slump" or clinical signs resembling this condition, when the source of EA is not E+ tall fescue.[47,49] It is also becoming increasingly apparent that genetic testing has the potential to be used as a management tool in the prevention of fescue toxicosis. A single nucleotide polymorphism (SNP) in the dopamine D_2 receptor gene has recently shown promise as a biomarker for resistance to fescue toxicosis in Angus-based cattle, and it is likely to be commercially available in the very near future.[68]

Knowledge of mare breeding dates, confirmation of pregnancy, and withdrawal from any dietary sources of EAs at least 30 days before the anticipated foaling date are critical for the prevention of agalactia in pregnant mares.[3,47,49-51] Frequent evaluation of mammary development and, if deemed necessary, daily administration of the dopamine D_2 antagonist domperidone (1.1 mg/kg body weight; watch for leaking colostrum) are additional ways to facilitate adequate lactation and prevent failure of passive transfer in foals.[47,49-51] Domperidone can also be used to mitigate prolonged gestation, along with the attendant risk of dystocia.[47,50,51]

Grain or grass screenings or "fines," in general, and/or any grains containing visible ergot bodies should *not* be incorporated into feeds intended for consumption by pregnant mares or cattle maintained under extreme weather conditions.[47,50,51] The only current FDA action level pertaining to EAs is expressed in terms of the percentage of ergot bodies (see Table 54.8) rather than concentrations of EPs.[9] On the basis of the average EP content of ergot sclerotia in barley, 0.1% ergot bodies translates to approximately 2.5 ppm, which, depending on the proportion of the diet represented by this ergotized grain, may not be very protective in many clinical instances.[47,53-57]

Snake Bites and Blister Beetle

C. Langdon Fielding

Most snakebites reported in horses and other large animal species in North America are associated with rattlesnakes, which belong to a group of venomous snakes, the pit vipers.[1-5] Other recent retrospective studies describing snakebites in horses include reports of elapid snake envenomation in Australia and viperid envenomation in Israel.[6-7]

Rattlesnake Envenomation

There are approximately 30 different species of rattlesnakes found globally, and their venom contains various enzymes, proteins, and peptides. Mortality rates for horses envenomated by rattlesnakes may be as high as 10% to 20%, but this depends on the severity of the bite and the response to treatment.[1-3] Rattlesnake bites typically occur during the spring and summer and should be suspected only in regions where the snakes are known to exist.[2]

The muzzle is the most commonly described location for rattlesnake bites in horses, and rapid, severe swelling is common (Fig. 54.5).[2] As the nostrils become swollen and the airways narrow, respiratory distress is common. In more severe cases, swelling may continue to spread up the head and down the neck. Epistaxis is observed in many horses following rattlesnake bite, and bleeding from the ocular tissues occurs as an effect of the venom progress (Fig. 54.6). Arrhythmias have been described in horses after rattlesnake envenomation, both acutely and chronically.[1,3,4] Diagnosis of rattlesnake bite is based on the characteristic swelling in a horse from an appropriate region during the typical time of year (spring and summer). The presence of fang marks, which are difficult to find in some cases, supports the diagnosis and helps to differentiate from other causes of acute head swelling. An ELISA to detect rattlesnake venom in the bite tissue and the urine of horses has been described.[8]

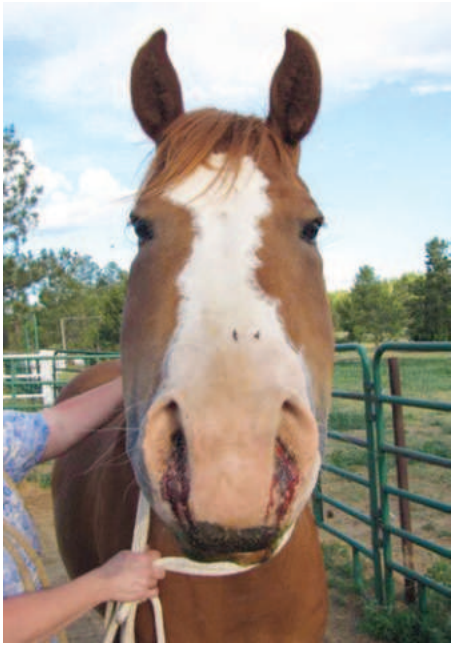

FIG. 54.6 A horse with bilateral epistaxis and swollen muzzle due to rattlesnake bite. *(Courtesy Dr. Skip Aaroe, Trinidad, Colo.)*

Thrombocytopenia and prolongation of clotting times are described hematologic abnormalities but have not been consistent across various studies in horses.[1-3] Anemia can also be observed and is suspected to be due to both hemolysis and blood loss. Increases in cardiac troponin I (cTnI) have been described in a recent study, confirming myocardial damage in horses with envenomation.[1]

Treatment of horses with rattlesnake envenomation largely depends on the severity of the clinical signs, with many animals requiring only careful monitoring for respiratory distress. Maintenance of a patent airway is the single most important aspect of treatment, and a tracheostomy may be necessary in up to 50% of animals presented for veterinary care.[2] A nasal stent (plastic tubing placed up one or both nostrils) can be used but may be challenging to place and maintain in a distressed horse experiencing pain.

VetBooks.ir

Antivenin has been described for the treatment of horses with rattlesnake envenomation.[2] Although clinical trials in other species have suggested efficacy, antivenin use in horses has only been retrospectively reported.[9,10] Currently, there are three USDA-approved veterinary antivenoms, but only one (Rattler Antivenin [Mg Biologics, Ames, Iowa]) is labeled for use in horses. Another product labeled for use in dogs (Antivenin, a polyvalent antivenin marketed by Boehringer Ingelheim Vetmedica, Inc., St. Joseph, Mo. [formerly by Fort Dodge Animal Health, Fort Dodge, Iowa]) was rehydrated according to the label directions, diluted in saline, and administered slowly to horses over 30 minutes.[2] Horses typically required 1 to 2 vials, and beneficial effects were anecdotally observed even when given 24 hours after envenomation.[2] Antivenin polyvalent crotalidae (VenomVet [MT Venom, LLC, Canoga Park, Calif.]) is approved for use in dogs, but use in horses has not been reported. A polyvalent antivenin (Crofab [BTG International (formerly Protherics), West Conshohocken, Pa.]) is labelled for use in humans, but its use has also not been reported in horses.[9]

Wound care, particularly cleaning of the bite site, and tetanus prophylaxis are important components of treatment. Intravenous fluids are often necessary if the horse is unable to drink, but catheter placement should be performed carefully because affected animals may be prone to bleeding. Many horses may not be able to eat well immediately following a bite, but soaked pellets or mashes can often be hand fed as the swelling subsides. The use of broad-spectrum antibiotics is controversial and not recommended in other species but has been advocated by some authors due to concerns of aspiration pneumonia and infection at the bite site. Nonsteroidal antiinflammatory drugs (NSAIDs) are frequently administered to horses and may help to decrease pain and inflammation. There is no evidence to support the use of corticosteroids or antihistamines for rattlesnake envenomation.

Elapid Envenomation

A large case series of elapid snake envenomation in horses was reported from Australia, where elapids represent the most common snake envenomations.[6] Envenomations had a seasonal pattern, with the spring and summer months most common. Neuromuscular weakness was the most commonly described clinical sign, with rhabdomyolysis and hemolysis occurring less frequently (Fig. 54.7). Increased creatine kinase (CK) activity, cTnI, and coagulation times were present in some horses but inconsistent in others. Treatment with polyvalent elapid snake antivenom was common, and the overall survival rate was 86%.

FIG. 54.7 A 3-year-old Standardbred gelding with profound generalized neuromuscular weakness and mental obtundation (note inability to retract the tongue). The horse returned to normal strength within 24 hours after administration of multivalent elapid antivenom. *(Courtesy Nicholas Bamford, BVSc(Hons), PhD, DACVIM, Melbourne Veterinary School, Faculty of Veterinary & Agricultural Sciences, The University of Melbourne, Australia.)*

Daboia (Vipera) palaestinae Envenomation

A large cases series of *Daboia palaestinae* envenomation in horses was reported from Israel, where most envenomations are caused by this snake.[7] A seasonal pattern also existed in this study. Most horses were bitten on the head, and local swelling was common. Other frequently reported signs included tachycardia and increased respiratory effort. Laboratory abnormalities included increased CK activity, hypoproteinemia, and hyperphosphatemia. Many of the horses in the study were treated with antivenom for *Vipera palaestinae*.

Blister Beetle

Cantharidin toxicosis in horses occurs following ingestion of alfalfa hay that is contaminated with blister beetles.[11] Affected animals are typically found in the midwestern United States due to the swarming of beetles in this region and subsequent incorporation into cut hay. In one study, cases were most likely to occur during the late summer and early fall.[12] Cantharidin causes irritation to the mucous membranes and interferes with a family of enzymes called the phosphoprotein phosphatases.[13]

Horses with cantharidin toxicosis develop signs of GI disease (colic, diarrhea), urinary system disease (renal failures, cystitis), and cardiac disease (arrhythmias).[11,14] Affected horses may also exhibit a stiff gait.[14] With increased severity, horses may exhibit synchronous diaphragmatic flutter, hypovolemic shock, and death.[11,14] Laboratory data reflect abnormal renal function (azotemia), as well as hypocalcemia, hypomagnesemia, and hypoproteinemia.[11] Myocardial damage may be reflected in changes in myocardial enzymes; however, this has not been evaluated in horses.

Presumptive diagnosis of cantharidin toxicosis in horses can be made following the identification of the beetles present in ingested hay. Testing of stomach contents and urine for cantharidin levels has been suggested as a common means for definitive diagnosis.[12,15] It has been shown that 450 µg/kg body weight of ingested cantharadin can cause clinical signs and even mortality.[14]

Treatment of cantharidin toxicosis is primarily supportive. Administration of activated charcoal to animals with recent exposure may be appropriate. Intravenous fluid therapy is important to correct hypovolemia and dehydration. If renal failure is present, therapy should be directed toward maintaining urine production. A balanced isotonic intravenous fluid can be used for resuscitation. Electrolyte and acid-base abnormalities should be corrected using additional supplements to intravenous fluids (e.g., calcium gluconate, magnesium sulfate). GI protectants are indicated, as are pain medications to provide relief for the ulceration of the GI and urinary systems. Hay that is suspected of contamination should be removed and not fed to animals.

Metals and Other Inorganic Compounds

Robert H. Poppenga

Metals are intrinsic to nature and ubiquitous in the environment of animals. Although the form or valence of any given metal can be changed, metals themselves cannot be destroyed.[1] Mining, industrial, and reclamation activities of humans have resulted in the large-scale redistribution of metals in the environment.

Metals can be categorized as those that play an essential role in biological processes (e.g., those that are nutritionally

VetBooks.ir

necessary, such as iron, copper, zinc, and selenium, among others) and those that do not (e.g., lead, mercury). It is important to point out that disease syndromes caused by deficiencies of nutritionally important metals are different in pathogenesis and clinical manifestations than those caused by exposure to excessive amounts of the same metal.

The toxicity of metals is often harder to define than that of other toxicants. One reason for this is that the form of a metal plays a critical role in its bioavailability.[1] For example, elemental mercury, when ingested, is essentially unavailable for systemic absorption. In contrast, organic forms of mercury such as methyl mercury are highly bioavailable. The interaction of metals also plays an important role in the determination of toxicity. For example, high dietary calcium can decrease absorption of lead, since lead uses calcium transport mechanisms for its uptake into the body. Other factors that can influence toxicity include animal age, gender, and the capacity of an individual for biotransformation of a metal.

The distribution and accumulation of metals in certain tissues in the body can mitigate damage. Lead can accumulate in bone where it is not available to affect target tissues such as those in the CNS. Also, metals can be sequestered in the body by cystine-rich proteins called metallothioneins that are highly inducible by metals and essential for metal homeostasis and detoxification.[1] The interaction of metals with sulfhydryl-containing groups like cystine is the basis for the efficacy of metal chelators, such as succimer or dimercaprol, which contain numerous sulfhydryl groups.

Arsenic

Historically, various forms of arsenic have been used as herbicides, insecticides, wood preservatives, growth promotants, and therapeutic agents.[2] Arsenic is found in various valences and forms. There are trivalent and pentavalent inorganic and organic forms. Pentavalent (arsenate, H_3AsO_4) and trivalent (arsenite, H_3AsO_3) forms of arsenic include sodium, potassium, and calcium salts. Paris green (copper acetoarsenite) and lead arsenate have been used as insecticides, and trivalent inorganic arsenic forms such as monosodium methanearsonate (MSMA) and disodium methanearsonate (DMSA) are used as herbicides. Historically, pentavalent organic arsenicals such as sodium arsanilate and 3-nitro-4-hydroxyphenylarsonic acid were used as feed additives for some livestock species but have been withdrawn by the FDA due to human health concerns (http://www.foodsafetynews.com/2015/04/fda-to-withdraw-approval-for-arsenic-based-drug-used-in-poultry/#.WvC5QX8h3RY). In addition, the use of arsenic as a wood preservative in the form of chromated copper arsenate (CCA) has been banned for residential use by the U.S. Environmental Protection Agency (EPA), although it is still permitted for use in commercial, industrial, and some agricultural settings.

As for most metals, the bioavailability of arsenic is variable and depends on its form (organic versus inorganic, solution versus powder). The arsenic in solutions of organic arsenicals is almost completely absorbed from the GI tract.[3-5] Alternatively, arsenic compounds of low solubility such as arsenic trioxide are absorbed less efficiently. Once absorbed arsenic is widely distributed in the body and reaches its highest concentrations in the liver, spleen, kidney, lungs, and GI tract. Persistent residues are found in keratinized tissues such as skin, hair, and nails. Clearance of arsenic from the blood is multiphasic, with the first phase having a 1- to 2-hour half-life.[4,5] Forty to seventy percent of an absorbed dose is eliminated via the urine within the first 48 hours. To a large extent, inorganic arsenic is metabolized in the liver by the addition of methyl groups prior to its elimination.

The toxicity of arsenic is variable and depends on its form, purity, solubility, particle size, and valence; the species exposed; and the condition of the exposed individual.[4,5] For example, trivalent arsenicals are 4 to 10 times more toxic than pentavalent arsenicals. Acute arsenite toxicity ranges from 1 to 25 mg/kg body weight (BW), whereas toxicity of arsenates is 30 to 100 mg/kg BW. Methanearsonate herbicides are toxic at 10 to 25 mg/kg BW over several days. Weak and debilitated animals are more susceptible to intoxication.[4,5]

The mechanism of toxic action of arsenic also depends on its form.[1] Trivalent inorganic arsenicals (i.e., arsenites) inhibit cellular respiration. They bind to sulfhydryl compounds, especially lipoic acid and α-keto oxidases. Lipoic acid, a tissue respiratory enzyme cofactor, plays an essential role in the tricarboxylic acid (TCA) cycle. Tissues with high oxidative energy requirements (e.g., actively dividing cells such as those of the intestinal epithelium, kidney, liver, skin, and lungs) are more severely affected. Trivalent arsenic affects capillary integrity by an unknown mechanism. The GI tract is most affected; capillary dilatation is followed by transudation of plasma into the GI tract, resulting in submucosal congestion and edema. In contrast, pentavalent inorganic arsenicals (i.e., arsenates) appear to substitute for phosphate in oxidative phosphorylation. Uncoupling of oxidative phosphorylation produces a cellular energy deficit. Elevated body temperature is not characteristic of pentavalent arsenical poisoning as it is in poisonings by other oxidative uncouplers (e.g., nitrophenols).

Organic arsenicals also vary in terms of their mechanism of toxic action. Trivalent organic arsenicals appear to have a mechanism of toxic action similar to that of the trivalent inorganic arsenicals. However, pentavalent organic arsenicals (e.g, those previously used as livestock feed additives) act on nerves by an unknown mechanism. They produce demyelination and eventual axonal degeneration, leading some researchers to believe that pentavalent organic arsenicals interfere with the B vitamins essential for maintenance of nervous tissue. Alternatively, neurotoxicity may be related to effects on the cytoskeleton of axons.[6]

The clinical signs and lesions are similar for the trivalent inorganic arsenicals, whereas the organic pentavalent compounds used as feed additives cause peripheral nerve degeneration in monogastric animals. The inorganic arsenic compounds (arsenites, arsenates) cause dosage-related peracute, acute, or subacute toxicosis with cardiovascular collapse, sometimes presenting as sudden death.[7,8] Acute poisoning occurs 3 to 12 hours after ingestion. Clinical signs include ataxia, diarrhea with or without blood, recumbency, and death, with the most prominent clinical sign in acute and subacute cases being diarrhea that is frequently hemorrhagic.[7,9] Other clinical signs include anorexia, dehydration, weakness, colic, and agalactia. No specific abnormalities are noted from CBC or serum chemistry tests. Because arsenic can damage multiple organs, changes associated with liver or kidney dysfunction can be present if the animal survives for several days. Protein, red blood cells, and casts can be noted in the urine. Clinical signs associated with organic pentavalent arsenical intoxication include ataxia, incoordination, torticollis, blindness, paralysis, and recumbency.[2]

For trivalent arsenicals, consistent necropsy lesions are present in the GI tract and may be hemorrhagic, edematous, necrotic, or eroded. The lesions may be confined to one region or spread throughout the GI tract.[3,7-9] In ruminants, the abomasum is often the most severely affected area. The gut lumen is sometimes filled with necrotic material from the sloughed lining of the GI tract. Other lesions include pulmonary edema and hemorrhage of the cardiac serosa and peritoneum.[4,5] Histopathologic examinations may reveal multifocal necrosis of the liver and proximal tubules of the kidney. Renal lesions are likely in animals that survive a subacute toxicosis. Peracute cases often have no abnormal gross findings. Pentavalent organic arsenicals cause both central and peripheral nerve lesions, including mild edema and Wallerian degeneration in optic and peripheral nerves.

VetBooks.ir

An antemortem diagnosis relies on a history of ingestion of arsenic, the occurrence of consistent clinical signs, and the detection of toxic concentrations of arsenic in GI contents, whole blood, or urine. Suspect sources of exposure can also be tested to confirm the presence of arsenic. The rapid elimination of the metal from the body makes the collection of appropriate samples as early as possible an important consideration. Most veterinary diagnostic laboratories can test for arsenic. It is important to point out that low-level concentrations of arsenic in blood or urine are not unusual and do not indicate arsenic intoxication. The interpretation of a given concentration of arsenic depends on an evaluation of the entire case and the timing of sample collection in relation to exposure. Postmortem analysis of stomach contents, liver, kidney, or urine can confirm exposure. Again, the significance of detected concentrations, especially relatively low concentrations, needs to be interpreted in conjunction with other case variables. Postmortem lesions may be absent in cases of rapid death. Otherwise, severe GI lesions consisting of reddening of the gastric mucosa and proximal small intestine, watery GI contents, and blood and sloughed mucosa in the feces are commonly noted with trivalent arsenicals. Detection of compatible central and peripheral nervous system lesions is important to demonstrate after intoxication by pentavalent organic arsenicals. Other organ lesions are not specific for arsenic.

The rapid onset of clinical signs often precludes initiating decontamination procedures. Activated charcoal is unlikely to adsorb significant amounts of arsenic, although with significant exposures its administration is recommended.[10] Symptomatic animals need to be stabilized first. This might entail treatment for circulatory shock and hypotension and maintenance of body temperature. Renal and liver failure and electrolyte abnormalities may need to be addressed. Glucose and glycogen stores should be maintained parenterally with dextrose or parenteral alimentation solutions.[10] Chelation therapy is typically indicated. Historically, dimercaprol (BAL or British anti-Lewisite) was the recommended chelator. It is a sulfhydryl-containing chelator that binds to arsenic and allows the arsenic-chelator complex to be eliminated. An alternative chelator, succimer, has several theoretical advantages over dimercaprol, including less toxicity and an oral (versus injectable) dosing form. It has been theorized that because succimer is hydrophilic, it may not remove arsenic that has escaped the extracelluar space as efficiently as dimercaprol does.[4,5] However, available studies suggest that succimer is equal to or even superior to dimercaprol in increasing arsenic elimination.[10] If dimercaprol is used, monitoring for adverse reactions, including pain at the injection site, GI signs, tremors, and seizures, is required. Succimer is likely cost prohibitive for most large animals. D-Penicillamine, another arsenic chelator used in humans, may be too expensive in livestock as well.[11,12] Ethylenediaminetetraacetic acid (EDTA) is not effective for arsenic toxicosis.[13]

Although the administration of B-complex vitamins and amino acids has been recommended, the evidence for their efficacy is lacking. Parenteral antibiotic administration might be considered to prevent secondary bacterial infections of the GI tract. The use of GI protectants may also be indicated. Recovering animals should be fed a high-quality diet in small portions that can be increased as time and circumstances permit. The prognosis in symptomatic animals is always guarded, particularly in the absence of early intervention and intensive monitoring and treatment.

Copper

Sources of copper used in livestock are widely available as sulfates, chlorides, and oxides. Concentrates of copper are found in feed premixes, fertilizers, copper footbaths, aquacides, and fungicides (Bordeaux mixture). Sheep are very susceptible to poisoning by chronic copper accumulation in feeds formulated with excessive copper and inadequate molybdenum and sulfur. Absorption in monogastric and young ruminants with a nonfunctional rumen is 75% but only 1% to 10% in cattle and sheep with normal rumen function.[14] Dietary molybdenum at 2 to 5 mg/kg diet and dietary sulfur at 0.4% of diet substantially reduce ruminant copper accumulation. High dietary zinc (>200 mg/kg diet) and iron also limit copper absorption in ruminants.[14]

Acute copper toxicosis has occurred in cattle given injections of copper disodium edetate as a therapy for copper deficiency.[15] Sheep are often poisoned when fed rations intended for cattle or horses,[16] and llamas have developed copper toxicosis when fed cattle feed.[17] Sheep have developed toxicosis on pastures fertilized with manure from swine or poultry fed copper.[18] Cattle develop copper toxicosis when supplemented with excessive copper,[19] when fields are contaminated by copper smelting,[18,20,21] or when they are fed litter from chickens supplemented with copper.[22] Excessive copper in calf milk replacers has been a source of toxicosis in both calves[23,24] and goat kids.[25] Dairy goats were intoxicated as a result of chronic feeding of a mineral mix containing high concentrations of copper.[26]

Copper poisoning can be acute or chronic. Acute toxicosis results from ingestion or administration of soluble copper salts in one of the sources listed earlier, usually from one to several large doses of copper regardless of sulfur or molybdenum status. Chronic copper toxicosis can be categorized as simple, hepatogenous, or phytogenous. Simple chronic toxicosis is caused by ingestion of excessive copper relative to molybdenum and/or sulfate in the diet. Sheep fed diets with a copper–to–molybdenum ratio greater than 10:1 are at high risk for developing clinical copper poisoning. Molybdenum and sulfate bind to dietary copper in the rumen and also form a copper-molybdenum complex post absorption, which decreases absorption, retention (through increased bile and urinary excretion), and eventual accumulation of copper in the liver.[27] For cattle, dietary copper–to–molybdenum ratios above approximately 40:1 allow chronic copper accumulation, and most clinical cases in cattle involve dietary copper in excess of 40 mg/kg diet. Hepatogenous copper toxicosis occurs when hepatotoxic plants such as *Senecio* species or *Heliotropium europaeum* damage the liver and cause copper retention.[27] Phytogenous copper poisoning occurs from prolonged grazing on plants (e.g., subterranean clover *[Trifolium subterraneum]*) with elevated copper/molybdenum ratios. In general, mature pastures have lower copper/molybdenum ratios than young, rapidly growing plants.[14] Breed differences in accumulation of copper in liver have been noted for both sheep and cattle.[27,28]

The pathogenesis of copper toxicosis involves absorption, binding to albumin and transcuprein proteins, and transport to the liver, where it binds with ceruloplasmin, a hepatic metalloprotein. The concentration of copper in hepatic lysosomes increases over several weeks to months, leading to excess accumulation. When this occurs, there is necrosis of liver parenchymal cells and swelling of Kupffer cells, followed by sudden spontaneous or stress-related release of copper into the bloodstream.[14,27,29,30] This acute phase includes reduced blood glutathione, increased erythrocyte fragility, hemoglobin oxidation, and methemoglobin formation. Resulting intravascular hemolysis leads to anemia, icterus, and hemoglobinuric nephrosis.

The clinical signs of copper poisoning are most prominent in sheep and include an abrupt onset of depression, anorexia, and weakness. Feces may be watery, dark, or blood tinged, especially in cattle. Evidence of a hemolytic crisis is apparent, and signs include anemia, methemoglobinemia, and hemoglobinuria. Mucous membranes are icteric, muddy brown, or a combination of both.[27,30-33] Cattle with copper toxicosis after injection of copper disodium edetate have dyspnea, head pressing, ataxia, and circling.[14]

VetBooks.ir

Antemortem, the diagnosis of chronic copper toxicosis relies on measuring copper levels in serum as well as measuring serum hepatic enzymes.[19,27,30] However, serum copper is not elevated until just before or during the hemolytic crisis. Therefore animals with toxic copper levels in the liver may have normal or low serum copper values, so serum copper levels alone are not useful for judging copper status. For sheep and cattle there is typically a substantial increase in serum aspartate amino transferase (AST) and gamma-glutamyl transpeptidase (GGT) released from damaged liver before the hemolytic crisis occurs and while the animals are still clinically normal.[14] Controlled studies of serum activities for AST and GGT have been shown to be good predictive indicators of hepatic copper accumulation in sheep or cattle that are clinically normal.[34]

Postmortem copper should be measured in both fresh liver and kidney. After the liver has released copper into the bloodstream, liver copper values may fall into a nontoxic range, but kidney copper values will remain in a toxic diagnostic range. Acute toxicosis from copper disodium edetate does not consistently cause elevated copper levels in the liver or kidney.[15]

The diagnosis should correlate with histopathologic lesions in formalin-fixed liver and kidney.[27,30] Gross lesions are present in the liver, kidneys, and spleen. The liver is yellow and friable and may be larger or smaller than normal. Hemoglobin casts in tubules cause the kidneys to appear dark red or blue-black. The spleen is enlarged and congested. Histopathologic changes in the liver include centrilobular necrosis, pigment-laden Kupffer cells, hepatic fibrosis, and bile duct hyperplasia.[19,27,30] Granules in the liver are positive for copper when stained with copper-specific rhodamine or rubeanic acid.[23]

Several treatment options are currently available but are often unsuccessful once an animal is in acute hemolytic crisis. Ammonium molybdate (50 to 500 mg PO once daily) and sodium thiosulfate (300 to 1000 mg PO once daily) for 3 weeks have been used for many years as a treatment.[14,27,30] Liver copper levels begin to decrease within 4 days of beginning therapy.[27] An unapproved treatment is ammonium tetrathiomolybdate at 3.4 mg/kg subcutaneously (SC) on alternate days for three treatments.[35] Either route of administration significantly decreases liver copper levels within 6 days. This change is accompanied by an increase of copper in the blood, bile, feces, and urine.[27] Most of this copper is bound with tetrathiomolybdate and albumin in an inert complex.[27,30] Xylazine given with tetrathiomolybdate is reported to double the amount of copper excreted in the urine as compared with tetrathiomolybdate alone.[36] D-Penicillamine (26 mg/kg PO twice daily for 6 days) results in a tenfold to twentyfold increase in urinary copper excretion in sheep,[37] but this option is expensive and may not be cost-effective for many livestock. Animals in the acute hemolytic phase of poisoning should be treated as needed for serious hemolytic anemia and potential methemoglobinemia from copper's oxidant effect.

Iodine

Iodine is used to prevent some infectious diseases and as a treatment for foot rot. Common sources of iodine include potassium iodide, sodium iodide, kelp, Chile saltpeter nitrate deposits, and ethylenediamine dihydriodide (EDDI). Oilseed proteins or their concentrates incorporated into foodstuffs contain 0.1 to 0.3 mg iodine/kg. Estimated iodine requirements are beef cattle, 0.5 mg/kg diet; dairy cattle (lactating), 0.8 to 1.0 mg/kg diet; sheep, 0.2 to 0.5 mg/kg diet; swine, 0.3 to 2.0 mg/kg diet; and horses, 0.1 to 0.2 mg/kg diet.[38] EDDI has been incorporated into animal feed and drug products for many years for both nutritional and therapeutic purposes. It has been formulated in salt-mineral mixtures and in liquids and powders for adding to feed or drinking water. EDDI has been used as a supplemental source of iodine and is considered generally recognized as safe (GRAS) for nutritional purposes when used at levels consistent with good feeding practices. EDDI products also have been marketed with claims for the treatment and prevention of certain diseases in several animal species but primarily for "foot rot," soft tissue "lumpy jaw," and "wooden tongue" in cattle. However, all such EDDI products (including feeds) bearing therapeutic claims now are considered adulterated (https://www.fda.gov/ICECI/ComplianceManuals/CompliancePolicyGuidanceManual/ucm074677.htm).

Oversupplementation can result in toxicosis. Iodine concentrations greater than 50 mg/kg diet for calves caused reduced growth rate and greater than 100 mg/kg diet resulted in coughing and nasal discharge, as well as reduced hemoglobin and serum calcium concentrations. Previous use of EDDI as an expectorant in feedlot cattle (400 to 500 mg/head/day) or swine (250 to 500 mg/head/day) sometimes resulted in signs of excessive expectorant activity.[39] Elevated iodine intake (50 mg/day) in dairy cows will raise milk iodine to concentrations that may be unacceptable for public health reasons. One report of abortions in dairy cows was associated with excessive iodine consumption. Maximum tolerable levels based on available literature are cattle, 50 mg/kg diet; sheep, 50 mg/kg diet; and swine, 400 mg/kg diet.[40]

The clinical signs of toxicosis include a nonproductive cough, lacrimation, serous nasal discharge, scaly hair coats, and hyperthermia. Other reported signs include decreased milk production, decreased gain and feed conversion, exophthalmia, nervousness, dermatitis, alopecia, and tachycardia. Young animals appear more susceptible than other age groups. Adults may not develop toxicosis unless stress, disease, or nutritional imbalances are also present.[41] Excess supplementation in mares is associated with goiter in foals.

A diagnosis can be confirmed only with serum or milk analysis. Iodine concentrations in milk are directly related to levels of iodine in the diet.[41] Elevated serum iodine concentrations (1600 μg/mL) may be associated with mild clinical signs. Nonlactating cows have higher serum iodine concentrations than lactating cows that are eliminating iodine in milk.

Treatment is restricted to removal of the dietary source of iodine. Clinical signs associated with the respiratory tract disappear 1 to 4 weeks after the iodine source is removed.[37]

Iron

There are a number of iron salts and formulations. Some insoluble forms of iron such as elemental iron and ferric oxide (i.e., rust) are not hazardous when ingested due to low bioavailability. One newer source of iron, a chelated iron called iron phosphate EDTA, is found in some slug and snail baits.

The kinetics of iron absorption are complex. Iron body stores are regulated at the site of absorption from the GI tract because the body is not able to actively excrete iron. From the GI tract, iron must first enter duodenal mucosal cells, possibly by a carrier-mediated process. Next the iron either is lost as the mucosal cells slough into the GI lumen or is bound to ferritin for later transfer to transferrin, a serum iron-binding transport protein. Serum transferrin concentrations greatly exceed the amounts necessary to bind iron under normal physiologic processes (normal binding capacity is three to four times the serum iron concentration). However, in intoxications, the binding capacity is exceeded, allowing free iron to cause cell damage.[42]

Free iron can cause direct or indirect tissue and cell damage. Iron acts as a free radical and can also produce free radicals. Free radicals have one or more unpaired electrons, which can initiate lipid peroxidation resulting in cell membrane damage. Tissues that have first contact with free iron are primarily affected, although all tissues are susceptible to damage if exposed. The primary targets are the GI, cardiovascular, and

hepatic tissues. Iron also damages mitochondria, leading to loss of oxidative metabolism.[42] Iron may have a direct negative inotropic effect on the myocardium.[43]

Toxicosis from iron overload has occurred in neonatal foals (normally born with high iron absorption and high serum iron levels) and adult horses given ferrous fumarate orally; calves injected with ferrous gluconate and ferric ammonium citrate; neonatal swine dosed with parenteral iron; pigs born from vitamin E– and selenium-deficient sows; and young bulls injected with ferric ammonium citrate.[44-48]

The clinical signs of iron toxicosis in neonatal foals include depression, icterus, head pressing, and disorientation.[44] Adult horses develop anorexia, icterus, and sometimes petechial hemorrhages.[49] Calves with iron toxicosis exhibit trembling, vocalizing, bruxism, colic, and convulsions.[45]

Clinicopathologic findings are related to cholestatic liver failure. Animals often have elevated serum levels of γ-glutamyl transferase, alkaline phosphatase (ALP), bile acids, and unconjugated bilirubin. Coagulopathies include abnormal coagulation profiles, thrombocytopenia, and elevated fibrinogen.[44,45,49]

Gross postmortem lesions are variable. The liver is discolored, pale tan, or mottled red-brown, and most are friable and swollen or shrunken. Hemorrhages may be present in the gastric mucosa, intestines, and urinary bladder. Microscopic lesions include bile ductile proliferation, periportal necrosis, lobular necrosis, and fibrosis.[44-47,49] Lesions in the liver tend to have a rather distinct periportal distribution since periportal regions of the liver are the first to be exposed to excessive free iron absorbed from the GI tract.

Iron toxicosis is diagnosed based on clinical signs and a history of recent iron exposure. When serum iron and total iron-binding capacity (TIBC) are evaluated, serum iron often exceeds TIBC. In dead animals, the liver iron is elevated to varying degrees in different species; iron may be above normal if the animal had hemolysis or blood congestion occurred within the liver. Although tissue iron concentrations may help support a diagnosis of iron intoxication, it is common, particularly in horses, to detect elevated liver iron concentrations unrelated to overexposure to iron. Treatment of iron toxicosis is usually limited to supportive care. Patient stabilization is a priority in symptomatic animals. Treating circulatory shock and metabolic acidosis is critical. Sucralfate might be useful to provide some GI protection. Repeated phlebotomy or chelation therapy with deferoxamine (40 mg/kg IM q4-8h) has been used to treat iron overload in humans and small animals.[48] It combines with iron to form ferrioxamine, which is subsequently eliminated via the kidneys.[43] Deferoxamine given intravenously too rapidly can cause cardiac arrhythmias; as well, it is a teratogen and should be used in pregnant animals only if the potential benefits outweigh the risks. The success rate and cost of these treatments in large animals has not been well documented. The prognosis is variable depending on the dosage ingested and availability of appropriate monitoring.

Mercury

Mercury toxicosis has been caused by application or ingestion of an inorganic mercurial product used as a counterirritant or from ingestion of seeds treated with organic mercurial fungicides, which are no longer used in most of the world.[50] If blistering agents are used with dimethyl sulfoxide (DMSO), mercury absorption is enhanced.[51,52] The kidney is the primary target and storage organ of inorganic mercury, but mercury also localizes in the GI mucosa and is eventually excreted by the kidneys.[50-53] Organomercurials such as methyl mercury are lipophilic and can be found in adipose and brain tissue.

Mercury causes two clinical syndromes depending on its form: acute poisoning from inorganic mercury salts and chronic neurologic damage from organomercurials. Acute inorganic mercury causes ulceration of the mouth, the esophagus, and the remainder of the GI tract followed by diarrhea and anorexia. If the animal survives, acute nephrosis develops. Anorexia, gastroenteritis, weight loss, nephritis, and alopecia occur in animals exposed to chronic low doses of inorganic mercury.[52] Organic mercury fungicides and methyl mercury cause brain damage, blindness, incoordination, and proprioceptive deficits. Most neurologic signs are long term or permanent.

The diagnosis of mercury salt toxicosis is supported by elevated serum creatinine and BUN levels, as well as proteinuria, glucosuria, and isosthenuria. Necropsy findings may include an ulcerated, necrotic, edematous, and hemorrhagic GI tract and pale, swollen kidneys. Confirmatory mercury concentrations may be found in liver, kidney, brain, whole blood, and urine.[50]

Therapy should include detoxification (oral sodium thiosulfate) for recent exposure and administration of an appropriate chelator. Sodium thiosulfate or BAL can be used for chelation therapy (see the Arsenic section earlier). Residual topical mercurial products (e.g., blisters) should be washed well from the animal's skin.[50-53] Supportive care should be provided for severe gastroenteritis and kidney failure. The treatment success rate is low when poisoning is severe or progressive; the presence of oliguria indicates a poor prognosis.[50-53] Surviving food animals should be monitored closely for potential mercury residues, which may persist for extended periods in organs or muscle.[50]

Other Toxicants

Additional inorganic toxicants are covered in the following chapters:

Fluoride, Chapter 38
Lead, Chapter 35
Molybdenum, discussed under copper deficiency in Chapter 32
Selenium (see the Poisonous Plants section earlier)
Sodium, discussed under salt poisoning in Chapter 35
Sulfate, discussed under copper deficiency in Chapter 32 and under polioencephalomalacia in Chapter 35
Zinc, discussed in the Osteochondrosis section in Chapter 38

Medications, Therapeutic Agents, and Illicit Substances

Dionne Benson • Lynn R. Hovda

Toxic and adverse drug reactions in large animals occur with some frequency but are not as routinely reported as occurrences in small animals. Blurred lines between toxicity and adverse reactions exists in the literature and in practice. Strictly speaking, toxic effects are dose related and do not occur at normal doses, whereas adverse reactions occur at normal as well as elevated doses.[1,2] The definition of an adverse drug reaction has not changed for 30 years and technically is "a response to a drug that is noxious and unintended and occurs at doses normally used in man for the prophylaxis, diagnosis or therapy of a disease, or for modification of physiological function."[2]

Adverse drug reactions can be classified in a variety of ways with six different presentations of the normal scheme.[2,3] A more simplified approach uses only two different types of reactions: dose related and idiosyncratic.[4] In dose-related reactions the signs move from physiologic to pharmacologic to toxic as the dose is increased. Often simply stopping the medication and allowing the drug to clear the system results in cessation of the clinical signs. Anaphylactoid reactions are included in this group because they are not immune mediated and depend on mast cell degranulation to manifest effects.

VetBooks.ir

Idiosyncratic reactions are generally not related to a specific dose or concentration of the medication administered. Immune-mediated reactions are included in the group.

Finding accurate information on adverse or toxic medication reactions in large animals is difficult. Preclinical studies are generally small and include a limited number of animals when, in fact, the medication will be used to treat thousands of animals and reactions may not show up until these numbers are reached.[5] Clinical trials are often helpful, but again small numbers of animals may be involved. Useful information, including preapproval medication data, can often be found on the FDA's website (http://www.fda.gov).

Treatment of adverse or toxic reactions varies for each medication and route of exposure. Few antidotes exist for large animal medications, and for the most part treatment is symptomatic and supportive.[6] The use of an offending medication should be discontinued as soon as a reaction is recognized. Bathing for topical exposures, gastric lavage followed by activated charcoal for most recent oral exposures, mineral oil, and intravenous fluids are all useful tools for dealing with the clinical signs.

The most commonly reported adverse or toxic drug reactions in horses are to antimicrobials (procaine benzylpenicillin), NSAIDs, anesthetic agents, sedatives, and antiparasitic drugs.[7] Reports in cattle and swine primarily implicate antimicrobials.[7] Some of these drugs are covered in separate chapters or discussed more generally throughout this text.

Antimicrobial Drugs

It is not possible in the scope of this chapter to begin to review all the antimicrobial drug adverse or toxic reactions. Two antimicrobials, however, have specific known risk factors for large animals and are covered here.

Doxycycline

Doxycycline is a tetracycline used in large animal medicine to treat a variety of illnesses. The IV use of doxycycline in horses is not recommended and has been associated with supraventricular tachycardia, systemic arterial hypertension, discomfort, collapse, and death.[8] The cause is unknown but may be concentration or infusion-rate dependent. Treatment is symptomatic and supportive.

Sudden death has been reported in calves accidentally receiving 3 to 10 times the recommended daily dose (5 mg/kg bid) of doxycycline.[9,10] There is no known breed or genetic predisposition. Clinical signs included lethargy, dullness, loss of appetite, cough, dysphagia from paresis or paralysis of tongue, tachycardia, and tachypnea. Major problems included myopathies and necrosis (tongue, myocardial, other striated muscle), acute tubular necrosis, and hepatic fatty degeneration or congestion.[9] The tongue is affected before the myocardium. The cause of acute tubular necrosis remains unknown but may be a combination of a decreased cardiac output from myocardial issues and an increase in myoglobin from muscle necrosis. Death was reported to be from myocardial necrosis, although a recent clinical study in healthy calves dosed at five times the recommended daily dose for 5 days failed to support this.[10]

Enrofloxacin

Enrofloxacin is a second-generation quinolone metabolized in the liver to ciprofloxacin, an active metabolite. Ciprofloxacin, itself a quinolone antimicrobial, should not be used orally in horses because it causes mild diarrhea to severe colitis, laminitis, and endotoxemia.[11]

The most common adverse reactions in horses include mild diarrhea, neurologic signs, and orthopedic disorders in young animals. The neurologic signs are generally dose related (i.e., high dose, bolus route) and transient, resolving in 10 to 15 minutes after administration.[12] Diluting the drug and administering it at a slower rate prevents the development of neurologic signs. Juvenile arthropathies with associated cartilage damage have been reported in neonatal foals and other species, but the true incidence is unknown.[13]

Several other adverse or toxic reactions have been reported. Intrauterine infusion in mares resulted in acute endometrial ulceration, necrosis, and hemorrhage, as well as fibrosis with inflammation.[14] Oral ulcers developed in animals treated with a gel compounded from the injectable cattle product.[15] Finally, to prevent toxicosis, the dose in neonatal calves needs to be lowered to accommodate their lower amounts of body fat and different metabolic capacities.[16]

β_2-Adrenergic Receptor Agonists (Clenbuterol, Ractopamine, Zilpaterol)

All three of these agents have been abused in horses for their known anabolic effects.[17,18] The use of clenbuterol in food-producing animals, once similarly abused, is now completely banned due to accumulation in meat.[19] Ractopamine and zilpaterol are still allowed as feed additives and are discussed later in this chapter (see the Feed Additives section later).

Clenbuterol is labeled for the management of acute and chronic respiratory disorders in horses. The normal dosage range is 0.8 to 1.6 µg/kg bid, with a maximum recommended dosage of 3.2 µg/kg bid for 3 days.[19] The dose needed for muscle partitioning in food-producing animals is estimated to be 5 to 10 times the therapeutic dose, whereas the dosage needed for repartitioning in horses is much lower at 2.4 µg/kg bid.[20]

At normal doses clenbuterol is a moderately selective β_2-adrenergic receptor agonist; at high doses all β-adrenergic receptors are stimulated, and a wide variety of signs occur. Clinical signs are dose dependent, with nervousness and mild agitation, sweating, and increased heart rate occurring in some horses 5 to 10 minutes after a therapeutic dose of 1.6 µg/kg.[19] Far larger overdoses, 10 µg/kg and 100 µg/kg, were used in three Quarter Horses treated with compounded, bootlegged products.[17] The horses showed excitation, profuse sweating, tachycardia, whole body muscle tremors, hypothermia, recumbency, and, in two cases, death. Laboratory abnormalities associated with these large overdoses included azotemia, elevated CK, hypocalcemia, hypochloremia, hyperbilirubinemia, hyperphosphatemia, and severe hyperglycemia. Treatment included, among other things, multiple sedatives and analgesics, GI protectants, IV fluids, propranolol (0.01 mg/kg IV diluted in 150 mL over 30 minutes), and insulin (0.22 U/kg IM).[17] It is important to note that propranolol is effective in treating tachycardia but will do little for other signs and that hyperglycemia, in these horses, did not resolve spontaneously and required multiple doses of insulin.

Long-Acting Tranquilizers

Fluphenazine Decanoate

Fluphenazine decanoate is a phenothiazine neuroleptic agent used as a powerful antipsychotic medication in human beings.[21,22] Although not approved or marketed for use in horses, it has been used for years off label to provide long-term sedation for anxious or nervous show horses and racehorses and for uncontrollable horses that need stall rest for surgical procedures.[22]

The suggested equine dose is 0.05 to 0.08 mg/kg IM, but clinical signs have occurred in horses 12 to 36 hours after doses of 25 mg to 125 mg (roughly 0.06 to 0.26 mg/kg).[22,23] Signs are consistent with development of an extrapyramidal syndrome and include extreme agitation followed by a brief

quiet period, hypermetria, profuse sweating, circling, rhythmic head tossing and neck arching, violent pawing, and self-mutilation.[22,23] These signs are nonresponsive to normal means of control. Hepatitis and urticaria (multiple, raised nodules; nonpruritic) occurred in one horse but may have been due to other factors.[24]

Short-term sedation with xylazine, detomidine, or romifidine may control the animal long enough to perform a physical examination and place an intravenous catheter. Often these drugs are ineffective and a barbiturate is necessary. Diphenhydramine (0.67 to 1.5 mg/kg IV q12-24h) or benztropine mesylate (0.018 to 0.035 mg/kg PO q12h) has been used to control the extrapyramidal signs.[22,23] They are not always effective and a barbiturate (pentobarbital or phenobarbital) may need to be used for several days until the signs resolve.

Reserpine

Reserpine, a medication infrequently used in humans to control blood pressure, is used off label in horses to provide long-term sedation.[25] Clinical signs of an adverse reaction include profuse sweating, trembling, shaking, flatulence, watery diarrhea, marked miosis, upper eyelid ptosis, and paraphimosis ranging from mild to almost irreversible.[25-27] Treatment is similar to fluphenazine decanoate, although diphenhydramine and benztropine mesylate are not effective because reserpine's mechanism of action is different.

Blood-Doping Agents—Erythropoietin and Darbepoetin

Blood-doping agents such as erythropoietin (EPO) and darbepoetin have been abused in horses, in particular those horses in endurance events such as horse racing.[28] They increase aerobic capacity and endurance by increasing red blood cell production and therefore oxygen transport.[29,30] The danger in using human products is the potential for an immune response with antibody development.[31] Clinical signs, including depression, lethargy, and anemia, can occur after a single dose or may not occur until many doses have been administered.[28,31,32] Two Standardbred racehorses developed severe anemia, elevated serum irons, and bone marrow–specific hypoplasia after receiving at least two doses of EPO (4000 IU).[28] Treatment for these horses included stopping the EPO and administering oral dexamethasone (0.05 mg/kg once daily) with tapering of the dose as anemia resolved.

Miscellaneous Medications

Isopropyl Alcohol

Isopropyl alcohol is not a problem when used topically, but toxicosis has occurred when it is inadvertently given orally. A horse accidentally received 2 L via nasogastric tube instead of mineral oil. Shortly thereafter it became dull, depressed, and collapsed with no menace response and slow pupillary light reflexes.[33] Treatment included gastric lavage, activated charcoal, and IV fluids, with recovery complicated by surgical correction of a cecal impaction.

Dimethyl Sulfoxide

When administered intravenously in concentrations greater than 50%, dimethyl sulfoxide (DMSO) results in severe hemolysis.[34] Few issues occur with topical and oral use of DMSO without additives. DMSO-associated toxicosis occurs when it is used in combination with other products, carrying them across membranes including the skin and the blood-brain barrier. In two instances, the application of a DMSO and mercury blister to limbs resulted in the development of mercury toxicosis.[35]

Dioctyl Sodium Succinate (or Docusate)

Dioctyl sodium succinate (DSS) is frequently used as a stool softener in horses with impactions. Single doses of 0.65 to 1 g/kg have resulted in agitation, abdominal pain, dehydration, watery diarrhea, intestinal mucosal damage, collapse, and death, with signs occurring within 1 to 2 hours of administration.[36] Treatment is supportive and includes GI protectants, IV fluids, correction of electrolyte abnormalities, and pain relief.

Lidocaine

Lidocaine, when used as a continuous IV infusion for ileus, has caused muscle fasciculations, anxiety, sedation, and visual dysfunction. The targeted serum level associated with this use of lidocaine is 1 μg/mL (0.98 μg/mL), with signs occurring at levels of 1.85 to 4.53 μg/mL.[37,38] Geriatric and neonatal horses, as well as those with hypoproteinemia, may develop signs at much lower doses and serum levels. Treatment consists of stopping the infusion and waiting a short time for the signs to resolve.[38]

Menadione Sodium Bisulfide (Vitamin K_3)

Menadione sodium bisulfide (vitamin K_3) is an ineffective anticoagulant in large animal species and toxic to horses in normal doses.[39] When administered to horses, weakness, stiffness, colic, laminitis, and a depressed appetite occur within 4 to 48 hours.[39,40] Acute tubular necrosis with azotemia, proteinuria, hematuria, hyperkalemia, hypochloremia, and hyponatremia develop.[39] Treatment is focused primarily on the renal system, with IV fluids and diuretics such as furosemide or mannitol recommended.

Propylene Glycol

Propylene glycol is used as antifreeze, a drug vehicle, and a treatment for bovine ketosis. A mature horse inadvertently received a gallon of propylene glycol instead of mineral oil and developed depression, ataxia, sweating, pain, and salivation in 10 to 25 minutes; some signs resolved. Cyanosis, respiratory distress, and sudden death occurred 24 hours later.[41] Although not effective in this case, sodium bicarbonate may be used to treat developing lactic acidosis. Cows receiving an overdose (median toxic dose of 2.6 g/kg BW) become ataxic, depressed, and recumbent 2 to 4 hours after administration; signs resolve in 24 hours with supportive care.[42]

Illicit Substances

Cobalt

Cobalt is an essential mineral for mammalian species. It is used in the creation of cobalamin (vitamin B_{12}). The dietary need for cobalt varies by species and is higher in ruminants (especially sheep) than in horses.[43-45] Toxicity in ruminants is often poorly recognized due to the lack of distinctive clinical signs.[46] Cobalt, however, has purportedly been used as a supplement to racing horses to induce erythropoietin creation by stabilizing hypoxia-inducible factor 1α.[47,48] Despite a lack of evidence-based medicine that this process occurs in the horse, there are allegations that this practice continues. Toxicity in the horse has been observed when high doses of cobalt are administered to research horses.[49] Toxicity has been documented in videos showing sweating, colic, and muscle fasciculations.[49] Signs resolved within hours without medical intervention.[49]

Glaucine

Glaucine was recently identified in several samples collected from racehorses. Glaucine is available in injectable products that can be purchased on the Internet. These are made from extracts of the yellow hornpoppy *(Glaucium flavum)*. Glaucine

VetBooks.ir

can also be found in bulk bedding shavings made from tulip poplar trees *(Liriodendron tulipifera)*.[50] Horses bedded on these shavings may ingest them, causing them to have measurable levels of glaucine. Glaucine is a weak dopamine receptor antagonist.[51] There have been no reports of toxicologic effect from either ingestion or IV injection in horses. However, there has been one case report of apparent ischemic heart effects where glaucine and diphenylprolinol were identified in a human patient.[52] In addition, glaucine has been associated with hallucinations, weakness, and sedation in humans.[53]

Dermorphin

Dermorphin is a peptide that bonds to mu opioid receptors.[54] It has been identified in samples collected from racing horses. It is purported to be administered for its analgesic properties. In a study investigating selected pharmacodynamic effects of dermorphin, researchers identified several responses to IV administration, including headshaking, colic-type symptoms, sweating, tachypnea, and sedation.[54] These behaviors also occurred to a lesser degree in some horses receiving IM administration. Most symptoms resolved quickly and without supportive care.[54]

Nomifensine

Nomifensine was recently identified in samples collected from several racehorses. Sold as a prescription antidepressant and later removed from the United States market, nomifensine may now be used in competitive horses for its dopamine-related analgesic effects.[55] There have been no reports of nomifensine-related toxicity in horses. In a study of nomifensine in dogs, dosages in the 3 to 10 mg/kg range had slight effects on blood pressure, heart rate, and blood flow.[56] These effects were transient in nature. It was withdrawn from the U.S. human drug market due to the risk of hemolytic anemia.[57]

Gamma-Aminobutyric Acid

Gamma-aminobutyric acid (GABA) is a major inhibitory neurotransmitter present in the CNS of mammals.[58] In show and racing horses there have been allegations of inappropriate use of exogenous GABA for its calming effects. In research, IV administration caused transient sedative effects and increased heart rate.[58] In addition, purported effects of IV injection include sudden death, although this claim has not been verified. Other potential detrimental effects are unknown.

Feed Additives

Robert H. Poppenga

Inclusion of a variety of chemicals in livestock feed is an efficient and cost-effective mechanism to improve animal performance and prevent disease. Livestock feed additives include growth promotants such as ionophores, partitioning agents such as ractopamine, antiparasiticides and larvicides such as tetrachlorvinphos, antibiotics, hormones such as melengesterol acetate, buffers, probiotics, nutritional agents, dietary supplements, and adsorbents such as sodium bentonite. Fortunately, most feed additives are safe when used appropriately. The following discussion is limited to those feed additives that are most commonly associated with adverse effects.

Urea and Other Nonprotein Nitrogen Sources

Nonprotein nitrogen (NPN) is converted by ruminal bacteria to ammonia by the enzyme urease. Ammonia is subsequently used by the bacteria to form amino acids and, ultimately, protein. Use of ammonia for bacteria protein synthesis depends on the availability of a highly fermentable carbohydrate source.

NPN can replace a portion of more expensive natural protein in ruminant rations, providing up to 40% of their nitrogen requirement. Rumen bacteria can effectively use ammonia nitrogen in limited quantities. However, when ammonia is produced beyond the capacity of the bacteria to use it, it will accumulate in the rumen at potentially toxic concentrations. The most commonly used form of NPN is urea, although other forms such as ammonium salts or ammoniated feed are also used. NPN is available either in a granular form that is incorporated into concentrates or range blocks or as a liquid that is incorporated into palatable vehicles such as molasses or encased (as urea) in a polymer network designed to release urea through pores in the polymer. Urea is typically recommended at a maximum rate of 3% of the grain ration or 1% of the total ration.[1]

The toxicity of NPN for ruminants depends to a certain extent on the adaptation of rumen bacteria to NPN; properly adapted animals can tolerate higher concentrations of NPN than naive individuals. Acclimation to NPN can be lost within 1 to 3 days, so maintaining a constant intake is important to prevent potential intoxication. One advantage to the use of polymer-encased urea is that the urea is slowly released over approximately 16 hours, which better matches NPN with carbohydrate availability. In unacclimated cattle, a toxic dose of urea is approximately 0.45 g/kg BW. In comparison, a lethal dose for acclimated cattle is approximately 1 to 1.5 g/kg BW. Younger ruminants are more susceptible than older animals to intoxication.[1,2]

Ammonia not used by rumen bacteria is absorbed systemically and can result in hyperammonemia within 30 minutes to 2 hours if it is not detoxified to urea by the liver for excretion. The amount of ammonia absorbed depends on the pH of the rumen. Normally, when rumen pH is below 7, most ammonia is in the form of the charged ammonium ion (NH_4+ versus the uncharged NH_3). As more ammonia is produced in the rumen, the pH of the rumen becomes more alkaline, with a resultant dramatic shift in the relative amounts of NH_4+ and NH_3 in the rumen. Unionized NH_3 readily crosses the rumen wall; in blood, ammonia is primarily in the form of ammonium ion.

NPN-induced ammonia toxicosis usually results from one of the following situations: (1) inadequate or improper feed mixing, (2) error in calculating the amount for inclusion in feed, (3) inadequate adaptation to NPN, (4) inclusion in carbohydrate-deficient rations, or (5) unrestricted consumption of palatable liquid NPN formulations.[2]

Clinical signs of ammonia toxicosis can occur within 30 minutes to several hours after consumption of excessive NPN. Signs include weakness; dyspnea; salivation; bruxism; bloat; excitation; belligerence; vocalizations; muscle tremors beginning with eyelids, lips, and neck and progressing posteriorly; and convulsions. Due to the rapid onset of clinical signs, it is common to find animals dead without signs being noted. There are no characteristic postmortem findings associated with intoxication. Gross or histopathologic lesions most often involve the lungs and brain and include generalized congestion, hemorrhages, and pulmonary and brain edema.

As evidenced by typical clinical signs, the CNS is a primary target of NPN intoxication. Mechanistically, ammonium ion causes a number of changes in the CNS, including amino acid disturbances, alterations in neurotransmission, cerebral energy deficits, and alteration of nitric oxide synthesis. Brain edema due to hyperammonemia is thought to occur through increased astrocyte osmolality and cytotoxic oxidative and nitrosative damage.[3]

A diagnosis of intoxication relies on a history of NPN supplementation, compatible clinical signs, and ideally measurement of elevated ammonia concentrations in rumen contents, whole blood, or ocular fluid. Unfortunately, ammonia is volatile, so appropriate sample handling and storage are critical for ammonia measurement. If urea is the NPN source, it can be measured in feed or, less usefully, in rumen contents. An

VetBooks.ir

antemortem rumen pH value greater than 8 is consistent with NPN intoxication. Postmortem pH values can be misleading depending on the time lag between death and necropsy.

Treatment is designed to decrease the amount of unionized ammonia absorbed from the rumen. Adult cattle should be given 20 to 30 L of cold water orally to reduce the ability of rumen bacteria to convert urea to ammonia by inhibiting and diluting urease. In addition, decreasing rumen pH shifts the form of ammonia to the unabsorbable ammonium ion; this is accomplished by administering 2 to 6 L of vinegar.

A number of strategies can minimize the risk of intoxication. These include a gradual adaptation to NPN, feeding readily fermentable carbohydrate sources, ensuring uniform feed mixing, maintaining a regular feeding schedule, feeding liquid supplements with phosphoric acid to maintain an acidic rumen, coating urea with fat and extruding urea with concentrates such as grain, using urease inhibitors to decrease its hydrolysis, and ensuring that mineral nutrition is adequate.[2]

Ammoniated Feed

Ammoniated feed intoxication is a hyperexcitability syndrome called "bovine bonkers" and is reported in cattle and calves fed ammoniated molasses, hay, straw, and silage.[1] The ammoniation process improves the palatability and digestibility of otherwise poor-quality roughages. Ammoniation of high-quality roughages such as wheat, Sudan grass, alfalfa, orchard grass, Bermuda grass, fescue, and sorghum containing high concentrations of soluble sugars is most often associated with the syndrome. The putative toxicants are the imidazoles, 2- and 4-methylimidazole, which are formed during the ammoniation process. The mechanism causing CNS excitation is unknown.

Hyperexcitability, either spontaneous or induced, is a hallmark of the syndrome. Affected animals will suddenly stampede and run in circles or a straight line until they collide with other animals, buildings, or fences. Other clinical signs include ear twitching, mydriasis, trembling, salivation, increased urination and defecation, and bellowing. The only postmortem lesions noted are secondary to trauma. The imidazoles can be excreted via milk, so nursing animals are at risk of intoxication.[4,5] Neurologic signs have been reported in nursing calves whose dams had been fed ammoniated barley greenfeed; dams were unaffected.[4]

A diagnosis of intoxication depends on a history of feeding ammoniated forages and consistent clinical signs. Treatment is nonspecific and typically limited by difficulties in handling affected animals. Sedation can be tried; acepromazine has been suggested.[5] Animals often recover once exposure is halted.

Prevention involves restricting ammoniation to poor-quality roughages that contain low concentrations of soluble sugars. The amount of ammonia used should not exceed 3% of the dry weight of the forage. In addition, the processing temperature of the forage should not exceed 70° C (158° F).[1]

Ionophores

Ionophores are commonly added to cattle and poultry feed for their growth promotant and anticoccidial properties. A number of ionophores, including narasin, salinomycin, lasalocid, monensin, semduramycin, laidlomycin, and maduramycin, are commercially available. In cattle, ionophores result in more propionic acid production in the rumen, which improves feed efficiency. They are also used to prevent rumen acidosis and emphysema. Intoxication most often occurs due to errors in feed mixing that result in overdosing of target species (cattle and poultry) or accidental inclusion in feed of nontarget species (e.g., horses, camelids).

Ionophores are potentially toxic to a variety of mammalian and avian species, although sensitivities vary between species and among different ionophores.[6,7] Intoxications have been documented for horses, cattle, goats, pigs, camelids, chickens, turkeys, quail, and ostriches. Ionophores bind and transport ions across cell and organelle membranes; the direction of movement depends on the concentration gradient of a particular ion. This results in disruption of multiple ion gradients as one or more ions move into or out of cells. Monovalent ionophores such as monensin, salinomycin, and narasin preferentially complex with either sodium (monensin) or potassium (salinomycin and narasin) ions. Divalent ionophores such as lasalocid and laidlomycin are capable of binding and transporting divalent cations such as calcium and magnesium across membranes. At a cellular level ionophores affect mitochondrial function and result in loss of aerobic energy production.

Horses

Horses are the most sensitive livestock species with reported median lethal doses (LD_{50}s) of 0.6 mg/kg for salinomycin, 2 to 3 mg/kg for monensin, and 21.5 mg/kg for lasalocid.[6] Clinical signs in horses are similar irrespective of the ionophore ingested, although signs can vary among individuals within an affected group. Signs most commonly occur with 24 hours of exposure, but delayed onset can occur in some cases. Acute clinical signs are primarily due to effects on muscle cells and the nervous and digestive systems. Feed refusal is one of the earliest signs noted in horses. Other signs include weakness, ataxia or incoordination, tremors, stumbling, exaggerated stepping, hesitance to move or turn, tachycardia, congested mucous membranes, hypotension, dyspnea, hyperpnea, sweating, and recumbency. Death can occur without signs being observed. In individuals surviving acute intoxication, longer-term clinical signs result from myocardial damage and decreased cardiovascular function and include unthriftiness, poor performance, poor exercise tolerance, arrhythmias, pitting edema, and hyperpnea. Delayed sudden death can occur long after exposure.

A variety of clinicopathologic changes can occur, including elevated ALP, AST, lactate dehydrogenase (LDH), creatine phosphokinase (CPK), creatinine, indirect bilirubin, BUN, glucose, hematocrit, serum osmolality, and phosphorus. Decreased concentrations of serum Ca^{++} and K^{+} and urine osmolality occur. Myoglobinuria is often noted. Unfortunately, the usefulness of such changes is limited by significant variation among affected individuals and the timing of their occurrence. Measurement of serum cardiac troponin I has been suggested to help with the early identification of horses with cardiac damage.[8]

The most significant necropsy findings are due to direct or indirect myocardial damage. Acutely affected horses develop degeneration and necrosis of cardiac muscle, whereas horses dying later have marked cardiac myopathy and fibrosis. Lesions can be absent in horses dying peracutely.

A diagnosis of intoxication relies on a combination of consistent clinical signs, necropsy findings where death occurs, and analytic proof of ionophore exposure. Because medicolegal considerations are often encountered in cases involving horses, it is critical to try to quantify ionophore feed concentrations.[6] This is difficult if representative feed samples are not available. Testing several feed samples can be important to confirm nonuniform feed mixing. In the absence of feed testing, stomach contents and/or tissue testing (preferably heart tissue) can be done to confirm exposure but not necessarily intoxication.[9]

There is no specific treatment for ionophore poisoning.[10,11] It is critical to quickly remove access to suspect feed and initiate decontamination (e.g., gastric lavage and/or activated charcoal) as soon as possible. The efficacy of decontamination in most cases is questionable. Supportive therapy is directed toward restoration and maintenance of cardiac output and tissue perfusion, stabilization of cell membranes, and treatment with anti-arrhythmics if unstable, life-threatening arrhythmias are present.[10] Affected horses should be rested for up to 3 months after exposure, and echocardiograms (echos) and exercising

VetBooks.ir

echos performed to identify evidence of chronic cardiomyopathy. Reported mortality is 60% or greater.[10]

Cattle Cattle are less sensitive to ionophores than horses. At prescribed use levels, ionophores are safe. The LD_{50} for monensin in cattle is reported to be 26.4 mg/kg, and lethal doses of lasalocid range from 50 to 100 mg/kg.[7]

In cattle, signs of acute intoxication include early anorexia, rumen atony, CNS depression, muscle tremors, watery diarrhea, tachycardia, ataxia, recumbency, and death. Animals can be found dead without clinical signs being noted. Animals surviving acute intoxication can subsequently develop congestive heart failure characterized by brisket edema, prominent jugular pulses, ascites, fluid feces, dyspnea, and tachycardia. Deaths can occur weeks to months after exposure and be precipitated by exertion such as calving. In dairy cattle, decreases in milk production are likely, with production requiring several days to a week to return to previous levels.

Clinical pathologic changes are similar to those described for horses. On necropsy, lesions include myocardial degeneration, pulmonary edema, enlargement of the heart and liver, hydropericardium, hydrothorax, and ascites.

Elements necessary for a diagnosis in cattle are similar to those for horses. However, in contrast to cases involving horses in which confirming exposure is likely to be significant, in cattle it is important to confirm exposure to feed concentrations higher than expected concentrations. Although, similar to horses, tissue testing can identify exposure to an ionophore, tissue concentrations associated with intoxication have not been definitively determined.[12] Treatment is similar to that for horses, although it is less likely to be as extensive in cases involving cattle.

Poultry Both salinomycin and monensin intoxication have been reported in turkeys.[13] Sensitivity to salinomycin is age dependent, with younger birds being less sensitive. Clinical signs in affected birds include dyspnea, drowsiness, sternal recumbency with rear legs extended posteriorly, inability to stand, stiffness, and weakness. Extensive fragmentation and necrosis of skeletal muscle fibers occurs, and myocardial damage can also be noted.

Acute onset of feed refusal, decreased water consumption, and severe paralysis ranging from an abnormal gait to complete inability to move have been described in a chicken broiler breeder flock after monensin was included in their feed at approximately seven times the intended concentration.[14] The flock experienced high morbidity and mortality. Postmortem lesions were similar to those reported for intoxicated turkeys. Although the mortality rate returned to normal 21 days after feed removal, loss of productivity resulted in elimination of surviving birds.

β_2-Adrenergic Agonists

In livestock, β_2-adrenergic agonists have been used as repartitioning agents (i.e., repartitioning nutrients away from fat in favor of muscle). This results in increased carcass weight and ratio of muscle to fat and improved feed efficiency. β_2-adrenergic agonists approved in one or more countries for use in livestock feed include ractopamine (finishing beef cattle, swine, and turkeys) and zilpaterol (finishing beef cattle). Clenbuterol is approved for treating recurrent airway obstruction in horses but is not approved for use in food animals.[15] Due to the anabolic effects of β_2-adrenergic agonists, there is the potential for their use as doping agents in racehorses.

Horses appear to be more sensitive to adverse effects than cattle following exposure to zilpaterol. In a limited number of horses, adverse effects were noted soon after a single zilpaterol dosage of 0.17 mg/kg BW PO; this is the recommended dosage for cattle.[16] Signs included nervous behavior, profuse sweating, muscle tremors, and tachycardia within 20 to 60 minutes post dosing. Clinical pathologic changes were consistent with muscle damage and included increased serum activity of LDH, CK, and AST. Myoglobin-induced nephropathy is possible in some individuals. The duration and severity of adverse effects were unanticipated, with some signs persisting for up to 2 weeks. Affected horses recovered completely without treatment. Widespread accidental contamination of horse feed with zilpaterol resulted in violative urine residues in 48 horses from four California race tracks (http://www.chrb.ca.gov/Board/committee_packages/Apr-2013MC.pdf). No horses were reported to be symptomatic, but the case illustrates that nontoxic concentrations of feed additives can potentially result in adverse consequences unrelated to an adverse health effect. Fortunately, because of the widespread nature of the feed contamination, no regulatory action was taken against any positive horse.

Based on human data, clenbuterol is approximately 19 times more potent than zilpaterol, and zilpaterol is approximately 125 times more potent than ractopamine. Dosages of ractopamine of up to 10 times the dose of zilpaterol given to horses have not been associated with adverse effects.[17]

Antibiotics

The erroneous addition of antibiotics to feed is of particular concern in horses. Antibiotics such as lincomycin, clindamycin, tetracycline, and erythromycin have been associated with lethal colitis in horses.[6] Adverse effects are believed to be due to disruption of the normal microbial flora, resulting in overgrowth of pathogenic bacteria such as *Clostridium* spp., *Salmonella* spp., or *Escherichia coli.* Subsequent production of endotoxins or enterotoxins causes digestive tract damage and systemic clinical effects. Treatment primarily involves IV fluid therapy and correction of acid-base and electrolyte abnormalities.

Pesticides

Tetrachlorvinphos (TCVP) is an organophosphorus insecticide fed to horses, cattle, and swine as a pass-through fly larvicide. It is a cholinesterase inhibitor, and intoxication is associated with overstimulation of muscarinic and nicotinic cholinergic receptors. TCVP has low mammalian toxicity, with an LD_{50} in laboratory animals of greater than 1 g/kg BW. However, anecdotal evidence suggested that horses receiving TCVP at recommended levels were more likely to exhibit GI problems and increased reactivity, leading to handling difficulties. In one study, six horses given the recommended dose of TCVP for 30 days were noted to have heightened reactivity to an external stimulus that correlated with a reduction in whole blood cholinesterase activity.[18] Another study demonstrated that TCVP at the recommended dose depressed plasma butyrylcholinesterase activity in horses but did not disrupt cholinergic neurotransmission in target tissues.[19] Although TCVP at recommended doses does not cause typical signs associated with organophosphorus insecticide overexposure, some clinicians have suggested that alternative methods for fly control be used for horses due to potential adverse effects on behavior.

Pesticides and Rodenticides

Michelle Mostrom

Pesticides comprise a wide variety of chemicals used to control insects and parasites in agriculture, animals, and public health, as well as to control weeds, fungi, and rodents or other animals determined as unwanted by man. The toxicology of pesticides covers several different chemical classes. This section focuses primarily on insecticides and rodenticides that are more commonly associated with toxicoses in large animals. Poisoning

VetBooks.ir

BOX 54.1

Approach to Unknown Exposure of Livestock to Pesticides

1. Type and number of animals exposed (age, weight, dairy or beef, pregnant, lactating, etc.).
2. Location of exposure (pasture, dry lot, aerial drift, etc.) or crops/pasture/hay land.
3. Clinical signs of exposed animals (consider taking whole blood for cholinesterase activity). If animal deaths are involved, perform necropsies and take samples for routine necropsy along with brain (cholinesterase activity and chemical analysis), fat, liver, kidney, lung, urine, and skin (if dermal exposure) for possible chemical analysis.
4. Try to obtain trade name of pesticide, particularly if accidental exposure such as aerial drift, and the wind direction if sprayed onto animals.
5. If a licensed applicator accident, the applicator will have pesticide label data and concentration, wind speed, and direction.
6. With a chemical name identified, you can access information on toxicity by several routes:
   a. Contact a veterinary diagnostic lab and toxicologist for toxicity data.
   b. Locate data on the EPA website, including "How to Search for Information about Pesticide Ingredients and Labels" (https://www.epa.gov/ingredients-used-pesticide-products/how-search-information-about-pesticide-ingredients-and-labels).
   c. Search for chemical toxicology data, which can often be located on the U.S. National Library of Medicine website, specifically the Hazardous Substances Data Bank (HSDB). Enter the chemical name in the HSDB and data on human and animal toxicity, emergency medical treatment, pharmacology, chemical safety and handling, and environment fate can be obtained (https://toxnet.nlm.nih.gov/newtoxnet/hsdb.htm).
7. If questions on grazing restrictions or crop use for livestock, check the pesticide label for data. In addition, some state extension bulletins can provide grazing restriction information on some chemicals.
8. Data on pesticide chemical tolerances for residues in crop commodities, meat, and meat by-products can be found in the Code of Federal Regulations (40 CFR Part 180) (https://www.ecfr.gov/cgi-bin/text-idx?c=ecfr&tpl=/index.tpl).
9. Check the electronic Code of Federal Regulations (eCFR) for updated data. Instructions for conducting an eCFR search for tolerances can be found on the EPA website: "How to Search for Tolerances for Pesticide Ingredients in the Code of Federal Regulations" (https://www.epa.gov/pesticide-tolerances/how-search-tolerances-pesticide-ingredients-code-federal-regulations).
10. Treatments for animals may be only supportive care for clinical signs. Consider using activated charcoal to bind pesticides by oral exposure; check individual chemical information for specific medications. If dermal exposure occurred, wash the animal with soap and water to decrease absorption. Clipping hair should be considered in long-haired livestock.
11. Chemical analyses for all pesticides, metabolites, and possible inert ingredients are not readily available (especially herbicide analysis in biological tissues). Chemical standards may not be available or could be expensive; laboratory methods in crop or biological matrices may have to be developed. Check with a veterinary toxicologist regarding costs and the possibility of chemical analyses.

or toxicosis in large animals generally occurs due to misuse or overdosage with a pesticide, malicious use of pesticides or baits, or occasionally from accidental exposure (e.g., drift from aerial spraying, cleanup of buildings with old stored products).

All pesticides sold and distributed in the United States must be registered by the EPA. Registration is based on scientific data demonstrating that the chemicals can be used without posing unreasonable risks to people or the environment. With advancement of science, all pesticides that were first registered before November 1, 1984, were required to be reregistered to meet the more stringent standards. General scientific data on the toxicity of pesticides can be located on the EPA website (www.epa.gov) and in numerous databases supported by the U.S. National Library of Medicine, such as ToxNet (http://toxnet.nlm.nih.gov), using search terms for the chemical, Chemical Abstract Service (CAS) number, trade name, or clinical signs. The product label can also provide data on potential toxicosis.

Unfortunately for large animals, a limited number of antidotes is available for treatment of pesticide and rodenticide toxicoses.[1,2] For example, atropine sulfate, epinephrine, and vitamin K_1 do not have New Animal Drug Approval and are not formally approved by the Food and Drug Administration/Center for Veterinary Medicine (FDA/CVM), but the labels are reviewed and on file with the FDA/CVM.[3] These drugs may be used as antidotes in food animals, but the veterinarian should contact the Food Animal Residue Avoidance Databank (FARAD; www.farad.org) regarding withdrawal times if animals or milk will be put into the food chain. Because toxicoses involving pesticides often occur in nontarget species or at high concentrations, withdrawal intervals for these chemicals in food animals are often not readily available. A reasonable place to start locating this information is through contact with your state veterinarian, the District Office for the FDA in your region, and the U.S. Department of Agriculture Food Safety and Inspection Service (USDA FSIS; www.fsis.usda.gov). The state veterinarian may also assist with recommendations for proper disposal of chemically contaminated carcasses.

Box 54.1 outlines suggested steps to handle unknown exposure of livestock to pesticides.

Organophosphates and Carbamates

The introduction of newer types of external parasiticides and chemical products has significantly reduced the incidence of these toxicoses in livestock. Both organophosphate (OP) and carbamate insecticides inhibit acetylcholinesterase (AChE) at cholinergic nerve synapses and at neuromuscular junctions, causing acetylcholine to accumulate at nerve junctions and cause excessive synaptic action. They also inhibit other cholinesterases in the body (e.g., red blood cells, serum, liver, pancreas, nervous tissue). These insecticides lack species selectivity and may pose a hazard to domestic and companion animals, wildlife, and aquatic species. The anticholinesterase compounds may adversely affect the cardiovascular, respiratory, ocular, reproductive, endocrine, dermal, and immune systems but primarily act on the nervous system and skeletal muscles.[4] Death is usually the result of respiratory failure, often with cardiovascular involvement.

Approximately 200 OPs and several dozen carbamate compounds have been synthesized for numerous purposes. They are incorporated into various products, including baits, dips, dusting powders, sprays, pour-ons, and oral anthelmintics. The OPs used as defoliants and herbicides, such as glyphosate and gluphosinate, have low acute mammalian toxicity but could induce delayed polyneuropathy.[4] Aldicarb, sold under the trade

VetBooks.ir

name Temik, was synthesized to mimic acetylcholine and is considered to have maximum potential for mammalian toxicity.[4]

Both OPs and carbamates inhibit the metabolism of acetylcholine at cholinergic sites. Acetylcholine is a neurotransmitter at postganglionic parasympathetic neurons in smooth muscles, cardiac muscles, or exocrine glands; at neuromuscular junctions of the somatic nervous system; at cholinergic synapses in the CNS; and between preganglionic and postganglionic neurons of the autonomic nervous system. The enzyme AChE normally breaks down acetylcholine at these cholinergic sites, but when bound by OPs or carbamates it is inactive. During toxicity, acetylcholine maintains depolarization of the postsynaptic membrane, which is initially stimulatory but may progress to paralysis. The OPs have high affinity for the cholinesterase enzyme and are considered irreversible inhibitors of AChE. Organophosphates can undergo an "aging" process, which stabilizes the OP-AChE bond and cannot be broken. Carbamates do not undergo "aging" and can be dislodged from AChE, resulting in spontaneous enzyme regeneration. These insecticides also induce toxic effects through noncholinergic mechanisms that may involve glutamate release and activation of *N*-methyl-D-aspartate receptors and the γ-aminobutergic, adenosinergic, and monoaminergic systems that are involved in seizures, which are reviewed by Gupta and Milatovic.[4]

The toxicity of OPs and carbamates varies widely, from highly toxic compounds (OP nerve gases such as Sarin, Soman, and VX, and carbamates such as aldicarb and carbofuran) to minimally toxic ones (e.g., malathion, tetrachlorvinphos). The very young, very old, and weakened animals are more susceptible to poisoning from these compounds. Following exposure, OPs and carbamates are rapidly distributed throughout the body and can undergo oxidation, hydrolysis, and conjugation. They are excreted in the urine and feces. The OPs tend to be more lipophilic than carbamates and are more likely to cross the blood-brain barrier; however, carbamates may cause marked CNS signs. Clinical signs can occur within minutes to hours of exposure depending on the dose, route of exposure, and toxicity of the insecticide. Death can occur within minutes with highly toxic chemicals or when large amounts are ingested. Repeated exposures can be clinically important. The insecticides may be metabolized and excreted within days of exposure, but the regeneration of AChE may require 2 weeks.[5] Clinical signs of acute toxicity due to OP and carbamate exposures result from overstimulation of muscarinic and nicotinic acetylcholine receptors because of the buildup of acetylcholine from inactivation of AChE. The clinical effect is excessive synaptic neurotransmitter activity and depolarization of effector organs.[6] Muscarinic signs include ptyalism, excessive tracheobronchial secretions and sweating, bronchospasms and laryngospasms, lacrimation, nausea, diarrhea, miosis, and bradycardia. The muscarinic clinical signs are frequently described by the term *SLUD* (salivation, lacrimation, urination, and defecation). Nicotinic clinical signs include muscle fasciculations, tremors, weakness, ataxia, flaccid paralysis, vomiting, and paralysis of respiratory muscles. Muscarinic signs generally appear first, followed by nicotinic signs, and finally by CNS effects (hyperactivity and seizures).

Not all clinical signs are observed in an OP or carbamate toxicosis. The clinical appearance of an AChE toxicosis may vary with the species exposed, toxic compound, dose, route of exposure, and timeline in exposure-response. For example, the use of methiocarb as a snail bait in Australia uncommonly causes problems in horses but can result in AChE inhibition, clinical signs, and death. A 400-kg gelding developed clinical signs of profuse sweating, hypersalivation, lateral recumbency, paralysis of a distal hindlimb, and generalized muscle tremors within a few hours after consuming almost 20 g of methiocarb in bait form (1 kg of 2% weight/volume).[7] The horse had signs of colic, ileus, and a significant amount of nasogastric reflux (total reflux volume after presentation at a veterinary clinic was 55 L) but never developed diarrhea. Because of the large volume of nasogastric reflux, activated charcoal was not given nor was atropine administered due to the lack of GI borborygmi. Gastric lavage had been performed about 6 hours post ingestion but was probably ineffective to recover ingested bait; the authors speculated that the worsening clinical signs were due to continued absorption of methiocarb, and the horse was euthanized about 54 hours post ingestion of the bait.

Delayed toxicosis has occurred with the use of chlorpyrifos, a chlorinated OP, as a pour-on in bulls and some exotic breeds of cattle. The toxicity appeared to be related to testosterone levels in cattle, with larger and older bulls affected. Clinical signs appeared 2 to 7 days post exposure and included weakness, muscle fasciculation, anorexia, rumen stasis and distention, and depression.[8] Decontamination of the skin and rumen, activated charcoal, and symptomatic treatment are recommended for treatment of chlorpyrifos poisoning in bulls.

Diagnosis of OP or carbamate toxicosis includes (1) history and clinical signs consistent with the toxicosis; (2) response of animals to treatment with atropine; (3) determining cholinesterase inhibition (whole blood, retina, brain), corresponding with adverse clinical effects; and (4) detection of the insecticide in biological tissues (GI contents or tissues). The diagnosis can be challenging. Clinical pathologic changes are not consistent and postmortem lesions are nonspecific. Often pulmonary edema is evident on postmortem, along with tracheal fluid and diarrhea, but these changes are not unique to AChE toxicosis.

Measurement of cholinesterase activity in whole blood and brain is commonly used to establish an OP or carbamate diagnosis. Generally, AChE activity less than 50% of normal level indicates exposure, and activity less than 25% of normal level in an animal with compatible clinical signs indicates toxicosis from an OP and/or carbamate. Use of AChE activity alone is not always diagnostic. The use of OP anthelmintics in horses at therapeutic doses decreased AChE activity to less than 25% of normal level, while no horses displayed clinical signs.[9] Interpretation of AChE activity is difficult in a carbamate toxicosis. Carbamates can spontaneously dislodge from the cholinesterase enzyme before or after sample collection; therefore AChE activity may be in the normal range even though the animal is experiencing toxicity from a carbamate compound.

Check with your diagnostic laboratory for proper collection of specimens (whole blood, brain, plasma, serum, retina) for AChE activity. With an OP exposure, AChE activity in whole blood is fairly stable for about 7 days after collection if the blood is stored under refrigeration.[9] For determination of AChE activity in the brain, submit a chilled whole or half brain because cholinesterase activity varies in different regions of the brain and the laboratory may have a preference for the brain region tested.

Identification of the insecticide can often be made on postmortem specimens, including rumen, GI contents, liver, fat, brain, and perhaps kidney. Samples should also be taken of the suspect source (e.g., bait, feed, water) for identification and concentration. It is not unheard of to have acute death losses in animals; finding depression of AChE in brain, whole blood, and retina; detecting the insecticide in rumen contents; but locating no source of insecticide on the farm.[10] With suspect insecticide toxicosis, check with the diagnostic laboratory for proper collection and shipment of samples. Generally, the samples are kept chilled or frozen before analysis. Management of OP or carbamate toxicosis depends on the clinical signs and time from exposure. Treatment should be initiated quickly. If the animal is having seizures, stabilize the animal and attempt to control the seizures with diazepam, which may need to be supplemented with methocarbamol, barbiturates, or general anesthesia. Oxygen therapy and ventilatory support may help

VetBooks.ir

with severe dyspnea. The noncompetitive antagonist for OPs and carbamate is atropine, which blocks excessive acetylcholine at synapses. It can control muscarinic signs and some CNS signs, but not nicotinic signs (e.g., muscle fasciculations, weakness, paralysis). The therapeutic range for atropine sulfate is between 0.25 and 1 mg/kg, with one quarter of the dose given intravenously and the remainder administered IM or SC.[5,6] It may be necessary to use the high end of the range in toxic situations. The dose should be repeated as needed (usually a lower dose and every 2 to 4 hours) to control bradycardia and secretions into the lungs. Avoid overtreatment with atropine, especially during prolonged treatment. Note that atropine has a low margin of safety in horses and causes GI stasis, which should be carefully monitored during use. It is recommended not to exceed a total dose of 65 mg of atropine in the average horse.[5] When atropine is used in multiple doses as an antidote for a toxicosis, check with FARAD (www.farad.org) for milk and/or meat withdrawal recommendations. Note that veterinarians must also consider the residue-withdrawal interval for the insecticide in tissues.

Acetylcholinesterases can be reactivated with oximes, such as pralidoxime chloride (2-PAM), if aging has not occurred or with the irreversible binding of an OP to AChE. The oxime attaches to the OP insecticide and dissociates the OP-cholinesterase bond. Response to oxime therapy is better when oximes are used within 24 hours after exposure to OP insecticides. Oximes ameliorate to some degree muscarinic, nicotinic, and CNS signs and work best with atropine. The dose, frequency, and route of administration of 2-PAM vary in the literature. A dose of 20 mg/kg IV q4-12h has been recommended in ruminants; its use should be stopped if no response occurs within 36 hours.[11] Excessive doses of oximes have the capability to inhibit cholinesterase.[4] The use of 2-PAM in treatment for a large animal OP toxicosis would be very expensive; in addition, 2-PAM is not approved for use in large animals and should be used with oversight under FDA/CVM guidance. In some cases, the use of 2-PAM in carbaryl (carbamate) toxicity has been considered detrimental.

Once the animal is stabilized, decontamination should be considered. Oral dosage of activated charcoal (1 to 2 lb/500 kg in a slurry) can bind the insecticides in the GI tract and prevent absorption; this treatment may also be helpful with topical application of some insecticides. The use of activated charcoal is particularly recommended for ruminants, which have the capacity for large retention of GI contents. With topical exposure to insecticides, animals should be washed with a liquid dishwashing detergent and rinsed off to reduce absorption. Gastric lavage with water may be indicated in high-dose exposures where only a few hours have passed since ingestion. Additional therapy may include fluids to treat dehydration and electrolyte imbalances.

Several drugs are contraindicated in OP and carbamate toxicosis (with cholinesterase inhibition), including opiates, physostigmine, phenothiazine tranquilizers, neostigmine, succinylcholine, levamisole, antihistamines, aminoglycoside antibiotics, and theophylline.

Glyphosate

Although glyphosate can be chemically described as an OP compound, it is a phosphanoglycine and not recognized as a cholinesterase inhibitor. It is usually formulated as an isopropylamine, sodium, ammonium, or timesium salt and is active as a broad-spectrum, postemergent, nonselective herbicide. Glyphosate is one of the most used herbicides worldwide. It interferes with the production of essential aromatic amino acids in plants.[12] Glyphosate is not metabolized efficiently in mammals and is mainly excreted unchanged into the urine; however, it can undergo GI microbial metabolism in humans and rats.[12] Recently, the International Agency for Research on Cancer (IARC) classified glyphosate as "probably carcinogenic to humans (Group 2A)" based on limited evidence in humans and with a positive association for non-Hodgkin's lymphoma and with "sufficient evidence in experimental animals for carcinogenicity."[12] Limited data are available in livestock. In a field study of Danish dairy cows, all cows on eight dairy farms excreted glyphosate, in varying concentrations, in their urine.[13] The authors reported increased activity of several serum enzymes, glutamate dehydrogenase, glutamate oxaloacetate transaminase, and creatinine kinase in cows on all farms, which could indicate a possible effect of glyphosate on liver and muscle cells. Low serum concentrations of manganese and cobalt were observed in all animals, which may be explained by the strong mineral chelating effect of glyphosate; however, the mean levels of copper, zinc, and selenium were within the normal reference range. In a recent study of glyphosate in lactating dairy cows, glyphosate residues in foodstuffs (0.8 to 84.5 mg glyphosate/day average intake in the experimental groups) were fed to cows during a 16-week trial.[14] No glyphosate residues were detected in the milk, and no adverse effects were detected in body condition score, net energy intake, net energy balance, or milk performance parameters. Given the health controversies surrounding the widespread use and exposure to glyphosate, additional animal studies are warranted.

Pyrethroids

Pyrethroids are active synthetic derivatives of natural toxins in the plants *Chrysanthemum cinerariaefolium* (or *Tanacetum cinerariaefolium*) and *Chrysanthemum cineum*. These chemicals are important insecticides used in crop protection to control insect vectors carrying infectious diseases of animals and humans and to control insects on premises. They are available as wettable powders, granules, and emulsifiable concentrates in sprays, dusts, dips, foggers, ear tags, pour-ons, and back rubbers. Pyrethrins are the naturally active insecticidal compounds from the plants; pyrethroids are synthetic analogs of the pyrethrin esters and tend to have more potent insecticidal activity, to be more stable in the environment, and to be more toxic. The pyrethroids are categorized as type I pyrethroids (a cyano group is absent) or type II pyrethroids (an alpha-cyano group that increases the insecticidal potency is present). Allethrin, bifenthrin, permethrin, resmethrin, and tefluthrin are examples of type I pyrethroids. Cyfluthin, cypermethrin, deltamethrin, and flumethrin are examples of type II pyrethroids. Often synergists such as piperonyl butoxide, propyl ethers, and sesamin are combined with pyrethroids to inhibit mixed-function oxidase and esterase enzymes in the target species and reduce detoxification of the insecticide and prolong its action in insects. Synergists may also enhance toxicity in animals. Pyrethroids interfere with conductance of nerve membranes by binding to the membrane and prolonging the sodium current. The pyrethroids act on axons in the central and peripheral nervous systems. Gamma-aminobutyric acid–gated chloride channels may also be affected by high doses of type II pyrethroids. Compared with insect sodium channels, mammalian sodium channels are much less sensitive to pyrethroids and recover more quickly from depolarization.

Most pyrethroids are applied dermally, and there is limited absorption through this route. Pyrethroids are absorbed more efficiently across GI and pulmonary membranes. Pyrethroids are lipophilic in nature and distribute into fat, central and peripheral nervous systems, milk, and other organs. Once absorbed, pyrethroids can undergo metabolism by nonspecific esterases and microsomal mixed-function oxidases. Pyrethroids and their metabolites are excreted in feces and urine, with a majority of pyrethroids excreted within 12 to 48 hours.[15]

Following application of pyrethroid pour-on products, cattle can exhibit a paresthesia-like syndrome, thought to result from direct action of pyrethroids on sensory nerve endings.[15] Cattle

VetBooks.ir

may be restless and uncomfortable, and twitch the skin on their backs. Young animals are more susceptible due to a lack of metabolism of pyrethroids; death can occur due to respiratory failure and convulsions leading to paralysis. No specific clinical pathologic or histopathologic changes have been reported with pyrethroid applications. In a toxicosis, check with the veterinary diagnostic laboratory regarding analytic testing on appropriate tissues. Pyrethroids concentrate more in nervous tissue than serum or plasma.

Pyrethroids have been implicated in disrupting the endocrine system, adversely affecting reproduction and sexual development, and interfering with the immune system. Pyrethroid treatment of laboratory animals and in vitro samples has induced a decrease in epididymal sperm count and sperm motility, as well as an increase in abnormal spermatozoa.[16,17] Pyrethroid treatments of mice and rats disrupt testosterone synthesis and downregulate 17β-hydroxysteroid dehydrogenase (convert androstenedione to testosterone) and biosynthetic enzymes that have a critical role in the synthesis of testosterone in Leydig cells.[18,19] In addition, pyrethroid exposure has been shown to disrupt luteinizing hormone–responsible ovulatory genes in rats and prostaglandin synthesis in granulosa cells in vitro.[20]

Exposure of bulls in a bull stud to bifenthrin was associated with poor semen quality, including (1) decreased motility, (2) reduced ejaculate volume, and (3) spermatozoa abnormalities with a high percent of distal midpiece reflexes.[21] At 64 days post exposure, semen quality recovered to levels observed before exposure in these bulls. In this case, the use of bifenthin was apparently an excessive use of product in a building (bull stud) with the animals present, so that excessive exposure was dermal, inhalation, and oral; in addition, these animals were being continually monitored for semen quality for cryopreservation, and therefore clinical abnormalities in semen were easily detected (Evans, T: personal communication, August 2012). Field cases of bulls exposed to pyrethroids that subsequently developed poor sperm quality and motility, with gradual recovery to normal after about 2 to 4 weeks, have been reported.[22,23] There are few scientific data, however, with controlled studies to support observations that use of pyrethroids will alter sperm quality in bulls.

Accidental pyrethroid exposure in bulls may result in inadequate semen quality (particularly for cryopreservation) but may not impair bull fertility when bulls are used in natural settings, such as pasture breeding where several males are available to breed female cows during a breeding season. The important considerations when using pyrethroids on pastured cattle are to exactly follow the application recommendations on the label, to use a product that the cattle producer has experience with for insect control, and to avoid using close to breeding if possible. Another recommendation is to use only one method of insect control with pyrethroids on breeding cattle at a time (e.g., only spraying, only ear tags).[23]

With dermal exposure, wash and scrub the exposed area using liquid dishwashing soap and rinse well. Avoid using power washers because they may cause dermal trauma.[15] If seizures occur, the use of diazepam, methocarbamol, and barbiturates may be effective.

Neonicotinoids

A relatively new class of insecticides are the neonicotinoids, which are heterocyclic nitromethylenes used primarily in crop protection against sucking and certain chewing pests. The neonicotinoids include imidacloprid, acetamiprid, dinotefuran, thiamethoxam, and clothianidin.

The neonicotinoids act on postsynaptic nicotinic receptors located in the CNS. They act as agonists against nicotinic acetylcholine receptors in insects and mammals.[24] The insecticides initially increase the frequency of spontaneous discharge, which is followed by a complete block of nerve propagation. Neonicotinoids have been considered relatively low risk for nontarget organisms and the environment.[25] The activity in vertebrates is much lower due to different binding properties to the nicotinic receptors, and they primarily act on the α7 nicotinic receptor subtype. However, with the widespread use of neonicotinoids, an increase in acute neonicotinoid poisoning cases has been reported worldwide.[24] Increasing evidence of a variety of toxic effects in animals and humans has been identified, including altered thyroid and reproduction hormones in birds and mammals; upregulation of cytokines and suppressed cell-mediated immunity identified in rat experiments; and oxidative stress-related damage to lipids, DNA, and proteins in vertebrates and invertebrates.[24] Use of neonicotinoids can represent a health risk to wild bees and honey bees, with the European Union considering a complete ban on the outdoor use of three neonicotinoids: imidacloprid, clothianidin, and thiamethoxam.[26]

Imidacloprid has widespread use as an insecticide for dermal application on animals, as well as an insecticide for crop protection. Imidacloprid is primarily metabolized in the liver.[27] Metabolism of imidacloprid in mammals is by two routes: (1) oxidative cleavage and glutathione conjugation and (2) hydroxylation. Most of the imidacloprid is rapidly excreted in the urine. Imidacloprid is not considered carcinogenic and has a high margin of safety due to low mammalian toxicity. The neonicotinoids do not readily pass the blood-brain barrier.

Adverse effects noted in laboratory animals dosed with imidacloprid were decreased activity and tremors, impaired pupillary function (dilated or pinpoint), and uncoordinated gait; higher doses were associated with hypothermia. The no-observed-effect level (NOEL) for chronic imidacloprid exposure in dogs was 15 mg/kg PO.[27]

Treatment for overdoses of imidacloprid is symptomatic. With dermal exposure, wash the animal with soap and water; with oral exposure, use activated charcoal for adsorption and a cathartic. Generally, imidacloprid absorption and elimination are rapid, and supportive care should provide recovery.

Organochlorines

Organochlorines are chlorinated hydrocarbons. These compounds include lindane, mirex, kepone, dichlorodiphenyltrichloroethane (DDT), aldrin, dieldrin, heptachlor, chlordane, toxaphene, and endosulfan. The persistence of some organochlorines in the environment and concern for neurotoxicity and endocrine disruption have terminated the use of most organochlorines. These compounds have limited to no distribution in the United States but may occasionally cause toxicoses when stored chemicals contaminate feed or premises. Organochlorines are available in other countries.

The organochlorines have several mechanisms of action. The DDT-type organochlorines affect the brain and peripheral nerves by slowing sodium influx and inhibiting potassium outflow, partially depolarizing the cell and increasing firing of the neuron.[28] Several organochlorines may act by inhibiting attachment of GABA to its receptor, which stimulates the neuron. The organochlorines are absorbed orally and dermally. These compounds are highly lipid soluble and distribute to adipose tissue, brain, liver, kidney, and milk. Metabolism of organochlorines can be through dechlorination and oxidation, glucuronidation, and sulfation. More toxic epoxides can be formed by the mixed-function oxidases. The organochlorines are excreted into bile and the GI tract. They can undergo enterohepatic recycling, prolonging exposure for weeks. These compounds bioaccumulate in fatty tissue and persist in the environment. Organochlorines can act as endocrine disruptors.

Acute clinical signs include salivation, vomiting, and nervous system signs of agitation, hyperexcitability, incoordination, apprehension, nervousness, and tremors. As clinical signs progress, animals may display clonic-tonic seizures, opisthotonus,

VetBooks.ir

paddling, and clamping of the jaw. Cattle may walk backward, lick excessively, or have abnormal postures.[29] Seizures can persist for several days. Between seizures the animals may be depressed or normal in appearance. Clinical pathologic changes and histopathology are nonspecific.

Diagnosis is based on history, clinical signs, and analytic determination of organochlorines in blood, fat, liver, brain, or milk. Contact the veterinary diagnostic laboratory for sample submission instructions. Generally, samples for organochlorine analysis should not be submitted in plastic but wrapped in aluminum foil and/or placed in clean glass containers. Note that tissue levels of organochlorines do not correlate well with severity of clinical signs or prognosis.

Detoxification is a crucial step in treatment. Animals with topical exposure need to be washed with soap and water, and animals with long hair should be clipped to reduce organochlorine exposure. Treating personnel should wear gloves and aprons to reduce human exposure. With oral exposure, activated charcoal (1 to 2 g/kg body weight in a slurry) should be administered orally. Feeding activated charcoal, at 500 to 1000 g/day for a limited time, to large animals will reduce enterohepatic cycling.[28] General supportive care, such as the use of diazepam or barbiturates to control seizures and placing the animals in an environment to prevent trauma and keep comfortable, are important. Organochlorines typically have a prolonged residue time in body tissue. Animals that are lactating or losing weight generally eliminate more organochlorines due to loss of milk fat or body fat, respectively.

The state veterinarian should be contacted regarding exposure of animals to organochlorines and proper disposal of contaminated tissue or materials. The long persistence of organochlorines in tissue prevents immediate placement of food animals or milk into the food chain; proper state or federal agencies will need to be contacted for withdrawal intervals.

Paraquat

Paraquat is a bipyridyl herbicide used as a desiccant on crops. Most questions about paraquat exposure in large animals relate to aerial spray drift onto animals and/or their pasture and application to forages that will be used for livestock. Paraquat absorbed onto soil particles is biologically inactive. Animals that have access to concentrated paraquat formulations or to wet forages following paraquat application are at risk for developing clinical signs.

Paraquat is poorly absorbed (5% to 10%) from the intestinal tract but has prolonged residual time in the digestive tract. Emulsifiers or other chemicals in paraquat formulations may enhance absorption and toxicity. Paraquat is concentrated in renal tissue and is eliminated in the urine.

Paraquat forms free radicals in the body and has special affinity for the lung. The production of superoxide radicals and hydrogen peroxide results in damaged cellular membranes and tissue necrosis.

Following ingestion, the initial signs reflect the irritating action of paraquat, resulting in abdominal pain, vomiting, anorexia, and depression. By the second to third day post exposure, the onset of renal failure appears along with liver damage (hepatocellular necrosis), which is followed by delayed development of pulmonary fibrosis, respiratory dyspnea, cyanosis, and pneumomediastinum.[30] Death may occur several weeks after exposure. With topical exposure to paraquat, erythema, blistering of skin, and corneal irritation can occur and may resolve without additional complications.

Histopathologic changes from paraquat toxicosis include apoptosis or necrosis of alveolar epithelial cells, denuded alveolar basement membranes, and with a chronic response, hyperplasia of type II alveolar epithelial cells and pulmonary fibrosis.[30] Hepatic and renal lesions may be present. The diagnosis is based on history of exposure to paraquat and chemical analysis of paraquat in urine, plasma (up to 30 hours post exposure), and lung tissue (after 30 hours post exposure).

Treatment should be initiated as soon as possible (within 24 hours) using activated charcoal, bentonite, or fuller's earth. Supportive care includes monitoring vital signs frequently, using fluids to maintain renal perfusion, treating secondary infections, and pain management. If treatment is delayed, the prognosis is extremely poor.

Rodenticides

Zinc and Aluminum Phosphide

Zinc phosphide is a rodenticide used since the 1930s. Zinc phosphide is a gray, crystalline powder that is relatively stable under dry conditions. Rodent formulations contain 2% to 5% zinc phosphide mixed with grains; therefore the baits are attractive to most species. Under wet or acidic conditions, zinc phosphide degrades to phosphine gas. Phosphine gas has the odor of acetylene or rotten fish, and poisoning can occur in people at detectable concentrations of 2 ppm. Acute, oral lethal doses of zinc phosphide were reviewed in various species.[31] The lethal dose of zinc phosphide in ruminants was approximately 60 mg/kg body weight.

Aluminum phosphide is a fumigant used in stored agricultural products to control rodents and insects. It has a high potential of acute toxicity with inhalation exposure. After application of aluminum phosphide tablets to grain, phosphine gas is released for up to 5 days. A general recommendation is that grain treated with aluminum phosphide should not be handled or fed for at least 10 days after treatment.

Phosphine gas is readily released in acidic environments and can block cytochrome c oxidase, resulting in disruption of oxidative phosphorylation within mitochondria of cells.[32] Blocking energy-producing pathways leads to cell death and eventual multiple-organ failure. Brain, heart, liver, and kidney are most affected by phosphine gas due to high metabolic rates and high demands for oxygen. Because of the higher pH of the rumen, as compared with an acidic monogastric stomach, ruminants should be more resistant to phosphide toxicants.

The onset of clinical signs occurs within 15 minutes up to 12 to 18 hours, depending on the dose and stomach contents (the more acidic, the quicker the release of phosphine gas). Death can occur within several hours after appearance of clinical signs. Ruminants show tympany and bloat, whereas horses can display signs of colic and abdominal pain. Horses fed a pelleted ration recently treated (within 14 hours) with aluminum phosphide showed rapidly developing clinical signs of profuse sweating, tachycardia, tachypnea, pyrexia, ataxia, seizures, and widespread tremors.[33] Clinicopathologic changes include hypoglycemia, high serum lactate and ammonia concentrations, and elevated activity of gamma-glutamyl transpeptidase, aspartate aminotransferase, and alkaline phosphatase. Several horses in this case developed clinical signs consistent with hepatic encephalopathy, and eventually 27 of 28 clinically affected horses died within 2 days after exposure. Postmortem changes were petechial and ecchymotic hemorrhages in numerous organs, widespread vascular congestion, hepatic lipidosis, pulmonary edema, and neuronal necrosis in the cerebral cortex.

Phosphine gas can be detected in gastric contents, vomitus, and possibly liver and kidney. The samples need to be packed in airtight containers and frozen immediately to prevent phosphine gas dissipation. Check with the veterinary diagnostic laboratory for analytic capability to detect phosphine gas.

The progression of clinical signs often limits treatment options. Early decontamination of the animal by emesis (if the animal vomits), gastric lavage (especially with 5% sodium bicarbonate), and products to increase gastric pH for zinc phosphide exposure is critical. Activated charcoal may be

VetBooks.ir

beneficial when mixed with an antacid and a cathartic (e.g., aluminum or magnesium hydroxide). No specific antidote is available for phosphine gas. Supportive therapy should be aimed at correcting acidosis, treating shock and liver failure, and controlling seizures. Horses that developed clinical signs after phosphine gas exposure were treated by gastric lavage followed by di-tri-octahedral smectite, atropine, fluids, 10% dextrose, flunixin meglumine, and sedatives.[33]

Metaldehyde

Metaldehyde is a molluscicide, usually sold in less than 5% concentrations as pelleted baits, granules, liquids, and wettable powders. Feed ingredients such as apples, molasses, rice, oats, and soybeans have been added to the baits to increase palatability to nontarget species. Most toxicoses occur in the coastal areas of the United States, where snail and slug populations can be high.

The mechanism of action of metaldehyde is unclear but may be related to alterations of neurotransmitters in the brain. Metaldehyde is toxic to all known animals. Oral ingestion is the most likely route of exposure. Acute, oral lethal doses of metaldehyde were reviewed in various species.[34] The lethal dose ranges for metaldehyde were 200 to 300 mg/kg body weight in ruminants and 60 to 360 mg/kg body weight in horses. Young animals appear to be more susceptible than adults.

Clinical signs of toxicosis usually occur within several hours of exposure and include salivation, restlessness, anxiety, hyperpnea, tremors, colic, ataxia, nystagmus, and convulsions. Blindness and loss of a menace reflex have been reported in cattle with metaldehyde toxicosis.[35] No specific changes in clinical pathology or histologic lesions occurred in animals poisoned with metaldehyde. Gross lesions have included congestion in renal, hepatic, pulmonary, and GI tissues and petechial and ecchymotic hemorrhages throughout the body. Demonstration of metaldehyde in GI contents (possibly serum/plasma and urine) confirms exposure. Samples should be submitted frozen to the diagnostic laboratory.

Initial therapy may involve control of seizures and tremors with diazepam and barbiturates; xylazine and acepromazine have been used in horses.[34] Decontamination by gastric lavage and activated charcoal, orally at 1 to 2 g/kg body weight, followed by mineral oil has also been recommended. Supportive care with intravenous fluids and a quiet environment may be beneficial.

Anticoagulant Rodenticides

Cases of hemorrhagic disorders reported in cattle generally involve repeated exposure to moldy sweet clover hay or sweet vernal hay (dicoumarol) over a prolonged period. Accidental ingestion of anticoagulant baits over a brief period may result in potential toxicosis in large animals. The anticoagulant rodenticides are divided into first-generation coumarin derivatives (e.g., coumachlor, coumatetralyl, warfarin), second-generation coumarin derivatives (e.g., brodifacoum, bromadiolone, difenacoum, flocoumafen), and the indanedione derivatives (e.g., chlorophacinone, diphacinone, pindone). Generally, the second-generation coumarin compounds are more toxic than the first-generation products and can poison with one feeding.

All anticoagulant rodenticides interfere with vitamin K epoxide reductase, which converts inactive vitamin K to the active vitamin. A depletion of active vitamin K may affect vitamin K–dependent clotting factors in the intrinsic, extrinsic, and common coagulation pathways. Anticoagulant rodenticides are well absorbed on oral exposure and are highly bound to plasma proteins. Oral availability of warfarin, chlorophacinone, and bromadiolone in sheep was estimated to be more than 79%.[36] Anticoagulants are metabolized in the liver, and some compounds may undergo enterohepatic recirculation. The half-life of anticoagulant rodenticides varies greatly with the compound and the species. The half-life of brodifacoum in horses was given as 1.22 ± 0.22 days, as compared with that of warfarin in horses at 16 hours.[36,37] The half-life of bromadiolone in cattle was reported to be approximately 20 hours.[36] As a general observation, the duration of action of anticoagulant rodenticides in large animals is about 14 days for warfarin, 21 days for bromadialone, and 30 days for brodifacoum and other second-generation coumarin derivatives. Ruminants are thought to have lower susceptibility to anticoagulants; however, a study in anticoagulant-dosed sheep revealed that the compounds were not degraded in the rumen and their bioavailabilities remained high after oral dosing.[37] The authors speculated that several factors may lower ruminant susceptibility, including the presence of a large forestomach (diluting the compound) and ruminal production of vitamin K_1, which may partially counteract the toxic effects.

Clinical signs may become apparent 2 to 10 days post exposure. Affected animals may display melena, epistaxis, hematuria, or excessive bleeding from a wound. If bleeding occurs within a body cavity, the animal may exhibit pallor, weakness, dyspnea, fever, and depression. Animals may die suddenly from excessive hemorrhage and shock. Generally, gross and histologic lesions are consistent with hemorrhage. Diagnosis is based on history, clinical signs, prolonged clotting times and anemia, and response to the antidote, which is vitamin K_1. Analytic detection of the anticoagulant rodenticide in whole blood, liver, and perhaps GI contents can confirm exposure.

Vitamin K_1 is the antidote for anticoagulant rodenticides; the duration of therapy varies with the specific compound causing the toxicosis and may last several days to several weeks. The recommended dose of vitamin K_1 in the adult horse is 2.5 mg/kg IM/SC once to twice daily.[38] The prothrombin time should return to normal within 24 hours. Vitamin K_3, although less expensive to use, is not as effective as vitamin K_1, will cause renal disease in horses,[29] and is not recommended.

Packed cell volumes should be closely monitored during clinical signs, and whole blood transfusions may be required if the animal is anemic. Decontamination of the GI tract with activated charcoal may lower absorption of the anticoagulant. After the animal has stabilized and the appropriate time has passed, vitamin K_1 should be discontinued for 48 hours and prothrombin time retested.

1080

Sodium monofluoroacetate, fluoroacetate, or 1080 is a nonselective rodenticide that is toxic to animals and humans. The compound 1080 has been available in the United States since the 1940s but now is restricted for use as a predacide in the United States. It is used in Australia and New Zealand to kill invasive, unwanted species. Fluoroacetate naturally occurs in several plants in Africa, Australia, South America, and perhaps southern Florida. Sodium monofluoroacetate also appears to be available over the counter in the United States as foreign rodenticides or "herbal" pesticides. This compound is colorless, odorless, and water soluble.

The mechanism of action of 1080 involves a critical cycle, the Krebs or tricarboxylic acid cycle, in cellular metabolism. Many of the effects of 1080 toxicosis result from impaired oxidative metabolism and reduced energy production.[39] The oral LD_{50} for monofluoroacetate in ruminants and equines ranges from 0.22 to 0.55 mg/kg body weight.[40] Sodium monofluoroacetate is quickly absorbed from the GI and respiratory tracts and through mucous membranes but slowly absorbed through intact skin.

In general, herbivores experience cardiotoxic effects, omnivores experience cardiac and CNS effects, and carnivores experience CNS effects. Clinical signs occur within 30 minutes to several hours post ingestion. Cattle may stagger, tremble, sweat, and display signs of GI irritation; they can die of heart failure.[41] Horses can display hyperesthesia to external stimuli

VetBooks.ir

and have marked cardiac arrhythmias and ventricular fibrillation from 1080 poisoning. Sheep and pigs may show a combination of cardiac and CNS signs. Animals may have decreased GI movements, salivation, restlessness, apparent blindness, ataxia, frequent urination, muscular tremors, polypnea, and tachycardia. Pigs may have intermittent vomiting. Clinical pathology changes may include hyperglycemia, increased serum citrate, hypocalcemia (ionized), and acidosis. Electrocardiograms on 1080-poisoned sheep revealed S-T segment elevation and a marked increase in T-wave amplitude, suggesting cardiac ischemia.[42] Severely affected animals generally die within hours to a few days post exposure. Postmortem lesions in ruminants may involve endocardial and epicardial petechiae, edema of the brain, and lymphocytic infiltration of perivascular tissue. A diagnosis of 1080 toxicosis is based on clinical signs, history of exposure, and detection of 1080 in the bait, vomitus/gastric contents, kidney, and liver. Few veterinary diagnostic laboratories in the United States analyze for 1080 in tissues. Generally, the assay is by gas chromatography/mass spectrometry with a detection limit of 10 µg/kg (or parts per billion).

In a recent case of multiple episodes of 1080 intoxication in a calf-raising operation, calves were found dead or displayed a stiff gait, dribbled urine, and became recumbent and died with ecchymotic and suffusive hemorrhages on the epicardial surface with moderate to large amounts of fluid in the pericardial sac.[43] Another case of 1080 toxicosis involved high, acute death loss in ewes and lambs following transfer of the flock to a new pasture over a municipal landfill site.[44] Clinical signs observed in affected animals were disoriented running and breaking through fences, apparent blindness, weakness, and ataxia. Gross lesions included pulmonary congestion and edema and epicardial petechiae and ecchymotic hemorrhages on the ventricles. Histologic changes were acute to subacute myocardial degeneration and necrosis with neutrophilic and lymphohistiocytic myocarditis. Compound 1080 was detected in several kidney samples, but the source of 1080 was not determined. No long-term effects on health or reproductive performance were observed in ewes that survived experimental dosing with a single, near-lethal amount of 1080.[42]

Compound 1080 has no known antidote, and the rapid onset of clinical signs may prevent effective, quick decontamination of the GI tract with activated charcoal. A treatment protocol for 1080 toxicosis in dogs involves gastric lavage followed by activated charcoal, control of seizure and convulsions with barbiturates or gas anesthesia, fluid therapy including sodium bicarbonate, monitoring serum calcium and potassium, and use of acetamide if available.[45] The prognosis for most cases of 1080 toxicosis is poor.

Strychnine

Strychnine is a rodenticide often sold at 0.5% to 1% concentrations in a powder, pellets, or with grain bait for below-ground application. Strychnine-treated seeds are often dyed red or green. In several states, the use of strychnine is restricted. Storage of old containers of strychnine-laced grains can be sources of accidental toxicoses. Accidental and malicious toxicoses continue to occur regularly.

Strychnine is an alkaloid from the seeds of *Strychnos nux-vomica* and *Strychnos ignatii*. Strychnine blocks inhibitory action of glycine at the inhibitory neurons, Renshaw cells, spinal cord, and medulla. The lack of inhibition leads to rigidity and tetanic convulsions. Strychnine is quickly absorbed from the GI tract and widely distributed in the body. A small portion of the dose is excreted into urine. Hepatic enzymes can readily metabolize strychnine.

Clinical signs can appear within a few minutes to a few hours and include sweating, nervousness, incoordination, recumbency, and tonic-clonic seizures. The seizures can be induced by stimuli such as bright light, loud noises, and touch. No specific clinical pathology or histologic changes occur in strychnine toxicoses. Analytic determination of strychnine in gastric contents (and to a lesser extent in urine, serum/plasma, liver, and kidney) confirms a strychnine toxicosis.

Decontamination by gastric lavage followed by oral administration of activated charcoal, which binds strychnine, is important; however, the degree of sensory stimulation may require initial treatment to control seizures and support respiration. The use of barbiturates along with diazepam and methocarbamol may control seizures. Severe respiratory dyspnea may require mechanical ventilation. In addition, intravenous fluid therapy and a quiet environment may be beneficial. Prognosis for treatment of large animals with strychnine toxicosis is poor because of the difficulty of treating animals in the field. In one case report, several horses had access to an old bag of strychnine-contaminated barley. Clinical signs of CNS stimulation were observed in five of six horses, with two horses dying. Treatment in the field consisted of activated charcoal and mineral oil to assist decontamination of the gut and xylazine, diazepam, and pentobarbital for CNS signs.[46]

Abdomen
  examination of, in neonates, 329–330, 331*f*
  ultrasound evaluation of, 17
Abdominal abscess, illustration of, 537*f*
Abdominal cavity, 10
Abdominal contours, in indigestion, 856, 857*f*
Abdominal distention
  description of, 106–107, 107*b*–108*b*
  in neonatal ruminants, 347–351
  in neonates, 329
Abdominal pain
  Cryptosporidium parvum as cause of, 25*f*
  duodenitis-proximal jejunitis and, 759
  in ruminants, 848
    causes of, 849*f*
    identification of, 850
Abdominal paracentesis, 703
Abdominal pings, 6
Abdominal radiography
  in equine alimentary system, 714
  in foals, 252
Abdominal splinting, 3–5
Abdominal ultrasound, in foals, 251–252
Abdominal vein, 8
Abdominocentesis
  in abomasal ulcers, 891
  in acute abdomen, 851
  fever of unknown origin evaluations, 41*t*
  in foals, 252
  in intussusception, 770
  in peritonitis, 789–790, 789*t*, 881, 881*f*
  in traumatic reticuloperitonitis, 885
  vomiting evaluations, 108
Abducent nerve
  dysfunction of, 137*t*
  examination of, 128–129
Abduction, 117*t*
Abiotrophy, 1071
Abnormal biomechanical load, for osteoarthritis, 1217
Abnormal labial approximation, 1487
Abnormal offspring syndrome, 308–309
Abnormal peripheral pulse, 93–94, 93*f*, 94*b*
Abnormal sounds, interpretation of, 73–74
Abomasal bloat
  in lambs, 350
  in neonatal ruminants, 349–350
  sudden death caused by, 231
Abomasal dilation, of Suffolk sheep, 893
Abomasal disorders, fluid therapy for, 1542
Abomasal displacement, 885–889
  etiology of, 885
  incidence of, 885–886
  left, 886–887
  in neonatal ruminants, 349
  pathophysiology of, 886, 886*f*
  prevalence of, 885–886
  right, 887
  surgical therapy for, 886
Abomasal impaction, 893–895
Abomasal pH, drugs that increase, 892
Abomasal ulcers, 889–893
  abdominocentesis in, 891
  ancillary tests in, 891–892
Abomasal ulcers *(Continued)*
  antiacids for, 892
  blood gas analysis in, 891
  classification of, 889, 890*t*
  clinical signs of, 890–891
  complete blood cell count in, 891
  control of, 892–893
  definition of, 889
  diagnostic imaging in, 891, 891*f*
  differential diagnosis of, 890–891
  epidemiology of, 889–890
  etiology of, 890
  exploratory laparotomy in, 891–892
  fecal occult blood test in, 891
  necropsy findings in, 892
  in neonatal ruminants, 348–349
  other blood tests in, 891
  pathophysiology of, 890
  prevention of, 892–893
  prognosis of, 892
  serum biochemistry profiles in, 891
  sudden death caused by, 231
  surgery for, 892
  treatment of, 892
    supportive, 892
Abomasal volvulus, 888
  clinical pathology of, 888
  clinical signs of, 888
  control of, 889
  differential diagnosis of, 888
  necropsy findings in, 889
  pathophysiology of, 888–889
  prevention of, 889
  prognosis of, 889
  schematic view of, 886*f*
  signs and symptoms of, 6
  treatment of, 889
Abomasum
  displacement of, 6, 6*f*
  gas ping localization to, 6
  left displaced, 6, 6*f*
  right displaced, 6, 6*f*
  torsion of, 6, 6*f*
  ultrasonography of, 840–841, 842*f*–843*f*
Abortion
  bluetongue, 1502
  border disease, 1502
  in bovine viral diarrhea virus, 825–827
  Brucella abortus, 1498, 1653–1654
  Brucella melitensis, 1504
  Brucella ovis, 1504
  in camelids, 1505
  Campylobacter fetus subsp. *fetus*, 1495*t*, 1503
  Campylobacter fetus subsp. *venerealis*, 1498
  Campylobacter jejuni, 1504
  Chlamydia psittaci, 1495*t*
  Chlamydophila abortus, 1504
  in cows
    bovine herpesvirus 1 as cause of, 1494–1496, 1495*t*
    bovine viral diarrhea viral as cause of, 1495*t*, 1496, 1496*f*
    causes of, 1495*t*
    epizootic bovine abortion, 1497
    leptospirosis as cause of, 1496
  Coxiella burnetii as cause of, 1495*t*, 1502
  diagnostic approach to, 199–200, 201*t*
  endotoxemia as cause of, 1494
Abortion *(Continued)*
  enzootic, 1629*t*–1633*t*
  epizootic bovine, 1497
  fungal, 1490, 1502–1505
  in goats, 1495*t*
  Histophilus somni as cause of, 1499
  in horses, 238*b*
    causes of, 1488*t*
    description of, 198–199
    endotoxemia as cause of, 1494
    equine herpesvirus-1 as cause of, 198, 1488*t*, 1491–1492
    equine viral arteritis as cause of, 1488*t*, 1492
    insect-related, 1493
    leptospirosis as cause of, 1493
    noninfectious causes of, 1489
    placentitis as cause of, 1489, 1490*f*
    protozoal causes of, 1493
    Salmonella as cause of, 1493
    trypanosomiasis as cause of, 1494
    twin pregnancy, 1488
  inducement of, 1470–1471
  insect-related, 1493
  laboratory tests, 201*t*
  leptospirosis as cause of
    in cows, 1496
    in horses, 1493
  Listeria monocytogenes as cause of, 1499
  mare reproductive loss syndrome, 198
  miscellaneous bacterial, 1500–1502
  Mycoplasma, 1499
  mycotic diseases causing, 1502
  Neospora caninum, 1501
  pregnancy loss caused by, 198
  protozoal, 1047, 1493
  in ruminants, 199
    Brucella abortus, 1498
    Campylobacter fetus subsp. *venerealis*, 1498
    causes of, 1495*t*
    epizootic bovine, 1497
    Histophilus somni as cause of, 1499
    leptospirosis, 1496
    Listeria monocytogenes, 1499
    Mycoplasma, 1499
    noninfectious causes of, 1494
  Salmonella as cause of, 1493
  Sarcocystis, 1501
  in sheep, 1495*t*
  tissue samples used in diagnosis of, 201*t*
  toxoplasmosis, 1504
  Tritrichomonas foetus as cause of, 1500
  trypanosomiasis as cause of, 1494
  in twin pregnancy, 199
  Ureaplasma, 1500
Abortion storms, 1492
Abscess
  abdominal, 537*f*
  brain
    in horses, 134*t*, 1045–1046
    in ruminants, 132*t*–133*t*, 1045–1046, 1045*f*–1046*f*
  cervical spinal, 140*t*
  Corynebacterium pseudotuberculosis as cause of, 93, 471, 610, 641, 1192, 1194
  of esophagus, 733, 734*f*
  gastric, in horses, 742
  laryngeal, 643

Note: Page numbers followed by "f" refer to illustrations; page numbers followed by "t" refer to tables; page numbers followed by "b" refer to boxes.

Abscess *(Continued)*
lung, 533, 541–542
periorbital, 559, 559*f*
pituitary, 1045
pleural, 534*f*–535*f*, 535
pulmonary, 519
renal, 963
retropharyngeal lymph node, 609–612
spinal, 1099–1100
stromal, 1288
subsolar, 1245–1246, 1246*f*
vertebral body, 266
Absolute erythrocytosis, 1179
Absolute thrombocytosis, 444
Absorption tests, in equine alimentary system, 718
Abuse, in equine patients, recognizing, 14, 19–22
Acaricides, 1333
Accelerated hydrogen peroxide, 1567*t*
Accelerometers, for identifying lame cows, 25–26, 26*f*
Accessory nerve dysfunction, 137*t*
Acepromazine, 206, 1238
Acer rubrum, 232
Acetate tape preparation, for parasites, 177
Acetazolamide, 1429
Acetyl CoA, 1408
Acetylcholine
carbamate effects on, 1803–1805
organophosphate effects on, 1803–1805
Acetylcholinesterase, 1805
Acetylcholinesterase-inhibiting agents
organophosphates, 1693
sudden death caused by, 232–233
Acetylsalicylic acid, 31
α1-acid glycoprotein, 440
Acid-base imbalances, 408–412, 408*f*, 408*t*
anion gap, 410–411
correction of, in acute abdomen, 852
metabolic acidosis. *see* Metabolic acidosis
metabolic alkalosis, 408–409, 409*b*
mixed, 410
respiratory acidosis, 409–410, 410*b*
respiratory alkalosis, 410, 410*b*
strong ion-centered, 411
Acidosis, in horses, 803–804
Aconitum spp., 233
Acorn calf syndrome, 903
Acquired equine polyneuropathy, 1106–1107
Acquired erythrocytosis, 1180
Acquired flexural limb deformities, 1250–1251
Acquired hemostatic disorders, 1157–1158
Acquired megaesophagus, in horses, 732–733
Acquired torticollis, 1096–1097
Acremonium spp.
A. coenophialum, 210, 1241
A. strictum, 553*t*, 558
ACTH. *see* Adrenocorticotropic hormone
Actinobacillosis, in ruminants, 810–811, 810*f*
Actinobacillus equuli
foal actinobacillosis caused by, 228
renal abscesses caused by, 963
Actinobacillus lignieresii, 810–811
Actinobacillus peritonitis, 792
Actinomyces bovis, 811–812
Actinomycosis, in ruminants, 811–813, 812*f*
Activated coagulation time, 445–446
Activated partial thromboplastin time, prolonged, 444, 446*b*, 1154
Activated protein C, 1153–1154
Acute abdomen, in ruminants, 847–854
abdominal examination for, 850
abdominal pain and, 848
identification of, 850
abdominocentesis of, 851
Acute abdomen, in ruminants *(Continued)*
acid-base imbalance, correction of, 852
ancillary tests for, 851
antimicrobial drugs for, 853
blood gas analysis in, 851
blood lactate concentration in, 851
classification of, 849*f*
complete blood cell count and differential in, 851
complete physical examination for, 850–851
diagnostic imaging of, 851
electrolyte imbalance, correction of, 852
electrolytes in, 851
evaluation of, 848–851
extraabdominal examination for, 850
fecal output and appearance of, 851
fibrinogen in, 851
fluid therapy for, 852
follow-up for, 853–854, 854*f*
history in, 848–850
inflammation, control of, 852–853
medical and supportive treatment of, 852–853
medical or surgical decision for, 852–854
other medical treatments for, 853
packed cell volume in, 851
pain, control of, 852–853
radiography in, 851
rectal palpation for, 850
serum biochemistry profile in, 851
surgery for, 852
total solids in, 851
ultrasonography in, 851
urinalysis of, 851
visual examination for, 850
vital parameters, evaluation of, 850
Acute blood loss
anemia caused by, 1151
blood transfusion for, 1151
causes of, 1151
diagnosis of, 1151–1152
exercise-induced pulmonary hemorrhage as cause of, 1152
treatment of, 1151–1152
Acute bovine pulmonary edema and emphysema, 680
Acute dyspnea syndrome, 645
Acute enteritis, 708–709, 709*f*
Acute fascioliasis, 229
Acute glomerulopathy, 959
Acute hepatitis, in horses, 927–928, 927*f*
Acute hypophosphatemia, 1400–1401
Acute interstitial nephritis (AIN), 959
Acute interstitial pneumonia
in feedlot cattle, 681–682
in horses, 568, 652
Acute leukemia, 1186
Acute liver atrophy, 927
Acute lung injury
definition of, 564–565
diagnostic criteria for, 564*b*, 564*t*, 566
pathophysiology of, 564–565
prognosis for, 566
treatment of, 566
veterinary, 564*b*, 565
Acute neurologic injury
fluid additives in, 1535–1536
fluid therapy for, 1532–1536, 1532*b*
Acute phase proteins, 37
α1-acid glycoprotein, 440
α2-antiplasmin, 439
apolipoprotein A1, 439
ceruloplasmin, 439
C-reactive protein, 439, 439*t*
definition of, 438
ferritin, 439–440
Acute phase proteins *(Continued)*
in foal, 260
haptoglobin, 439, 439*t*
pig major, 439
serum amyloid A, 439, 439*t*, 995, 1210
types of, 439*t*
Acute-phase proteins, for traumatic reticuloperitonitis, 884
Acute phase reaction, 37
Acute phase response
definition of, 438–440
fibrinogen, 438–439, 438*b*
Acute renal failure, 956–963
acute glomerulopathy as cause of, 959
acute interstitial nephritis secondary to, 959
aminoglycosides as cause of, 956–957
diagnosis of, 960–961
in foals, 962–963
heavy metal ingestion as cause of, 958
Leptospira interrogans as cause of, 967–968
nephrotoxicity as cause of, 962–963
nonsteroidal antiinflammatory drugs as cause of, 957–958
pigment nephropathy as cause of, 957

epidemiology of, 1035–1036
etiology of, 1035
nonbovine hosts, public health consideration and BSE in, 1037
pathogenesis of, 1036
treatment of, 1036–1037
Bovine tuberculosis, 695–698
Bovine viral diarrhea virus (BVDV), 327, 820–830
abortion caused by, 1495*t*, 1496, 1496*f*
abortions in, 825–827
acute, 826
disease associated with, 823–826
immunosuppression, 824
reproductive disease, 824–826, 825*f*
respiratory disease, 824
acute-transient, 823
antigen detection in, 828
biosecurity for, 829–830
clinical signs of, 822
congenital defects in, 825–827
control of, 828–830
definition of, 820–821
diagnosis of, 827–828, 827*t*
diarrhea, 356
differential diagnoses of, 822
early embryonic death in, 825
epidemiology of, 821–822
etiology of, 820–821
forms of, 822*f*
hemorrhagic, 824
herd-to herd transmission of, 822
host range in, 821
infection control for, 1589
infertility in, 825
during later stages of pregnancy, 825–826
mucosal disease in, 826
necropsy findings in, 826–827
persistent
acute mucosal disease in, 826
chronic mucosal disease in, 826
Bovine viral diarrhea virus (BVDV) *(Continued)*
disease associated with, 826
identification and elimination of, 828–829
in offspring, 825
prevalence of, 821
prevention of, 828–830
prognosis of, 828
reverse transcription polymerase chain reaction in, 828
serology in, 828
severe acute, 823–824
transmission of, 821–822
treatment of, 828
vaccination for, 829
virus isolation in, 827–828
Bovine viral diarrhea-mucosal disease
abortion caused by, 199
description of, 112*t*, 113, 653
Bovine virus diarrhea
diagnostic tests for, 360
diarrhea and, 351
Bovine virus diarrhea virus
Borna disease and, 1017
bovine respiratory syncytial virus and, 652
cerebellar hypoplasia caused by, 1072, 1072*f*
hydrocephalus associated with, 1057
mucosal disease associated with, 1646
ocular manifestations of, 1290–1291
reproductive control and, 1646–1647
vaccination for, 1645–1647, 1646*t*
Bovine-specific ophthalmia, 1305
Bowel inflammation, 97
Bowel irritation, 97
Boxwood, 1776*t*–1778*t*
Brachial plexus lesions, 1112–1113
Brachyspira pilosicoli, 99–100
Bracken fern, 993, 998, 1772*t*–1774*t*, 1775
Bracken fern toxicosis, 1179
Bradycardia, 7
in indigestion, 859
Brain abscess
in horses, 134*t*, 1045–1046
in ruminants, 132*t*–133*t*, 1045–1046, 1045*f*–1046*f*
Brain-heart syndrome, 1022
Brain injury, hyperosmolar therapy for, 1534–1535
Brain swelling, 1025
Brain trauma, 1021–1025
Brain tumors
in horses, 134*t*
in ruminants, 132*t*–133*t*, 1027–1028
Brainstem
auditory evoked potentials measurement of, 137
auditory evoked responses, 1011, 1011*t*
diseases of, 138*t*
dysfunction of, diseases manifesting with, 1062–1077
Branhamella ovis keratoconjunctivitis, 1285
Brassica spp., 684
Breath-holding technique, for urine sample, 5
Breath sounds
bronchial, 516
in neonatal ruminants, 343
vesicular, 516
Breath tests, in equine alimentary system, 718–719
Breathing, 524–525
Breeding programs, 1707, 1707*b*
Breeding season, 1456–1457
in camelids, 1457
in cows, 1456
Breeding season *(Continued)*
in does, 1463–1464
in goats, 1456–1457
in mares, 1456
in ruminants, 1456–1457
in sheep, 1456
Breeding soundness examination, 189, 192*b*
Bretylium tosylate, 499*t*
Brisket disease, 493–495
Brix refractometers, 322, 1738
Broken teeth, in ruminants, 807
Bromcresol green (BCG) albumin binding, 435
Bromide intoxication, 140*t*
Bronchiolitis obliterans, 687
Bronchoalveolar lavage
for cough evaluations, 49
for epistaxis evaluations, 59–60
exercise-induced pulmonary hemorrhage, 603–604
in horses, 520–521
inflammatory airway disease, 594–595
procedure for, 520
respiratory secretion collection using, 520–521
sedation for, 520–521
summer pasture-associated obstructive pulmonary disease, 592–593
Bronchoconstriction, 43–44
Bronchodilators
inflammatory airway disease treated with, 597
interstitial pneumonia treated with, 569
pulmonary edema treated with, 584*t*
recurrent airway obstruction treated with, 590–591
response testing for, 50–51
Bronchointerstitial pneumonia, 567
Bronchopleural fistulas, 535
Bronchopneumonia
aerobic bacterial isolates associated with, in vitro antimicrobial susceptibility of, 532*t*
antimicrobial agents for, 531–533
in cattle, 645–646, 646*b*, 667
characteristics of, 645
in dairy calves, 666
definition of, 526
differential diagnosis of, 528
in Eastern equine encephalomyelitis, 1016
equine adenovirus as cause of, 1292
in horses, 526
physical examination of, 527–528
Rhodococcus equi infections as cause of, 468–469, 535–548, 536*f*, 1289
in ruminants, 645–646, 646*b*
undifferentiated, 646
Bronchoprovocation testing, 525
Bronchoscopy, bacterial pneumonia evaluations, 528
Broodmares
udder edema in, 210
vaccinations in, 1600–1601, 1604*t*–1612*t*
Broomweed, 1776*t*–1778*t*
Brucella spp.
B. abortus, 1248–1249, 1292, 1578*t*–1585*t*, 1653
abortion, 1498
B. melitensis, 1578*t*–1585*t*
abortion, 1504
B. ovis
abortion, 1504
vaccine for, 1633
Brucellosis, 1578*t*–1585*t*
BTSCCs. *see* Bulk tank somatic cell counts

Respiratory distress, 60–68
  blood gas analysis of, 67
  causes of, 63*b*–65*b*
  complete blood count in, 67
  definition of, 60
  diagnostic approach to, 66–68
  endoscopic examination of, 67
  in foals, 253
  hemoglobin, detection of abnormal, 67
  history-taking, 66
  in horses, 63*b*–64*b*
  insufflation of 100% oxygen, 67
  pathophysiology of, 60–68
  physical examination of, 66–67
  radiographic examination of, 67
  in ruminants, 64*b*–65*b*
  treatment of, 298–299
  ultrasound examination of, 67–68
Respiratory failure, 246
Respiratory function
  alterations in, 43–81
  testing, 524–526
Respiratory inductive plethysmography, 525–526, 525*f*
Respiratory infection, 296–297
  in ruminants, 346–347
Respiratory protection, 1572
Respiratory rate
  in acute abdomen, 850
  assessment of, 60
  description of, 7*t*
Respiratory secretions, 520–521
Respiratory sounds
  abnormal, 73–74
  description of, 71
Respiratory system
  arterial blood gas analysis of, 519–520, 519*f*
  evaluation of, 59
  in horses, 16, 76
  resistance, 595
  training-related adaptations, 76
Respiratory tract
  endoscopy of, 517
  evaluation of, in exercise intolerance, 77–78
  exercise-induced, 234
  in foals, 253–254
  fungal infections of
    Acremonium strictum, 558
    adiaspiromycosis, 558
    amphotericin B, 552
    antifungal agents for, 552–554
    aspergillosis, 555–557, 557*f*
    azoles, 552–554, 554*t*
    blastomycosis, 556*t*, 557
    candidiasis, 556*t*, 558
    clinical signs of, 551
Respiratory tract *(Continued)*
    coccidiomycosis, 558
    conidiobolomycosis, 554–555
    cryptococcosis, 555, 556*t*
    definition of, 550–551
    diagnostic sampling of, 551–552
    etiologic agents, 554–559
    etiology of, 550–551
    histopathologic studies for, 551
    histoplasmosis, 556*t*, 557–558, 558*f*
    immune function testing for, 552
    iodide therapy for, 554
    microbiological culture for, 551
    molecular techniques for, 552
    organisms that cause, 553*t*
    pneumocystosis, 556*t*, 558–559
    pseudallescheriasis, 555
    scopulariopsis, 558
    treatment of, 552–559, 556*t*
  heat dissipation in, 63–66
  nuclear medicine imaging of, 519–524
  radiographs of, 517–518
  ultrasonography of, 518–519
Restraint, during ophthalmic examination, 1267
Restriction fragment length polymorphism, 475
Resuscitation
  in fluid therapy, 801–802
  foal, 244–245
Retained fetal membranes, 207–209, 1472
  in camelids, 1474
  in cows, 1473
  in does, 208, 1474
  in ewes, 208, 1474
  history-taking, 208
  in mares, 207, 208*b*, 1472
  physical examination of, 208–209
  in ruminants, 208, 208*b*, 1473–1474
Reticulated leukotrichia, 1347, 1348*f*
Reticulitis, 861–862
Reticulocytes, 460–461
Reticuloomasal orifice, obstruction of, 865
Reticuloruminal fermentive function, disorders of, 867–877
Reticuloruminal milk accumulation, 878, 878*f*
Reticuloruminal motor function, disorders of, 859–867
Retina
  separation of, 1271*f*
  trauma to, 1281, 1281*f*
Retinal degeneration, 1271*f*
Retinal vessels, 1270–1271, 1270*f*
Retinitis, 1308
Retroperitoneal abscess, in ruminants, 882–883
Retropharyngeal lymph nodes
  abscessation of, 609–612
  description of, 559, 610
Retropulsion, 1268
Reverse transcriptase-polymerase chain reaction
  in bovine viral diarrhea virus, 828
  respiratory disease evaluations, 524
Reynolds number, 87
Rhabdomyolysis
  acute, 1434–1435, 1434*f*
  chemical toxins as cause of, 1440–1441
  creatine kinase levels in, 79
  exertional, 1425–1426, 1425*b*, 1444–1454
    causes of, 1445
    chronic, 1446
    clinical signs of, 1444, 1444*f*
    description of, 1381
    dietary imbalances as cause of, 1445
    etiology of, 1445

treatment of, 1056–1057
for neonatal calves, 366
Vitamin B_{12}, 1413
reference values for, 918*t*
Vitamin D
in calcium and phosphorus homeostasis, 1379
hormone concentrations of, 1378*t*
insufficiencies, 1404
intoxication, 958
milk fever prevention using, 1396
in milk replacers, 390
Vitamin E
deficiency, 342
description of, 1437–1438
myopathy associated with, 1440, 1441*f*
in milk replacers, 390
Vitamin K, 445, 607, 1808
Vitamin K_1, 1808
Vitamin K_3, 957, 1799
Vitamin K-dependent coagulation factors, 1155–1156
Vitiligo, 1347
Vitreous
examination of, 1269
trauma to, 1281
Vocal folds, 633
Voiding, 166
Volatile fatty acids (VFAs), 1408
in acute ruminal lactic acidosis, 870
Volvulus
abomasal, 6
colonic, 706–707
in small intestine, 768–769
Vomiting, in indigestion, 859
von Willebrand disease, 444
von Willebrand factor, 444
deficiency, 1155
Voriconazole
aspergillosis treated with, 556–557
fungal infections of respiratory tract treated with, 554, 554*t*
fungal keratitis treated with, 1288
V-pads, 264, 264*f*

W

Warble fly larvae, 234
Warbles, 1336–1337
Warfarin toxicosis, 1162
Warts, 1327–1328, 1328*f*, 1328*t*
Water hemlock, 1767*t*–1769*t*
Water intoxication, 1174
Waterless hand sanitizers, 1570
Wattle cysts, 1344
Weak calf syndrome, 381, 656
Weakness, 89–90, 223–225, 223*b*
in foals, 265–267
metabolic acidosis and, 340
in neonatal ruminants, 335–343, 336*b*
Weanlings, gastric disease of, 740–741
Weaver syndrome, 1078*t*–1079*t*
Weight, alteration of, 141–165
Weight gain
decreased
causes of, 142*b*–143*b*
diagnostic approach to, 143–147
in horses, 142*b*
management of, 143–147
mechanisms of, 141–148
Weight gain *(Continued)*
in ruminants, 147–148
toxicities as cause of, 142
in horses, 145*f*
Weight loss
biochemical analysis of, 158–159
causes of, 154*b*–156*b*
conditions associated with, 152
copper deficiency and, 159–162
description of, 152
diagnostic approach to, 157–159, 157*f*
flowchart for, 157*f*
in horses, 154*b*–155*b*, 157–159, 1372
in liver disease, 921–922
mechanisms of, 152–157
parasitism as cause of, 157
resistance, 1372–1373
in ruminants, 155*b*–156*b*, 159–164
Welfare
assessment of, 2–13, 12*t*
compromised, 12
definition of, 12
freedoms of, 12*b*
veterinarian's responsibility to, 22
West Nile encephalitis, 1018–1019
causative agent of, 1018
clinical signs of, 1019–1020, 1020*f*
control of, 1021

Reference Intervals for Ruminants and Horses

	Cattle[a]	Sheep[b]	Goats[b]	Horses (Hot-Blooded Breeds)[b]	Horses (Cold-Blooded Breeds)[b]
PCV/HCT (%)	22-33	27-45	22-38	32-53	24-44
Erythrocytes ($\times 10^6/\mu L$)	5.1-7.6	9-15	8-18	6.8-12.9	5.5-9.5
Hemoglobin (g/dL)	8.5-12.2	9-15	8-12	11-19	8-14
MCV (fL)	38-50	28-40	16-25	37-58.5	—
MCHC (g/dL)	36-39	31-34	30-36	31-38.6	—
Reticulocytes	—	0	0	—	—

[a]From George JW, Snipes J, Lane M: Comparison of bovine hematology reference intervals from 1957-2006. *Vet Clin Pathol* 39:138, 2010.

[b]From Jain NC: *Schalm's veterinary hematology*, ed 4, Philadelphia, 1986, Lea & Febiger.

PCV, Packed cell volume; *HCT,* hematocrit; *MCV,* mean cell volume; *MCHC,* mean cell hemoglobin concentration.

Normal Values for Leukogram Data (Adult Animals)

	Cattle	Sheep	Goats	Horses
White blood cells ($1 \times 10^3/\mu L$)	4.9-12	4-12	4-13	5.4-14.3
Neutrophils ($1 \times 10^3/\mu L$)	1.8-6.3	0.7-6	1.2-7.2	2.3-8.6
Bands ($1 \times 10^3/\mu L$)	Rare	Rare	Rare	0-1
Lymphocytes ($1 \times 10^3/\mu L$)	1.6-5.6	2-9	2-9	1.5-7.7
Monocytes ($1 \times 10^3/\mu L$)	0-0.8	0-0.75	0-0.55	0-1
Eosinophils ($1 \times 10^3/\mu L$)	0-0.9	0-1	0.05-0.65	0-1
Basophils ($1 \times 10^3/\mu L$)	0-0.3	0-0.3	0-0.12	0-0.29
Neutrophil/lymphocyte (N/L) ratio	0.4-2.34	0.3-0.7	0.6-3.6	0.8-2.8

Normal Serum Protein Values for Horses, Cows, Sheep, and Goats

	Value	Horse	Cow	Sheep	Goat
Total	g/dL	5.2-7.9	6.74-7.46	6-7.9	6.4-7
Albumin	g/dL	2.6-3.7	3.03-3.55	2.4-3	2.7-3.9
Globulin	g/dL	2.62-4.04	3-3.48	3.5-5.7	2.7-4.1
Fibrinogen	mg/dL	200-400	200-700	200-500	200-300
